The search for scientific "truth" regarding the causes of human disease is a laborious multistep process, a winnowing of a large number of postulated hypotheses down to the few that can be supported with data derived from testing and observation. It depends upon the replication of results, coherence of evidence from many different fields and, ultimately, an understanding of the underlying biological mechanisms of action. In evaluating the potential human health effects of chemical exposures, there are three major sources of scientific information used by the courts, various government agencies, and the larger scientific community: experimental laboratory research, controlled clinical investigations, and observational epidemiology studies. These three are not mutually exclusive in method or thought; each makes a unique contribution toward understanding the etiologies of human disease; but each has certain inherent limitations. Ultimately, the determination of causation depends upon the demonstration of a meaningful elevated risk for the disease among those with the "exposure" and a biological explanation for the excess. The former can only be obtained via epidemiology studies; the latter usually comes from an interplay of information derived from experimental laboratory research and controlled clinical investigations.

Toxicology is one of the key experimental disciplines. In toxicology, investigators are able to carefully con trol the exposures of genetically homogeneous groups of animals, some purposefully bred so that they exhibit a marked predilection for specific diseases. The latter can provide toxicologists and pharmacologists with important clues about the biological mechanisms which predispose, aggravate, or cause disease. Toxicologists also have the opportunity of evaluating each and every subject to the same exquisite detail. Therefore, at least in theory, the experimental method can provide comprehensive results unperturbed by extraneous variables; but it is increasingly being recognized that this approach does not automatically eliminate, or reduce to a level of insignificance, all forms of technical bias (97). Nor does it protect against personal bias, a problem that can plague all types of research irrespective of the affiliations of the investigators (70, 74, 118). Toxicology also has become stylized to the extent that the format of research results is both predictable and quantitative. This has made it very convenient for information derived from toxicology experiments to be used in quantitative risk assessments and related regulations. Paradoxically, this convenience facilitates a major violation of scientific principles: an

extrapolation beyond the data to make inferences about health effects not only for levels of exposure that were not administered but also for species who were not studied.

< previous page page_449 next page >

Clinical investigators also administer measured doses according to a predetermined schedule, but do so to the species of major interest, humans. Although this type of work is "controlled," it is at best quasi-experimental because humans are not passive participants in health research. At the very least, they must consent to be studied. Some do not and key characteristics of those who do and do not may be markedly different. In other words, most study groups used in clinical trials are not random samples of the general population. This means that care must be exercised in extrapolating the findings too broadly.

On the plus side, clinical research can collect data both on objective signs of pathology and also on more subjective symptoms, data that animal research cannot provide. On the negative side, an equivalent and comprehensive data set for each study subject may not be obtainable. For example, histopathology of all the organs is only available on those few of the deceased whose next-of-kin allow an autopsy to be performed. Any study of humans also means that the research subjects are not homogeneous with regard to either genetic makeup or alternative exposures such as diet, personal habits, or medications. To address this problem, randomization of subjects to different treatment groups is utilized during study design, the assumption being that key alternative variables are randomly distributed across groups and confounding thereby controlled. Sometimes it doesn't work.

There are two major strengths of observational epidemiology research. One, it studies humans. Two, it deals with the effects of real exposures—actual levels, durations and patterns of exposure to individual agents and to mixtures. If epidemiology studies are well done, they furnish results that reasonably can be extended to larger populations. Unfortunately, epidemiologists are often forced to handle exposure as a qualitative variable (either as a yes/no or some variation of high, medium and low). This can limit the utility of the research results for those who require quantitative information. In addition, because the research is observational in the sense that the investigators simply observe natural experiments and do not exercise control over the key variables, epidemiologists routinely must grapple with a number of technical biases that are largely transparent to those in the other two fields. If these biases—in particular, selection, misclassification, and confounding—are not adequately addressed during study design or data analysis, the study results may be unduly imprecise and important associations missed. Alternatively, the results may be relatively precise but precisely inaccurate, thereby leading to interpretations that are incorrect. Some of these problems can be exacerbated if the epidemiologist utilizes secondary sources of data (data originally gathered for purposes other than the specific research project, possibly even for reasons unrelated to research), especially if the methods for the original data collection process were poorly documented.

There is one other point that differentiates epidemiology from the other two fields. Although acceptance into the American College of Epidemiology provides an imprimatur of professional competence, in practice epidemiology requires no graduate degree, certification, or licensure. Some enter the field with strong statistical skills; others have extensive training in human biology. The formal graduate degree programs require a proficiency in both; but anyone with any level of education can gather a data set, analyze it, report the results, and call their efforts epidemiology research. There is no law against it and no professional body condemns the practice. Epidemiologists can be very egalitarian. The rule of thumb for the consumer of epidemiology results, therefore, especially if a report appears in other than the peer reviewed literature, is *caveat emptor*.

Epidemiology has been defined as the study of the distribution and determinants of disease in humans (75). Although commonly used, this definition is incomplete. Although epidemiologists certainly search for the factors associated with human disease, they also attempt to identify both interventions that likely will benefit those who are at risk for getting the condition (perhaps because of unique patterns of exposure to combinations of putative agents or a genetic predisposition for reacting adversely to such exposures) and treatments that will help control or cure any significant pathology once it occurs. They also, implicitly or explicitly, try to determine which agents do not cause a specific disease, which interventions will not be successful, and which treatments are not effective.

As with toxicology and clinical research, good epidemiology is an amalgam of subject-specific knowledge and methods. And just as there are clinical specialties and areas of expertise in toxicology that have evolved with the growing complexities of each of those two fields, epidemiology is divided into a number of overlapping subgroups: occupational, environmental, reproductive, cardiovascular, cancer, infectious disease, molecular, genetic, nutritional, medical device, clinical, etc. Some of these are subdivided still further, for example, AIDS is a subcategory of viral which, in turn, is a subset of infectious disease. Although certain knowledge and techniques may be unique to a subgroup, many concepts are common across the discipline.

The primary objective of this chapter is to introduce those concepts that span the field so that toxicologists might become better consumers of the epidemiology literature. Table 10.1 provides an outline of the major topics: data, measures of disease frequency, measures of risk and association, methods, and issues. All of these are interrelated so the order of presentation is somewhat arbitrary; but the first three set the stage for the last one,

Table 10.1 Major topics

Data
- Prevalence
- Incidence

Measures of disease frequency
- Prevalence rate
- Incidence rate

Measures of risk and association
- Absolute risk
- Relative risk
- Standardized mortality ratio (SMR)
- Proportional mortality ratio (PMR)
- Rate difference
- Attributable risk

Methods
- Cohort
- Case control
- Cross-sectional
- Case studies or case series

Issues
- Selection
- Misclassification
- Confounding
- Chance
- Causation

in particular the key issues impacting validity—selection, misclassification, and confounding. Each of these in turn is presented to show how it can bias the measures of association. The intent is to make the readers more sensitive to possible flaws so that they might determine for themselves how well the investigators recognized a potential problem and addressed it during study design, data collection or data analysis, and during data interpretation.

Most of the major points are illustrated with recent examples from the epidemiology literature or, to a lesser extent, with toxicology or clinical references. In part, this was done to emphasize the point that all science—experimental, quasi-experimental, and observational—is based upon assumptions that may not be correct. Some of these assumptions are relatively innocuous. Conversely, some are so important that, if violated, the science is severely flawed and any policies based upon that science likely also are flawed. Those are the two poles of a continuum; but validity is not a dichotomous variable like pregnancy. The challenge for the consumer of scientific reports is to determine which provide useful information, which do not, and which lie somewhere in between—intriguing enough to warrant additional research, but not strong enough to merit intervention. This winnowing equates to first, identifying potential problems that may have compromised the validity of the research; second, determining the probability to which the problems occurred; and third, estimating the impact, if any, they had upon the results.

This chapter is by design a limited overview. For those who wish to have a more detailed presentation of the field, the list of references includes a number of recently published textbooks (19, 48, 62, 98, 101). Note, throughout this chapter key "terms of art" are emphasized with italics. A small number of these are defined in the book's glossary; but most can be found in Last's *Dictionary of Epidemiology* (72), an invaluable resource to any technical library. Additionally, at the end of the chapter there is an appendix: the *Guidelines for Good Epidemiology Practices for Occupational and Environmental Epidemiologic Research* (GEPs), an analog of *Good Laboratory Practices* (GLPs).

DATA AND MEASURES OF DISEASE FREQUENCY

Data, information, and knowledge are related but not equivalent terms. Data are the raw materials gathered by the investigator during the course of an investigation, information is analyzed data, and knowledge is meaningful information that can be used to predict or solve problems. By way of analogy, data are bricks, information the wall, and knowledge the building. Just as good bricks can be put together poorly to build an unstable wall, so can data be valid, but aggregated in a fashion that produces useless information. Pseudoknowledge may be a function of either bad data or useless information, just as a structurally unsound building may result from poor quality bricks or an unstable

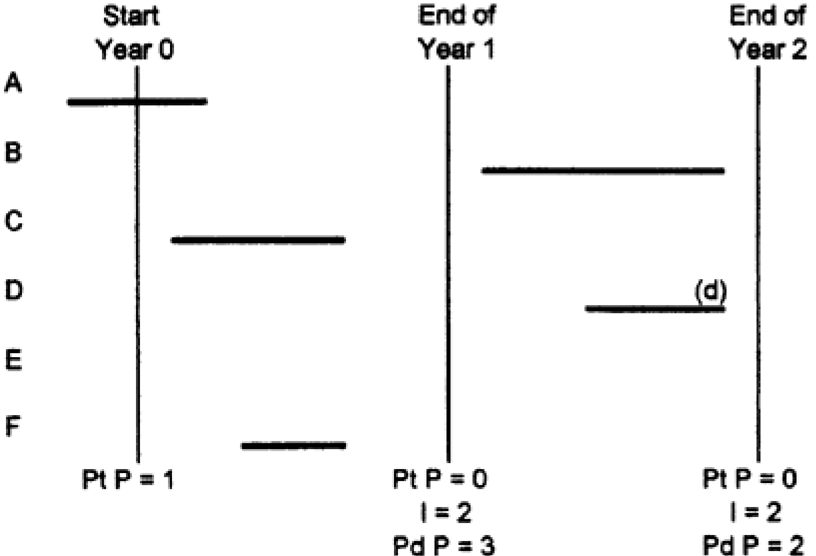
wall.

Prevalence and Incidence

For the epidemiologist, there are two general types of data: *prevalence* and *incidence*. Prevalence is what is observed at a single point; a snapshot of what is prevalent, what exists, at a specific point in chronological or biological time. For example, the number of toxicologists currently employed by federal regulatory agencies is prevalence data.

Incidence is the number of incidents, of new events, that develop over time. Because it represents a delta, a change, incidence data have to be gathered at two or more points in time. In a sense, if prevalence is a snap-shot, incidence is a movie. The number of toxicologists hired by federal agencies in any given year is an example of incidence data. They didn't work for the agencies at the start of the year (observation point one); but they did work for the government later in the year (observation points two or more).

Parenthetically, when epidemiologists speak of prevalence data they are usually referring to *point prevalence* but they may *mean period prevalence*. Period prevalence is a combination of what exists at the beginning as well as what occurs during a specified period. The number of toxicologists who were employed by federal agencies at any time during a given year is period prevalence data. It includes those who were working at the beginning of the year (point prevalence data) and those who were hired during the year (incidence data). Period prevalence may or may not be the same as the number of those who were employed at the end of the year (more point prevalence data) because some toxicologists may have left government employment during the period of observation.
Whether data are period prevalence or incidence can sometimes be difficult to discern, because both refer to events occurring during a span of time. The key is whether the data represent a combination of existing and new events (period prevalence) or just new events (incidence). Unless otherwise noted, the term prevalence is used in this chapter as a synonym for point prevalence.
The difference between prevalence and incidence data is important for at least three reasons. One, incidence data can be used to evaluate cause and effect; prevalence data usually cannot, at least not without additional assumptions. Two, because prevalence data can be gathered at a single point in time, it is much easier to obtain and therefore many reports in the medical literature are based upon prevalence data. Three, the medical literature often incorrectly uses the two terms interchangeably. As a consequence, reports that use valid prevalence data to develop nonsense information about cause and effect appear in even the most prestigious journals.
Although the two are different, they are related. Prevalence *(P)* is a function of both the incidence *(I)* and the duration *(D)* of the disease *($P=I\times D$)*. What that means is a chemical may not cause a disease, may not increase the incidence of the disease, but it may still be associated with a higher prevalence of the condition. Whether that is good news or bad depends upon the circumstances. For example, the incidence of diabetes may be quite stable in a population; but if that population is given access to a chemical called insulin, the prevalence of the condition likely will increase dramatically. It will increase because the insulin extends the duration of the disease by allowing more of the afflicted to live longer. Conversely, the prevalence of minor birth defects (prevalence because the events are measured at a single point in biological time, birth) may be lower among live children born to women exposed to some agent, not because the agent prevents the development of minor defects in utero, but because the agent and causes major malformations that lead to early spontaneous abortions.



Pt P is point prevalance; I is incidence; and Pd P is period prevalence.
FIG. 10.1. Prevalence versus incidence (time-limited condition).

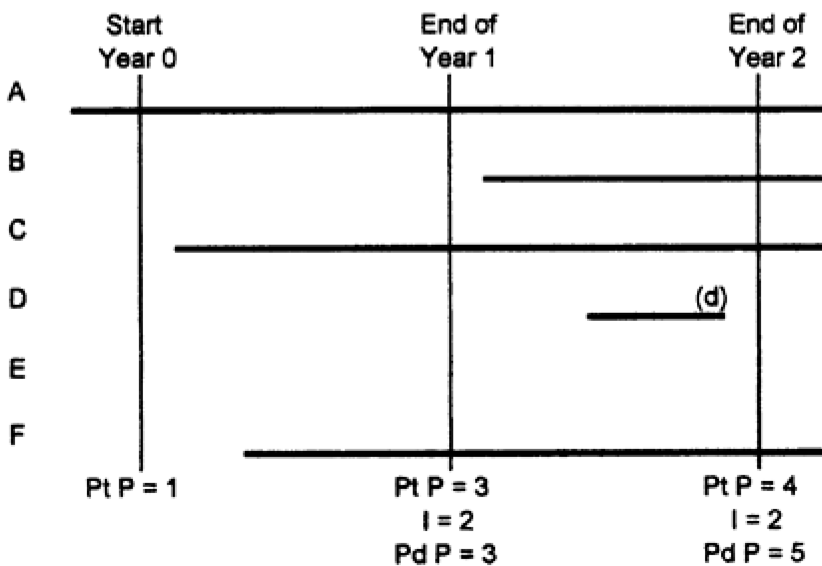


FIG. 10.2. Prevalence versus incidence (condition chronic).

The incidence of minor defects is quite stable in this example, but their duration has been shortened and therefore fewer malformations observed among live births.

Figures 10.1 and 10.2 illustrate these points. In both, a group of six patients (A through F) is observed for 2 years. In Figure 10.1, the condition is time limited. It either spontaneously resolves, is cured through some treatment, or the patient dies. The point prevalence at the initial baseline observation (year 0) is one. Two additional cases subsequently occur and all three resolve before year's end. At the end of year 1, the point prevalence is zero, the incidence is two, and the period prevalence is three. During the following year, two more cases develop and one patient dies (patient D) of an unrelated cause before the end of the year. Therefore, at year's end, the point prevalence is zero, the incidence two, and the period prevalence also two.

In Figure 10.2, the condition is chronic, perhaps because, like diabetes, it has been extended through treatment. Note the incidence is exactly the same as in the previous example. It is two in each year. However, the extended duration has impacted both measures of prevalence. The point prevalence at the time of the three observations is respectively one, three, and four. The period prevalence for the first year is three. For the second, it is five even though patient D died before year's end. Each of these three measures of disease provides valuable information, but using either type of prevalence data for interpretations about cause and effect depends upon assumptions about *incidence time* (i.e., when the health event actually occurred) and disease duration that are often untestable or incorrect.

Rates

Technically, the terms incidence and prevalence refer to numerator data; however, in both the epidemiology and medical literature, these terms often are used interchangeably with, respectively, *incidence rate* and *prevalence rate*. An incidence rate is the number of new events of a disease in a defined population that occur during some specified period of time. A prevalence rate is the number of cases of disease observed in a defined population at a point in time. In both, the numerator is a subset of the denominator. Obviously, errors of count in either the numerator or the denominator can impact the accuracy of a rate. Nonetheless, in some technical reports the former may not be a subset of the latter and the description as to how either was compiled may be less than clear.

Rather than presenting a rate as the actual numerator (the exact number of new events observed) in comparison to the actual denominator (the precise count of the group under study) at or during the period of observation, for convenience a rate is usually given as the number of cases per 100 or per 1000 or per 10,000. For example, if there were 486 persons in the study group and 5 new events occurred during a 12-month period of observation, the incidence rate might be presented as 1.0 per 100 per year (5 divided by 486 times 100) or, alternatively, as 10.3 per 1000 per year.

As opposed to toxicology, in epidemiology the study groups can be either *fixed* or *open* (sometimes called *dynamic*). In a fixed study group, those included are defined at the start and followed over time. If no losses occur during the period of study, the group may be called a *closed population*. In an open study group, individuals may be added or lost during the time of study. Just the events that occur and just that time that passes during the period each individual was under observation are counted. This so-called *person-time experience* assumes that observing 10 people for 1 year is the same as observing 1 person for 10 years. In some situations, the assumption is appropriate. In others, it may not be. Determining which is which depends upon the underlying biological model.

MEASURES OF RISK AND ASSOCIATION

Absolute Risk

It is an immutable fact of life that we are all going to get ill at sometime and ultimately we are all going to die. On a personal level, the questions for each of us are by what disease and when? Epidemiologists are also interested in those questions, but they are particularly interested in whether the disease occurs more frequently or more severely in association with some type of exposure. In other words when it comes to identifying the causes of disease, what is at issue is whether the *absolute risk* for a specific disease among the exposed is greater than the absolute risk of that same disease in the unexposed.

Relative Risk

An incidence rate provides a measure of absolute risk. The ratio of the incidence rates in two different groups is a *rate ratio*, *risk ratio*, or *relative risk*, a key measure of association between exposure and disease. If the relative risk *(RR)* is appreciably greater than 1 among those with a particular exposure, it is evidence that the agent may be causing the disease. May be. Conversely, if the relative risk is below 1, the agent may be protecting against the disease. May be. And if the relative risk approximates 1, there may be no meaningful association between the two variables. Once again, may be. May be is an important caveat in all three situations because how well the *apparent relative risk* (the number derived as the result of a particular investigation) corresponds to the *true relative risk* (the actual underlying biological truth) depends not only on the statistical stability of the estimate of relative risk, but also on how well the potential technical biases of selection, misclassification, and confounding were controlled in study design, during data collection, and by data analyses.

Standardized Mortality Ratio (SMR)

In cohort mortality studies, the measure of association may be provided as a *standardized mortality ratio* or SMR. Because this is simply the ratio of the number of deaths observed in the study group to the number that would have been expected if the study group had the same death rate as a reference (i.e., standard) population, it is sometimes presented as *observed to expected* deaths or

O/E. By convention, this measure of association is given as a percentage, but the interpretations parallel those of the relative risk. A SMR of 150 is analogous to a RR of 1.5; a SMR of 75 to a RR of 0.75; and a SMR of 100 to a RR of 1.0. Because the observed number of deaths occurs in discrete increments and the number of expected deaths is for all intents and purposes a continuous variable (i.e., the expected deaths might be a biologically impossible number such as 1.27365…), by convention many epidemiologists will not calculate a SMR if the number of observed deaths is less than 2 (19). They may simply provide the two numbers, the observed and the expected, or just give a confidence interval. Sometimes, they'll do neither and merely indicate that the numbers were too small to be meaningful
Note, the "controls," the comparison group, in a SMR analysis are essentially those in a hypothetical group statistically constructed from the reference population to have approximately the same age, race, and gender characteristics as the exposed group. For many occupational studies, the mortality experience of United States white males is used as a reference even if a small number of those in the occupational cohort are of a different race or ethnic group, the assumption being that the calculations of expected deaths will be adequate. Using a SMR approach also means the investigator is assuming that no one in the reference population was exposed to the agent of interest. If the exposure is relatively rare among those in the reference population, the assumption is probably reasonable because the mortality experience of those few who were exposed would have had very little impact on the population statistics. On the other hand, if the exposure is relatively common—for example, something like chlorinated drinking water—the assumption may be unreasonable and another type of study would have to be done to obtain valid information.

An interpretation of a "crude" measure of association assumes that both the exposed group and the reference population had similar habits regarding smoking, dietary preferences, medical care, etc. This assumption may be incorrect. For example, a number of years ago a study was done in California of men who lived in communities adjacent to petrochemical facilities along the Sacramento river (8). The comparison population was composed of those who lived in the same county, but remote from the industrial sector. An apparent elevated risk for lung cancer was discovered and the finding was initially presumed, at least by the news media, to be due to emissions from the petrochemical plants. However, during this first stage of the investigation, no attempt had been made to control for the effects of cigarette smoking. For efficiency, that activity had been deferred to subsequent stages of the research. It was later found that those who lived near the plants were largely blue collar workers and those who lived elsewhere tended to be white collar professionals who commuted to work in San Francisco. Why was this important? Blue collar workers on average smoke more than white collar workers (at least that has been past experience) and therefore blue collar workers have higher rates of lung cancer. When the subsequent research gathered the necessary data and adjusted for these differences, the elevated risk disappeared (20). As a result, the proposed intervention strategies changed from targeting industrial emissions to implementing smoking cessation programs.

The SMR can also be an acronym for a *standardized morbidity ratio*. Instead of death being the outcome of interest, it is illness; but the calculations and the resultant interpretations are basically the same. So too are the underlying assumptions. If the assumptions were violated to the degree that the study results were affected, the reader should look for confirmation elsewhere.

Proportional Mortality Ratio (PMR)

Neither the RR or the SMR should be confused with a *PMR*, a *proportional mortality (or morbidity) ratio*. The PMR is a measure of the relative importance of an individual category of disease among those with disease. As such, both numbers in the ratio are "numerator data." Although it is a convenient measure to obtain, it must be used with caution in etiologic research because it compares proportions and not rates. It makes the assumption that a higher proportion of a particular disease is the same as an increased frequency of that disease. Because a PMR calculation works like a teeter-totter, that assumption may be invalid. Although a higher proportion of disease A may be due to an increased incidence of disease A, it also simply may be a function of a lower frequency (and therefore a lower proportion) of some other condition, disease B. For example, a higher PMR for cancer among an occupational group with a certain exposure may mean that more of those with the exposure were developing (and dying) from cancer than those in the standard population; but it is also consistent with the interpretation that those with the exposure were not dying more often from cancer, they were just dying less often from noncancer events. In other words, in a PMR analysis an apparently "adverse" finding may be spurious, for example, solely a function of the *healthy worker effect* (79).

Rate Difference and Attributable Risk

With two incidence rates it is possible to calculate not only a rate ratio, but also a *rate difference*. If the

association between the exposure and the disease is truly causal, the rate difference provides a measure of the excess

burden of disease an exposed population might expect to experience as a result of the exposure. Stated another way, it represents the amount of the disease that would never have occurred if the exposure had been prevented. In such situations, it may be called an *attributable risk, attributable risk percent, attributable fraction,* or a number of other related terms as derived for just the exposed group or for the general population as a whole. Unfortunately, some will calculate a risk difference and use the term "attributable" even when causation has not been established.

Note the two measures, the rate ratio and the rate difference, provide very different information. The higher a RR is above one, the greater the likelihood that there is a true cause-and-effect relationship; but a high RR for a very rare disease among a few individuals with a unique exposure may be of *de minimis* concern from a public health perspective, whereas a lower RR for a relatively common condition might equate to an enormous number of cases. By way of example, it is generally accepted that excess exposures to vinyl chloride monomer cause angiosarcoma of the liver. The RR for this association is quite high; but the total number of excess cases, worldwide, approximates 100. By way of contrast, the RR for heart disease among cigarette smokers is only about 1.5; but the rate difference equates to a large number of cases—many, many orders of magnitude more than 100. This is because both the disease and the exposure are relatively common. From a public health perspective, it is much more important to control the excess risk of disease related to smoking than it is the risk associated with vinyl chloride monomer. Yet for the purpose of establishing a cause for the disease, it took many fewer epidemiology studies to establish an etiologic association between vinyl chloride monomer and liver angiosarcomas than it did for cigarettes and cardiovascular problems.

Rate ratios and rate differences are derived from research in which two groups are defined based upon exposure status and the disease patterns of each are followed forward in time. On occasion, it is easier to get groups based upon whether they do or do not have a specific disease and then collect data on previous exposures. For example, it may be more convenient to identify all those who developed lung cancer during some period, possibly via the use of data from a tumor registry, and identify a comparable group of healthy individuals from the general population, perhaps by means of random digit dialing within the same area codes as the cases. Gathering data on previous exposures from those in each group (or from their next of kin) would allow the calculation of an *odds ratio* or *OR,* that is, the odds of having been exposed to a particular agent given one had the disease versus the odds of having been exposed to that same agent among the healthy controls. If a study is done properly, the OR will approximate the RR. For example, if the RR for getting lung cancer among cigarette smokers is 10, the OR of having been a cigarette smoker among those with lung cancer also will be about 10. For simplicity, the rest of the text will focus predominately on two measures of association, the relative risk and the odds ratio.

METHODS

Cohort

Over the years, epidemiologists have developed a variety of methods to evaluate cause and effect. The most intuitively obvious, and the most analogous to the approach used in toxicology, is the *cohort* study. A cohort is simply a group with some common characteristic, for example, gender, ethnic background, health behavior, or exposure to a particular chemical or medicine. In a cohort study, the health experiences of at least two cohorts are compared, one with an exposure to the agent of interest and one without. Ideally, multiple cohorts, each with a different level of exposure, are identified so that the effects of low, medium, and higher levels of exposure can be assessed. Irrespective of the number of groups, conceptually exposure status is determined first and health data—on subsequent mortality, morbidity, blood cholesterol levels, etc.—are then gathered forward in time. If the exposure status is determined in the present and the health data then gathered into the future, the term *prospective cohort study* is used.

Prospective cohort studies, for all of their advantages, may not be the method of choice in preliminary investigations of the causes of disease, especially if the disease has a long latency. As opposed to toxicologists who dose animals of species with relatively short life spans (a standard chronic feeding study of mice takes 2 years), epidemiologists examine a long-lived species, humans; therefore if they only did prospective cohort studies of chronic disease, they likely would complete very few projects during their professional careers. To overcome this problem, epidemiologists often times will use historical records—personnel files, medical archives, industrial hygiene reports, etc.—to define their exposed and unexposed study groups at some arbitrary date in the past. They will then gather health data on each individual in the study groups from that point up to the present. These are sometimes called *retrospective cohort studies* or, to differentiate them from the case control method that also

gathers data on former events, they may be labeled *nonconcurrent prospective studies* or *historical prospective studies* or even *retrospective prospective studies*. Irrespective of whether the starting point for a cohort study is at the present or in the past, the results

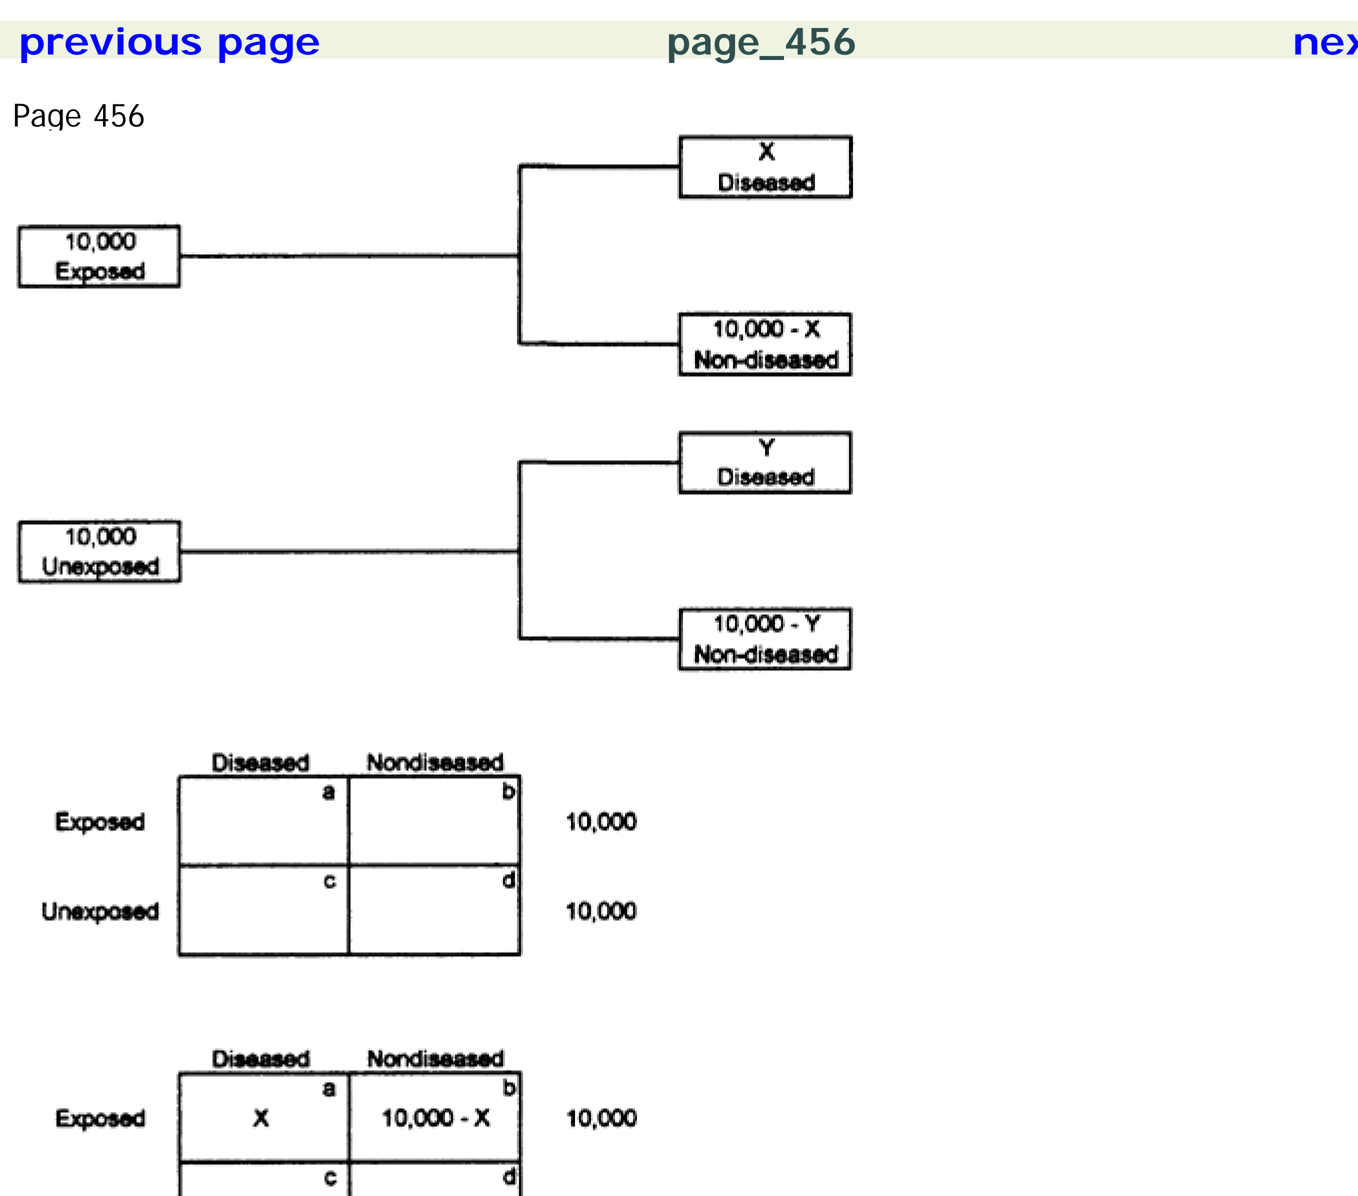

FIG. 10.3. Illustration of the cohort method.

are based on incidence data presented as relative risks (and, if appropriate, risk differences). Figure 10.3 illustrates how this is done. Two groups of healthy individuals are identified at a point in time. One group is selected because they have (or had) a known or presumptive exposure to a specific agent; the second, because they don't have (and ideally never had) the exposure. The health experience of those in each group is then compiled in an equivalent fashion over some defined period of time. This health experience is converted into incidence rates and the rates compared by means of a relative risk.

It is possible to calculate relative risks for all health events combined (e.g., total causes of mortality) or for any number of distinct outcomes (e.g., just deaths due to angiosarcoma of the liver). When the cohort approach is used in exploratory data analysis, it can be considered "an exposure in search of a disease," a hypothesis generating exercise. If it targets just one or a limited number of specific associations of a priori concern, it is akin to hypothesis testing. Many epidemiology studies are a combination of both and it may be difficult for the reader to discern which associations were of concern at the beginning of the research and which were simply serendipitous findings (3). At times, it is possible to make this determination only by reviewing the original study protocol—if there was one.

In the example shown in Figures 10.3, there were 10,000 individuals in each group at the start of the study. Therefore, the marginals for the 2 by 2 table are both 10,000. During the period of study, *X* individuals in the exposed group were observed to have developed the disease (cell a) whereas the

remainder, 10,000 minus *X*, did not (cell b). Therefore, the incidence rate for the exposed is *X* divided by 10,000 (10,000 being the totals of those in cells a and b). Among the unexposed, *Y* developed the same disease (cell c) and 10,000 minus *Y* did not (cell d). The incidence rate among the unexposed is therefore *Y* divided by 10,000. Dividing *X* over 10,000 by *Y* over 10,000 gives the relative risk. Because both groups had the same denominator, this particular RR simplifies to *X/Y*. In real life that seldom happens.

Hypothetically, the investigators might have found that 50 individuals among the exposed developed the disease and only 10 among the unexposed (Figure 10.4). After plugging these numbers into the table, the resultant calculations would produce a RR of 5. The exposed had five times the risk of developing the disease as did the unexposed—assuming there was no selection, misclassification, or confounding bias, and the finding was not a chance occurrence.

Note, in a cohort study those in both groups must be free of the condition at the start of the investigation. This implies that no one in either the exposed or the unexposed group is eligible until they are first examined and determined to be disease free. In other words, the first step of any prospective incidence study is, conceptually, a *cross-sectional* or *prevalence study*. The data from this cross-sectional study, even though they are collected on two or more "cohorts," cannot be used to make interpretations concerning etiology. They are prevalence data.

In actual practice, it may be impossible to determine baseline health status. For example, in a nonconcurrent cohort morbidity study, an investigator cannot go back in time to examine the study participants in any of the groups. Moreover, even when the study has a prospective orientation, it may not be feasible to examine those in the control group if a SMR-type approach is used, because that would mean everyone in the standard group (e.g., the U.S. white male population) would have to be examined, a logistical impossibility. Nevertheless, if the natural history of the health condition is well understood, adjustments can be made to overcome this problem. With diseases of long latency, the investigators might simply ignore the health data from the first couple of years. For mortality research, a person might be pre

	Diseased	Nondiseased	
Exposed	a 50	b 9,950	10,000

sumed living at the start of the study if he or she was then employed, paying taxes, or receiving retirement benefits.

A cohort study can be a very labor-intensive process. Exposure histories have to be compiled and validated. Study subjects (or their next of kin) may have to be traced and contacted and data obtained on personal habits, hobbies, and a host of other variables. Medical records then must be collected and coded. Many things can complicate the process.

The first major obstacle is simply finding the study subjects. In our society, it is not unusual for someone to change their residence multiple times during his or her lifetime. Women may leave the workforce, get married, and, in the process, assume a new last name. Conversely, someone may have a name so common that it is very difficult to determine which “John Miller” is the right study subject and which is not.

A second major obstacle is finding comparable health data on each individual. The amount of medical information can vary from person to person simply because of differences in health care-seeking behavior. The study subjects may have many different physicians, each providing a different level of care, possessing diverse diagnostic skills, and having office records with unique formats. Many states and municipalities have disparate rules governing access to government records such as death certificates. In addition, litigation and regulations may obstruct the process of data collection (5, 7, 29).

Case Control

Even if all of these obstacles can be satisfactorily addressed, it means that a great deal of effort may be needed to gather a lot of data that produce relatively little useful information. In the hypothetical example, 20,000 individuals were tracked to identify the 60 who actually got the disease. To overcome the inefficiencies of cohort studies, epidemiologists developed the *case control* method. With case control studies, the past exposures of those with some disease are compared to the past exposures of those who don't have the disease. For

example, smoking histories might be compared between men who do and do not have lung cancer. Due to the fact that data are gathered from the past, a case control study may be called a *retrospective study* or a *trohoc* (cohort spelled backwards) to differentiate it from a retrospective cohort study. Because the study participants for a case control investigation are first determined in the disease axis of the 2×2 table and data are then gathered on exposure status to fill in each of the four cells, it makes no sense to calculate incidence rates or relative risks. Instead a different measure of association is used based on the odds of past exposure. The odds of past exposure are calculated respectively for the diseased group and for the nondiseased control group. These odds are then compared to develop an OR. Because the magnitude of the OR in well-done case control research closely approximates that of the underlying RR, it allows the interpretations of a case control study to parallel those of the cohort method: An OR appreciably above one suggests a causal association between the disease and the exposure; an OR appreciably below one suggests protection; and a ratio near one, plus or minus, suggests no association between the exposure and the disease.

If we go back to the hypothetical example, there were 60 new cases of disease in this closed population (Figure 10.5). Knowing the age, gender, race, and perhaps other key characteristics of the diseased, 60 "matched" nondiseased individuals could be randomly selected from the remainder of the 20,000. These 120 would constitute the bottom marginals of the 2×2 table, 60 in each column. Data could then be collected on past exposure.

	Diseased	Nondiseased	
Exposed	a 50	b 30	
Unexposed	c 10	d 30	
	60	60	20,000

Odds Ratio = odds of exposure among the diseased versus the odds of exposure among the nondisease

Odds Ratio = 50/10 divided by 30/30

OR = 5

the cross-product ratio is *ad* divided by *bc*

OR = 50 x 30 divided by 30 x 10

OR = 5

FIG. 10.5. Illustration of the case control method, OR=5.

< previous page page_458 next page >

Page 459
In this particular example, 50 of the diseased group would end up in cell a and 10 in cell c. Among the nondiseased, approximately 30 would end up in cell b and another 30 in cell d. Parenthetically, the nondiseased in each exposure category were approximately the same, 9950 and 9990. Therefore, random sampling of 60 from the aggregate 19,940 should select equal numbers from each group: 30 and 30. With data in all four cells, the odds of exposure among the patients would be 50 to 10 (5 to 1) and the odds of exposure among the controls would be 30 to 30 (1 to 1), giving an odds ratio or OR of 5. Conveniently, the calculations for case control studies often simplify to a *cross-product ratio,* ad divided by bc. In the example, 50 times 30 divided by 30 times 10 simplifies to 5.
For this case control study, an evaluation of just 120 individuals provided the same information as a study of 20,000. In the context of the time, effort, and cost, the need to gather data on such a limited number of study subjects can be a tremendous advantage. Paradoxically, the small size of the study can also be a problem because seemingly minor amounts of bias can have a dramatic impact on the OR. Unfortunately, avoiding inadvertent bias can be more difficult in case control studies because the health outcome has already occurred. If the investigators or the study subjects are not properly "blinded," this knowledge can impact both the participants in the research and the data they provide. Social forces still may influence the results even if "blinding" is incorporated. For example, those with disease may be more inclined to participate in the research because they have a greater need to understand why they became ill. Furthermore, the cases who selectively participate may expend greater effort toward trying to remember their past exposures and thereby may provide more comprehensive or more valid data than the controls. This is called *recall* or *rumination bias*. It is a type of *information bias* that very often leads to overestimates of risk.
There is one other problem. A case control study may utilize a combination of prevalence and incidence data instead of just incidence data and thereby limit its utility for etiologic interpretations. For all of these reasons, results from case control studies are considered "lesser evidence" than those derived from cohort research.
Even with its limitations, a case control approach can be very attractive. Because the two groups are initially defined based on disease status, data on any number of exposures can be collected. As a consequence, a large number of different associations can be evaluated simultaneously and rapidly reduced to just a few that deserve further study. For that reason, an exploratory case control study can be considered "a disease in search of an exposure," the mirror image of the hypothesis-generating exercise done in a cohort mode.
A case control study also can focus in depth on just one disease-exposure association, testing a hypothesis derived from case reports or other types of research with much greater sophistication than might be feasible in a cohort study. In certain situations, it can be advantageous to use the cohort and the case control approaches in series to generate a relatively small and well-defined number of hypotheses. Such a *nested case control study* can combine the strengths of both methods. For example, the cohort approach could be used to identify a cluster of disease within a broadly defined group, perhaps all those ever employed at a multiple chemical manufacturing facility, and a case control study could then be implemented within the larger cohort not only to narrow the focus to those few agents that appear to be most important for that particular disease but also to do so with proper adjustments for confounding. This integrated approach, therefore, can achieve both efficiency and rigor.
Cohort and case control studies are sometimes called *analytic* research—in contrast to other types of epidemiology investigations that are simply *descriptive* of time, place, and person. In theory, the term "analytic" should be restricted to those studies that are designed to test a priori hypotheses; but in practice, it is often used more broadly to refer to any cohort or case control research, irrespective of whether it generates or tests hypotheses. That is unfortunate because it blurs the distinction between these two important concepts and the role each plays in the search for the causes of human disease.
As illustrated by the cartoon strip Sally Forth (Figure 10.6), determining disease etiology is basically a four-step process. Step 1 is formulating a theory. Step 2 is testing that theory. To be tested, it must be constructed in a form that is refutable. Although the theory may be stated as "exposure X is associated with an increased risk to disease Y," conceptually it has to be tested in the null (i.e., exposure X *is not* associated with an increased risk to disease Y) and the null disproved (4). If the null is rejected, that is, if an epidemiology study detects an apparent increased risk for disease among those with a particular exposure and the reasons for this excess are not otherwise obvious, step 3 is research to understand the underlying biological mechanisms of the association. Finally, step 4 is to be confident that the key results derived in the second and third steps were not statistical flukes or the consequence of one or more technical biases, each has to be replicated. As a rule of thumb, the more important the

association, the more important is the need to replicate the findings.

Case Studies or Case Series

Hypotheses for analytic epidemiology may originate from toxicology studies or from epidemiology investiga

tions; but many evolve from clinical observations and are published in the form of *case studies* or *case series*. Although based a great deal on intuition, a case study is a time-honored way for a physician to develop new theories about the causes of human disease. It has been said, with some justification, that every human carcinogen was first identified by an astute clinician who published his findings in the form of a case study or case series. Nonetheless, that does not mean case studies can be used to unerringly identify new etiologic associations. Although the theories derived from case studies are not always wrong, history teaches that they are seldom right (9, 31, 95). Determining which is which depends upon data developed by others using experimental, quasi-experimental, and observational research. If we go back to the 2×2 table, we can see why.

To test a hypothesis about a new cause for human disease (to identify an elevated risk in analytic epidemiology research), data are needed in all four cells of the 2×2 table—data that are properly defined on both variables. Case studies tend to focus just on those in one of the four cells, cell a, the exposed with disease. Very little, if any, data are gathered by the clinician on those in the other three cells. Furthermore, those from whom data are gathered are a *convenience sample*. They are not a representative sample of any well-defined group, especially not a representative sample of the healthy—irrespective of their exposure history. They are not because physicians tend to direct their efforts toward diagnosing and treating those with medical problems.

In Figure 10.7, examples a through c, the three 2×2 tables represent the three possible types of association. In the first, the 50 in cell a translates to a RR of 5; in the second, the 30 to a RR of 1; and in the third, the 20 to a RR of 0.5. The three relative risks have very different meanings. Although it is conceivable that any clinician practicing in a community might become suspicious if a cluster of three or so patients came to him with the same rare disease and all had a similar exposure history, based upon the information available he would not be able to determine whether the cluster was a subset of those in cell a from example 10.7a, or from 10.7b, or from 10.7c. Most clusters, however provocative, are meaningless (96). Furthermore, additional case reports do not satisfy the need for replication and confirmation. Once a testable hypothesis has been formulated, additional case reports proposing the same hypothesis contribute nothing.

By way of example, in the silicone breast implant controversy, it was originally hypothesized that women who received this medical device were at increased risk for breast cancer. The theory was based on clinical observations and concern was increased because of an animal toxicology study that demonstrated an Oppenheimer

effect, the tumorigenic properties of foreign bodies as observed in rodents (12, 45, 83). As a result of subsequent research, both experimental and observational, something between examples 10.7b and 10.7c is now thought to most closely approximate the association between silicone breast implants and human breast cancer. It is being theorized that these medical devices or the materials from which they were constructed offer some type of protective effect against breast cancer (15, 120). The current data-based theory is in exact opposition to the hypothesis originally derived from the case reports. Interestingly, no action has been taken on this information. Why? Probably because even though the epidemiology study results have been reasonably consistent and demonstrate coherence with the findings of the experimental animal research, and the public health implications of such an association could be profound considering both the frequency and the life-threatening characteristics of the cancer, the underlying biological mechanisms of protection have not been identified.

ISSUES

Peer review is an imperfect process. Even the most prestigious journals publish findings that are wrong. As a consequence, everything must be read with a degree of healthy skepticism (90). This can be difficult enough within a single field; but it is truly a daunting task when a scientist tries to evaluate the merit of work from a different discipline. If a toxicologist understands the basics of data, measures of

disease frequency, measures of association and methods, the epidemiology literature can be screened fairly rapidly using the "mantra" of *selection, misclassification, confounding, chance*, and *causation*. Consultation with an epidemiologist or biostatistician might still prove necessary; but only for the smaller number of studies.

The order of this mantra is important. If there are obvious technical biases related to selection, misclassification or confounding, it may make very little sense to spend time trying to evaluate the merit of the investigators statistical machinations, much less to assume the findings of statistical significance have biological meaning. It is no accident that the scientific literature has a highly stylized format: some variation of abstract, introduction, methods and materials, results, discussion, and conclusion. This format allows the reader to rapidly focus on the key components of the work. If the authors provide a one-sided presentation of the topic in the introduction, supply insufficient detail regarding their methods and materials, or do not critique their own work in the discussion—pointing out the potential biases of selection, misclassification, and confounding and how they were addressed—the reader should exercise extreme caution before accepting either the results or the conclusions, even as provisional truth.

Selection

In epidemiology, the term *bias* is used to denote a deviation from the truth; but not necessarily to imply that the deviation occurred intentionally (3, 125). *Selection bias* refers to errors that are related to systematic differences between those who are and are not selected into a study. Therefore, even if the data gathered are valid for the examined, it may be inappropriate to use any information derived from these data for purposes of extrapolation to a larger population. For example, the results of a study of hormone replacement therapy among women cannot logically be extended to men. In epidemiology research, various types of selection bias can be introduced by the study subjects, by the investigators, or even by traditional medical practice and other social forces.

Self-selection occurs in both clinical research and some epidemiology studies. It is well recognized that those who

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_461.html[2010/10/28 18:44:27]

participate in controlled clinical investigations, those who actually sign informed consents, may not be representative of the general population. Therefore, even with subsequent randomization of treatment, care must be taken before extending the study results too broadly. A similar problem occurs in observational studies in which some type of active participation, some type of action on the part of the study subjects, is required. For example, informed consent is needed for any epidemiology study in which biological samples are collected. Usually the more invasive the procedure, the more disinclined are the potential subjects to participate, and the greater the potential for bias. However in other situations, this bias may be less obvious or, paradoxically, so obvious that it is largely overlooked. For example, how many times have you received a questionnaire in the mail and, rather than filling it out, tossed it away? By doing so, you introduced a *potential participation bias* into that investigator's work.

In certain types of observational research, self-selection is not a problem. Projects that can be conducted without the active cooperation of the subjects often are able to achieve close to 100% follow-up. For example, occupational cohort mortality studies that utilize personnel records and industrial hygiene reports to identify the exposed, and death certificates to document the cause of death, can be conducted with little or no self-selection (84).

The same arguably holds for some studies that utilize medical records, but only if the medical records relate to the total health experience of a well-defined population. Such is the case in certain countries with socialized medicine in which all the hospital and clinic records are available for the entire citizenry. In the United States, such opportunities are rare and even those few are disappearing rapidly. For example, Mayo Clinic is a world renowned referral center, providing both state-of-the-art medical treatment and highly sophisticated research on the underlying mechanisms of disease. In addition, it serves most of the primary medical needs for those who live in the relatively isolated community of Rochester, Minnesota, and shares medical records by agreement with the few other primary care facilities that operate in that area (49, 50). Having access to the total health experience on those in the community has allowed the Mayo epidemiologists to focus some of their research just on the residents and thereby to conduct high quality population-based epidemiology research that had minimal self-selection or referral bias. Recently, ostensibly for reasons of privacy and confidentiality, the state legislature passed a law requiring study-specific informed consent from all study subjects before any of their data may be utilized for research purposes, even if the patients had previously expressed a willingness to have their medical records used for any such activities

(69). This action by the Minnesota legislature, although undoubtedly politically expedient, will not only complicate the logistics of future research at Mayo Clinic, it unfortunately may also compromise the validity of the work.

Either intentionally or not, investigators can introduce selection bias when they decide who to study, especially if they make a greater effort to get participation among the exposed than the unexposed, or the diseased rather than the healthy. Figure 10.8 is an advertisement that appeared in a Kansas paper in the late 1980s. It apparently was placed by investigators who wished to identify more subjects for a research project and thereby improve its statistical power. What they presumptively did not recognize was that by recruiting simultaneously on both health outcome (non-Hodgkin's lymphoma) and exposure (2,4-dichlorophenoxyacetic acid), they would introduce a significant selection bias into their work, one potentially so severe as to invalidate any of their findings.

More recently, a study was published in the *Journal of the American Medical Association* of children with esophageal dysfunction who had been born to mothers with silicone breast implants (73). Once again, the key study subjects had been selected on the dual characteristics of health outcome and exposure. The investigators characterized their work as a case control study and indicated they had findings that were supportive of a cause and effect association. The fact that their report was little more than a case series was missed during the peer review process and corrected later in the form of an obscure errata, and apparently only then because of ad hoc peer review, that is, a series of highly critical letters to the editor (25, 36, 39, 87).

Figure 10.9 illustrates the dynamic which leads to *Berkson's bias*, a particular type of selection bias that occurs as a result of the patterns of referral, either self-referral or physician-referral (51). Although there is some merit in asserting that the 250 individuals who

FIG. 10.9. Berkson's bias: potential selection bias by referral.

initially consulted a physician represent those with the more definitive illness among the 1000 in the population at risk and thus were legitimate subjects for etiologic research, it is less likely that the same thing can be said about the 5 referred to a specialist or the 1 who finally ended up at a university center. Patients seen by specialists or at tertiary referral centers include a disproportionate number whose disease is complicated, obscure, or atypical. In our chemophobic society, these patients also may be referred because of a suspicion that the condition is related to what Peter Huber has called the latest *terror du jour* (64). A spuriously elevated relative risk will predictably be found in any research in which the study subjects are selected on the joint characteristics of the condition of interest and the putative agent of concern.

Even if no formal study is conducted, the specialist may develop a marked suspicion concerning the presumptive cause for the condition—and then act upon that presumption. Once it becomes known in the community that a physician or a referral center is interested in patients with a particular condition, especially when it occurs in conjunction with exposure to a specific agent, additional referrals or self-referrals further compromise the value of the sample for etiologic research (115). Ironically, the more caring the physician in the sense of being more willing to provide therapy to those who have been unsuccessfully treated or refused treatment by others, the more that physician becomes a magnet for these patients.

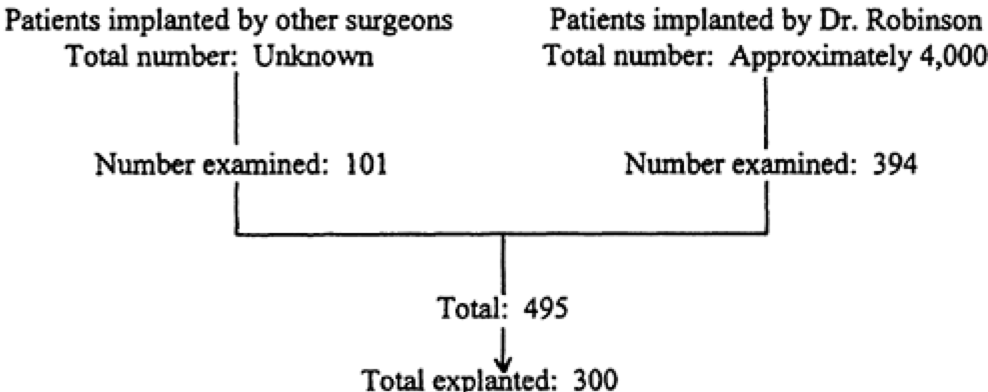
The 1995 publication by Robinson and colleagues entitled "Analysis of explanted silicone implants: A report of 300 patients" illustrates a number of different types of selection bias (93). Among the 300 women who Dr. Robinson explanted over the course of 3 years, 214 (71.3%) reportedly had "disruption" (defined as frank rupture of an implant or severe silicone bleed). Interestingly, these authors noted that there was "virtually no difference in the disruption rates between those patients relating symptoms to their implants and those who did not (71.8% versus 70.9%)," suggesting health complaints were not a consequence of implant status. Nonetheless, they extrapolated from this sample to predict that most implants will lose their integrity somewhere between 8 and 14 years and recommended that all gel-filled implants be removed "preferably before 8 years from implantation."

Robinson et al. based their "rates," their interpretations, and formulated a policy of explantation on

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_463.html[2010/10/28 18:44:28]

"Materials and Methods

From February 1, 1991 to January 1, 1994, 495 patients consulted O. Gordon Robinson with concerns about their silicone-gel implants. Of these 394 were his patients and 101 had been operated on elsewhere. All 495 had the same consultation and were offered implant removal. Of the 495 patients, 300 elected implant removal, and these constitute our study group."



Excerpted from Robinson et al. Analysis of explanted silicone implants: a report of 300 patients. *Ann Plast Surg* 1995;34:1-7

FIG. 10.10. Convenience sample.

data from a denominator of 300; but that was not the group they actually studied (Figure 10.10). According to the paper, Dr. Robinson saw 495 women who would have been eligible for this investigation, 101 who had been implanted by other surgeons, and 394 of his own patients. The 300 were drawn from the 495, but note, even if he had studied all 495, he still would not have been able to develop rates that were free of potential selection bias. Even with 100% participation of his sample, he would not have been able to develop rates that meaningfully could be extrapolated back to a larger group. That is because the 495 were a convenience sample, an ill-defined and likely highly biased sample of the larger population from whence they came. The larger population included all of Dr. Robinson's implant patients and, by implication, all the breast implant patients of the other 15 to 20 plastic surgeons who practiced concurrently in the same community (2). Court records indicate that Dr. Robinson implanted approximately 4000 women and it is quite possible that at least some of the surgeons in his community implanted comparable numbers (92).

So what can we make of the Robinson information? The data collected for this report were prevalence data. Although gathered over a 3-year period, for the individual study subjects they were obtained at a single point in biological time, time of surgical explantation. Because they had prevalence data, the researchers could not differentiate between events that occurred at the time of surgical implantation, during the period the implant was within the body, or at explantation. Therefore, their interpretation that implant failure was a function of the aging of the device, presumptively related to biological degradation of the silicone elastomer shell, required assumptions (e.g., the incidence time of rupture was just before explantation) that were not adequately addressed in this research.

Based on the work of others, at least some of those assumptions appear to be incorrect. Rapaport et al. have found an appreciable number of implant ruptures occur secondary to micropunctures caused by needles or other medical devices used during the implant procedure (88). Others have done work that expands on this observation (13). Brandon and colleagues, using lot-matched controls, reported that the material properties of the silicone shell were not affected by implantation for time periods up to 21 years, and concluded "that the silicone elastomer undergoes little or no change during implantation" (14). Also, Slavin and Goldwyn noted that approximately 25% of the implant ruptures they observed occurred during the explant procedure (110). At least two other mechanisms contribute to implant ruptures in vivo: closed capsulotomies (manual compression of the breast to rupture the tissue capsule surrounding the medical device) and so-called "fold flaws" (disruption of the elastomer by excessive

flexing at the site of folds in the shell). Both involve mechanical trauma. Obviously, dif

ferent approaches might better be used to prevent, control, or otherwise address implant ruptures caused by different mechanisms.

Setting aside the questions of the validity of the data and the causes of implant rupture, if the 300 who were explanted were a representative sample of the ever-implanted, then it is quite possible that a high proportion of implanted women have "disrupted" implants. Further, if "disruption" equates to implant rupture, either overt or occult, it suggests there may be a high rupture rate for these medical devices, at least for those brands and models favored by Dr. Robinson and his colleagues (22). On the other hand, if the 214 with disrupted implants are the majority of those in the numerator of a true rate, especially if disruption does not equate to rupture, then it is likely that the actual rupture rate is quite low, quite possibly a single-digit phenomenon. Of course if neither scenario is correct, then the information is invalid and has no utility at all. Furthermore—and in spite of the question about rupture rates—if these authors are correct in their observation that there is a lack of association between implant integrity and health outcome, a conclusion reached independently by others, is it good public health policy to expose all implanted women to the predictable risks of explant surgery (17, 131)? Probably not.

There are a number of lessons to be learned from this report. One, not understanding the difference between prevalence and incidence data can lead to flawed interpretations (26–28, 53–55). Two, selection bias can occur even when 100% of those selected for the study participate because the selection process itself may be flawed. Three, anytime there is less than 100% participation among those originally selected, even in a descriptive study of just the exposed group, the results are susceptible to an additional selection bias. Particularly troublesome are those situations in which the participation rates differ between the groups in analytic research—that is, among the exposed and the unexposed for a cohort study or the diseased and the healthy in a case control study—because this suggests the reasons for participation may not have been equivalent and therefore there may have been a spurious correlation between health outcome and exposure among one group or the other. The consequence of selection bias is an incorrect measure of association, possibly an underestimate of risk but often an overestimate. Complicating the situation still further, the dynamics of selection bias can change over time as a result of a well-publicized environmental controversy, a lawsuit, a provocative news program, or any number of other things. Thus, different types of selection bias can wax and wane. Four, flawed studies can lead to flawed policies, policies that ironically may put those whom they are designed to protect at greater risk.

In evaluating the literature, the reader needs to ask two questions related to selection bias. One, was the sample that the investigators were attempting to study truly representative of some larger group? Two, were the researchers successful in getting participation from all or a large majority of those they sought to study? An individual epidemiology report probably will have little or no value if the answer to either question is "no." The operative term in the last sentence is "probably." It is important to note that not every potential selection bias is real and therefore not every study in which there is less than 100% participation need be dismissed as meaningless. The question is how one determines whether a study with less than optimal participation provides relatively unbiased results. Usually one cannot make that determination from the single study. The question can only be addressed in the context of the larger body of literature. If the results of the potentially flawed study are comparable with those of other work in which selection bias is a lesser concern, the consistency suggests a cross-validation of findings. On the other hand, if the results of multiple studies are markedly different, it raises concern that the findings of one or more of the reports are biased.

Misclassification

Measurement or *misclassification bias,* also called *information bias,* is systematic error arising from the inaccurate measurement or inappropriate classification of subjects on the study variables—either exposure (to the putative agent or confounder) or health outcome. At some level, all measurement or classification is inaccurate. The errors may be large or small and, in turn depending upon the use to which the data are put, these errors may be important or meaningless. For example, in measuring blood pressure some physicians routinely round up to the next increment of 5 (e.g., 140 mm Hg systolic and 90 diastolic, or 145 and 95, etc.), others round down, and still others record to the closest unit of 2. The experienced clinician tends to make these measurements consistently on the same two of the five Korotkoff sounds; but which two may vary from physician to physician (47). These variations from the true blood pressure probably have very little importance in the clinical setting if the patient is consistently measured and treated by the same physician; but they could be very important if treatment is provided by multiple physicians. They also could be important if the clinical data were used to judge the relative efficacy of a variety of treatments as administered by different physicians.

Misclassification can be introduced into an epidemiology study by the study subjects, the measurement tool, the observer, or even, after the fact, by the consumer

of the research findings. For example, Edwards and associates conducted interviews to gather data on alcohol consumption (37). They observed that men reported significantly lower age-adjusted mean levels of alcohol use when a third party was present during the interview (probably the spouse in most instances). Conversely, study subjects may over-report specific conditions. Cautioning against placing too much reliance on self reported data, Star et al. noted that the self-reported diagnosis of rheumatoid arthritis could be confirmed in only about 20% of elderly women, a finding replicated more broadly across age strata by Sanchez-Guerrero and colleagues in a larger study of nurses (102, 116).

Overreporting or underreporting by study subjects may be a function of a number of factors unrelated to the biology of the disease (59). For example, medical students tend to develop the symptoms of the latest disease they are studying even to the extent that some male students reportedly have complained of sympathetic labor pains during their obstetrics training! To address such *reporting bias,* Turner and associates emphasized the importance of "double blinding" in clinical trials of pain medications, positing that even inadvertent clues of voice inflection or facial expression by an "unblinded" investigator could influence how a patient might report his or her symptoms (124).

There are various techniques that an epidemiologist might use to avoid or reduce the potential for either purposeful or unintentional misreporting. Concealing the intent of the research from the study subjects is one; but such "blinding" of subjects is increasingly difficult to use in a climate of mandated informed consent and almost instantaneous dissemination of news about the latest health controversy. Another approach is to add a dummy health variable whose association with the exposure is biologically implausible. For example, a query about dental caries could be incorporated into a study evaluating the effects of exercise on angina. If there is a strong correlation between the frequency with which the study subjects reported the dummy variable and the health outcome of concern, one should suspect a misreporting problem. In such a situation, it may be necessary to validate the reports—perhaps, if feasible, by examining a subset of the respondents or via review of medical records that predate the controversy or by use of a biological marker such as salivary cotinine for cigarette smoking (71, 94, 128).

At a minimum, the processes by which the data were collected should be well defined. Even then, there could be problems. It is well recognized by the seasoned researcher that mechanical or electronic instruments of assessment periodically must be calibrated to assure a consistency of measurement over time. To achieve validity, they need to be calibrated to an external standard. Yet the application of other data collection tools like questionnaires may be less than rigorous. With survey instruments, the order in which the questions were posed can be important. Even if the questionnaire is not open-ended, the words themselves may have alternative connotations for different ethnic or racial groups. To the extent possible, epidemiology research should use tools whose strengths and limitations are well recognized, or should incorporate a validation pilot into the research project.

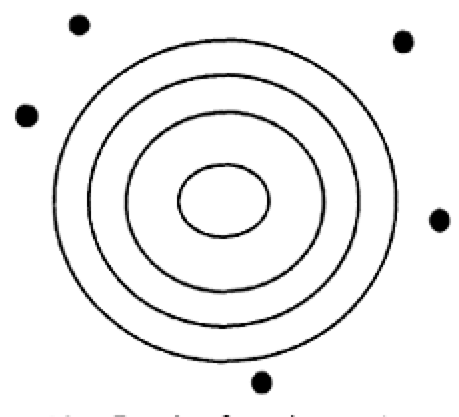
Diagnostic bias, a type of observer bias, occurs when a physician's diagnosis is influenced by his or her knowledge of certain exposures or surrogates of such exposures. In a study of eosinophilia-myalgia syndrome, Wagner et al. found up to a sixfold increase in diagnosing the condition when physicians were told the patients had ingested L-tryptophan, even though use of this dietary supplement was not part of the definition for the condition (129). In unpublished work, Cook submitted a series of chest x-rays to a board-certified radiologist and resubmitted the same x-rays about 1 month later. As is customary, a short description of each patient accompanied his respective radiograph. During one submission the patients were identified as office workers, during the other as pipe-fitters. When presented as pipe-fitters, they were more frequently diagnosed as having asbestosis.

Even laboratory tests that logically should be free of this bias may not be. In attempting to satisfy himself of the utility of a new laboratory test that purported to distinguish between those who did and did not have a particular environmental exposure, Young found a stronger correlation between test positivity and a history of exposure than the correlation with actual exposure, even when some of the histories had been fabricated. He concluded that "since the test costs at least $350, it is probably wise for surgeons to advise their patients to find a better way to spend their money" (130).

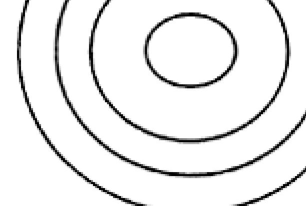
Conflict of interest is another form of observer bias. It occurs when special interests of the investigators unintentionally or intentionally compromise observer objectivity. Journal requirements for disclosure of the authors affiliations and financial interests are an attempt to control this bias, or at least make the readers aware of its potential; but this implies that affiliation and money are the only threats to objectivity (41, 56, 77, 97). There are others that are much more insidious: power, prestige, position, promotion, social philosophy, and a need to publish being just a few. The best protection against observer bias, whatever the cause, is for the investigators to be aware that it might exist and design it

out at the project's inception. This equates to a well-thought out protocol, review and approval of the protocol by an appropriate third party, slavish adherence to the approved procedures, and possibly even independent oversight of the conduct of the research. In other words, it requires good epidemiology practices.

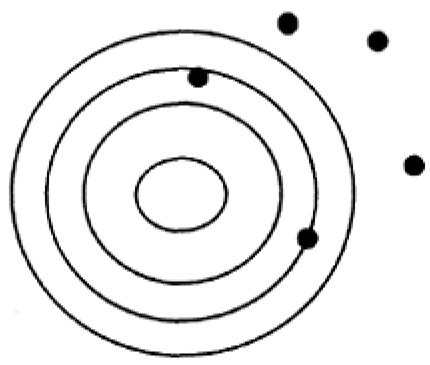
RELIABILITY
(Precision, Repeatability)
versus
ACCURACY



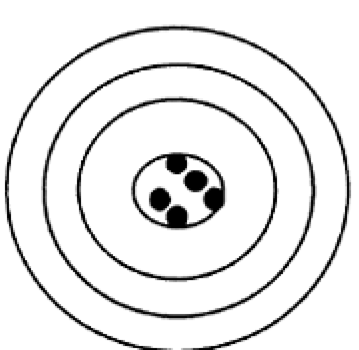
Not Precise but Accurate



Precise but not Accurate



Neither Precise nor Accurate



Both Precise and Accurate

FIG. 10.11. Precision and accuracy.

Misclassification can even occur after a study has been published! In the Robinson et al. article, silicone breast implants were classified as "disrupted" if, at time of explantation, the device shell was broken or it was simply judged subjectively that there was an excess of what appeared to be silicone gel surrounding the intact implant (93). Others, referencing the published paper, erroneously have implied that all the "disrupted" implants were ruptured (17, 53). Familiarity with the literature is the best protection against this form of misclassification bias. For those new to a field or an issue, it may be necessary to go back to the original sources before accepting the conclusions of a literature review or a meta-analysis.

Sensitivity and Specificity

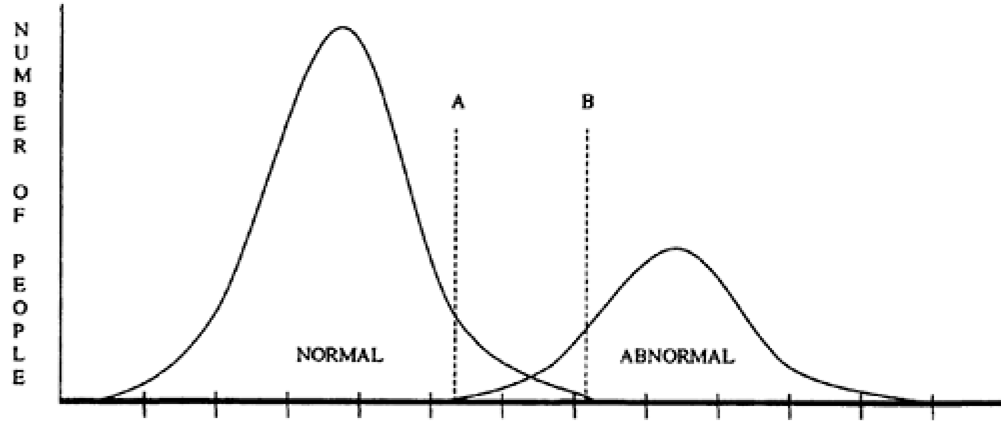
Consistency or precision of measurement, although important, does not assure the absence of measurement bias, whatever its underlying cause. As illustrated in Fig ure 10.11, it is possible to be precise and precisely inaccurate. What is more important is accuracy, that is the validity of the data. The key measures of validity are *sensitivity* and *specificity*. Sensitivity is a measure of how well the test

identifies a true condition (disease or exposure). Specificity is a measure of how well it documents a true noncondition (the absence of disease or exposure).

It is actually more complicated than that. A number of tests that are used in medicine, like blood cholesterol or antinuclear antibody status, do not clearly separate the normal individuals from those who are abnormal (62, 121). The distribution of values in each group overlap (Figure 10.12). In such situations, the operational diagnostic break point between the two can be somewhat arbitrary. It can be set to identify all the true abnormals (point A), all the true positives, but only at the expense of accepting a certain number of false positives, of

< previous page page_467 next page >

SENSITIVITY versus SPECIFICITY



TEST RESULTS

FIG. 10.12. Sensitivity versus specificity.

incorrectly labeling some normal individuals as abnormal. Or the break point could be moved to correctly identify all the true normals (point B), but only at the expense of getting more false negatives, of misclassifying some of the abnormal patients. In other words, where the break point is set can impact the sensitivity and specificity of a test; if sensitivity is improved it usually means the specificity has been compromised, and visa versa. For example, one could arbitrarily call all chemicals human carcinogens. Such an "error on the side of caution" would certainly correctly label all the true carcinogens, would guarantee a sensitivity of 100%; but the specificity of such a strategy would be abysmal because the number of false positives would be huge.

Note, to determine the sensitivity and specificity of a test, its results must be compared to those of a *gold standard*, an accepted test or procedure that reliably determines the presence or absence of the condition. Why then is it necessary to have the new test? Why not just use the gold standard? The new test may be needed because the gold standard is not as useful a tool in the clinical setting. It might be more expensive, inconvenient, invasive, or dangerous.

Paradoxically, data gathered by means of a gold standard actually might have little utility for etiologic research in and by itself, but still may be important for the development of tools that can be used in such investigations. Explantation, for example, is the gold standard for determination of implant rupture (17). However, for both technical and ethical reasons, it can only be used to collect prevalence data. There are other noninvasive techniques like mammography, ultrasound, and magnetic resonance imaging (MRI) that can collect incidence data and at lesser risk to the patient; but the relative validity of each can only be established via the gold standard of explantation.

Given there is a suitable gold standard, Figure 10.13 shows how these measures are calculated. TP is true positive, FN is false negative, FP is false positive, and TN is true negative. Sensitivity is obtained by dividing TP by (TP+FN), specificity by dividing TN by (FP+TN). For this particular example, the sensitivity and specificity are both 90%, quite good for most clinical tests (101). Sensitivity reflects how well, given the condition is actually present, the test detects the condition. Conversely, specificity is a measure of how well, given the condition is really absent, the test does not erroneously document its presence.

Predictive Value Positive and Predictive Value Negative

In real life, whether the condition is actually present or not is unknown before the test is performed. That's the reason for doing the test! For most investigations, what is of greatest interest is the predictive capabilities of a test: how well, given the test result is positive or negative, it respectively predicts the presence or absence of the condition. These measures, *predictive value positive* (PV+) and *predictive value negative* (PV−), can be obtained by making calculations in the vertical axis of the 2×2 table (Figure 10.14). In this example, the PV+ is 50% and the PV− is 98.8%. What this indicates is that among those who are diagnosed as having an illness on the basis of an "abnormal" test result, only 50% of them are truly diseased; and among those whose test result was in the "normal" range, 98.8% are actually healthy.

The two sets of measures are related but not equivalent. Although the sensitivity and specificity are relatively

	Test positive	Test negative	
Disease present	TP	FN	TP + FN
Disease absent	FP	TN	FP + TN
			TOTAL

Sensitivity = TP/(TP+FN)

Specificity = TN/(FP+TN)

	Test positive	Test negative	
Disease present	90	10	100
Disease absent	90	810	900
			1,000

Sensitivity = 90/100 or 90%

Specificity = 810/900 or 90%

FIG. 10.13. Sensitivity and specificity.

Predictive Value Positive = TP/(TP+FP)

Predictive Value Negative = TN/(FN+TN)

	Test positive	Test negative	
Disease present	90	10	
Disease absent	90	810	
	180	820	1,000

Predictive Value Positive = 90/180 or 50%

Predictive Value Negative = 810/820 or 98.8%

FIG. 10.14. Predictive value positive and predictive value negative.

stable attributes of a test, the predictive values vary widely as a function of the background frequency of the condition being studied. Figure 10.15 illustrates this point. For a given test, the less frequent the condition, the lower the PV+ and the higher the PV−. When the disease frequency drops to 1 in a 1000, the PV+ is less than 1%. In other words, if used as a screening tool, the test would label patients as "abnormal" incorrectly more than 99 times out of a hundred. This interplay between the underlying validity of a test and the relative frequency of the condition being studied impacts not only epidemiology, it also has important implications for medical surveillance (and the government regulations that mandate, fund, or otherwise support such procedures) as well as toxicology, in particular as it impacts risk assessment.

For example, a blue ribbon panel of experts recently recommended that routine mammography screening be restricted to women over 50 or those in high risk groups. In both, the frequency of breast cancer is orders of magnitude higher than it is in the general population of younger aged women. This recommendation ignited a fire storm of controversy and the panel, in part apparently due to pressure from Congress, subsequently modified its recommendation to include younger women (40). This probably will prove to be a mistake. Predictably what will happen is that the medical system will be flooded with false positives (38).

There are a number of downsides to a false-positive breast cancer screening test among younger women. One, a false-positive test can severely frighten patients. Even among those subsequently told the test was incorrect, many will retain a lingering anxiety at the very least. Two, an abnormal mammogram is often checked by means of a biopsy. This surgical procedure is associated with a cer

Given:

Sensitivity=90%
Specificity=90%

Disease Frequency	PV+	PV−
1 in 10	50%	98.8%
1 in 100	8.3%	99.9%
1 in 1,000	0.9%	99.99%

FIG. 10.15. Predictive values as a function of diseasef requency.

tain small but predictable risk of infection, bleeding, loss of sensation, and adverse reactions to anesthesia. For women without breast cancer, it is an unnecessary risk. Three, false positives put a strain on our medical care delivery system and misdirect limited resources. Four, even procedures that produce false results cost money, a financial burden that must be borne by the individual patient in the form of direct payments and by society at large in the form of increased insurance premiums and higher taxes. Five, arguably of greatest importance, some young women after one, two, or more false positive reports may lose confidence in the procedure. A certain number of these will drop out of the mammography program and never re-enroll. This means that they will not get the screening test later when they would benefit from it most.

The results of toxicology studies are not immune to this problem, in part because their results are routinely extrapolated to humans. If a high dose of an agent is found to cause tumors among rodents, it is current policy to assume it will cause some form of cancer in humans at lower levels of exposure. Unfortunately, although the sensitivity of toxicology research is quite high (but not perfect), its PV+ for extrapolations between different species of rodents is low, in the order of 50% in a study of various chemicals purposefully selected because of their presumed carcinogenicity (67). Arguably its PV+ is even lower for humans, especially for chemicals being tested simply to satisfy a mandated protocol (see questions).

Nondifferential and Differential Misclassification

Descriptive epidemiology research such as that done by Robinson and colleagues focuses on a single group (93). Nonetheless, misclassification obviously can produce erroneous information. In analytic epidemiology, the problem is compounded because data are gathered on and compared between two or more groups. This can lead to errors which are either *nondifferential* or *differential*.

With the *nondifferential mismeasurement* or *misclassification*, error is equivalent across all study groups. For example, an investigator may wish to compare the effects of growth between two groups with different dietary habits. As the health outcome, height might be assessed and recorded to the nearest inch. Even if the measurements were made carefully, two individuals with identical recorded values could easily vary in height by a half inch or more. In spite of the mislabeling, if the measurements were conducted consistently, the rank order of the various study subjects by height, short to tall, would be reasonably accurate. Furthermore, this would be the situation irrespective of the exposure group to which a particular individual might belong. As a consequence, meaningful comparisons could be made between the two groups. What the nondifferential misclassification might do is add a degree of statistical variability to the data and thereby bias the measure of association, the RR or OR, towards the null—to a greater or lesser extent depending upon the magnitude of the bias.

With *differential misclassification bias*, the relative invalidity of the data varies by study group. This may give rise to unpredictable shifts of the RR or OR either toward or away from the null and may generate marked under- or overestimates of RR depending on the size and direction of the differential error. It can even generate large measures of apparent excess risk where none really exists. In addition, this error is magnified as a function of the underlying frequency of the condition. Figure 10.16 illustrates these points. In this example, the respective sensitivities and specificities were quite high; but a slightly better job of identifying problems was done among the employees exposed: there was a better sensitivity, but also a concomitant decrement in the measure of specificity. Although the *true relative risk* was 1, that is, there was no excess risk in either group, the *apparent relative risks* among the exposed employees in plant A were quite high.

Does this happen in real life? Yes. Dr. Irving Selikoff justifiably has been recognized as one of the icons of modern occupational medicine. In 1968, he and his associates published a paper in the *Journal of the American Medical Association* entitled "Asbestos exposure, smoking and neoplasia" in which they reported an excess risk of lung cancer among insulation workers (104). Quoting from the article, "A copy of the death certificate was obtained for each of the 94 deaths. In addition we examined hospital records, postmortem findings (41 cases), as well as the surgical and pathological reports when surgery was performed (39 cases). We also re-examined histologic

Givens:

Background Incidence Rate	Apparent Relative Risk
10 per 100 per year	1.9

1 per 100 per year	5.5
1 per 1,000 per year	9.2

FIG. 10.16. Risk estimates in presence of differential misclassification.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_470.html[2010/10/28 18:44:32]

specimens. It was found that the death certificate was inaccurate in 14 instances." For comparison numbers, that is, expected deaths by cause, they used "United States 1964 life tables for white males." In their well-meaning attempts to be thorough, they introduced a significant bias into their study because, by using multiple sources to diagnose the exposed and only one source (life tables based on death certificates) to determine cause of death among the unexposed, they compromised their study results with differential misclassification. As a consequence, they overestimated the true relative risk.

Differential misclassification continues to contaminate research and clinical practice. Propelled by a series of case reports in the late 1980s and early 1990s, a cascade of systemic diseases were alleged to have been caused by silicone breast implants (105, 108, 114). Many of these theories have been evaluated in case control and cohort studies and found wanting (33, 119). An unresolved question is whether women with implants are at higher risk to something called atypical connective tissue disease (ACTD) or, by some, siliconosis and, more recently, systemic silicone related disease (SSRD) (107, 111). One of the problems with this alleged condition is that no one can define it well enough so that it can be rigorously studied to determine whether it occurs uniquely or more frequently among women with breast implants. Investigators who have tried have reported that the condition is essentially the same as fibromyalgia or chronic fatigue syndrome and the risks appear to be equivalent in women who both do and do not have breast implants (21). However, those who allege a unique disease does exist and waits to be discovered criticize this work as "studying the wrong disease" (112, 132).

To address this presumptive shortcoming, one physician proposed epidemiologists utilize a set of criteria that he developed to diagnose SSRD in his medical practice (113). It is based on a series of inclusionary, exclusionary, and relatively nonspecific clinical criteria. By definition, one of the two inclusionary criteria are needed to make a diagnosis, either "current or past silicone gel-filled breast implants" or a "local disease" such as capsular contracture or implant rupture. Parenthetically, neither of the latter could occur unless a woman had an implant. They are, therefore, surrogates for the exposure of interest, silicone breast implants.

Restricting a diagnosis of SSRD to those with the joint characteristics of exposure and health outcome means that two women with exactly the same signs and symptoms, one with silicone breast implants and the other without, could never be classified as having the same condition. By means of the inclusionary criteria, Dr. Solomon assured, however inadvertently, that any epidemiology study that used his definition would be biased by essentially a 100% differential misclassification (113). In theory, any etiologic research based on his definition would produce a spurious elevated relative risk that approached infinity.

Similar biases occur in toxicology research, both nondifferential and differential. The traditional acceptance of tumors, benign and malignant, as a surrogate for cancer is one form of misclassification. In well-conducted studies, it probably is nondifferential; but any time the methods for disease determination differ between the exposed animals and the controls, it could be differential. For example, if more histopathological slides are made or read for the exposed animals than the controls, it is more likely that small occult tumors will be found among the exposed. This is differential misclassification, one that would introduce an overestimate of risk.

The reader of scientific reports can garner clues regarding the potential for misclassification bias, both nondifferential and differential, from the Methods and Materials section of these articles. The variables, both exposure and disease, should be well defined and equivalent throughout. If they are not, the reasons for the differences should be discussed. The techniques for data collection should be reasonable and applied consistently across all groups. It is important to be particularly vigilant if a study report did not discuss the potential for misclassification bias and how it was addressed. This suggests the authors were either naïve regarding the problem or chose to ignore it. In either situation, the potential for bias could be high.

Confounding

A potential *confounder* is a determinant for the disease in question, an alternative "cause" whose effects may confound or confuse the results of an epidemiology study. It can either be an agent itself or a surrogate for that agent. For instance, age is a surrogate for a constellation of biological, environmental, and social factors that individually and in aggregate are associated with increased risks to certain diseases. The same can be said for race and ethnic background. One of the two major characteristics of a confounder is that it is a "cause" for the disease under study. Different agents have different effects. None are universal confounders.

A confounder is not the same as an *effect modifier,* although an agent, depending on the study, can be one, both, or neither. With effect modification, there is a nonuniformity of effect across various levels of

the effect modifier (98). For example, the consequences of exposure to pathogenic organisms varies by immunization status.

In addition to being an alternate cause, the other major attribute of a confounder is that it must be unequally distributed across study groups. That is, *confounding* only occurs when a determinant of the outcome of interest

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_471.html[2010/10/28 18:44:33]

(a confounder) is unequally distributed among the exposed and the unexposed in a cohort study or among the diseased and the nondiseased in a case control study. As with the biases related to selection and misclassification, the degree of differential distribution determines the direction and magnitude of the error. In addition, the relative "potency" of the confounder can also, to a greater or lesser extent, influence the apparent relative risk or odds ratio.

For example, cigarette smoking is one of the major determinants of lung cancer. Any epidemiology study investigating the carcinogenic potential of a particular agent vis-à-vis lung cancer has to take this into consideration, has to "control for smoking." If not, the greater the proportion of the exposed who are or were smokers, the greater will be the overestimate of actual risk. On the other hand, if more controls smoked, the true risk to the putative agent will be underestimated.

Smoking is also associated with mortality due to cardiovascular disease; but not to the degree to which it causes lung cancer. In other words, equivalent amounts of unequal distribution between the two study groups may not have the same impact on the measures of risk for different conditions because the potency, the biological activity of a confounder, varies from disease to disease. With lung cancer, smoking equates to a relative risk of perhaps 10, whereas for cardiovascular mortality the relative risk lies closer to 1.5, and for still other diseases it has a RR which approximates 1 (no effect).

Very few, if any, diseases have only one etiology. Even a rare malignancy like angiosarcoma of the liver has a number of alternative causes aside from vinyl chloride monomer (42). Agents with high potency are relatively easy to discern. It is those with lesser biological activity that are more difficult to identify. An indeterminate number of the latter undoubtedly have not yet been discovered. Theoretically, because all the causes for the various diseases are unknown, some level of confounding may occur in any epidemiology study (and any toxicology study for that matter). In addition, it is highly likely that there are synergistic and antagonistic actions between various agents, both exogenous and endogenous, further complicating the picture. Evidence is also growing that suggests that effects seen at high dose may actually be reversed at low dose, a phenomenon that makes the interpretation of the dose response curve more challenging (18).

In experimental studies, the number of variables are purposefully kept to a minimum and ostensibly all of them are under the control of the investigators. Those who conduct observational studies of humans do not have the same advantages. The number of variables are only limited by life itself. Each participant in an epidemiology study has his or her own unique genetic makeup and own unique pattern of extraneous exposures (diet, medications, personal habits, etc.). Although either or both may be only weak confounders for a particular health outcome under investigation, they may be one reason why epidemiology research, especially any single study, has difficulty in reliably identifying putative agents with lesser biological potency, with true relative risks less than 3 or so (123). That is because even in the absence of selection and misclassification biases, the signal may be swamped by the noise of uncontrolled confounding. In epidemiology, the signal-to-noise ratio is improved via more research, especially more targeted research. As the exposure-disease associations become more focused, the relative risks should increase in size. If they don't, be suspicious of claims of causation. Also be suspicious of etiologic interpretations based on one study unless there is supporting evidence.

Control of Confounding

Confounding can be addressed through study design, data analysis, or a combination of both. For example, if smoking is a confounder for a particular disease (i.e., those who smoke get the disease more frequently than those who don't smoke, but those who don't smoke still get the disease), confounding by smoking can be dealt with via a technique called *subject category restriction;* that is, by restricting the study subjects (both those exposed to the putative agent and the controls) to just those who never smoke. This design strategy simplifies the analysis and interpretation of the data; but it also restricts how broadly the results can be extrapolated. If only nonsmokers are studied, the results derived from the sample usually only apply to the larger population of nonsmokers. Comparable information about smokers must come from another study restricted to exposed and unexposed individuals, all of whom smoked.

Alternatively, if a certain number of subjects are being evaluated and it is known that a proportion of those in the exposed and unexposed groups were smokers, controlling for confounding could be attempted at the analysis stage of the research, possibly by means of a *stratified data analysis* whereby different strata of smokers are analyzed and the results combined across strata. With the advent of high speed computers, ever more sophisticated statistical techniques have been developed to control confounding; but most of these incorporate assumptions that may or may not be valid depending upon the circumstances and, because they involve complex calculations within a "black box," it is often

impossible for the reader (and perhaps even the investigators) to assess the relative impact of the various assumptions on the results.

Matching on potential confounders—age, race, gender, smoking, etc.—is an intuitively attractive way of address

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_472.html[2010/10/28 18:44:34]

Page 473

ing confounding that combines elements of both study design and data analysis. However, it is not a panacea (98). Not only may it be difficult to do properly, it also places certain constraints on the types of information that can be developed. And it may lead to *overmatching,* that is, to matching on surrogates of exposure or health outcome (54).

No matter what method is used to prevent or control confounding, decisions about which specific potential confounders might be important need to be made at the stage of protocol development, if for no other reason than to assure that adequate data are collected. Obviously, it would be impossible to control for smoking during the analysis stage of the research if no data had been collected concerning cigarette smoking.

Confounding is not restricted to epidemiology research. It also occurs in toxicology. For example, Hart and associates have explored the impact of food intake in laboratory animals (61). They noted that animals fed *ad libitum* have poorer health and longevity than those whose diet has been restricted. The total caloric load appears to play a role, but trace contaminants may also be important. As reported recently by Paolini and colleagues, most standardized diet formulations used by cancer research laboratories worldwide, "contain the well-known mutagenic carcinogenic element manganese at the same level and, in some cases, at an even higher level (up to ninefold) compared to that used to study the carcinogenicity of manganese itself' (85). Obviously, the more animals eat, the higher their caloric load and the higher their dose of this carcinogen. However, the amount ingested could be an unintended consequence of the experiment, for example, ever larger amounts of the test chemical mixed with the food may make the food less and less palatable. For those experiments in which ingestion varied by dose level of the experimental agent, it is quite possible that the results reflect a measure of confounding, and perhaps effect modification. Paolini et al. also summarized a number of problems with using historical controls. For example, "B6C3F1 mice have a higher natural incidence of tumors than humans, and this incidence has also changed over time, increasing in excess of 50% over a period of just 10 years."

Although it is impossible to control for all possible confounders in any single study, the reader of epidemiology reports should determine whether attempts were made to control those factors which likely would have had the greatest impact on the results. As with other types of potential bias, a paper can offer a number of clues as to how well this issue was or was not properly managed. If confounding was ignored or obviously inadequately addressed, be skeptical of the information. Look for confirmation in other work which did try to minimize confounding.

Chance

Within the mantra of selection, misclassification, confounding, chance, and causation, the rubric *"chance"* covers all things mathematical and statistical and some that are methodological. For example, did the investigators add, subtract, multiply, and divide properly? Were the number of subjects consistently the same in the abstract, results, discussion, and tables? With more complex statistical procedures, especially those conducted in the mode of exploratory data analysis, it is possible for even the most seasoned epidemiologist to inadvertently lose part of a data set or to ignore a key assumption and thereby produce erroneous results. If numbers are inconsistent within a report, do the authors explain why? If they do, does the explanation seem appropriate or does it smack of gerrymandering or numerology? If either of the latter, look for confirmation of the results elsewhere. Or look for a correction published as an errata in a subsequent issue of the journal.

The term "statistical significance" is used by both epidemiologists and toxicologists. It means that within some acceptable measure of statistical "wobble" two findings were not equivalent, a measure of association such as the relative risk was different than 1, a trend was found, two variables were highly correlated, etc. It is not the same as biological significance because it does not speak to the underlying validity of the data. As a consequence, if it is apparent that the data set in a research study is likely biased by selection, misclassification, or confounding, it may make very little sense to analyze the data or to accept any information resulting from a data analysis.

Nor does statistical significance equate to cause and effect even in situations where the underlying data may be valid. For example, Vojandi, Campbell, and Brautbar published a study in 1992 that compared the results of a large number of tests of immune function among women who had breast implants for more than 10 years with those of a sex- and age-matched control group composed of women who did not have these medical devices (127). In this study, they identified a number of differences ($p<.001$) between the exposed and the unexposed and concluded that "these immunological abnormalities in individuals who underwent silicone breast augmentation indicate a mechanism of tissue injury to these patients causing autoimmune diseases or syndromes…"

Their data may have been valid; but their inference regarding breast implants was not. In the study, all of the implanted women had "symptomatology in relation to the musculoskeletal and nervous system" and all the unimplanted women did not. In the context of the 2×2 table, they only collected data for two of the four cells, a and d: the exposed/diseased and the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_473.html[2010/10/28 18:44:34]

unexposed/healthy. As a consequence, they could not disentangle the two variables and determine whether the implants "caused" the disease. They could not calculate a relative risk or odds ratio and therefore could not determine whether women with breast implants were more likely to get disease. At best, what their study could do was to appraise the efficacy of their test battery for differentiating between those who did and did not have disease, irrespective of exposure (24). But even for that, the exercise was of little utility because the "disease" was so poorly defined and the battery of tests so broad.

p Values and Confidence Intervals

Increasingly, epidemiologists are moving away from the use of *p values* and toward *confidence intervals (CI)* (43). *p* values, although useful, can obscure important characteristics of the underlying data set. By itself, a *p* value less than .05 or .01 suggests a finding that deviates from the null (e.g., a RR that differs from 1), but not whether the result is higher or lower. Nor does it necessarily provide insight regarding statistical power. With confidence intervals, one set of numbers representing the range of values which are consistent with the data observed, for example, the 95% confidence interval, provides not only an indication of where the point estimate of risk lies relative to the null, but also gives the reader a sense of the underlying variability of the data and, therefore, the *statistical power* of the study to detect a problem given one exists. If 1 lies within a 95% CI, it indicates the finding is not statistically significantly different from 1. If the lower value of a 95% CI is greater than 1, the estimate of risk is statistically significantly elevated. If the upper value is less than 1, it is statistically significantly decreased. Furthermore, the width of a confidence interval is an indication of the power of that study, at least for that particular outcome. If narrow, the power of the study was large. Conversely, if wide, the power was low.

It is important to note that a study result may have a wide confidence interval and still be valid. Statistical power and study validity are not equivalent concepts. One addresses precision, the other accuracy. In fact, a result from a small study relatively unbiased by selection, misclassification, and confounding may be more valid than the result from a larger study that has a narrower confidence interval. Although the former may have limited utility in and by itself to support or refute causation as a consequence of its low power, when combined with the results of other studies of comparable quality, it may prove to be very valuable. This is the rationale underlying *meta-analysis*.

Meta-Analysis

Meta-analysis refers to the use of statistical tools to combine the results of different studies. Originally, it was confined to randomized controlled clinical trials, to combining results of multiple small studies of the equivalent design, that is, those with identical dosing regimens and comparable, well-defined outcomes. It is increasingly being used to aggregate the findings of multiple epidemiology studies, even when their results were derived by means of disparate methods (e.g., cohort and case control studies), the sample sizes varied by orders of magnitude, the categories of exposure differed, and the disease outcomes were similar but not equivalent (11). Although some decry the use of meta-analysis for this purpose, others view it as an important adjunct to the traditional, more subjective literature review. Done properly, meta-analysis promises not only an aggregate quantitative measure of risk that has a narrower confidence interval than each individual study, but it also facilitates the identification of any studies that may be outliers, perhaps because of various types of technical bias or differences in study design.

Meta-analysis is not the same as *data pooling*. Whereas meta-analysis depends upon the research results as obtained from epidemiology reports, pooling refers to the aggregation of the actual raw data from many different studies and the subsequent analysis of this larger, single data set. Conceptually, pooling has some advantages over meta-analysis; but in practice it also has a number of disadvantages, a major one being access to the data. Unlike meta-analysis where the results have been distributed publicly via the scientific journals, data are not as readily available. In part, this is because of concerns related to protecting the privacy of individual study subjects and the confidentiality of their data (6).

The validity of a meta-analysis is dependent upon the validity of the studies included in the exercise. To address this problem, some have suggested that a priori rules must be established with respect to which studies to include or exclude. Unfortunately, these rules may reflect the personal biases of the person doing the meta-analysis. For that reason, a type of sensitivity analysis is arguably a better approach (86). In this type of analysis, the results of all available studies are first evaluated together and then various combinations are used to better understand how the different methods, number of study subjects, classifications of exposure, or definitions of health outcome may have influenced the calculations. It can even be used to compare and contrast the results of different studies that may have

different types of bias and to explore whether potential bias is a likely explanation for why one or just a few of the studies seem to be outliers. If a comprehensive sensitivity analysis is conducted and the results published, readers also have the opportunity to make their own interpretations, something that can be difficult to do with the traditional literature review or even with pooling.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_474.html[2010/10/28 18:44:35]

There is one particular type of bias to which meta-analyses are particularly prone: *publication bias*. Publication bias is a type of selection bias. It refers to the tendency of authors to submit and editors preferentially to accept studies with provocative findings (3, 34, 68). This has also been called *positive results bias* and can be exacerbated by a *hot stuff bias* (100). The publication of "I had a patient like that too" case reports is an example of the latter. Such a flurry of case reports following the initial announcement of an interesting finding in either a medical journal or the popular press can give undue credibility to hypothesized associations, even if they are not real. There are a number of different approaches that can be used to assess the possibility of publication bias, but the best way to avoid it is to aggressively search for pertinent research reports, including those in the form of dissertations, abstracts, and publications in obscure journals (90).

Exploratory Data Analysis and Multiple Comparisons Bias

To the general public, all findings of statistical significance have basically the same merit. They either accept them as exact and correct or, when faced with apparent contradictions, become frustrated with science. The late Senator Edmund Muskie, following an exhaustive series of federal hearings in which various experts testified about a complex environmental issue, epitomized that frustration when he reportedly said that he wanted to meet a one-armed scientist, someone who did not always say, "On the one hand this, but on the other hand that."

Scientific discovery is not a destination. It is a journey with many side trips along the way. It starts with a hypothesis, a theory whose genesis may be any number of things ranging from the subjective (clinical observations that seem unusual for intuitive reasons) to the super quantitative (statistically significant findings derived during *exploratory data analysis* of a large medical data set, e.g., the health claim files of a private insurance company or of Medicare/Medicaid). Before these findings can be accepted as even provisional truth, they have to be confirmed by additional research, preferably well-focused hypothesis-testing research.

In both hypothesis-generating and hypothesis-testing exercises, the same statistical tools and the same levels of statistical significance may be used. Yet the findings of the former do not carry the same interpretive weight as those from the latter (109). That's because the former, in addition to uncontrolled confounding, are subject to a *multiple comparisons bias* (122).

The statistical tests used in health research factor in both a type I and a type II error. A type I is the error of rejecting a null hypothesis, of concluding that a difference exists when, in truth, it does not. By convention, the alpha level (the probability of a type I error) is usually set at .05 (that equates to a 95% CI). This means that a certain predictable number of statistically significant findings are incorrect, about 1 in 20. The greater the number of comparisons, the greater is the number of spurious associations that may be found, that is, the larger is the multiple comparisons bias. Various techniques have been developed to address this bias, the simplest perhaps being the *Bonferroni correction* in which the putative alpha is divided by the total number of comparisons and the "corrected alpha" used to determine the presence or absence of statistical significance (78). For example, if the study alpha level was preset at .05 and 10 comparisons were made, a Bonferroni-corrected 95% CI would, in essence, be a 99.5% CI.

In many studies in which a large number of comparisons are made, the authors will do a Bonferroni correction or some analogous procedure and report the confidence intervals with and without the adjustment. In others, they will not; but they will indicate the total number of comparisons and thus allow the reader to develop his or her own opinions about the merit of the findings. In still others, it may be difficult for the reader to recognize the potential for a multiple comparisons bias, especially if investigators practice surreptitious data dredging—engage in exploratory statistical analyses of large and diverse data sets, but selectively report only those results which support their own pet theories (82, 103, 122). Because few comparisons are presented, the reader is given the erroneous impression that only those few were considered and therefore they must have been of some a priori concern. This approach can be particularly attractive to quasi-scientific advocacy groups who recognize the publicity value of a statistically significant cluster.

Post Hoc Reasoning

The latter is but one of a number of variations on the theme of purposefully biased science (66, 81). In another, the investigator simply scans a data set and determines which hypotheses he wishes to test. Or he may gerrymander the data set and thereby construct an artificial cluster. In either case, by having foreknowledge of what the cluster is and where it is located in the data set, he can reduce the total number of actual statistical procedures and therefore, even with "overly conservative" corrections for multiple comparisons, claim to have refuted the null hypothesis. The nefarious may even point to a

hypothesis in a protocol that predated the formal statistical analysis. Although the work seems to fit the scientific method, giving the results an aura of biological credibility, the findings are a product of *post hoc reasoning*. They are worthless. Using this approach, statistically significant clusters even can be generated from a table of random numbers.

Investigators who are guilty of post hoc reasoning are sometimes derisively called *Texas sharpshooters* (58).

In most target shooting, one shoots at a bull's eye. The Texas sharpshooter first shoots at the side of the barn (perhaps from very close to the building) and then draws the bull's eye around the holes. By doing so, he claims his marksmanship is both precise and accurate.

If clusters of disease are the catalyst for an epidemiology study, they can introduce another form of self-fulfilling reasoning into the research. It occurs when an investigator stumbles upon a cluster of disease, perhaps in an occupational group, and then uses the cluster both to develop a hypothesis about one or more of the chemicals to which the group was exposed and also to test this hypothesis, that is, the cluster is incorporated into any subsequent analytic research. If the disease is rare, it is quite possible that an elevated relative risk will be found in the formal epidemiology study even if no new cases are discovered in the expanded cohort. Although the additional research in this situation may be designed, initiated, and conducted after the theory was developed, it will not be an independent test of hypothesis (3, 23, 44).

In summary, even the most precise results may be wrong, a consequence of simple mathematical errors, technical bias, or less innocent intent. Although exploratory data analysis is a valuable tool, more is not always better. This maxim applies equally well to epidemiology, toxicology, and clinical medicine (Figure 10.17). To be interpreted properly, the results of tests must be put in the context of the size of the data set, the number of tests that were performed, the body of information that is already available, and even, if possible, the mind-set of the investigators at the inception of the research. The latter may be obvious from the introduction of the paper or from the protocol; but sometimes it can only be surmised.

Causation

Even when selection, misclassification, and confounding are minimal, the identification of the causes of human disease is not simply an exercise of calculating which exposure-disease associations are statistically significant. It is a thoughtful process based upon the preponderance of evidence and a logical ordering of that information. Sir Bradford Hill, a British statistician/ epidemiologist, presented his criteria for determining causation in the mid-1960s and subsequently refined them for his textbook (63). These criteria are still in wide use. In interpreting data, he noted that an investigator must deal with two basic problems: *significance* (the statistical reliability of a finding) and *inference* (the deductions one might make from such a finding). With the former, he cautioned against overinterpreting statistical significance and also noted that, if absent, "chance is a not unlikely reason" for an apparent difference, for an apparent association, and for an apparent elevated relative risk. As for inference, he offered nine criteria for differentiating between "causation or merely association" when faced "with a clear and significant association

You seem to be in fine health but let's run a few tests. I'm sure we can find something wrong with you.

FIG. 10.17. Multiple comparisons bias in clinical medicine.

between some form of sickness and some feature of the environment" (Table 10.2).

His first criterion was *strength of the association;* in other words, the size of the relative risk or odds ratio. Obviously not every statistically significant relative risk is meaningful; but the larger the number, the less likely any observed association is simply the result of random error or the consequence of selection, misclassification, and confounding. The question is, "How large is large enough?" For isolated findings, seasoned epidemiologists are reluctant to accept relative risks of less than 3 or 4 (123).

Sir Bradford's second criterion was *consistency*, the finding of similar relative risks for the same condition and exposure in different epidemiology studies conducted by different investigators on different groups of participants. In part, this is important because it is unlikely that the equivalent errors would be replicated in all the studies. Therefore, a finding that is consistent across many studies is more likely true. It logically follows that a summary measure of risk as derived from consistent findings will more likely reflect the underlying biological truth than the results of any single study. As mentioned earlier, meta-analysis provides such a summary measure. It is a way of teasing out a signal from the cacophony of noise that is inherent to epidemiology. If statistically significant, the findings of multiple small studies may be biologically important; but also meaningful can be the absence of elevated risks in study after study after study or as de Grasse Tyson has emphasized, "Null results matter, too" (31). Although it is theoretically impossible to prove the negative, when multiple studies fail to identify an association between disease and a particular exposure, pragmatic scientists conclude proof of causation is lacking and move on.

As his third criterion, Sir Bradford offered *specificity*, elevated risks to a single or small number of well defined health problems. When many disparate conditions are attributed to an agent, at some point it becomes question able whether any of them are a likely consequence of exposure. The need for specificity also applies to the disease itself. No meaningful body of etiologic research can be conducted to determine if a condition occurs more frequently among the exposed if the "disease" cannot be defined because, perforce, each individual study would be evaluating a different outcome. The same holds for exposure. Although the initial stages of investigation may incorporate broader categories of disease such as "pulmonary disease" and mixtures of chemicals, knowledge comes with focus.

Sir Bradford's fourth criterion dealt with the *temporal relationship* of the exposure and the disease or, as he put it, "which is the cart and which is the horse?" In cross-sectional or prevalence research, it is often impossible to make this determination. Conditions with long latency or those whose signs and symptoms wax and wane over time can further complicate the picture (124). Nonetheless, if the condition occurs before the exposure, it cannot have been caused by the exposure.

His fifth criterion was *biological gradient,* that is, if small doses cause harm, do larger doses cause greater harm? Parenthetically, this is not a variation of the assumption inherent to quantitative risk assessment, that is, that if large doses are associated with health problems, lesser doses cause lesser problems (18). Something akin to linear extrapolation back through zero exposure must be assumed for the latter. Such an assumption is not required for the former.

Biological plausibility was presented as a sixth criterion. This he implicitly categorized one of the lesser tier of criteria because "what is biologically plausible depends on the biological knowledge of the day." Some consider this necessary to prove causation, that is, that the underlying mechanisms of action must be understood before cause and effect can be accepted. For many, it is too stringent a requirement. They are satisfied if a meaningful association is found for a risk factor even if the exact causal agent and the process by which it works is unknown. In a sense, biological plausibility also is a lesser criterion because it is subordinate to other criteria. For example, a biologically plausible explanation for a disease excess is meaningless if there is no disease excess.

The seventh criteria addressed the *coherence of the evidence,* the amalgamation of what is known

concerning the natural history and biology of the disease, the presumptive actions of the etiologic agent, the results of experimental research on animals, and the contributions of other types of information. The evidence can come from within a single study or across studies from many different disciplines. Cigarette smoking, for example, is associated with both an increase in lung cancer and an excess risk for a constellation of other diseases, in part because smoke is a mixture of noxious agents. Although lung cancer may be the outcome of interest in a particular

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_477.html[2010/10/28 18:44:36]

Page 478
study, say one evaluating the impact of low levels of smoking, an increase in both lung cancer and the other pertinent diseases would add coherence to any evidence of harm. As for multidisciplinary evidence, the decrease of mammary tumors among methylnitroso urea-exposed animals implanted with silicone gel-filled devices adds credibility to the epidemiology findings of lower breast cancer risk among women with silicone breast implants (120).

The next attribute was *experiment;* but not necessarily in the context of a laboratory experiment. He also considered the removal of the presumptive etiologic agent a type of experiment. If a problem resolves following such removal, it may provide support for cause and effect; but even this is not absolute proof. Diseases wax and wane. If the putative exposure is removed at the apex of disease severity, resolution may take place coincidentally and the condition, in the absence of exposure, may return at a later date. If that were the case, it would suggest the original "experiment" was incomplete and therefore lent fallacious support to conclusions about cause and effect. To eliminate this possibility, there must be adequate follow-up of the patients following removal of the putative agent. Even then, there are a number of other things that can confound such experiments. Humans react to subliminal clues, exhibiting both placebo and nocebo effects, and these can present as either subjective symptoms or more objective signs of disease (117). Resolution of a condition may be related to concomitant treatment. Alternatively, its original presentation and subsequent resolution can be due to malingering (106).

Sir Bradford's ninth and final criterion was *reasoning by analogy,* that is, if agent *X* can cause disease *Y,* then perhaps a material similar to X can cause a disease comparable to Y. Some have argued that because new environmental immunologically mediated diseases such as eosinophilia myalgia secondary to L-tryptophan exposure are still being identified, it is possible (they imply probable) that silicone is also associated with a new disease. However, eosinophilia myalgia has a relatively short latency. It also has a characteristic clinical presentation. Both of these attributes are missing with silicone. If there is an epidemic of a unique autoimmune disease caused by silicone, it has not yet been discovered. If this is because it is a disease of long latency and therefore the epidemic has not yet occurred, one has to ask the question, "What then is the basis for the legal controversy?"

Legal Causation

At one time, courts tended to disregard epidemiology as simply a statistical exercise that provided information of little probative value; however, within the last 10 to 15 years, it has become key to the legal theory of causation as used in a particular type of litigation, that dealing with tort or product liability (10). Epidemiology research not only helps establish whether an agent is causally associated with a particular disease, but also whether the association supports a finding of "more likely than not." This equates to an attributable risk percent of greater than 50% and, with knowledge of the relative risk, can be calculated with the following formula: $AR\%=(RR-1)/RR$. For example, a relative risk of 3 would equate to an attributable risk percent of 67%.

As mentioned earlier, the various calculations regarding attributable risk have no meaning until causation for human disease is established, until an acceptable number of the Hill Criteria have been satisfied. Therefore, in theory, there are four characteristics of an exposure-disease association that are needed before a claim of causation logically can be accepted in legal deliberations. One, the putative agent must be a known cause of the disease. Two, the causal relationship must be more likely than not. Three, the plaintiff must have been exposed to the agent in adequate quantity and for sufficient duration. Four, the plaintiff must have developed the appropriate disease after the exposure. The first two deal with *general causation*. The last two pertain to *specific causation*. In tort liability cases, the plaintiff has the burden to prove all four, at least in theory. Trials are emotional events and jury deliberations can sometimes be more influenced by the subjective rather than the objective.

Prior to the 1993 Daubert decision, juries were the triers of fact and judges basically functioned as the umpires of the proceedings (30, 46, 89). They made rulings regarding process but few about content. The Daubert case changed that. After a series of appeals that went all the way to the Supreme Court, judges were given the additional responsibility of "gate-keepers." Juries retained the role of triers of fact; but judges were charged with determining which body of "facts" were relevant and reliable versus which were simply "junk science"—which testimony would "assist" the jury in their deliberations and "whether the 'probative value' of the testimony substantially outweighed the risks of prejudice, confusion or wasted time" (65). In practice, this means federal judges now must decide which "expert witnesses" can and cannot testify and what opinions they will be permitted to convey to the jury. Many state courts are also moving toward a process based upon the Daubert principles.

Some courts have done an impressive job in rendering judgments that included sophisticated legal

arguments well infused with scientific principles (80). Others have accomplished the same result with the help of outside experts employed directly by the court, an option acknowledged in the Daubert decision (60). Still others at the state level have yet to apply the Daubert principles, in part because some judges feel uncomfortable with their

Page 479
new role and in part because the new rules technically pertain to just the Federal judiciary (35). Lawyers and judges, even at the federal level, are still exploring the limits of the gatekeeper function and how certain statistical and epidemiologic thought might be translated into legal concepts. For example, statistical significance means a finding has a lower confidence limit above 1, that is, there is some assurance that the estimate of risk is different than 1. The legal notion of "more likely than not" requires a relative risk above 2; but it is unclear whether the key finding, to be admissible, has to be statistically significantly different than 1 or statistically significantly different than 2. When there is just one or a limited number of epidemiology studies, the latter makes more sense. However, the former is not inconsistent with epidemiology opinion when there are a large number of studies which have similar results.

Clinical Causation

Neither epidemiology causation (what Sir Bradford Hill called "medical causation") nor legal causation should be confused with *clinical causation*. The primary goal of clinical medicine is diagnosis and treatment. In a sense, the major reason for a diagnosis is to predict which treatment will most successfully reverse, eliminate, or control a patient's troublesome symptoms or signs of pathology. If the diagnosis is correct, the resulting treatment works and the patient is well served. If not, the patient likely gets no better, possible may get worse, or even may develop additional adverse outcomes as a result of the inappropriate therapy.

Experienced clinicians are adept at the technique of *differential diagnosis*. Through the use of various signs, symptoms, and test results, and factoring in the risks inherent to alternative treatments, they identify the most probable diagnoses, weigh the merits of each, and use the resultant information to help select a treatment that likely will be most successful. If that particular treatment does not work, they move on to the next most likely diagnosis and a different treatment—and if that doesn't work to still another, continually balancing benefit and risk.

When clinicians speak of searching for the "cause" of a patient's problems, they usually are referring to identifying the most likely diagnosis, quite possibly one whose underlying mechanisms of action are unknown. Arguably, knowledge regarding the underlying cause of a particular disease is only important in the clinical setting if it materially impacts treatment decisions; for example, if a specific type of bacterial pneumonia is more efficaciously treated by a particular antibiotic. Also, the underlying causes are not initially discovered by the process of differential diagnosis. Such knowledge is derived from experimental animal research, controlled clinical investigations, and observational epidemiology studies. Contrary to what some physicians have asserted, differential diagnosis, no matter how sophisticated, does not obviate the need for etiologic research (1, 52, 57, 91). As the many programs of the National Institutes of Health demonstrate, research regarding cause and effect and that related to diagnosis and treatment are complementary but not equivalent.

Parenthetically, proper diagnoses are made by means of pattern recognition; by what Margolis has called "habits of the mind" (76). Within the context of clinical causation, this has a number of implications. One, the more extensive a physician's training and experience, the larger the number of mental templates he acquires against which he can compare the next patient's combination of signs, symptoms, and test results. Thus, even if the underlying etiology for a condition is unknown (i.e., the condition is "idiopathic"), a physician may develop successful strategies for treating the syndrome. Two, this knowledge, no matter how prodigious, is always finite. Physicians recognize this. They specialize so that they might concentrate their energy on developing in-depth knowledge within one sector of medical practice; and even within that specialty, they refer patients to their peers, a tacit acknowledgment that another physician may be better suited to diagnose and treat a particular individual. Three, because the number of templates increases as a direct result of experience, the more seasoned the clinician, the greater his ability to diagnose and paradoxically, the greater the potential for a multiple comparisons bias. The latter is reflected in case reports.

CONCLUSION

As de Grasse Tyson noted in his recent essay, entitled "Certain Uncertainties," "the frontier of science is a messy place" (32). As a consequence, to the uninitiated, science appears to provide contradictory and therefore unreliable findings, irrespective of whether the research is experimental, quasi-experimental, or observational; but perhaps more so for the latter (Figure 10.18). Part of the reason for the apparent inconsistencies is related to technical bias: selection, misclassification, and confounding; but part is due to overinterpretation of the findings of any single study, either by the study investigators or by the consumers of research reports.

One of the primary goals of any scientist should be the elimination of bias from his or her research. The

first step is to acknowledge that various types of bias exist. The second is to understand how they occur. The third is to develop methods and procedures to avoid, minimize, or control bias. Over the years, well-trained epidemiologists have found ways to address potential error and improve the validity of their research. The same can be said for toxicologists and clinical investigators. The scientific method has been core to all of these endeavors.

The scientific method is one of the major discoveries in human history (16, 126). It has allowed mankind to gain a more objective view of the universe; to better understand the workings of the atom; and to successfully identify the causes of disease and with that understanding to treat, control, and even eliminate some of the major scourges that once were endemic worldwide. Unfortunately, the scientific method can be laborious, inconvenient, time consuming, and expensive. The temptation to take shortcuts can be great; but history teaches that shortcuts often just lead to further confusion (99). Identifying the truth can be difficult enough even in the best of circumstances; but it is impossible with biased data, inappropriate methods, or muddled logic.

One of the responsibilities of the technical journals is to screen research papers and determine which have sufficient rigor in data, methods, and interpretation to warrant publication. However, scientific investigation is a human endeavor and peer review an imperfect process, therefore flawed studies still get published, even in the best of journals. For that reason, the ultimate judgment regarding the value of any single report or group of reports may have to be made by the consumer: the epidemiologist, toxicologist, physician, lawyer, judge, newspaper reporter, or other member of the general public less well versed in the scientific method. This chapter provides a conceptual framework whereby such winnowing of fact from fancy might be accomplished. Within a basic understanding of epidemiology data, measures of association, and methods, it is based on the mantra of selection, misclassification, confounding, chance, and causation.

QUESTIONS

Exercise One

Among 50 employees of a chemical company producing ethylmethyl chicken wire, the company phys

ician identified 2 last year with lung cancer. In the general population, the incidence rate of lung cancer is 5 per 1000 per year. What is the relative risk for lung cancer among the chemical company employees? Does this finding support the legal concept of "general causation"? What about "medical causation" as defined by Sir Bradford Hill?

Answer

Based upon the information provided, the presumptive incidence rate for lung cancer among the employees was 2 per 50 per year, which is the same as 4 per 100 or 40 per 1000 per year. Because the incidence rate in the general population is 5 per 1000 per year, the apparent relative risk is 40 divided by 5 or 8.0.

To support the legal concept of "general causation," two conditions must be satisfied. One, the putative agent must be a known cause of the condition. Two, the association must be "more likely than not." In other words, the relative risk must be above 2 and statistically significant. In this situation, we don't know whether ethylmethyl chicken wire is generally accepted as a known cause for lung cancer, in part because we have no knowledge of the results of any other experimental or observational research on this chemical. Furthermore, we don't know whether the finding in this particular study is statistically significantly greater than 2 or even whether it is significantly above 1. Calculating the 95% confidence interval could be done; but, with due consideration for the small number of cases that were observed, it is quite possible that this was a chance occurrence.

General causation aside, even if this had been the first report of lung cancer associated with the chemical, the data provided are insufficient to conclude that ethylmethyl chicken wire should be considered a potential risk factor for this type of malignancy. For example, we don't know how the two diagnoses of lung cancer were made. Were they based on x-ray or confirmed by biopsy? The former is much less likely to be correct than the latter. We also don't know whether the two lung cancers developed before or after first exposure. Although the determination of the exact incident time of a malignancy is usually impossible to determine, if the company had been producing the chemical for just a short time or the two employees had just recently been hired, the known latency of lung cancer would suggest that the condition predated any possible putative exposure. Moreover, who made the original diagnosis and when? If the diagnoses had been made earlier by the employees' personal health providers and only "identified" later by the company physician during the course of a routine clinic visit, the cancers could have been *prevalence* and not *incidence* cases.

In addition to more information about those in the numerator, what about the denominator? Did this company only have 50 employees? If there were considerably more and only 50 had been seen at the company's medical clinic, it is quite possible that a *selection bias* could have artificially inflated the incidence rate for lung cancer. If such was the case, the relative risk was seriously elevated. Furthermore, to calculate the incidence rate for the plant population, we had to assume the two who developed the condition, given they were diagnosed accurately, actually were exposed. If they worked in a part of the company remote from the production facilities, for example, in accounting or sales, an incorrect assumption that they were exposed could have introduced a *misclassification bias* into the calculations, one that resulted in another spurious elevation in relative risk.

Finally, the comparison incidence rate, the absolute risk among the unexposed, 5 per 1000 per year, was that of the general population. That means there were other causes for lung cancer, like smoking. Furthermore, the term "general population" suggests the rate was based upon the experience of both men and women. The two genders have distinctly different incidence rates of lung cancer. If the distribution of either the attribute of gender or smoking was not the similar in both the exposed and controls, then *confounding* could have biased the results.

Exercise Two

There are two hospitals in the same city, a smaller one with 30 births a month and a larger one with 300 births a month. At the end of the year, which hospital is likely to have experienced more months with more than 60% male births?

Answer

The sample size is smaller for the smaller hospital. As a consequence, the variability of the data is greater. Thus there is a greater chance that the smaller hospital will have more months with more than 60% male births.

Exercise Three

In a study of chemicals associated with site-specific neoplasia in rodents, Huff and colleagues reported that "25 chemicals were carcinogenic to the liver in both rats and mice, 9 chemicals caused liver cancer only in rats; 53 caused liver cancer only in mice; and in 226/313 studies, no chemically related liver

tumors were observed in either rats or mice" (67). They also stated that "the overall interspecies concordance in liver carcinogenicity is 80% (251/313)." That means if the mouse bioassay

were used as a screening test of the carcinogenic potential of chemicals for rats, it would have a sensitivity of 73.5% and a specificity of 81.0%. In this example, what was the predictive value positive and the predictive value negative of the mouse bioassay?

Answer

The easiest way to solve this problem is to set up a 2×2 table similar to that found in Figure 10.14. If the outcomes in rats is the "truth" that we wish to predict, there were 25 true positives (TP), 9 false negatives (FN), 53 false positives (FP), and 226 true negatives (TN).

Predictive value positive was TP/(TP+FP) or 25/78. In other words, less than a third (32.1%) of the chemicals that were positive in the mouse bioassay were actually carcinogenic to rats.

Predictive value negative was TN/(TN+FN) or 226/235. The mouse bioassay correctly predicted which chemicals would not cause liver tumors in rats 96.2% of the time.

Exercise Four

In Exercise Three, 34 of the 313 chemicals tested caused liver tumors in rats, about 1 in 10. If among additional chemicals to be tested randomly, only one in a hundred would actually cause liver tumors in humans, how predictive would be the results of the mouse bioassay? Calculate the predictive value positive, the predictive value negative, and the concordance. Assume the same level of sensitivity and specificity for the mouse bioassay as found with rats. For convenience, assume also that 3400 chemicals were tested.

Answer

Among the 3400 chemicals tested, 34 are actually human carcinogens. With a sensitivity of 73.5%, that would mean 25 would be true positives (TP) and 9 would be false negatives (FN). With a specificity of 81%, among the remaining 3366 chemicals, approximately 2726 would be true negatives (TN) and 640 would be false positives. Using these numbers, a 2×2 table can be set up, and the predictive values and the concordance calculated.

Predictive value positive would be TP/(TP+FP) or 25/665 or 3.8%. Of the 665 positive tests in mice, less than 4% of them would correctly predict what would happen in humans.

Predictive value negative would be TN/(TN+FN) or 2726/2735 or 99.7%. In other words, of the 2735 negative mouse bioassay studies, 99.7% would correctly predict that the chemicals would not produce cancer in humans.

Concordance would be (TP+TN)/(TP+FN+TN+ FP) or 2751/3400 or 80.9%, basically the same as that found by Huff for his interspecies study.

APPENDIX

Guidelines for good epidemiology practices for occupational and environmental epidemiologic research

The *Guidelines for Good Epidemiology for Occupational and Environmental Epidemiologic Research* are included in this text by courtesy of the Chemical Manufacturers Association (CMA). They were developed by the CMA Epidemiology Task Group as part of the Epidemiology Resource and Information Center (ERIC) Pilot Project and, prior to publication in 1991, were modified following review and comment by an ad hoc panel of epidemiologists from academia, various government agencies, and the private sector. Although they do not have the force of law, they have been recognized by a number of groups and are analogous to the toxicology *Good Laboratory Practice Standards* or GLPs. The *Guidelines for Good Epidemiology Practices* (GEPs) were developed in part to provide an alternative to the GLPs, one that would appropriately address the issues confronted by epidemiologists conducting nonexperimental research.

The *Guidelines for Good Epidemiology Practices* address the conduct of studies generally undertaken to

answer questions about human health in relation to the work place or the environment. The GEPs propose minimum practices and procedures that should be considered in order to help ensure the quality and integrity of data used in epidemiologic research and to provide adequate documentation of the research methods. Epidemiologic studies often evolve through a number of stages that precede the development of a protocol, for example, proposals, feasibility studies, and measurement instrument validation. Although the GEPs are intended to address all activities that begin with protocol development, it was the opinion of the Task Group that adherence to the spirit of the guidelines would prove beneficial for those activities preceding protocol development as well as more informal investigations such as health hazard assessments/evaluations or small cluster investigations.

A copy of the original guidelines as published by ERIC can be obtained from the CMA. The complete document includes an introduction, eight sections, and three appendices. Only the eight sections are presented here, and in a slightly abridged form. A more detailed discussion of these GEPs can be found in the proceedings of a conference published in December 1991 issue of the *Journal of Occupational Medicine.*

I. Organization and Personnel

A. *Organizational Structure*

The organization or individual conducting the research shall be fully responsible for the operation and perform

ance of the research. The organization shall be a legal entity with a governing body that sets policy and that is fully responsible for the administrative aspects of the organization and its related research activities. The relationship, roles, and responsibilities of the organizations and/or individuals sponsoring or conducting the study should be carefully defined in writing.

B. *Personnel*

Personnel engaged in epidemiologic research and related activities shall have the education, training, and/or experience necessary to competently perform the assigned functions. The organization shall maintain a current summary of training and experience of these personnel. A job description for each individual engaged in or supervising activities shall be maintained and updated periodically.

II. Facilities, Resource Commitment, and Contractors

A. *Facilities*

Adequate physical facilities shall be provided to all those engaged in epidemiologic research and related activities. Sufficient resources, for example, office space, relevant equipment, and office/professional supplies, shall be available to ensure timely completion of all studies. Suitable storage facilities shall be available to maintain research materials in a safe and secure environment.

B. *Resource commitment*

Sufficient commitment shall be made at the beginning of each study to ensure its timely and proper completion.

C. *Contractors*

For the purposes of ensuring and documenting the contractor's conformance with the *Guidelines for Good Epidemiology Practices,* it is recommended that the study sponsor have the right during the course of the study, and for a reasonable period following completion of the study, to inspect the contractor's facilities, including equipment, technical records, and records relating to the work conducted under the sponsor's contract.

III. Protocol

Each study shall have a written protocol. This protocol must be approved before the study begins. The protocol should include the following:

A. A descriptive title.

B. The names, titles, degrees, addresses, and affiliations of the study director, principal investigator, and all coinvestigators.

C. The name and address of the sponsor.

D. An abstract of the protocol.

E. The proposed study tasks and milestones, including study approval date (date protocol signed by all signatories), study start date (first date that the protocol is implemented), periodic progress review dates, and estimated completion date.

F. A statement of the research objectives, specific aims, and rationale. The statement should identify the immediate purpose of the investigation. For example, it might indicate whether the study will be exploratory data analysis, hypothesis testing, or a combination of both.

G. A critical review of the relevant literature to evaluate applicable findings. This should include pertinent animal and human experiments, clinical studies, vital statistics, and previous epidemiologic studies. The literature review should be in sufficient depth to identify potential confounders and effect modifiers and to determine areas where new knowledge is needed.

H. A description of the research methods, including:

1. The overall research design and the reasons for choosing the proposed study design.
2. The data sources for exposure, health status, and risk factors.
3. Clear definitions of health outcomes, exposure, and other measured risk factors as well as selection criteria, as appropriate, for exposed and nonexposed persons, morbidity and mortality cases, and referent groups.
4. The project's study size and, if appropriate, statistical power.
5. The methods to be used in assembling the study data, including a description of, or reference to, methods used to control, measure, or reduce various forms of error—for example, bias due to selection, misclassification, interviewer, or confounding—and their impact on the study. Pretesting procedures for research instruments and any manuals and formal training to be provided to interviewers, abstractors, coders, or data entry personnel also should be described or referenced.
6. The procedures for handling the data in the analysis.
7. The methods for data analysis.
8. The major limitations of the study design, data sources, and analytic methods.

9. The criteria for interpreting the results.
I. A description of plans for protecting human subjects.

< previous page page_486 next page >

J. The quality assurance and quality control procedures for all phases of the study. As appropriate, a certification and/or qualifications of any supporting laboratory or research groups.
K. A description of plans for disseminating and communicating study results.
L. The resources required to conduct the study.
M. The bibliographic references.
N. Addenda, as appropriate; for example informed consent forms, questionnaires, and representative samples of other documents to be used in the study.
O. A data protocol review and approval sign-off sheet for the study director, principal investigator, coinvestigators, and all reviewers.
P. The dated amendments to the protocol.

IV. Review and Approval

A. *Scientific Review*

The study protocol shall receive appropriate scientific review by qualified persons who are not part of the investigative team to ensure that the study is designed to address the objectives of the research and that the protocol is written according to the *Guidelines for Good Epidemiology Practices*. The nature and the circumstances of this review shall be documented.

B. *Ethical Review*

The ethical aspects of each study protocol shall be reviewed by an institutional review board or other comparable review procedure. This review should consider:
1. Obligations to research subjects.
2. Obligations to society.
3. Obligations to funders and employers.
4. Obligations to colleagues.

C. *Administrative Review*

The administrative aspects of the study protocol shall receive appropriate review and written approval by sponsors, contractors, and associated third parties to ensure that sufficient resources are available to complete the study in a timely and proper fashion.

V. Study Conduct

While the study director shall be responsible for the overall research program, the principal investigator shall be responsible for the individual research project, including the day-to-day conduct of the study, interpretation of the study data, and preparation of a final report. These responsibilities extend to all aspects of the study including periodic reporting of study progress as well as quality assurance. In some situations, the study director and the principal investigator may be the same person. To ensure the proper conduct of the study, personnel shall adhere to sound research principles and practices established according to the protocol. A protocol must be approved before the study begins. The study shall be conducted in accordance with the protocol; all deviations from the protocol shall be properly documented and authorized by the principal investigator. If a decision is made not to complete a research project, the reasons for that decision shall be put in writing, dated, and signed by the responsible party, that is, the individual who makes the decision to terminate the study.

A. *Protection of Human Subjects*

Procedures for protecting human subjects shall be followed. Confidential information about study subjects shall be protected using established procedures. If stipulated by the study protocol and/or required by an institutional review board, each study subject shall be informed about the purpose of the study and any risks associated with participating in the study. Written consent, if required, shall be obtained from each study subject before he/she participates in the study. Written consent shall include at a minimum:
1. The purpose of the research or study.
2. The names, addresses, and phone numbers of personnel available to answer questions about the research and the rights of study subjects.
3. The expected duration of a subject's participation
4. The eligibility requirements for study participation.
5. The possible benefits of the study results to the study subject or others.
6. A statement on the voluntary nature of participation in the study and the right of the study subject to discontinue participation at any time.
7. A statement of confidentiality of records identifying the study subject, including reasonable exceptions to absolute confidentiality, for example, sharing of information with the study subject's personal physician or as required by court order.

8. A description of any foreseeable risks or discomforts to the study subject.
9. A statement of the availability of the results.

B. *Data Collection and Verification*

All data collected for the study should be recorded directly, accurately, promptly, and legibly. The individuals responsible for the integrity of the data, computerized and hard copy, shall be identified. All procedures used to verify and promote the quality and integrity of the data shall be outlined in writing. A historical file of these procedures shall be maintained, including all revisions and the dates of such revisions. Any changes in data entries shall be documented.

page_488

C. *Analysis*

All data management and statistical analysis programs and packages used in the analyses should be documented. All dated versions used in research shall be kept with accompanying documentation.

D. *Study Report*

Completed studies shall be summarized in a final report that accurately and completely presents the study objectives, methods, results, and the principal investigator's interpretation of the findings. Although the content and length of any technical publication based on the research may be subject to requirements of the particular journal, if a more comprehensive report is written, it should include:

1. A descriptive title.
2. An abstract.
3. The purpose (objectives) of the research as stated in the protocol.
4. The names, titles, degrees, addresses, and affiliations of the study director, principal investigator, and all the coinvestigators.
5. The name and address of the sponsor.
6. The dates on which the study was initiated and completed.
7. An introduction with background, purpose, and specific aims of the study.
8. A description of the research methods, including:
a. The selection of study subjects and controls.
b. The data collection methods.
c. The transformations, calculations, or operations on the data.
d. The statistical methods used in data analyses.
9. A description of circumstances that may have affected the quality or integrity of the data.
10. A summary of the data analyses, including sufficient tables, graphs, and illustrations to present the pertinent data and to reflect the analyses performed.
11. A statement of the conclusions drawn from the analyses of the data.
12. A discussion of the implications of the study results.
13. A list of references.
14. A statement describing the location where all source data and the final report are stored.
15. A dated study report review sign-off sheet for the study director, principal investigator, coinvestigators, and reviewers and/or auditors.

VI. Communication

Each organization shall predetermine procedures under which communications of the intent, conduct, results, and interpretations of an epidemiologic study will occur, including what function individuals associated with the research will fulfill. These individuals should include the principal investigator, study director, and/or the sponsor. This procedure may be documented in the form of a standard operating procedure, in the study protocol, or through contractual agreement. Government agencies shall be informed of study results in a manner that complies with applicable regulatory requirements. To the extent possible, scientific peers shall be informed of study results by publication in the scientific literature or via presentations at scientific conferences, workshops, or symposia. As feasible, all study subjects shall be informed of the study results and any interpretations of the study findings and conclusions. Information about the study results should be presented in language appropriate to the audience.

VII. Archiving

Physically secure archives must be designated for the orderly storage and expedient retrieval of all study-related material. An index shall be prepared to identify the archived contents and their location, and to identify by name and location any material that by their general nature are not retained in a specific study archive. Access to the archives shall be controlled and limited to authorized personnel only. Special procedures may be necessary to ensure that confidential information about study subjects is protected. Individual study archives should contain, or refer to, the following:

A. The original signed and dated study protocol and all approved modifications.
B. The original signed and dated final report of the study.
C. All source data and, where feasible, biological specimens. A printed sample of the master computer data files with reference to the location of the machine readable master.
D. Documentation adequate to identify and locate all computer programs and statistical procedures used, including version numbers where appropriate.
E. Copies of computer printouts, including relevant execution code, that form the basis of any tables, graphs, discussions, or interpretations in the final report. Any manually developed calculations shall be

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_488.html[2010/10/28 18:44:43]

documented on a work sheet and similarly retained.

F. Correspondence pertaining to the study, standard operating procedures, informed consent releases, copies of all relevant representative material, copies of signed institutional review board and other external reviewer reports, and copies of all quality assurance reports and audits. As appropriate, this would

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_488.html[2010/10/28 18:44:43]

include questionnaires, the name, make and model numbers of relevant measurement instruments and calibration information and procedures.

G. Original documents for the certain research materials that may be unique to the study such as laboratory notebooks and coder modification records.

VIII. Quality Assurance

Written procedures shall be established to ensure the quality of the data used in a study. These procedures shall address data collection and completeness, coding and computer input, storage and retrieval, and data validation and analysis. Any deviations from the GEPs shall be explained and documented in the final report. An individual who is not part of the investigative team should be assigned as a study quality assurance auditor. This individual shall, no less than annually, review study compliance with the written quality-assurance procedures. The study quality-assurance auditor shall prepare a written summary of the audit. The principal investigator should respond in writing to the audit report, including any remedial actions taken. Quality-assurance activities shall address the preceding sections of these guidelines as well as monitor conformance with established standard operating procedures.

Chemicals capable of causing adverse effects in humans are present in food as naturally occurring components, contaminants, intentional additives, or as components formed in the course of food processing. The simultaneous presence of dietary components capable of enhancing or protecting against the adverse effects of food toxicants has, without a doubt, contributed to the lack of correlation between experimental animal and epidemiological data. An understanding of such agents and direction and magnitude of their effects on specific toxicants in the complex dietary milieu is presently lacking. This together with a lack of good methods for risk extrapolation of mixtures of toxicants/anti-toxicants from animals to humans hampers our effort toward realistic human risk estimations related to food toxicants.

NATURAL TOXICANTS

Natural toxicants are derived from food and feed components of plants and animals. Acute intoxications from chemicals naturally occurring in the human diet are limited to individuals and to selected classes of compounds, for example, favism in individuals deficient in RBC glucose-6-phosphate dehydrogenase (123). Food derived from animal sources can also contain toxic components/contaminants that causes acute intoxications. However, long-term or delayed effects resulting from plant and animal toxins are more widespread and are likely to be more important.

Toxicants in Foods of Plant Origin

Foods of plant origin account for most (>70%) of the world's supply of protein. Although plants with obvious toxic effects have been excluded from human diet by trial and error, deleterious (toxic as well as antinutritive) effects from the following groups of compounds are deemed significant for human health.

Alkaloids

Nitrogenous heterocyclic organic compounds have protective roles against herbivorous consumption and attack by insects, parasites, and competitors. Major alkaloid groups of concern from the standpoint of human consumption include pyrrolizidines, xanthines, and solanines. Others including piperidines from *Conium* and tobacco; quinolizidines from *Lupinus;* and indolizidines from *Astragalus*, *Swainsona*, and red clover are mainly consumed by grazing animals and potentially can be transferred to humans through milk. For a review of toxic effects of alkaloids in humans and animals see Cheeke (38).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_491.html[2010/10/28 18:44:44]

Pyrrolizidine alkaloids (PAs) are a group of more than 250 geographically ubiquitous plant metabolites posing a major threat to animal health by their presence in plants including *Senecio, Crotalaria,* and *Heliotropium*, among others. Human exposure and possible health effects result from the wide use of coltsfoot *(Tussilago)*, comfrey *(Symphytum)* and petasites *(Petasites)*, as herbal remedies, foods (salads, etc.), and tea; contamination of food grains with seeds from PA-containing plants; honey derived from pansy ragwort *(Senecio sp.)* and Patterson's Curse *(Echium sp);* and/or through milk from animals grazing on these alkaloid-containing plants (44).

Among the several structural groups of PAs, the acyclic diesters and macrocyclic diesters such as retronecine, senecionine, and petasitenine are more toxic (77). Highly reactive pyrrole derivatives of PAs and/or their hydrolysis products formed by the action of mixed function oxidases are considered responsible for the toxic effects of PA (130). Huxtable (83) reviewed human intoxications with PA. Typically, liver involvement with venoocclusive disease is characterized by occlusion of small branches of the hepatic vein thus leading to ascites, edema, reduced urinary output, and high mortality which occur mostly in children. Survivors often manifest cirrhosis. Histologically, endothelial proliferation and medial hypertrophy lead to occlusion of small hepatic veins which then advances to centrilobular congestion resulting in sinusoidal widening and blood pooling. Necrosis and fibrosis ultimately result. Certain dehydro PAs, monocrotaline in particular, are known to induce similar occlusive changes in pulmonary arterioles, developing into pulmonary hypertension and right ventricular hypertrophy and, ultimately, to cor pulmonale (right heart congestive failure). Impairment of serotonin and norepinephrine clearance by endothelial cells appears to contribute to pulmonary hypertension (83).

Many PAs and their pyrrole metabolites are bifunctional alkylating agents crosslinking to macromolecules, including DNA (77, 83), thus accounting for their mutagenicity and carcinogenicity in experimental animals (77). At least six species of plants *(Senecio longilobus, Petasites japonicus, Tussilago farfara, Symphytum officinale, Farfugium japonicum,* and *Senecio cannabifolis)* and eight PAs have been shown to induce one or more of the following types of cancer: hepatic carcinoma, hepangioendothelial sarcoma in the liver, liver cell adenoma, cholangiosarcoma, astrocytoma, squamous cell carcinoma of the skin, pulmonary adenoma, adenocarcinoma of the small intestines, adenomyoma of the ileum, and rhabdomyosarcoma (77). One of the PAs, heliotrine, was shown to be teratogenic in rats. Oberved malformations included lower jaw hypoplasia, musculoskeletal defects involving ribs, and general growth retardation (77).

Solanum alkaloids, predominantly, solamine, chaconine, and tomatine are found in potato, eggplant, and tomato (species of *Solanum genus*) among others. Reviews on the biosynthesis, occurrence, and toxicology of solanum alkaloids include those by Sharma and Salunkhe (183) and Keeler et al. (94). Potatoes, especially the sprouted, greened, blighted, injured, or spoiled, have raised the most concern relating to alkaloid intoxication with over 200 cases of human poisonings documented (141). Signs of human intoxication, some of which may be related to the irritant and cholinesterase-inhibiting activity of the alkaloids, appear at >20 mg alkaloid/100 g of tuber and include headache, vomiting, diarrhea, neurological signs, debilitation, and death. Association of consumption of blighted potatoes to the incidence of anencephaly-spina bifida (ASB) in humans has been questioned by subsequent studies which failed to produce defects in animals consistent with ASB in humans (177). Although normal levels of glycoalkaloids in potato conform to the U.S. Department of Agriculture (USDA) guideline of 20 mg/100g of tuber, exposure to light, immature tubers, wounding of potatoes, and stresses such as fungal attack can increase its content severalfold (25). Baking, boiling, or microwaving do not destroy solanine or chaconine in potatoes. Some simple methods to prevent glycoalkaloid formation during storage appear to be protection of tubers from sunlight, γ-irradiation, soaking in water under controlled conditions, dipping damaged potatoes in emulsified water, treating potatoes with sprout inhibitors during storage, waxing, and heating, dipping in oils (corn, olive, or mineral), spraying tubers with lecithin (such as PAM), or simply spray rinsing tubers with an aqueous solution of an edible surfactant (Tween 85) (183).

Xanthine alkaloids. Three major related alkaloids, caffeine, theobromine, and theophylline, are found as major components of coffee *(Coffea arabica)*, cocoa *(Theobroma cocas)*, and tea *(Thea sinenis)*, respectively. Caffeine, in addition, is added to many beverages, foods, and medications (56). Caffeine-related adverse effects begin when 0.5–1.0 g of caffeine (10 cups of coffee) is ingested by an adult, leading to fatalities at 5 g in children and 5 to 10 g in adults (45, 56). Caffeine and other methylxanthines inhibit phosphodiesterase, leading to intracellular accumulation of cyclic AMP, blockage of adenosine receptors, and increased release of Ca2+ from the terminal cisternae of the sarcoplasmic reticulum (45). Major effects of xanthines involve the central nervous system (CNS) stimulation

(hyperesthesia to convulsions), emesis, cardiovascular effects (cardiac stimulation to arrhythmias), diuresis, and smooth muscle effects leading to decreased vascular resistance and bronchodilation (45). In addition, caffeine enhances gastric secretion of acid and pepsin. Caffeine and theobromine are mutagenic in bacterial systems and can potentiate DNA damage

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_492.html[2010/10/28 18:44:45]

caused by other genotoxins but are neither directly carcinogenic in animals nor are they associated with human cancer (10, 45). Caffeine is teratogenic in experimental animals, causing mostly limb and facial defects (177). Although high caffeine consumption during pregnancy may increase the risk of low birth-weight babies, no correlation exists between caffeine consumption and birth defects in humans (190). In 1980, the U.S. Food and Drug Administration (FDA) however, issued a warning to pregnant women to limit coffee consumption (45).

Allergens

Food allergies are a group of disorders characterized by an exaggerated immunological response to a component of food. All foods are capable of eliciting an allergic reaction. Most allergens in foods are heat-stable proteins, glycoproteins, or peptides with a MW between 5000 and 70,000. Prevalence of food allergies appears to be age-dependent, with up to 8 percent of children under 3 years and 1.5 percent of adults (155, 174) affected. Milk (casein, β-lactoglobulin) and eggs (ovomucoid, ovalbumin) are the most commonly incriminated agents (13), followed by peanuts (Aha I & II, aglutinin), wheat (globulins, glutenine), soy proteins (in formulae), fish, crustaceans, tomatoes, strawberries, chocolate, and certain beverages (15, 26, 213). Although multiple tissues of the body are often affected, the skin (eczema and urticaria) and the respiratory tract (rhinitis, pneumonitis, asthma, etc.) account for 90 percent of food allergies (156). Abdominal distress, vomiting and diarrhea, hypotens in and shock secondary to hypovolemia, and nervous system involvement as indicated by headaches, convulsions, and behavioral problems (156) are also suggestive of allergic reaction to food. Rapid-onset allergies are dependent on reaction of the antigens with circulating antibodies of the IgE class (reagin) and the eventual release of vasoactive substances such as serotonin and histamine, sometimes leading to life-threatening anaphylaxis. Non-IgE-type food allergies are dependent on specifically sensitized lymphocytes that are attracted to the site of antigen exposure by lymphokines released by already existing T-lymphocytes and require several hours or days to fully manifest. Recent evidence suggests a role for food allergies in autoimmune disorders (celiac disease), juvenile or insulin-dependent diabetes mellitus, migraine, and arthritis in children (26, 97). Idiosyncratic reactions such as lactose intolerance, a result of genetic deficiency of lactase leading to luminal accumulation of lactic acid and osmotic diarrhea, must be differentiated from immunologically mediated allergic reactions.

Cyanogens

Cyanogenic glycosides which release highly toxic hydrocyanic acid on hydrolysis are derived not only from plants (more than 2000 species) but, also, from fungi, bacteria, and even members of the animal kingdom (140). Although cassava, sweet potatoes, yam, maize, millets, bamboo, sugarcane, peas, beans, almond kernel, lemon, lime, apple, pear, cherry, apricot, prune, and plum constitute sources for humans, poisonings are mainly associated with the consumption of improperly processed cassava in Africa, Asia, and Latin America (140, 158). Among more than 20 glycosides identified, only four (i.e., amygdalin, dhurrin, linamarin, and lotaustralin) appear to be of toxicological importance. Cyanogenic lipids, although of unknown toxicological significance, are also present in plants and yield carbonyl compounds and HCN upon hydrolysis (50).

The hydrolysis of the glycoside is triggered by physical disruption (mastication, trampling, etc.) or stress (drought, cooking, frost, etc.) and is catalyzed by β-glucosidase and hydroxynitrile lyase, which are present within the plant or in bacteria found in the gastrointestinal tract of humans and animals (158). The scheme of breakdown leading to the formation of glucose and hydrosynitrile from the glycoside, followed by breakdown of hydroxynitrile into carbonyl compounds and HCN, is presented in Figure 11.1. Rhodanese catalyzes the conversion of HCN to thiocyanate in the presence of thiosulfate (158).

Animals have often been acutely poisoned by young sorghum and arrow grass. Young bamboo shoots and tea made from peach leaves are examples of dietary sources of HCN poisoning in children. The minimal lethal dose of HCN in humans and animals is 0.5–3.5 mg/kg and 2–10 mg/kg, respectively. The acute effects of HCN result from its affinity toward metalloporphyrin-containing enzymes, more specifically, cytochrome oxidase. Cyanide concentration of only 33 μM can completely block electron transfer through the mitochondrial electron transport chain and thus prevent O2 utilization (158). Death results from generalized cytotoxic anoxia. Signs of acute cyanide poisoning in humans are hyperventilation, headache, nausea and vomiting, generalized weakness, coma, and death due to respiratory depression and failure. Treatment of acute cyanide intoxication involves, in addition to artificial respiration, the conversion of hemoglobin in the blood to methemoglobin with nitrites (sodium or amyl). Methemoglobin competes with cytochrome oxidase for HCN and forms cyanmethemoglobin. Co-administration of sodium thiosulfate will convert free cyanide present in the blood to thiocyanate, which is eliminated. As free cyanide in the blood decreases, additional cyanide dissociates from the

cyanmethemoglobin and is subsequently eliminated (36).
Tropical ataxic neuropathy (TAN), characterized by myelopathy, bilateral optical atrophy, deafness, and polyneuropathy; konzo, an irreversible upper moto-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_493.html[2010/10/28 18:44:46]

FIG. 11.1. Enzymatic hydrolysis of cyanogenic glycosides. Initially, the glycoside is hydrolyzed by a β-glucosidase releasing glucose and α-hydroxynitrile. The hydroxynitrile dissociates either enzymatically or nonenzymatically to yield HCN and the corresponding aldehyde or ketone.

neuron paralytic disease (20) of women and children; goiter; epigastric burning pain; dizziness; abdominal distension and vomiting (2)—all have been linked to longer-term consumption of cassava diets in Africa and other tropical countries (150). These diets were also poor in protein and sulfur-containing amino acids which can detoxify HCN to thiocyanoalanine and subsequently to the inert 2-amino-4-thiazolidine carboxylic acid (158). Although it is generally assumed that chronic effects of cyanogen exposure are due to thiocyanates, recent evidence suggests that the glycoside, linamarin, itself may be responsible for konzo in cassava-consuming populations (20).

Enzyme Inhibitors

Although plant and animal foods contain inhibitors of proteases, amylases, and lipases, only the inhibitors of proteases pose some hazard to human health, if any.

Kunitz inhibitor, the major protease inhibitor of soybeans, is a heat labile protease capable of inhibiting trypsin and, to a lesser degree, other proteases (93). The cationic form, which accounts for a majority of human trypsin activity, is only weakly inhibited, whereas the anionic form is fully inhibited (114). In addition, there appear to be a heat stable, lower molecular weight Bowman-Birk inhibitor, an insect protease inhibitor, and a papain inhibitor associated with raw soybeans. Egg white, milk, a number of varieties of beans, peas, cereal grains, alfalfa, and potatoes also have been shown to contain one or more protease inhibitors (86).

The major effects of protease inhibitors in animal diets include pancreatic hypertrophy, adenomas, and nodular hyperplasia associated with growth depression (115). Pancreatic hypertrophy is postulated to result from constant pancreatic hypersecretion necessitated by release of a humoral agent (possibly cholecystokinin pancreozymin) in the upper small intestine in response to the lack of free trypsin and chymotrypsin following their binding with the inhibitor (66). Although any single food source such as soybean is likely to be consumed by humans in quantities of toxicological significance, consumption of multiple sources of protease inhibitors may increase the risk of pancreatic hypertrophy and cancer. Ironically, soybean trypsin inhibitors are gaining attention for their inhibition of initiation and promotion, as well as dissemination of transformed cells during the carcinogenic process (46).

Estrogens

There are more than 220 species of plants containing estrogenic isoflavonoids (e.g., genistein, glycetein, daidzein) and/or their glycosides (genistin, glyectin, daidzin). Coumestans (e.g., coumestrol, 4-O-methylcoumestrol) and lignans represent other important groups of plant estrogens (3, 191). Phytoestrogens, although capable of causing infertility in animals heavily grazing on estrogen(coumestan)-containing forages (subterranean clover, alfalfa), have not been proven to cause human problems. Genistein (soybeans) appears to be the plant estrogen of most (if any) significance in human health (6). Zearalenone and zearalenol, two major resorcylic acid

lactone estrogens, are produced in corn in response to infection by toxigenic strains of the fungus *Fusarium roseum* and are discussed later. Human infants can be exposed to 4 mg/kg body weight or more of isoflavones from soy-based formula (6). Phytoestrogens bind to the same intracellular receptors as those that bind estradiol but at 20–200 times lower affinity, resulting in 500–10,000 times lower potency in vivo, compared to estradiol. Recently, Safe (173) estimated that human adults are exposed to 102 μg estrogenic equivalents (reflecting both potency and exposure) daily compared to 3.35 mg/day for estrogen replacement and 16.7 mg/day for oral contraceptives. Due to inefficient binding, phytoestrogens can actually impede the action of endogenous mammalian steroidal estrogen and at higher doses also induce antigonadotropic effects at the hypothalarnic, pituitary, and gonadal levels in both sexes (6). In addition to the above effects, genistein inhibits protein tyrosine kinases associated with a number of growth factors and other enzymes with roles in cell proliferation and differentiation (6).

The only reported animal effects of phytoestrogens include infertility in sheep fed subterranean clover and cattle consuming alfalfa (6), and feminization of males following exposure during development (40). In humans, however, although reversible changes in menstrual cycle and FSH and LH surges in premenopausal women appear to result from soy consumption, no developmental or infertility problems were noted in populations consuming large quantities of phytoestrogen (6). Phytoestrogens, on the contrary, may protect humans against coronary heart disease, cancer of the breast, prostate, and colon, and postmenopausal osteoporosis (4), possibly due to their antiestrogenic effects. Phytoestrogens are not mutagenic in the Ames assay (22) and appear to be noncarcinogenic when given orally (206). Whether exposure to relatively high levels of isoflavones in soy-based formulae in human infants leads to longer-term effects needs to be investigated.

Glucosinolates

Glucosinolates (GS) are a group of more than 100 flavor-imparting thioglucoside compounds found at up to 60 mg/g in crucifers such as broccoli, cabbage, brussels sprouts, cauliflower, calabrese, turnip, radish, horseradish, mustard, rapeseed, and related plants. Common names of some important GS include sinigrin, progoitrin, epi-progoitrin, glucobrassicin, and neoglucobrassicin. Not only the parent GS but, also, their products of plant and human digestive tract bacterial myrosinase (thioglucosidase) hydrolyze —isothiocyanates, nitriles, oxazo-lidinethione (OZT), and thiocyanate ions—contribute to their biological activity (208).

Although evidence is lacking in humans, in animals the thiocyanate ion inhibits the uptake of iodine by the thyroid, leading to iodine-reversible hyperplasia and hypertrophy of the thyroid (cabbage and legume goiter) and growth suppression. OZT also inhibits thyroxine synthesis and induces goiter (brassica seed goiter) in rats by inhibiting the incorporation of iodine into precursors of thyroxine (129). This condition is not reversible by iodine supplementation. In addition to goiter, epiprogoitrin and progoitrin also induce liver and kidney enlargement and death at 2.6 percent in the diet via their nitrile metabolites (203). Bile duct hyperplasia, hepatocyte necrosis, and megalocytosis of renal tubular epithelium were also seen in these animals (200).

Isothiocyanates are embryocidal and cause fetal weight reduction (25). Isothiocyanates and certain GS (e.g., sinigrin) are mutagenic in the Ames assay, whereas thiocyanates are not (25). Higher intake of cruciferous vegetables in humans and animals, however, may exert an anticarcinogenic effect attributable to the formation of isothiocyanates (at least seven), indoles, indole-3-car-binol, 3-indoleacetonitrile, and 3,3′-diindolylmethane (208). Anticarcinogenic effects of glucosinolates may result from their induction of phase II enzymes (quinone reductase) in the gastrointestinal (GI) tract and liver (197) and stimulation of apoptosis (188).

Lectins (Phytohemagglutinins)

Lectins are high MW (100,000 to 150,000), heat labile proteins, lipoproteins, or glycoproteins (up to >10% of total seed protein) detected in over 800 edible plant species, including 600 that belong to the leguminosae (beans, peas, etc.). In addition, lectins are also present in animals including sponges, crustaceans, mollusks, fish (blood), amphibian (eggs), and even mammals (tissue) (50). Their interactions with membrane glycoproteins (e.g., red blood cells causing hemolysis) made them suitable in the study of blood typing, tumor cell recognition, cell adhesion, signal transduction, mitogenesis, immune function, and cell death (139).

Binding of lectins from edible sources to cells in the crypts and villi of the intestines followed by nonspecific inhibition of active and passive absorption of many nutrients (amino acids, fats, vitamins, minerals, thyroxin, etc.) across the intestinal mucosa and necrosis of intestinal epithelial cells (96) appears to account for growth reduction and possibly goiter after long-term oral exposure to high levels

(86). Mortality following acute systemic lectin exposure is associated with damage to the liver (84) and other organs. The most toxic lectin, ricin from castor bean, can cause severe intestinal epithelial cell necrosis and death from multi-organ damage (204). Recent evidence has suggested that lipid peroxidation mediated by reactive oxygen species may be involved in ricin-induced thyroid damage (175). Epithelial-bound ricin is taken up by cells via clathrin-dependent as well as clathrin-independent endocytosis and then subjected

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_495.html[2010/10/28 18:44:47]

to lysosomal degradation. A portion of ricin enters golgi and ER, inhibits protein synthesis, and causes cell death (176, 204). Less toxic lectins may act by the same mechanism to stimulate protein synthesis, mitogen activation, and immune stimulation.

Lipids

Adverse effects can result from naturally occurring plant lipids when factors such as the departure from established food use patterns, the use of new lipids in human diets, or inborn errors of metabolism are introduced. Erucic acid (cis-13-docosanoic acid) is a predominant component of rape (*Brassica napus* and *B. campestris*) and mustard (*B. hirta* and *B. juncea*) seeds. Canada, Argentina, Mexico, China, India, Pakistan, Japan, and several European countries are the major producers and users of these oils. Growth suppression, myocardial fatty infiltration, mononuclear cell infiltration, and fibrosis were observed in weanling rats fed erucic acid at levels supplying greater than 20 percent of the dietary calories. In addition, ducklings showed hydropericardium and cirrhosis, and guinea pigs developed splenomegaly and hemolytic anemia (131). Organ-specific inhibition of glutamate oxidation and adenosine triphosphate (ATP) synthesis in cardiac mitochondria (79) could be mechanistically involved in the pathogenesis of these lesions. In humans, however, although the long-term use of Lorenzo's oil (oleic acid and erucic acid) in the treatment of adrenoleukodystrophy or adrenomyeloneuropathy leads to thrombocytopenia and lymphopenia (202), adverse effects from dietary consumption of erucic acid have not been reported.

Refsum is disease is a genetic peroxisomal fatty acid oxidase and catalase deficiency resulting in an inability of the affected individuals to convert phytanic acid (3,7,11,15-tetramethylhexadecanoic acid, a product of chlorophyll metabolism in the rumen) from dairy products and ruminant fats to α-hydroxyphytanic acid in preparation for further oxidation. This results in accumulation of lipids containing phytanic acid in many tissues and a disorder characterized by poor physical and mental growth, blindness, deafness, and other neurological signs (38). Elimination of dairy and ruminant fats from the diet of these individuals results in partial remission.

Cyclopropene fatty acids such as sterculic acid (C19) and malvalic acid (C18) are natural components of oils from plants of the order *Malvales,* most important of which are cotton and kapok seeds. Cyclopropene fatty acids have been incriminated in the pink discoloration of egg whites and reduced egg production in cottonseed-fed laying hens, growth suppression and impaired female reproduction in rats, and increased saturated fatty acids (possibly causing atherosclerosis) in the tissues of pigs and other animals (131). Cyclopropene fatty acids are carcinogens and markedly increase the carcinogenicity of aflatoxin in trout (10).

Increased consumption of dietary polyunsaturated fatty acids to lower blood cholesterol, although beneficial in decreasing the incidence of coronary disease, has raised concern about adverse effects such as induction of Vitamin E deficiency (131). Carrol (32) reported a strong correlation between dietary fat and age-adjusted mortality rates for breast and intestinal cancer. Pancreatic cancer was found to be enhanced by a diet containing 20 percent corn oil but not by one containing 18 percent hydrogenated coconut oil and 2 percent corn oil (167). Unsaturated fatty acids are easily oxidized during cooking to a variety of mutagens, enols and other aldehydes, and alkoxy and hydroperoxy radicals (10). Lipid oxidation products alter signal transduction pathways (196) and thus enhance cell proliferation and promote carcinogenesis. Lipid-induced inhibition of immune responses and enhanced formation of some of the known tumor promotors such as prostaglandins and bile acids also have been reported (32). Interestingly, Hayasu et al. (74) showed that oleic and linoleic acids may, in fact, be antimutagenic. The overall effect of dietary fats may depend on the ratio of beneficial fatty acids to causative fatty acids for each effect.

Oxalates and Phytates

Certain plants including spinach, rhubarb, beet leaves, tea, and cocoa contain high (0.2–2.0% on a fresh weight basis) levels of oxalic acid. Although dietary oxalates present little problem in humans, cattle and sheep have been poisoned following ingestion of the toxic plants *Halogeton* and *Sarcobatus* (grease wood). Toxic signs result from binding of the oxalic acid to serum calcium leading to hypocalcemia, coagulation defects, and tetany. Degeneration and necrosis of kidneys and vasculature from Ca^{++} oxalate deposition may result in severe cases. Oxalates also interfere with absorption of calcium, iron, magnesium, and copper and inhibit succinate dehydrogenase and carbohydrate metabolism (151). Approximately 2.5 kg of tomato or 0.5 kg of spinach leaves need to be consumed to approach a lethal dose (5 g or more) of oxalates.

Phytic acid, the hexaphosphoric ester of myo-inositol, is present at high levels (up to 1.5 g%) in the bran and germ of wheat followed by other cereals, nuts, seeds, spices, and legumes (87). Phytates bind

di- and tri-valent metals in the order: $Cu^{++} > Zn^{++} > Co^{++} > Mn^{++} > Fe^{+++} > Ca^{++}$, causing mineral deficiencies (especially of Ca^{++} and Fe^{+++}) in developing countries that are heavily reliant on cereals as the exclusive source of protein. Inclusion of phytase, an enzyme that releases phosphate from plant phytic acid, in animal feeds ensures phosphate utilization and reduces environmental phosphate pollution from animal production. Supple

mentation with minerals and Vitamin D can antagonize most effects of oxalates and phytates (87).

Plant Phenolics

Plant phenolics comprise a group of several thousand substituted phenolic compounds occurring in trace amounts as esters or glycoconjugates. Acute human and animal poisonings are mostly caused by phenolics uncommon in human food and include coumarius, aflatoxins, and gossypol. Phenolics common in human foods belong to three general classes, that is, non-flavonoids (gallic, syringic, caffeic, and other acids); flavonoids (flavones such as tangeritin, flavonols such as kaempferol and quercetin, isoflavones such as coumestrol, aurones, chalcones, and anthocyanin pigments); and polyphenols (tannins and lignin). Polyphenols are widely distributed and present in relatively large amounts in cereals, millets, legumes, and fruits. Deleterious effects of long-term exposure of both hydrolyzable (polyphenolic acid) and condensed (polyflavonoid) tannins include reductions in the digestibility of foods and feeds, protein utilization, and body weight gain, damage to and sloughing of the mucosal lining of the gastrointestinal tract, and cancer of the mouth and esophagus (77, 164). In contrast to mild acute effects in humans, livestock losses can exceed $10 million annually, attributable to the toxic effects of hydrolyzable oak tannins consumed when other forages are unavailable (186).

Epidemiological correlation exists between high consumption of condensed tannins (sorghum and dark beer prepared from sorghum, tea, red wines, and areca nuts) and high rates of oral and esophageal cancer (50). Parenteral exposure to tannins reportedly has led to high incidence of liver and other tumors in rodents (77). On the other hand, a negative association between tea drinking and stomach cancer (192) and coffee consumption and kidney cancer (85) also exists.

Polyphenols, however, are not directly damaging to DNA (35) and experimental evidence of anticarcinogenic effects of penta-O-gallyl-beta-D-glucose and epigallocatechin gallate, two green tea tannins (64), exists. Flavonoids and non-flavonoids exert no less than 40 different physiological and pharmacological actions accounting for their therapeutic and health food use. These include anticoagulant, antihistaminic, antihypercholesterolemic, anti-inflammatory, antioxidant, antiproliferative, antipruritic, antipyretic, antirheumatic, antiseptic, antithrombogenic, antitumor, apoptotic, estrogenic, and vasoactive effects. Many if not all of these actions are based on their UV-absorbing, chelating, oxidative phosphorylation uncoupling and antioxidant properties. In addition, their sparing effect on vitamins C and E; induction of P450-mediated enzymes; and alteration of enzymes (phospholipases, ATPases, cyclo xygenases, lipoxygenases, protein kinases), oncogenes, and other signaling components critical for cell survival and proliferation (35, 61) contribute to an array of opposing effects in many systems.

Although human consumption of flavonoids alone can be greater than 1 g/day (87), the toxicological implications of exposure to flavonoids and other simple phenolics arise from lifetime exposure to them. Recently, high intake of flavonoid supplements was suggested to have caused acute renal failure due to hemolysis (116). More than 30 flavonoids, including the most abundant quercetin, kaempferol, myricetin, hesperetin, naringenin, wogonin, and norwogonin, as well as their glycosides have been shown to be mutagenic in bacterial and/or mammalian systems (77, 122). Quercetin induced hyperplasia and benign renal tubular epithelial tumors and appeared to enhance pancreatic pre-tumorous lesions induced by nitrosomethylurea in rats fed a 5% dietary level for 2 years (21, 54). The proponderance of evidence (77), however, points to the antagonistic effects of flavonoids against mutagenic and carcinogenic effects of a number of genotoxicants and promotors in many organs (18, 35, 77, 117). These conflicting results are likely due to differences in test systems and the dose levels used because phenolics exert antioxidant effects at low doses and prooxidant effects at higher doses (219).

On balance, however, both polyphenols and simple phenolics may play a protective role against the carcinogenic and oxidative influences (e.g., those causing coronary heart disease) in humans. Anticarcinogenic effects of phenolics are likely due to the inhibition of metabolic enzymes leading to reduced levels of reactive intermediates, induction of detoxifying enzymes such as glutathione-S-transferase, reduced formation of oxidation products, and/or inhibition of enzymes such as protein kinases and oncogenes that stimulate cell proliferation, among other mechanisms (117, 215). Cardiovascular protection appears to result from reduced low-density lipoprotein oxidation (antiatherogenic effect), reduced platelet aggregation (antithrombotic), vasodilation, relaxation of cardiovascular smooth muscle, and antihypercholesterolemic effects of flavonoids (61, 80).

Gossypol (1,1,6,6,7,7-hexahydroxy-5,5-diisopropyl-3, 3-dimethyl [2,2-binaphthalene]-8,8-dicarbovxaldehyde), a yellow phenolic pigment in cottonseed, can bind to proteins and minerals and reduce the biological availability of iron and lysine (86). Similar to other phenolics, free gossypol (>60 ppm) inhibits oxidative phosphorylation and causes myriad other effects leading to acute toxicity in

animals on a high cottonseed diet. In general, higher acute doses cause cardiac failure associated with liver and lung (pulmonary edema) damage whereas chronic exposure leads to general malnutrition and reproductive effects (35). Signs of gossypol toxicity include loss of

appetite and body weight; rough hair coat; edematous fluid in body cavities, lungs, and pericardium giving rise to gasping; hemorrhagic degenerative changes in liver, and necrosis of cardiac myocytes (223). Changes in plasma $K+$ (increase in calves and decrease in humans) may be responsible for gossypol toxicity. Olive discoloration of yolk and decreased egg hatchability occur in poultry (35). Male antifertility effects of gossypol in mammals are only partially reversible and include reduced sperm production as well as motility during the late stages of spermatogenesis, likely caused by mitochondial damage (160) or inhibition of protein kinases (199). Gossypol is not mutagenic in the Ames test (35) but appears to induce genetic damage (dominant lethal mutations) in rats and may be both an initiator and promotor of carcinogenesis (10).

Gossypol and polyphenol (tannin) toxicity can be prevented by the addition of iron, supplemental protein, vitamin K, and alkalinizing agents such as sodium hydroxide. In addition, non-ionic detergents such as Tween 80, methyl donors such as choline and methionine, and dehulling and peeling of grains and fruits have also been shown to counteract the toxic effects of tannins (49, 186). A glandless (gossypol-free) variety of cottonseed, although it is expected to eliminate gossypol toxicity in animals, appears to be more susceptible to insect attack and has yet to gain popularity.

Proteins and Peptides

In the average American diet protein supplies 15 percent of total calories. Long-term consumption of higher amounts of protein, especially animal-derived, may contribute to diabetes, renal glomerular sclerosis, Crohn's disease, and osteoporosis (by increased Ca^{++} loss from bones in response to acidosis) (23, 185, 217).

Protein toxicants such as allergens, hemagglutinins (lectins) and enzyme inhibitors have been discussed. Certain microbial protein toxins are discussed in subsequent sections. Toxic peptides from mushrooms are discussed below.

Mushroom peptides. Among several thousand species of mushrooms only about 100 may be toxic and 12 are known to contain lethal toxins (57, 108, 214).

Emesis and profuse diarrhea followed by rapidly developing hepatic and renal insufficiency (similar to acute hepatitis) and death are characteristic of poisoning by mushrooms related to *Amanita verna* (destroying angel) in the United States and *A. phalloides* (green death cap) in Europe (209). Approximately one-half of a mature cap of *A. phalloides* can be lethal in an adult (132). Among the three classes of thermostable peptide toxins (amatoxins, phallotoxins, and virotoxins) in the deadly Amanitas, the cyclic octapeptides, amatoxins (Figure 11.2), appear to be responsible for the observed clinical effects which begin to appear after a 12-hour latency period. Evidence of hepatotoxicity includes an increase in serum transaminases, decrease in blood glucose and clotting factors, and, occasionally, jaundice. Hepatogenous encephalopathy and renal failure may be present terminally.

Fatalities are common even following intensive symptomatic care, which includes fluid replacement, activated charcoal hemoperfusion, and forced diuresis, etc. In countries other than France and the United States, use of silibinin (from *Silybum marianum*), which prevents hepatocyte uptake of amatoxins, has produced beneficial effects in direct relationship with the speed of onset of therapy (132, 209). A return toward normal glucose, factor V, and fibrinogen is prognostic of recovery (132). Amatoxins inhibit RNA polymerase II by binding to the enzyme directly, and subsequently inhibit mRNA synthesis by blocking the formation of phosphodiester bonds at the elongation step, due to stabilization of the ternary complex of template, enzyme, and the nascent ribonucleotide chain (209).

The other two groups of polypeptide toxins, the phallotoxins and virotoxins, are capable of causing toxic effects only at relatively higher doses. The effects of phallotoxins include swelling of the liver due to engorgement of hepatic sinusoids with blood, and depletion of blood in the peripheral circulation, leading to shock. Reduction of cellular G-actin concentration by a combined effect of stimulated G-actin polymerization into F-actin, and inhibition of F-actin depolymerization leading to a loss of membrane elasticity and thus cell surface vesiculation may explain subsequent hepatocyte damage (209).

The toxic effects of several mushroom species that are rarely lethal are summarized in Table 11.1. Treatment in most cases is supportive. Other identified human conditions associated with mushroom production, commerce, and consumption are: hypersensitivity to edible mushrooms in certain populations; hypersensitive allergic alveolitis and other pulmonary allergic changes in mushroom workers from spores of certain edible mushrooms (mushroom worker's lung); hemolytic reactions following consumption of mushrooms belonging to the genera *Gyromitra*, *Boletus*, and *Paxillus;* and dermatitis (allergic) from contact with one or more species of the genera *Boletus*, *Lactarius*, *Calvaria*, and *Agaricus*.

Saponins

The saponins are bitter-tasting, steroidal (C27) or mono, di-, tri-, and sesqui-terpenoid (C30) glycosides

from plants, fish, and sponges, and are capable of reducing surface tension, hemolyzing red blood cells, and causing toxic effects in cold-blooded animals. Their occurrence, biological effects, and relevance to food,

agriculture, and medicine are reviewed by Walker and Yamazaki (211, 212).

So far, d-limonene from citrus oils, ginseng saponins, and medicagenic acid and hederosides in alfalfa and *Hedera helix,* respectively, and oleanolic and ursolic acid in a variety of food, medicinal, and other plants, as well as their aglycones (sapogenins), have been studied to some extent. Their analgesic, anti-atherosclerotic, anticarcinogenic, anticholinergic, antihypercholesteremic, antihyperglycemic, anti-inflammatory, antitubercular, cardioprotective, diuretic, and hepatoprotective effects are likely to encourage increased dietary, supplemental, and medicinal utilization of saponin-containing plants such as ginseng (119, 124, 161, 218). Mechanisms of protection involve Ca^{++}-antagonistic and vasodilatory/venoconstrictive; immune-modulatory, bile acid-binding, anti-proliferative, and membrane permeabilizing; and antioxidant and anti-cytochrome P450 effects (119, 161). Feeding high levels of saponin from a variety of sources, however, resulted in lower growth rate; increased serum LDH and GOT associated with hepatocellular necrosis; and increased BUN, hematuria, and proteinuria associated with renal tubular necrosis (99, 143) in animals. Several steroidal and nonsteroidal saponins from pasture weeds such as *Hypericum perforatum* and *Narthecium ossifragum,* vines such as *Tribulus terrestris,* and tropical grasses such as *Brachiaria* and *Panicum* sp. cause primary or hepatogenic photosensitization in animals (34). Alpha-hederin, a saponin that induces metallothionein in maternal tissues, appears to induce visceral and skeletal defects in offspring born to exposed rat dams by possibly reducing zinc availability to the fetus (52). Similar to phenolics, the beneficial effects of saponins can be derived from daily doses present in a balanced diet.

Toxic Amino Acids

In general, foodstuffs do not contain individual amino acids of nutritional importance in amounts that cause adverse reactions. Therapeutic use of greater than ten times the required dose of amino acids, on the other hand, when given on an empty stomach, can lead to adverse effects, including gastric distress (essential amino acids), nausea, febrile reaction and/or headaches (methionine, isoleucine, and threonine), and disorientation (methionine and tryptophan) in psychiatric patients treated with monoamine oxidase inhibitors (73).

Monosodium glutamate (MSG) had long been used as a flavor enhancer in commercially processed

foods. MSG, as well as other acidic amino acids, but not basic or neutral amino acids, produced lesions in rats and mice

Table 11.1 Mushroom-induced syndromes

	Mushroom species	Toxic compound(s)	Effects	Mechanism	Prevention/ Treatment
Rapid onset:					
Syndrome	*Chlorophyllum molybditis* *Entoloma lividum* *Omphalotus olearius* *Paxillus involutus* *Trichodoma pardinum*	Many unknown	Emesis, diarrhea	Unknown	Cooking/Fluid replacement
Parasympathetic	*Inocyte* sp. *Clitocybe* sp. *Omphalotus illudens* *Amanita* sp.	Muscarine and related	Increased salivation, lacrimation, and urination; diarrhea; dyspnea; sweating; bradycardia; tremors, etc.	Parasympathetic stimulation	Avoid/Atropine
CNS Syndrome	*Psilocybe* sp. *Panaeolus* sp. *Copelandia* sp. *Gymnopilus* sp.	Psilocybin Psilocin	Hallucinations involving all sensations; hyperthermia, convulsions, coma, and death.	Serotonin agonist	Avoid/Diazepam and cooling
	Amanita pantheria *A. muscaria*	Ibotenic acid, muscinol, stizolobic and stizolobinic acid	Alternating depression and neuromuscular stimulation	Stimulation of bicuculinreactive postsynaptic receptors	Avoid/Diazepam and respiration
Alcohol sensitization	*Coprinus* sp. *Clitocybe claviceps* *Boletus luridus* *Verpa bohemica*	Coprine and others	Nausea, vomiting, headache, hypotension, tingling, palpitations, tachycardia; testicular damage, etc.	Inhibit acetaldehyde dehydrogenase	Avoid mushroom and Alcohol/ supportive
Delayed onset:					
Headache	*Gyromitra; esculenta* (false morel) *Gyromitra* sp.	Gyromitrin, Monomethyl hydrazine, etc.	Fatigue, head and body ache, vomiting, liver damage, death, carcinogenic	Interfere with pyridoxine?	Cook or dry, don't inhale vapors
Nephropathy	*Cortinarius* sp.	Orellanine Cortinarin	Polydypsia, oliguria, nausea, head and body aches, chills, etc., Renal tubular and liver necrosis, death	Membrane damage from oxygen-derived free radicals (similar to paraquat)	Hemodialysis
Carcinogenic	*Agaricus bisporus* (edible)	Agaritine, hydrazines	Lung tumors	Genotoxic	Cooking
Hepatotoxic	*Amanita phalloides* (Europe) *A. Virosa*	Amatoxins, phallotoxins, and virotoxins	Emesis and diarrhea, increase in serum enzymes, decrease in glucose and clotting factors, hepatic and	1. Inhibit RNA polymerase 2. Enhance G-actin	1. Correct glucose and clotting effects 2.

(United States) *Galerina* sp. *Lepiota* sp.	renal damage, jaundice, coma, and death	polymerization into F-actin 3. Inhibit F-actin depolymerization	Decontaminate 3. Penicillin and silobinin 4. Supportive 5. Transplant liver

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_500.html[2010/10/28 18:44:50]

in the arcuate nucleus of the hypothalamus, retina, and lateral geniculate nucleus, and in other brain areas devoid of the blood-brain barrier (148). Numbness of the neck and back, weakness, and palpitations, typical signs of the so-called Chinese restaurant syndrome, were later found not to be associated with dietary MSG (198).

Hypoglycin A (β-methylene cyclopropyl alanine) and its γ-glutamyl conjugate, hypoglycin B, are components of the fruit of the plant, *Blighia sapida* (ackee in Jamaica and isin in Nigeria). Consumption of this fruit in the unripened stage has been associated with hypoglycemia, resulting from inhibition of gluconeogenesis involving inhibition of fatty acyl-CoA dehydrogenases and thus β-oxidation of fatty acids by cyclopropylacetyl CoA (a metabolite of hypoglycin A). Signs of intoxication include vomiting, convulsions, hypothermia, coma, and even death. Pretreatment with clofibrate (stimulator of peroxismal fatty acid oxidases) prevented many but not all signs, lesions, and biochemical effects (205).

Koa haoli *(Leucaena leucocephala),* a legume found in Hawaii, and other legume species belonging to the Mimosidae family, have potentially high nutritive value for animals and humans (144). However, use of these legumes is precluded in ruminants by the goitrogenic effect of the metabolite (3,4-dihydroxypyridine) of an unusual amino acid, mimosine [3-N-(3-hydroxypyridone-4)-2aminopropionic acid], present in this plant. Mimosine also causes reversible destruction of the hair follicle matrix (loss of hair), reduced bone strength and mineral composition in poultry, and growth depression in both ruminants and nonruminants. The ability of mimosine to chelate Zn and Mg, reduce plasma thyroid and other hormone levels (159), inhibit a large number of enzymes leading to DNA synthesis inhibition and cell-cycle arrest (88, 113) explains many of the effects.

Djenkolic acid, which is an amino acid that is structurally similar to cystine, is present in the djenkol bean *(Pithocolobium lobatum),* found in Sumatra and Java. It can neither substitute for cystine nor can it be totally metabolized, but it can crystallize in the kidney, causing hematuria and crystalluria (113).

Favism, a hemolytic disease (accompanied by jaundice and hemoglobiuuria) in persons genetically deficient in glucose-6-phosphate dehydrogenase (G6PD) and, thus, in NADPH and reduced glutathione content, results from the consumption of the amino acid, 3,4-dihydroxyphen-ylalanine, and the pyrimidine aglycones (divicine and isouramil) of the glycosides vicine and convicine in broad beans *(Vicia faba),* mainly in the Mediterranean region and in the Middle East (37). Ohga et al. (147) observed beneficial effects of human heptaglobin administration in managing this crisis.

The etiology of the neurological disease characterized by posterior sensory ataxia in cattle consuming cycads may be an amino acid, β-N-methylamino-L-alanine. Cer tain seleno-amino acids such as methylselenocysteine, selenocystathionine, selenocysteine, and selenomethionine in plants that grow on high Se soils (113), when incorporated into structural animal proteins, may, during longer-term exposure in livestock, produce defective hair and hooves that are eventually lost. In human beings, a syndrome characterized by abdominal distress, nausea, vomiting, diarrhea, and loss of scalp and body hair had been reported following consumption of coco de momo *(Lecythis ollaria)* nuts containing high levels of selenocystathionine (16).

The amino acids L-2,4-diaminobutyric acid (DABA), 3-N-oxalyl-L-2,3-diaminopropionic acid (ODAP) 3-cyanoalanine, 4-glutamylcyanoalanine, and related homologues, present in seeds of several species of *Lathyrus* and *Vicia sativa* in the Indian subcontinent, have been implicated in the pathogenesis of neurolathyrism, a syndrome characterized by muscular rigidity, weakness, paralysis of leg muscles, and death following long-term, high-level consumption of *L. sativus* seeds (204). The mechanism of action appears to involve irreversible binding of ODAP to the glutamate receptor, and enhanced release/reduced re-uptake of glutamine at relevant nerve terminals, leading to vascular degeneration and necrosis of neurons (152). In certain individuals, amino acids such as β-aminopropionitrile and the dipeptide (N-γ-glutamyl) aminopropionitrile as well as certain urides, hydrazides, and hydrazines from the green parts of *Lathyrus* and other plants, lead to osteolathyrism characterized by bone deformities and reduction in the tensile strength of the aorta (72) resulting from the irreversible inhibition of lysyl oxidase and interference with crosslinking of collagen (216).

Creeping indigo *(Indigofera endecapylla),* a tropical forage, contains a nitric oxide synthase inhibitor, indospicine, which causes liver damage in sheep, rats, and mice by inhibiting the incorporation of arginine, the amino acid it resembles, into protein (113, 154). 3-Nitropropionic acid, a neurotoxin capable of inhibiting mitochondrial succinate dehydrogenase and, thus, cellular respiration, is also present (7).

Vaso- and Psychoactive Substances

High levels of amines such as tyramine and its methyl derivatives octopamine, dopamine, epinephrine, norepinephrine, histamine, serotonin, and others are present in cheese, yeast products, fermented

foods, beer, wine, pickled herring, snails, chicken liver, coffee, broad beans, chocolate, and certain cream products, and in plants such as pineapple, banana, plantain, and avocado (121). Moderate amounts of cheese and yeast products often contain sufficient tyramine (10 mg) to cause severe hypertensive crisis in individuals treated with non-selective monoamine oxidase (MAO) inhibitors for mood disorders (19). Inhibition of MAO leads to a combined

vasopressor effect of unmetabolized biogenic as well as dietary amines. In addition, tyramine enhances release of catecholamines that are present in supranormal amounts in the adrenal medulla (19). Palpitations, migraine headaches, and, in some instances, intracranial bleeding and death may ensue. Use of selective (MAO-A or B) inhibitors for therapy appears not to sensitize individuals to dietary tyramine (101).

Psychoactive substances include CNS stimulants such as xanthines (caffeine, theophylline, and theobromine present in coffee, tea, and cocoa); depressants such as alcohol and high doses of atropine (from jimsonweed and henbane); and hallucinogens such as myristicin from nutmeg, psilocybin and psilocin from mushrooms, and nondietary sources of cocaine and lysergic acid derivatives (130). Chronic overindulgence in xanthine beverages may lead to restlessness, disturbed sleep, myocardial stimulation reflected as premature systoles and tachycardia (palpitations), and tremors. Herbs containing psychoactive agents include California poppy, catnip, cinnamon, hops, hydrangea, juniper, kola nut, nutmeg, periwinkle, thornapple, and wild lettuce (25). The essential oils of coffee and the tannins in tea may cause diarrhea and constipation, respectively (45). Caffeine is neither mutagenic by itself nor enhances the mutagenic effects of other compounds in mammalian cells and may actually be anticarcinogenic (39).

Vitamins and Antivitamins

Vitamins A (retinol), D, and pyridoxine have a lower safety margin (ten times the RDA) and should be used on a longer-term basis only under medical supervision (126). Other vitamins with a safety ratio of 50–100 relative to the RDA are generally safe. Therapeutic uses of vitamin A for night blindness, steatorrhea, hyperkeratosis, acne vulgaris, certain immune disorders, and cancer, along with daily consumption of carotenoids and vitamin A in plant and animal tissues (especially the liver), account for the total vitamin A exposure in humans (149). Oral doses of 18,000–60,000 IU/day and 100,000 IU/day can cause hypervitaminosis A in infants and adults, respectively, with premature epiphyseal closure and retardation of long bone growth in children; and headaches, blurred vision, fatigue, hair loss, drying and flaking of skin, pruritus, nose bleeds, anemia, and liver and spleen enlargement in adults (149). Therapy of acute promyelocytic leukemia with tretinoin (all-trans-retinoic acid) as an adjunct to antineoplastic therapy induces retinoic acid syndrome (fatal leukocytosis, body weight gain, respiratory distress, cardiac and renal failure) in 25 percent of cases (60). Excess vitamin A (retinoids) is teratogenic, causing craniofacial, thymic, heart, and CNS malformations subsequent to interaction with cellular retinoic acid/retinol binding proteins (47). The oral doses of vitamin A not exceeding 6000 IU/day are considered safe during pregnancy in human beings.

Vitamin D, following hydroxylation at C25 and C1 in the liver and kidney, respectively, functions to facilitate the action of parathyroid hormone to release Ca^{++} from bone and to promote intestinal absorption of Ca^{++} and inhibit its renal loss. Ergosterol (a plant steroid) converted to ergocalciferol (Vit-D2) by ultraviolet light, endogenous dehydrocholesterol (in skin) converted to cholecalciferol (Vit D3) by sunlight, and vitamin D-fortified milk are predominant sources of vitamin D for humans (149). While the recommended dose is 400 IU/day, excessive exposure to vitamin D from 1000–3000 IU/day in infants and 10,000–500,000 IU/ day in adults has resulted in toxicosis. Poisonings in dogs and cats have resulted from accidental consumption of insecticidal vitamin D packages. Toxic signs of vitamin D in humans, which are similar to those seen in laboratory animals, are a result of hypercalcemia leading to extraskeletal calcifications, especially blood vessel walls and kidneys, leading to hypertension, renal failure, and cardiac insufficiency (149). Recent evidence suggests that supplementation with vitamin D3 may lead to an increase in LDL and may negate putative cardioprotection by hormone replacement therapy in post-menopausal women (76), and may exacerbate intimal hyperplasia in balloon-damaged rat arteries (106).

Long-term supplemental use of vitamin E can result in coagulopathy (by reduced iron utilization and increased vitamin K requirement) as well as tumor promotion (both stage I and II); such use of pyridoxine can result in photoallergic reaction and sensory neuropathy (126, 137, 149). Table 11.2 lists examples of anti-vitamin factors in foods, the effects of which, in general, only manifest in individuals with already low levels of the vitamin in question.

Miscellaneous Plant Toxicants

A common human intoxication called milk sickness was one of the most dreaded diseases from colonial times to the early 19th century in an area extending from North Carolina to Virginia and to the midwestern United States (112). The disease manifested as weakness, nausea and vomiting, constipation, tremors, prostration, delirium, and even death, resulted from consumption of dairy products made from milk derived from cows (even healthy ones) grazing on white snakeroot

(Eupatorium rugosum) or rayless goldenrod *(Haplopappus heterophillus)*. The causative agent appears to be trematol, an unsaturated alcohol, in combination with a resin acid (112). Other plant toxins excreted through milk that pose toxic hazards for children and nursing animals include pyrrolizidine, piperidine, and quinolizidine alkaloids; sesquiterpene lactones of bitterweed and rubberweed; and glucosinolates (153). Animals grazing high Se forages

Table 11.2 Examples of anti-vitamin factors in foods

Vitamin	Antagonist(s)	Mechanism	Effect(s)	Source(s)
A	Lipoxidase Citral	oxidize β-carotene inhibit retinoic acid (P=450) dehydrogenase	Lower blood Vit A level Endothelial damage cardiovascular disease?	Soybeans Oranges
B Thiamine	Thiaminase, tannins, and ortho-catechols	inactivate thiamine	Neurological syndrome	Bracken fern other plants and seafood Ackee plum Cereal crops
Riboflavin Niacin Biotin Pyridoxine	Hypoglycin A Leucine? Avidin, Linatine, Agaritine	Irreversible binding Hydrazine metabolites condense with the vitamin	Vomiting, sickness Pellagra	Egg white Flaxseed, Shiitake mushroom Pea seedlings Soybeans
Pantothenic acid	Unknown			
B12	Unknown	Unknown		
C	Ascorbic acid oxidase	Oxidizes Vit C	Normally none	Fruits and vegetables
D	β-carotene, plant steroids	Reduce absorption	Rickets and osteomalacia	Green leafy vegetables
	(some) Unknown	Unknown		Soybeans
E	α-tocoferol oxidase	Oxidizes Vit E	Muscular dystrophy	Kidney beans and others
	Polyunsaturated fatty acids	Increases Vit E demand	Liver necrosis	Vegetable oils Beans
K	Diconmarol	Inhibit epoxide reductase	Hemorrhages	Sweet clover

may excrete high levels of Se in milk and contribute to chronic Se toxicosis in the offspring (153). Current processing methods have kept these conditions in check for the most part. In cattle, consumption of 5–10 pounds of snakeroot causes weakness and trembling of various groups of muscles, labored respiration, and death.

Fool's parsley *(Aethusa cynapium)* and other members of the *Umbelliferae* family contain highly toxic acetylene derivatives (e.g., aethusin) that are responsible for many human poisonings (114). Carotatoxin and other acetylene compounds in carrots are neurotoxic (25) but are not likely to cause problems in humans.

Purple mint *(Perilla frustescens)*, widely distributed in the United States and Japan, is used as a flavoring agent, for medicinal purposes, and as animal feed. The presence, in mint, of a ketone-substituted furan capable of causing acute pulmonary emphysema and other lung lesions in cattle and other animals (181) raises questions about the safety of these uses in humans and animals.

Cycads, the palm-like plants adapted for adverse climatic conditions of the tropical and subtropical areas of the world, are still used (seeds and stem) as a source of starch in Guam, Kenya, Amami Oshima, Miyako Island, and southern Japan by small groups of people (128). Adverse effects result from incomplete extraction of toxicants, including cycasin and β-N-methyla-mino-L-alanine (BMAA), during preparation of the flour. Several neurological conditions, including a paralytic disease (amyotrophic lateral sclerosis, ALS) and Parkinsonism-dementia (PD) were observed among the native Chamorro in Guam who consume cycad, gait disturbances, motor weakness, and paralysis in cattle grazing on cycads, and Parkinsonian features and degenerative changes in CNS motor neurons in monkeys—all appear to be related to either or both of these cycad toxicants (128, 190). Attenuation of the cycad-induced neurotoxic syndrome by AP7 and MK801, two selective antagonists of N-methyl-D-aspartate

receptor and its associated ion channel, suggests a role of the excitatory neurotransmitters in the causation of ALS-PD, other motor-system diseases (Huntington's chorea, Parkinson's disease, and olivopontocerebellar atrophy), and Alzheimer's disease (190). Other effects of cycasin, its aglycone, or cycad flour include hepatic necrosis, subserosal hemorrhages, accumulation of yellow fluid in serosal cavities, benign and malignant tumors in the liver, kidney, lungs, and gastrointestinal tract (mainly colon), neuroteratological effects in offspring, death in experimental animals, and mutagenic effects in a variety of in vitro and in vivo systems. Interestingly, cycasin is neither toxic nor carcinogenic when given parenterally to conventional rats or when given either orally or parenterally to germ-free rats, suggesting that the intestinal flora mediate cycasin toxicity. Bacterial β-glucosidase hydrolyzes cycasin to the active carcinogen, methylazoxymethanol (MAM), which produces hepatomas in rats. MAM spontaneously breaks down to methyldiazonium hydroxide which methylates hepatic DNA, RNA, and proteins (128). Certain cycad glycosides inhibit aromatase and may be useful in the treatment of estrogen-dependent cancer (102).

Toxicants in Foods of Animal Origin

The discussion on plant toxicants has included certain agents from this category (e.g., vasoactive agents in cheese, plant-derived toxicants in milk). Others such as bacterial toxins in meats are discussed in a subsequent section. Residues, in meats and milk, from pesticides, antibiotics, and growth promotants (including hormones such as estrogenic substances) are addressed briefly in the section on food additives and in the chapter dealing with pesticides. Natural toxicant hazards in foods of animal origin are mostly limited to those derived from marine sources.

Marine Toxins in Food

Of the many marine organisms containing toxins (up to 1200 species), only a few are involved in food poisoning. Problems of seafood poisoning have spread to inland areas from coastal fishing sites as a result of modern transportation and shipping. Toxicants may be produced by the fish itself, and/or by the marine plankton or algae consumed by the fish, with or without the aid of certain marine bacteria. Leftley and Hannah (111) and Russell and Dart (172) have presented a detailed discussion of the toxicological information relating to fish-borne toxins.

Shellfish poisoning is one of several (amnesic, digestive, neurotoxic-paralytic) disease entities resulting from the consumption of shellfish (clams, crustaceans, lobsters, mussels, oysters, scallops, etc.) that have ingested toxic marine algae, especially certain dinoflagellates. The shellfish are toxic during seasons of heavy algal bloom (such as red tide) containing 200 organisms/ml or more. Toxicity increases in proportion to the concentration of algae and disappears within two weeks after the toxic plankton has disappeared from the waters (171). Saxitoxin, neosaxitoxin, and gonyautoxins are the most potent of the more than 20 toxins present in the group of paralytic shellfish poison, produced by dinoflagollates belonging to *Alexandrium, Gymnodinium, Guanyalax,* and *Pyrodinium* sp.

Saxitoxin blocks the action potential in nerves and muscles by preferential blockade of inward flow of sodium ions with no effect on the flow of potassium or chloride ions (90). Consumption of 1 mg of the toxin (in 1 to 5 mussels or clams weighing 150 g each) can be mildly toxic whereas 4 mg can be fatal if not treated vigorously. Toxic symptoms begin as numbness of the lips, tongue, and fingertips within minutes after eating. Numbness then extends to the legs, arms, and neck and is followed by general muscular incoordination, which progresses to respiratory paralysis and death. Decreased heart rate and contractile force, headache, dizziness, increased sweating, and thirst may also be noted. Boiling in bicarbonate-treated water and discarding the broth is suggested as a means of preventing shellfish poisoning (71).

Diarrhetic shellfish poisoning results from consumption of shellfish contaminated by one of several species of *Dinophysis* that containing okadaic acid (OA) and/or dinophysistoxins (DPT). Both OA and DPT are powerful inhibitors of protein phosphatases and potent tumor promoters (101). Whether protein phosphatase inhibition by OA leads to the observed increase in the permeability of intestinal epithelial cells OA and the diarrhetic effect is unknown.

Neurotoxic shellfish poisoning is characterized by nausea, vomiting, diarrhea, chills, headache, muscle weakness and pain, eye and nasal irritation, and, in severe cases, paresthesia, difficulty in breathing, double vision, dysphonea, and dysphagia. It has been reported along the Gulf of Mexico, the eastern coast of Florida, and New Zealand following consumption of shellfish with a heavy load of *Gymnodinium breve* and/or similar organisms (111). The lipophilic polyether toxin, the brevitoxin, promotes $Na+$ influx and thus depolarization by its action on site-5 of the voltage-dependent $Na+$ channels (111).

Amnetic shellfish poisoning, characterized by short-term and sometimes permanent memory loss associated with gastrointestinal signs and hallucinatory state, has been reported mostly from coastal

areas in North America. Damage to the hippocampus, coma, and death result in severe cases. A water-soluble acidic non-protein amino acid, domoic acid (and its isomers),

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_504.html[2010/10/28 18:44:52]

produced by the diatom *Pseudonitzschia* sp. and acting as a competitive glutamate antagonist at various sites, has been ascribed the etiological agent (111).

Between 300 and 400 tropical reef and semipelagic species of edible marine animals, including barracudas, groupers, sea basses, snappers, surgeon fishes, parrot fishes, jacks, wrasses, eels, and certain gastropods, accumulate in their liver and other viscera toxins capable of causing ciguatera poisoning, with an estimated 20,000 cases/year worldwide (118). The intoxication, common in the South Pacific and the Caribbean, appears to follow the spacial and temporal pattern of the distribution of a photosynthetic dinoflagellate *Gamblerdiscus toxicus,* which is consumed by the smaller herbivorous fish and, in turn, by the ciguatoxic fish (171).

Ciguatoxins, the colorless and heat stable lipophilic polyethers (MW of 1100), appear to play a major role in intoxication with some contribution from the water-soluble maitotoxin (111). Ciguatoxins increase membrane permeability to sodium ions causing depolarization of nerves. In addition, ciguatoxin inhibits subsequent inactivation of open Na^+ channels and possesses anticholinesterase activity in experimental animals (111, 171). Maitotoxin, on the other hand, inactivates voltage-dependent and receptor-mediated Ca^{++} channels leading to high intracellular Ca^{++} and cell death (111). In humans, tingling of the lips, tongue, and throat, followed by numbness, nausea, vomiting, abdominal pain, diarrhea, pruritus, bradycardia, dizziness, and muscle and joint pain occurs. Severe cases exhibit paresis of the legs and, infrequently, death due to cardiovascular and/or respiratory failure (111, 171). Prevention of ciguatera poisoning is difficult, although extensive evisceration of fish may help.

Pufferfish (fugu fish) poisoning, known to occur as far back as 2000–3000 B.C. in China and Japan, results from consumption of tetrodotoxin present in the liver and ovaries of puffer fish, ocean sunfishes, porcupine fishes, blue-ringed octopus, and certain amphibians of the family *Salamandridae* (91, 171). Toxin accumulation is greatest just prior to spawning in the spring. Tetrodotoxin (TTx), with a cyclic hemilactal structure, is highly lethal (LD50, 10 mg/kg) to all vertebrates and is active after boiling for one hour but is inactivated under alkaline conditions (63). Tetrodotoxin prevents the increase in the early Na^+ permeability in both motor and sensory neuronal membranes similar to that of saxitoxin (171). In humans, numbness of the lips, tongue, fingers, and arms, muscular paralysis and ataxia, hypotension, and respiratory paralysis leading to death progress rapidly beginning 30–60 minutes after consumption of 1 to 2 mg of tetrodotoxin (1–10 g of roe or liver). Although current treatment is only symptomatic, experimental evidence (33, 166) indicates that anti-TTx antibodies or 4-aminopyridine may be effective in antagonizing the cardiorespiratory effects of tetrodotoxin. Training of personnel in proper evisceration techniques and licensing of fugu restaurants is a must.

Scombroid poisoning is the most widespread fish-borne intoxication. It results from the consumption of inadequately preserved abalone, amberjack, bluefish, tuna, mackerel, mahi-mahi, and sardines in which histamine and saurine are produced by bacterial scombrotoxic action (118). Scombroid fish apparently has a sharp or peppery taste. Signs of intoxication include nausea, vomiting, diarrhea, epigastric distress, flushing of the face, throbbing headache, and burning of the throat followed by numbness and urticaria. Severe cases may lead to cyanosis and respiratory distress but, rarely, death. These signs appear within 2 hours of the meal and disappear in 16 hours (171). The disease readily responds to antihistamine treatment.

FOOD CONTAMINANTS

Although some naturally occurring toxicants and food additives impart resistance against pests to plants and help preserve and/or enhance the nutritional quality of the diet, respectively, the biological and synthetic industrial chemical contaminants sometimes increase the risk of food-borne illness and deserve a much broader margin of safety in their control than food additives. The FDA, in consultation with other federal agencies, establishes legal action levels, that is, the maximal level of a contaminant allowed in foods and feeds based on economic considerations and technological feasibility (75).

Bacterial Toxins

Foods contaminated with microbial agents are a major source of human disease estimated to afflict up to 80 million people and to cost $22 billion annually in the United States (8). With a few exceptions, these can be prevented by adequate cooking and proper cooling, storage, and reheating of cooked foods in clean containers (127). Bacterial food-borae disease may result from the consumption, in food, either of bacteria (e.g., *Salmonella* sp. and *Clostridium perfringens*) that can cause disease by multiplying in the intestinal mucosa where they may elaborate toxins (enterotoxins), or of a sufficient amount of preformed microbial toxins (staphylococcal enterotoxins and botulinum toxin). In addition to the above well-known etiologies, genetic changes in bacteria that increase virulence, changes in eating habits, altered food production and distribution systems, the increased number of immunocompromised

consumers, and improved detection systems have led to identification of other pathogens such as *Escherichia coli*, *Listeria* sp., and *Yersinia* sp. as causing food-borne illness.

< previous page page_505 next page >

C. perfringens frequently causes food-borne infections which subsequently lead to sporulation of the organism in the large intestine. The enterotoxin, released during sporulation of the bacteria, is capable of causing fluid accumulation in the intestines. The α-toxin, possessing lethal, necrotizing, and hemolytic activities, is also produced by certain types. Among the five distinct types of *C. perfringens* (type A through E), type A is almost always involved in food-borne gastroenteritis and associated signs in human beings in the United States. Only meat and fish products are capable of providing all the amino acids and growth factors required for the growth of *C. perfringens.* Roast beef, beef stew, gravy, and meat pies for type A, and pork, other meats, and fish for type C, are frequently involved (27). Typically, foods involved are cooked at 100°C for less than an hour and are subsequently kept warm or slowly cooled. Spores that survive the heat shock multiply faster in the food than those not subjected to heat treatment, and elaborate the enterotoxin in the gut. The enterotoxin appears to form ion-permeable channels in the cell membrane, leading to movement of extracellular calcium and water into the cells, leading to cell death (194). Entry of the toxin into the blood stream leads to release of potassium from hepatocytes, hyperkalemic cardiac failure, and death (194). Due to the ubiquitous distribution of the organism in soil, and in the gastrointestinal tract of humans and animals, prevention of contamination is difficult. Multiplication and toxin production can be inhibited by heating food to the proper temperature (165–212°F), prompt and effective cooling, and avoiding prolonged reheating before consumption.

Staphylococcus aureus is probably the leading cause of food-borne disease worldwide. The organisms are gram-positive, non-motile, and non-spore-forming cocci that occur ubiquitously in the environment. Although humans are the leading source of food contamination by way of nasal discharge and infected cuts and wounds, the organism can be present in milk derived from mastitic cows and meat derived from arthritic poultry (136). Baked ham, poultry, fish and shellfish, meat and potato salads, cream-filled bakery goods, and high-protein leftover foods are frequently involved in such intoxication (27). Multiplication of *S. aureus* in raw food products is inhibited by other spoilage organisms present. As a result, mostly cooked products subsequently contaminated by infected handlers and stored at warm temperature for several hours before consumption cause intoxication. The causative agent is one of more than six immunologically distinct heat stable enterotoxic proteins (MW 26,000–34,000) whose secretion is genetically regulated during growth (A, D, and E by chromosomes or by plasmids B and C). In addition, *S. aureus* also produces many other substances such as coagulase, DNase, hemolysins, lipases, fibrinolysin, and hyaluronidase, that are toxic to one or more animal species. Although all strains of *S. aureus* are potentially pathogenic, the enterotoxin production is closely related to the presence of coagulase and DNase. Signs and symptoms begin one to six hours after consumption of contaminated food, and include nausea, salivation, vomiting, retching, occasional diarrhea, abdominal cramps, sweating, dehydration, and weakness followed by recovery in one to three days. Severe cases may show fever, chills, a drop in blood pressure, and prostration (136). Preventive measures effective against *S. aureus* food intoxication include education of food handlers regarding hygienic practices to reduce post-cooking contamination of high-protein foods and eliminating prolonged storage of cooked foods at room temperature before consumption.

Botulism is a neurotoxic syndrome caused by consumption of improperly cooked and stored foods containing one of seven (A through G) heat labile neurotoxins produced by *Clostridium botulinum.* It is an ubiquitous, anaerobic, gram-positive, and motile rod capable of forming heat-resistant spores. High moisture, a pH above 4.6, and prolonged anaerobic storage are required for sufficient toxin production (136). Common foods involved are home canned fruits and vegetables such as beans, corn, leafy vegetables, and, especially, peppers, all of which contain toxins A and B. Non-poultry meats contain toxin B, and cheese and other dairy products contain toxin A. Type E is isolated mostly from fish products (136). Types C and D, which cause botulism in animals and birds, do not affect humans. Botulinum toxin is stable in the acid pH of the stomach where it is protected from the gastric juice and pepsin by a nontoxic component of the toxin molecule. Once in the duodenum, it is activated by trypsin, with no change in molecular size, and subsequently absorbed into the lymphatics. The toxin irreversibly binds to the myoneural junction and, acting as a Zn endopeptidase, degrades peptides involved in the release of acetylcholine (ACh), thus inhibiting its release at the peripheral cholinergic nerve endings (136). Signs and symptoms of botulism usually appear 12–24 hours (range: 2 hours to 6 days) following consumption of the toxin-containing food. Initial signs of nausea, vomiting, and diarrhea are followed later by predominantly neurological symptoms including headache, dizziness, blurred and/or double vision, loss of light reflex, weakness of facial muscles, and pharyngeal paralysis (difficulty in speech and swallowing). Fever is absent. Sensory reflexes and mental alertness are intact. Paralysis of the respiratory muscles leads to failure of respiration and death, usually in 3–10 days (187). Food-borne

botulism can be prevented by proper canning technique, boiling vegetables for at least 3 minutes before serving, and discarding all swollen and damaged canned products. Treatment of botulism involves the use of

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_506.html[2010/10/28 18:44:54]

monovalent (E), bivalent (A and B), or polyvalent (A, B, and E) antitoxin, recall of all involved commercial products, proper reporting, and epidemiological investigation. Boiling for 3 minutes or heating at 80°C for 30 minutes destroys the preformed toxin, and the use of salt, the antimicrobial compound nisin, polyphosphates, smoke, spices, lactic acid, and nitrite can inhibit the growth of *C. botulinum* and, thus, toxin formation (136). If the nitrite content of cured meats and fish as well as fermented sausages is reduced from current levels as a means of decreasing the carcinogenic dietary nitrosamines, it is conceivable that the incidence of botulism from the consumption of such foods could increase unless suitable replacements are found.

Food-borne disease outbreaks involving *Bacillus cereus* have occurred in Northern and Eastern Europe. A diarrheal illness involving a wide variety of meats and vegetables, various desserts, fish, pasta, milk, and ice cream (similar to that of *C. perfringens*), and a vomiting illness involving flour-based foods such as cereals and fried rice served in Chinese restaurants (similar to that of *S. aureus*) are both apparently caused by this organism (136). At least seven toxins including a heat stable (121°C for 90 minutes) emetic toxin and a heat labile (56°C for 5 minutes) enterotoxin contribute to the syndrome (136). The enterotoxin appears to disrupt cell membranes, leading to increased permeability, whereas the mechanism of emetic toxin is unknown.

Salmonella sp. consists of over 2200 serotypes possessing somatic O, flagellar H, and capsular Vi antigens, of which 50 serotypes commonly occur. *S. typhi, S. paratyphi,* and *S. sendai* are adapted to human hosts which serve as the sole carrier for those organisms. Feces of infected humans, domestic and wild animals, and birds serve as sources of contamination in a variety of meat and milk products, causing severe gastrointestinal signs along with fever, septicemia, shock, and the sequelae of embolism including pneumonia, meningitis, and abortion. Mortality is rare and occurs in very young, very old, and immunocompromised patients. Enteritis can result from bacterial multiplication within the mucosa or from enterotoxins secreted by some serotypes. Salmonella-free birds can be raised in salmonella-free environments using salmonella-free pelleted feed or by vaccination. Thorough cooking of meats; pasteurization of milk and dairy and egg products; prevention of cross-contamination between cooked and raw products; and, finally, testing, isolation, and treatment of carrier animals and food handling personnel are all extremely important in controlling the incidence of this most common food-borne disease (58).

Campylobacter jejuni and other species in this genus (*C. sputorum* etc.) are associated with up to 4 million cases of diarrheal illness similar in many respects to salmonellosis (9). Reactive arthritis, inflammation of the urethra and conjunctiva, and Guillain-Barré syndrome have been described as sequalae in occasional cases (9).

Escherichia coli, a close relative of the genus *Shigella,* has recently raised concern as a fatal, food-borne disease agent. There are more than 160 serotypes (based on O, H, or capsular K antigen), of which 43 have been associated with bloody diarrhea and hemolytic uremic syndrome (HUS) in humans (165). Pneumonia, meningitis, thrombotic and thrombocytopenric purpura, bladder and kidney infections, and septicemia may also result from *E. coli* infections. Based on virulence factors (which bestow the organism with the ability to attack, invade, and produce toxin in the host cells) located in the plasmids, five virotypes have been identified as pathogenic. These are: enterotoxigenic *E. coli* (ETEC), enteroaggregative *E. coli* (Eagg EC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), and enteroinvasive *E. coli* (EIEC). Serogroup O 157: H7, belonging to the EHEC group and producing a shiga-like toxin, may be the most common serotype causing bloody diarrhea and HUS mainly traceable to consumption of contaminated beef products (165). Less frequently, unpasteurized milk and juices; ham, turkey, and cheese sandwiches; dry fermented sausage; salad; and non-chlorinated water have been involved. Once in the intestines, *E. coli* produce shiga-like toxins SL1 and SL2 which similar to vicin, act by inactivating ribosomes to cause intestinal cell death (165).

Listeriosis, in addition to being transmitted by other routes, is an emerging food-borne disease resulting from the consumption of *Listeria monocytogenes-contami*nated soft cheeses, milk and other milk products, poultry, meat (especially delicatessen meats and frankfurters), and coleslaw and other products (salads, etc.) derived from contaminated vegetables. Food products are contaminated by contact with soil, feces, discharges, and urine from infected animals and humans. The clinical food-borne disease, occurring mostly in pregnant women, neonates, older, and immunocompromised adults, is characterized by gastrointestinal or flu-like symptoms within 12 hours of exposure followed by bacteremia leading to abortions, stillbirths, or premature births in pregnant women; meningitis, respiratory distress, and skin nodules in neonates; and meningitis-related signs in adults (41). The disease can be treated with antibiotics and other supportive measures. Prevention involves improvement

of sanitation of the environment and equipment, and education to identify and avoid contaminated food products.

Another recent controversy involves food-borne transmission of *spongiform encephalopathies* (SE) of animals (bovine SE [BSE] and scrapie of sheep and goats) to humans that may manifest as Creutzfeldt-Jakob (CJ) disease, characterized by fatal neuronal vacuolization and

cell death (70). Although experimental evidence suggests that these diseases can sometimes be orally transmitted, no definitive proof exists that human disease results from consumption of edible animal products or that toxins play a role in its pathogenesis (70). Nevertheless, the fact that BSE may be transmitted to other species should increase the vigilance of the veterinarians responsible to ensure that products from animals with progressive degenerative neurological disease do not enter the human food chain.

Yersiniosis resulting from consumption of improperly cooked chitterlings (porcine large intestines), cryptosporidiosis from contaminated water and unpasteurized apple cider, *Cyclospora* infection from contaminated water and fresh berries, and brucellosis from unpasteurized milk and meats from infected cattle, sheep, goats, and their products are other examples of potential food-borne outbreaks.

Prevention and Control of Microbial Food Hazards The National Animal Health Monitoring System (USDA) has stepped up efforts to monitor food animal and poultry health on the farm and thus develop strategies to deal with potential increases in existing as well as emerging food-borne disease threats. The USDA's Food Safety Inspection Service (FSIS) began implementing a hazard analysis and critical control point system (HACCP) for pathogen reduction in 1996 for all slaughter and processing operations. The HACCP directs each processing unit to: conduct a hazard analysis; identify critical control points at which a safety hazard can be prevented; establish limits at each point; develop monitoring procedures and corrective action when limits are exceeded; and implement record keeping that will allow subsequent verification for compliance by FSIS (78). Data for the *E. coli* and salmonella burden of carcasses are used as evidence of fecal and enteric pathogen reduction. Together, these two programs are aimed at minimizing overall food-borne disease from animal foods in the U.S. population. The approval, by FDA, of low-dose irradiation of red meats to control pathogens, coupled with previously approved irradiation of poultry for pathogen reduction, pork for control of trichinae, fruits, vegetables, and grains for insect control, and spices, seasonings, and dry enzymes used in food processing for microbial reduction (14), should not only contribute to the prevention of food-borne disease caused by microbial pathogens but also help in increasing the shelf life of such products without undesirable organoleptic, toxicological, or nutritional changes. Irradiation is yet to be approved for pathogen control of seafood products and is unsuitable for dairy products because of development of off-flavors and discoloration. In the final analysis, however, the key to minimizing the microbial food-borne illness is at the food preparer/consumer level in the form of proper canning, cooking at the correct temperature, hygienic service, and/or prompt and appropriate storage and reheating.

Mycotoxins

From the standpoint of human and animal health, toxigenic molds belonging to the genera *Aspergillus, Fusarium*, and *Penicillium* have received the most attention, owing to their frequent occurrence in food and feed commodities. Unfavorable conditions such as drought and damage to seeds by insects or mechanical harvesting can enhance fungal toxin (mycotoxin) production during both growth and storage thus making mycotoxicoses a problem of both developing and developed countries. Although more than a hundred mycotoxins have been identified, the public health significance of most remains unknown.

Aflatoxins

The aflatoxins are a group of highly substituted coumarins containing a fused dihydrofuran moiety (Figure 11.3) and produced by the molds *Aspergillus flavus* and *A. parasiticus*. Four major aflatoxins designated B1, B2, G1, and G2 (based on blue or green fluorescence under ultraviolet light) are produced in varying quantities in a variety of products that has not been adequately dried at harvest and has been stored at relatively high temperatures (30). Commodities most often shown to contain aflatoxins are peanuts, various other nuts, cottonseed, corn, and figs. Human exposure can occur from consumption of aflatoxins from these sources and the products derived from them, as well as from tissues and the milk (AFM1, a hydroxylated metabolite) of food animals consuming contaminated feeds. Aflatoxin B1 (AFB1), the most potent and the most commonly occurring aflatoxin, is acutely toxic (LD50, 0.3–0/9.0 mg/kg) to all species of animals, birds, and fishes (42). Acute effects of AFB1 in animals include death without signs, or signs of anorexia, depression, ataxia, dyspnea, anemia, and hemorrhages from body orifices. In subchronic cases icterus, hypoprothrombinemia, hematomas, and gastroenteritis are common. Chronic aflatoxicosis, characterized by bile duct proliferation, periportal fibrosis, icterus, and cirrhosis of the liver, and associated with loss of weight and reduced resistance to disease, is more prevalent in domestic animals and is also likely to occur in humans (151). Prolonged exposure to low levels of AFB1 in animals also leads to hepatoma, cholangiocarcinoma, or hepatocellular carcinoma and other tumors (30).

The National Research Council (146) reviewed epidemiological studies to conclude that the risk of

primary hepatocellular carcinoma from AFB1 exposure may be

AFLATOXINS

	R_1	R_2	R_3

T-2 toxin $R_1 = R_2 = CH_3COO-$, $R_3 = (CH_3)_2\ CHCH_2COO-$;
HT-2 toxin $R_1 = OH$, $R_2 = CH_3COO-$, $R_3 = (CH_3)_2\ CHCH_2COO-$
Neosolaniol $R_1 = CH_3COO-$, $R_3 = OH$, $R_2 = CH_3COO-$;
Diacetoxyscirpenol $R_1 = R_2 = CH_3COO-$, $R_3 = H$;
Monoacetoxyscirpenol $R_1 = OH$, $R_2 = CH_3COO-$, $R_3 = H$.

ZEARALENONE

FIG. 11.3. The structure of the mycotoxins, aflatoxins, trichothecenes, ochratoxin A, and zearalenone.

one in 10,000 in the United States. However, in populations infected with hepatitis B, the risk may be 10 to 100 times higher. AFB1 is mutagenic following metabolic activation in many systems including HeLa cells, *Bacillus subtilis, Neurospora crossa,* and *Salmonella typhimurium* (30). A portion of AFB1 is metabolized by microsomal mixed-function oxidase system in the liver into a variety of reactive products (AFB1 2,3-epoxide, or e.g.) that from adducts with DNA. Hsieh (82) suggested that subsequent formation of repair-resistant adduct, apurination, or error-prone DNA repair may lead to single strand breaks, base-pair substitution, transversion, or frame shift mutations. Recent evidence has suggested that a higher proportion of liver cancer in high aflatoxin-exposure areas had mutations of the *ρ*53 gene involving G>T transversions of codon 249 (109) and that such effect-biomarkers as well as exposure biomarkers such as AFB1-DNA or AFB1-albumin adducts can be used to assess the effectiveness of preventive agents and strategies in public and animal health (95). In addition, AFB1 inhibits DNA synthesis, DNA-dependent RNA polymerase activity, and messenger RNA synthesis and protein synthesis (81) which may be related to several lesions and signs of aflatoxicosis including fatty liver (failure to mobilize fats from the liver), coagulopathy (inhibition of prothrombin synthesis), and reduced immune function.

Other less widespread human clinical syndromes in which aflatoxins have been implicated include childhood cirrhosis in India; possibly Reye's syndrome in many parts of the world, and, rarely, acute hepatitis (aflatoxicosis) in India, Taiwan, and certain countries in Africa (182).

Widespread concern regarding the toxic effects of aflatoxins in humans and animals and the possible transfer of residues from animal tissues and milk to humans has led to regulatory actions governing the interstate as well as global transport and consumption

of aflatoxin-contaminated food and feed commodities. Action levels for total aflatoxins in corn and other feed commodities used to feed mature nonlactating animals range from 100–300 ppb. For milk, the action level is 0.5 ppb. For other commodities destined for human consumption and interstate and potentially global commerce, the action limit is 20 ppb (FDA Compliance Policy Guides 7106.10, 7120.26, 7126.23).

Ergot Alkaloids

Ergotism, which is now rare, was first associated with the consumption of scabrous (ergotized) grain in the mid-16th century (St. Anthony's fire). Subsequent studies led to the identification of *Claviceps purpura* as the fungal agent invading rye, oats, wheat, and Kentucky bluegrass, and *C. paspali* invading Dallis grass. Lysergic acid derivatives, the peptides and the anime alkaloids of ergot, were identified as the causative agents of the gangrenous and CNS forms of the disease (104). The gangrenous form, resulting from a predominance of alkaloids with α (ergotoxine) and vasopressor (ergotanine) action (104), typically manifested as prickly and intense heat and cold sensations in the limbs, and swollen, inflamed, necrotic, and gangrenous extremities which eventually sloughed off. Convulsive ergotism, characterized by CNS signs, numbness, cramps, severe convulsions, and death. Abortions have been reported in animals.

Fumonisins

Fusarium moniliforme Sheldon is a common fungal contaminant of cereals, especially corn, around the world. Contamination of corn by *F. moniliforme* as well as its major metabolites, fumonisins B1 and B2, can induce one of several human and animal diseases including leukoencephalomalacia (LEM) in horses, pulmonary edema in swine, renal and hepatotoxicosis in horses, swine, and rats, and hepatocarcinogenic effect in rats (55). Recent evidence has suggested that FB1 increases chromosomal aberrations in primary rat hypatocytes (98) and developmental effects in the offspring of pregnant mice (163). Consumption of high levels of fumonisins in home-grown corn has been associated with an higher incidence of human esophageal cancer in certain regions of South Africa and China (125). Although the mechanisms of the toxic and carcinogenic effects are not understood, inhibition of spingolipid biosynthesis (210), enhancement of lipid peroxidation (1), elevated secretion of tumor necrosis factor-alpha (53), depletion of glutathione levels (89), elevated nitric oxide synthesis (169), induction of protein kinase C translocation via its action on phorbolester binding site (222), and inhibition of protein serine/threonine phosphotases (65) are among the changes that can explain some of the effects of FB1.

Ochratoxins

The ochratoxins, a group of seven isocoumarin derivatives linked with phenylalanine by an amide bond, are produced by *Aspergillus ochraceus* and *Penicillium verrucosum* (among others) in barley, corn, wheat, oats, rye, green coffee beans, peanuts, wine, cocoa, and dried fruits (180). In experimental animals ochratoxin A (OTA) produces predominantly renal proximal tubular lesions and liver degeneration. The acute oral LD50 of OTA ranges between 0.2 mg/kg for the dog and 59 mg/kg in mice. The association between consumption of a high level OTA in the diet and nephropathy in humans and swine in the Balkan countries and swine in Denmark and the United States has been clearly established (103, 120). Signs include lassitude, fatigue, anorexia, abdominal (epigastric or diffuse) pain, and severe anemia followed by signs of renal damage. Reduced concentrating ability, reduced renal plasma flow, and decreased glomerular filtration occur sequentially, accompanied by gross and microscopic renal changes including necrosis, fibrosis with some tubular regeneration, glomerular hyalinization, and interstitial sclerosis. Death results from uremia. Ochratoxins are teratogens and genotoxic carcinogens (180) inducing hepatomas and renal adenomas in mice (92).

Relevant cellular effects specific to OTA include alteration in enzymes involved in glucose metabolism and anion-transport leading to intracellular alkalinization and associated morphological change (105, 133). Creppy et al. (43) and Schramek et al. (178) proposed roles for free radicals and prostaglandins, and extracellular signal-regulated kinases, respectively, in ochratoxin-induced renal damage.

Psoralens

Psoralens are furocoumarin compounds that have been used in repigmenting achromatic skin lesions in an acquired disease called vitiligo, in some suntan lotions, and in drugs used to treat psoriasis (31). Abuse of such compounds can result in dermatitis following exposure to the sun along with nausea, vomiting, vertigo, and mental excitation. A phototoxic dermatitis in celery pickers has been linked to the presence of psoralens (8-methoxypsoralen, 5-methoxypsoralen, and trimethylpsoralen) in stalks infected with *Sclerotinia sclerotiorum* (pink rot), *S. rolfsii, Rhizoctonia solani,* or *Erwinia aroideae,* or in celery stalks soaked in 5 percent NaCl (182). Fig, parsley, parsnip, lime, and clove also contain psoralens. 8-Methoxypsoralen appears to undergo epoxidation of the furan ring similar to aflatoxins and may react

with DNA in a similar fashion. Treatment with 8-methoxypsoralen and ultraviolet light led to squamous cell carcinomas of the ear in mice (31).

Page 511
Unlike other photosensitizing agents, psoralens seem to act by photoreacting with DNA, and to a lesser extent, with RNA. The mechanism of psoralen photosensitivity appears to involve intercalation and crosslinking of psoralen in the DNA which occurs in three steps:
(a) reversible intercalation of psoralen between two pyrimidines on opposing sides of the helix;
(b) formation of a monoadduct with the 5, 6 double bond of the pyrimidine following absorption of 1 quantum of ultraviolet light; and
(c) crosslink formation by absorption of a second quantum of ultraviolet light and linking of the monoadduct to the 5, 6 double bond of thymidine (179). In general, there is an excellent correlation between photoadduct formation and photosensitization of psoralens.

Trichothecenes

Trichothecenes are a group of 12,13-epoxy trichothecenes produced by *Fusarium poae, F. tricinctum, F. graminearum, F. nivale, F. solani, Myrothecium roridum,* and *Stachybatrys atra,* among others, in cereal grains, including wheat. The group of macrocyclic trichothecenes including satratoxins, verrucarins, and roridins is produced mainly by *Stachybotrys* sp. in hay. Although more toxic, this group does not pose significant human health threat due to lack of prevalence. Group A trichothecenes (T-2 toxin, diacetoxyscirpenol) contain a side chain and are relatively less polar compared to group B (nivalenol, deoxynivalenol, fusarenon). A two-volume treatise about trichothecene toxins and their role in human and animal health is available (24).

Most trichothecenes of health significance are produced by *Fusarium* sp. Characteristic signs of alimentary toxic aleukia (ATA), caused by T-2 toxin and related trichothecenes, including radiometric damage such as irritation and necrosis of skin and mucous membranes, hemorrhage, destruction of the thymus and bone marrow, hematological changes, and nervous disturbances; necrotic angina and shock are common to all toxic syndromes (24). Feed refusal, vomiting, and immune suppression are common problems in farm animals, especially swine, in the midwestern United States and are associated predominantly with the presence of the trichothecene, deoxynevalenol (vomitoxin) in wheat and corn (151). Paradoxically, nivalenol and deoxynivalenol exposure of a prolonged duration induced autoimmune-like effects similar to human IgA nephropathy (170). Trichothecenes (T-2 toxin) can cause fetal death, abortions, and teratogenic effects (24). Although several trichothecenes are genotoxic in bacterial, yeast, and cell culture systems (98, 201), they exhibit no initiator or promoter effect in whole animal systems (107).

Metabolism of trichothecenes occurs rapidly through deacetylation and hydroxylation and subsequent glucuronidation in the liver and kidneys (24, 170), thus posing little problem of residues in meats from contaminated animals. Trichothecenes inhibit protein synthesis which either by itself or together with their ability to induce apoptosis (138) can explain many of their toxic effects. In addition, deoxynivalenol and possibly other trichothecenes affect serotonergic pathways in the brain and also induce expression of a number of cytokines (170). The significance of these effects in trichothecene intoxication in humans and animals is unknown.

Zearalenone

Zearalenone and zearalenol are nonsteroidal estrogenic contaminants (produced by *Fusarium roseum*) in grains such as corn, wheat, sorghum, barley, and oats. Zearalenone induces effects consistent with those produced by excessive steroidal estrogens, that is, anabolic and uterotropic activities and regulation of serum gonadotropins. Although swine appear to be the most sensitive species and exhibit signs of hyperestrogneic syndrome—that is, changes in serum leutinizing hormone, swollen and edematous vulva, hypertrophic myometrium, vaginal cornification and prolapse (in extreme cases), and infertility (151)—human exposure to zearalenone and its metabolites by way of cereal products can also be significant.

The mode of action of zearalenone involves interaction with estrogen receptors, translocation of the receptorzearalenone complex to the nucleus, combination with chromatin receptors, selective RNA transcription leading to biochemical effects including increased water and lowered lipid content in muscle, and increased permeability of the uterus to glucose, RNA, and protein precursors (67). Available evidence indicates that rapid conversion of zearalenone and zearalanol to conjugated metabolites to be excreted in urine and feces makes consumption of meat and milk from animals receiving Ralgro an insignificant risk to humans.

Zearalenone is genotoxic in bacterial systems (68), forms DNA adducts in female mouse tissues, and induces hepatocellular adenomas in female mice (157). Unknown presently is the carcinogenic risk to humans and whether potentiative interaction exists between the adverse effects of zearalenone and those of dietary or endogenous estrogens as well as the xenoestrogens in the environment.

Other Mycotoxins

A number of other mycotoxins (Table 11.3) have been identified either as contaminants in foods destined for human consumption, or as metabolites of fungi isolated from human foods (29). Although some of these have been associated with outbreaks of domestic animal diseases, no link between human consumption and disease

Page 512

Table 11.3 Miscellaneous Mycotoxins

Mycotoxin	Major producing organisms	Source of fungi	Principal toxic effects
Alternariol and alternariol methyl ether	*Alternaria* sp.	sorghum, peanuts, wheat	highly teratogenic to mice; cytotoxic to HeLa cells; lethal to mice
Altenuene, altenuisol	*Alternaria* sp.	peanuts	cytotoxic to HeLa cells
Altertoxin 1	*Alternaria* sp.	sorghum, peanuts, wheat	cytotoxic to HeLa cells; lethal to mice
Ascladiol	*Aspergillus clavatus*	wheat flour	lethal to mice
Austamide and congeners	*Aspergillus ustus*	stored foodstuffs	toxic to ducklings
Austadiol	*Aspergillus ustus*	stored foodstuffs	toxic to ducklings
Austin	*Aspergillus ustus*	peas	lethal to chicks
Austocystins	*Aspergillus ustus*	stored foodstuffs	toxic to ducklings; cytotoxic to monkey kidney epithelial cells
Chaetoglobosins	*Penicillium aurantiovirens* *Chaetomium globosum*	pecans	toxic to chicks; cytotoxic to HeLa cells
Citreoviridin	*Penicillium citreoviride*	rice	neurotoxic, producing convulsions in mice
Citrinin	*Penicillium viridicatum*, *Penicillium citrinum*	corn, barley	nephrotoxic, swine
Cyclopiazonic acid	*Penicillum cyclopium*	ground nuts, meat products	nephrotoxic, enterotoxic
Cytochalasins	*Aspergillus clavatus* *Phoma* sp. *Phomopsis* sp. *Hormiscium* sp. *Helminthosporium dematioideum* *Metarrhizium anisopliae*	rice, potatoes millet, pecans, tomatoes	Cytotoxic to HeLa cells, teratogenic to mice and chickens
Diplodiatoxin	*Diplodia maydis*	corn	nephrotoxic and enterotoxic to cattle and sheep
Emodin	*Aspergillus wentii*	chestnuts	lethal to chicks
Fumigaclavines	*Aspergillus fumigatus*	silage	enterotoxic to chicks
Kojic acid	*A spergillus fla vus*	squash, spices	lethal to mice
Malformins	*Aspergillus niger*	onions, rice	lethal to rats
Maltoryzine	*Aspergillus oryzae*	malted barley	hepatotoxic and causes paralysis
Moniliformin	*Fusarium moniliforme*	corn	cardiotoxic in rodents
Oosporein (chaetomidin)	*Chaetomium trilaterale*	peanuts	lethal to chicks
Paspalamines	*Claviceps paspali*	Dallisgrass	neurotoxic to cattle and horses; causes paspalum staggers
Patulin	*Penicillium urticae*	apple juice	lethal to mice; mutagenic; teratogenic to chicks; pulmonary effects in dogs; carcinogenic to rats

Page 513

Mycotoxin	Major producing organisms	Source of fungi	Principal toxic effects
Penicillic acid	*Penicillium* sp.	corn, dried beans	lethal to mice; mutagenic; carcinogenic to rats
PR toxin	*Penicillium roqueforti*	mixed grains	hepatotoxic and nephrotoxic to rats; abortion in cattle
Roseotoxin B	*Trichothecium roseum*	corn	toxic to mice and ducklings
Rubratoxins	*Penicillium rubrum*	corn	causes hemorrhage in animals; hepatoxic to cattle
Secalonic acids	*Aspergillus aculeatus Penicillium oxalicum*	rice, corn	lethal, cardiotoxic, lungirritant, and teratogenic to mice
Slaframine	*Rhizoctonia leguminicola*	red clover	salivation and lacrymation in horses and cattle
Sporidesmins	*Pithomyces chartarum*	pasture grasses	hepatotoxic, causes photosensitization in ruminants
Sterigmatocystin	*Aspergillus flavus*	mammals	mutagen, carcinogen, and hepatotoxic to mammals
Tenuazonic acid	*Alternaria* sp.	grains, nuts	lethal to mice hepatoxic to mice;
Terphenyllins	*Aspergillus candidus*	wheat flour	cytotoxic to HeLa cells
Tremorgenic Mycotoxins Fumitremorgens A and B	*Aspergillus fumigatus*	rice	neurotoxic (prolonged tremors and convulsions)
Paxilline	*Penicillium paxilli*	pecans	neurotoxic (prolonged tremors and convulsions)
Penitrems A, B, and C	*Penicillium cyclopium*	peanuts, meat products, cheese	neurotoxic (prolonged tremors and convulsions) to cattle, sheep, dogs, and horses
Tryptoquivalines	*Aspergillus clavatus*	rice	neurotoxic (prolonged tremors and convulsions)
Verruculogen (TR-1)	*Penicillium verru culosum*	peanuts	neurotoxic (prolonged tremors and convulsions)
Unidentified Toxin(s)	*Aspergillus terrus Balansia epichloe Epichloe typhina Fusarium tricinctum* and others	fescue grass	gangrene (Fescue foot); summer slump syndrome; fat necrosis and agalactia in cattle
Xanthoascin	*Aspergillus candidus*	wheat flour	hepatotoxic and cardiotoxic to mice

Condensed and modified from Refrence 29.

has been established. Others have been shown to induce toxic and lethal effects in laboratory animals with no association between consumption of these toxins by animals or humans and a disease syndrome. Several of these, for example, cytochalasins and secalonic acid D (162), have been used to expand our understanding of normal as well as abnormal cellular responses to xenobiotics.

Although it is difficult to assess the total significance of the consumption of mycotoxins in human foods, it is easy to conceive that such a task requires extensive research into hundreds of known and a potentially large number of as yet unknown mycotoxins. In spite of the vast number of toxic metabolites, reduction in mycotoxin levels in foods and feeds and the prevention of mycotoxicoses in humans and animals can be achieved for the most part by avoiding stress in crops and damage to seeds by pests and by mechanical harvesting. Rapid postharvest drying and avoiding conditions that promote mold growth during storage are equally important.

Pesticides

Pesticides are essential in agriculture. The National Monitoring Program for Food and Feed, comprised of three federal surveillance programs (i.e., the Total Diet Study of market foods by the FDA, nationwide monitoring of unprocessed food and feed by the FDA, and analysis of meat and poultry by the USDA), monitors residues of chlorinated hydrocarbon insecticides, organophosphates and carbamates, and, very infrequently, herbicides and inorganic pesticides such as Arsenic and bromide in various agricultural products. Despite the ban on DDT in 1972 and aldrin and dieldrin in 1975, a partial ban on heptachlor and chlordane in 1978, and a complete ban on heptachlor in 1983 and others later, residues of these and other chlorinated pesticides and their metabolites continue to appear, especially in dairy products, meat, fish, and poultry. In most cases, however, the daily intake of a pesticide did not exceed the ADI established by a Joint Food and Agriculture Organization (FAO)/World Health Organization (WHO) Expert Committee on Pesticide Residues. Intoxication with a pesticide usually results from accidental or suicidal ingestion, careless storage, or improper use. The toxic effects of individual pesticides are discussed in Chapter 13.

Toxic Metals

A high proportion of the general population's total daily exposure to metals occurs from their natural presence in foods. Beverages, water, air, and contact with metal-containing consumer products contribute to the rest. Children consume more calories per unit body weight and have a higher absorption rate than adults, placing them at a higher risk for metal toxicity than adults.

Industrial and agricultural uses of metal products pose the hazard of food-contamination associated with their use, storage, accidental spillage, and improper disposal. The recent decline in the use of heavy metal-based pesticides, including herbicides, makes acute poisonings from dietary toxic metals less likely. A decline in the use of containers with metal coatings that dissolve during food manufacture, cooking, and storage has also contributed to the decline in acute toxicities associated with metals. Food-borne intoxications from metals are mostly limited to long-term consumption of water and food products from environments that contain naturally high levels of metals (e.g., selenium and fluoride) or that are contaminated by mining, smelting, and industrial discharge (e.g., methylmercury and Minamata disease). The reader is referred to Chapter 14 for information on the toxic effects of metals.

FOOD ADDITIVES

The increasing demand for food by an ever-increasing world population, and for ready-to-eat foods because of changes in lifestyles in developed societies, has necessitated the use of chemical additives to help preserve, nutritionally fortify, and process foods. Concerns about adulteration (masking of low-quality food by chemical additives) and of toxic effects from chronic dietary chemical exposure have led to the passage of the Food and Drug Act of 1906; the Food, Drug, and Cosmetic Act of 1938; the Miller Pesticide Amendment of 1954; the Food Additive Amendment of 1958; the Color Additive Amendment of 1960; the Animal Drug Amendment of 1968; the Federal Food, Drug, and Cosmetic Act (FFDCA) of 1976; and the Federal Food Quality Protection Act (FFQPA) of 1996. The term, *food additive,* is defined in these acts as

"…any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristic of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; and including any source of radiation intended for any such use), if such substance is not generally recognized, among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case of substances used in food prior to January 1, 1958, through either scientific procedures or experience based on common use in food) to be safe under the conditions of its intended use…"

Food additives fall into two broad categories, direct and indirect. Direct additives are those intentionally added to foods to preserve or improve the quality of

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_514.html[2010/10/28 18:44:58]

the product or to aid in the processing. Some examples of 32 functional classes of direct additives are antioxidants, inhibitors of bacterial and mold growth, vitamins and minerals, color, and antifoaming agents. Among the approximately 3000 direct additives, more than 500 are "generally recognized as safe" (GRAS), and about 150 are sanctioned as safe prior to September 6, 1958, with their number likely to increase. They are exempt from regulation as food additives unless the scientific review of these substances currently underway warrants reclassification in the future. Sucrose, corn syrup, dextrose, and salt (all on GRAS list) account for 93 percent, by weight, of all the food additives used. Indirect additives are chemicals that gain their way into foods unintentionally or unavoidably during some phase of production, processing, storage, or packaging. Components of packaging containers and materials that migrate into foods fall under this category. In addition, the presence of pesticide residues in crops and processed foods and residues from animal drugs in milk, meat, and eggs is allowed based on their potential health risk as balanced against the benefits of their use.

Safety Assessment of Food Additives

Foods in their natural forms are assumed safe unless they are "ordinarily injurious." The presence of avoidable contaminant(s) posing a risk of injury to health renders the food unsafe and subject to recall, while the presence of unavoidable contaminant(s) posing such risk is considered unsafe if it exceeds tolerance levels set by FDA (or EPA) or action levels (informal and not subject to law) set by FDA. Intentional additives other than those GRAS or those that are prior sanctioned (e.g., colors) are subject to regulations described above and can only be used at levels posing a risk at or below the level considered acceptable.

Safety evaluation of direct food additives involves establishment of a no observable adverse effect level (NOAEL) in experimental animals followed by establishment of acceptable daily intake (ADI) in the total diet for human beings using a suitable safety factor (usually 100). For unavoidable contaminants, tolerance levels are set to limit the quantity of the agent in each commodity based on risk-benefit-cost analysis.

The FDA-recommended safety testing approach is based on the concept of "level of concern" (28). Level of concern is based on the level of exposure, structural correlation with known toxic compounds (if no toxicity data are available), and existing toxicological data. Subjective categorization of additives into concern levels I, II, or III (level III being of highest concern) is done for compounds contributing <0.05 pmm, 0.05–1.0 ppm, and >1.0 ppm, respectively, to the total diet. Also, low, medium, or high toxicity or a structural similarity to com pounds with low, medium, or high toxicity places a compound in concern levels I, II, or III, respectively. Furthermore, formation of active metabolites would place the compound in level III.

Table 11.4 lists recommended toxicological tests for each level of concern. This testing scheme allows compounds producing effects only at high levels and those with lower levels of human exposure to be tested less extensively. Protocols for testing color additives and indirect food additives are similar to direct food additive testing. Safety testing of animal drugs and feed additives, however, is more complex not only because an additional animal species (target animal) is involved but also because of the necessity of understanding the impact of target animal metabolism on the diversity and toxic potential of the metabolites to humans, the need for the development of residue detection methods and elimination strategies in the target animal species, and to set maximum allowable residues (tolerance) of the parent compound and metabolites in tissues of the target animal.

Food and color additive use is regulated by a special anti-cancer clause, the Delaney Clause, in the Food Additive Amendment. The Delaney Clause prohibits the use of these additives "if they are found to induce cancer when ingested by man or animal, or if found, after tests which are appropriate to the evaluation of safety of such substances, to induce cancer in man or animal" (59). Although the addition of the Delaney Clause reflected the then-prevailing concern for cancer, subsequent scrutiny and recent developments in the understanding of the mechanisms of carcinogenesis required changes as reflected in the FQPA of 1996. Currently, the regulation of pesticide residues has become the responsibility of EPA and, thus, is not an issue for the FDA as a food additive. EPA can approve pesticide applications if it concludes that there is "a reasonable certainty that no harm will result from its aggregate exposure." This would translate to no greater than a risk of 1 in 1 million lifetime risk for carcinogens and levels with a 100-fold safety margin to NOAEL for threshold-limited effects. For already approved carcinogenic pesticides, EPA is allowed to retain tolerance posing greater than negligible risk (1 in 1 million) if the pesticide either protects consumers from a greater health risk or is necessary to avoid disruption of an adequate, wholesome, and economical food supply (134). In addition, the FQPA directs EPA to take higher intakes for certain pesticides in children into consideration in setting tolerances and to apply an

additional safety factor of 10 for threshold effects in calculating ADI.

Animal Drugs

All new animal drugs and feeds containing them must receive premarket clearance from the Bureau of Veterin

Page 516

Table 11.4 Test schedule recommended by FDA for additives at various concern levels

Concern Level I	Concern Level II	Concern Level III
1. Short-term (at least 28 days) feeding study in a rodent species	1. Subchronic feeding study in a rodent species	1. Chronic (at least 1 yr) feeding study in a rodent species
2. Short-term test for carcinogenic potential	2. Subchronic feeding study in a non-rodent species	2. Chronic (at least 1 yr) feeding study in a nonrodent species
	3. Multi- (at least two) generation reproduction study with teratology, in a rodent species	3. Multi- (at least two) generation reproduction study with teratology, in a rodent species
	4. Short-term test for carcinogenic potential	4. Short-term test for carcinogenic potential
		5. Carcinogenicity studies in two rodent species (test 1 can be a part of this)

ary Medicine of the FDA. Antibiotics and steroidal as well as nonsteroidal growth promotants are used in feeds for the prevention of disease or for growth promotion in raising 60 to 100 percent of food-producing animals. Two major concerns with the use of antibiotics in animal feeds are: the development of resistance in enteric bacteria in animals that could be transferred via plasmids to pathogenic bacteria in the gut of animals and, thus, to humans through meat or milk, making antibiotics currently used in human medicine ineffective; and, the presence of carcinogenic residues in meat or residues that form carcinogenic nitrosamines following reaction with nitrite in the meat. Increasing pressure on the FDA has already resulted in the exclusion of many antibiotics (kanamycin, gentamicin, semisynthetic penicillins, chloramphenicol etc.) as feed additives with exclusion of all likely in the future.

Similarly, concerns about the use of hormonal and other growth promotants in feeds are related to possible chronic toxic effects, mainly carcinogenicity. The synthetic estrogen, diethylstilbestrol (DES), was banned as a feed additive due to its carcinogenic effects and the lack of a method sensitive enough to detect residues of health significance (causing >1 life time cancer in 1 million population). Steroids approved for feed additive use in one or more animal species include estradiol, progesterone, testosterone, melengestrol acetate, and zearalanol. Other additives commonly used in animal production include monensin, iodides (EDDI), phenothiazine, and thiabendazole. Carcinogenic animal drugs can be approved for use by the FDA if an adequate withdrawal period is recommended between the last dose of the additive and slaughter to allow residues to fall below those judged capable of inducing greater than negligible (1 lifetime cancer in 1 million) incidence of cancer.

Toxic reactions associated with the use of selected additives that have been restricted, banned, or are currently being critically reviewed are presented below.

Direct Food Additives

Aspartame (Nutrasweet)

The use of aspartame (L-aspartyl-L-phenylalanine methyl ester) as a sweetener in a large variety of food products increases the likelihood that acceptable daily intake is exceeded. Previously suspected association between aspartame consumption and the anecdotal reports of headache, dizziness, and seizures in adults and hyperkinesia in children appears to be unsupported. Although nitrosation products of aspartame are moderately mutagenic (184), the question of the role of aspartame in the recent increase of lymphoma of the brain remains unresolved. The metabolism of aspartame to phenyl alanine led to the suggestion that patients with phenylketonuria should avoid aspartame-containing products.

Butylated Hydroxy Anisole (BHA)

Synthetic phenolic antioxidant BHA has been GRAS and used for decades as an antioxidant to retard the autoxidation of lipids and prevent rancidity in foods. Together with ascorbic acid, α-tocopherol, gallate esters, and BHT, it fulfills almost 100 percent of the antioxidant needs of foods. BHA may be a rodent carcinogen involving squamous cells in the forestomach but these cells are not the human equivalent of glandular or other cells. The carcinogenicity of BHA appears to involve O-demethylation of BHA to tertiarybutyl hydroquinone (TBHQ), oxidation of TBHQ to tertiary butyl semiquinone and tertiary butylquinone (TBQ), conjugation of TBQ with glutathione (GSH), and formation of DNA-reactive oxygen species including the hydroxyl radical (207). However, genotoxicity of BHA has not been demonstrated. Since humans lack a forestomach, evidence for direct genotoxic effect is lacking, and since human exposure is well below inducing nongenotoxic effects it is highly unlikely that BHA carcinogenicity in rodents is relevant to the safety of BHA in human foods.

Cyclamates

Sodium and calcium cyclamate were introduced as non-nutritive sweeteners in 1950 and were included in the 1959 GRAS list. Significant consumption of cyclamates in low-calorie foods and drinks followed. Subsequent demonstration of cancer-promoting or co-carcinogenic activity in animals led to the removal of cyclamates from the GRAS list and, thus, from food additive use in the United States, despite a lack of evidence in human beings (5). Cyclamates, however, are still used in many other countries.

Monosodium Glutamate (MSG)

MSG has been on the GRAS list since 1958, used as both a seasoning agent and a flavor enhancer with an ADI of 120 mg/kg. The demonstration of lesions in the retina and the lateral geniculate nucleus in MSG-exposed neonatal rats and mice led to a voluntary discontinuation of its use in infant foods in the United States. This appears justified since neonatal effects of MSG may last through adulthood (193). In adults, the MSG symptom complex (headache, muscle tightness, numbness/tingling, general weakness, and flushing, among others) occurs in a third of the population with a threshold dose of 2.5 g of MSG (220).

Nitrates, Nitrites, and Nitrosamines

Of the total daily dietary intake of nitrates of 10–150 mg/day (48), leafy vegetables contribute 99 percent. Nitrate use to cure meats (to give characteristic flavor and pink color, to prevent rancidity, and to prevent growth of the spores of *Clostridium botulinum*) contributes <0.1 mg/day (48). Nitrates can be reduced endogenously by microbial systems to nitrites which then oxidize the hemoglobin to methemoglobin (heme iron from ferrous to ferric state). Methemoglobin, being unable to combine with oxygen, following accumulation in sufficient quantities, can lead to anoxia. The use of water with high (>30 mg/1) nitrate content (from soils, fertilizers, etc.) in making baby formula and foods, spinach with high nitrate content, and occasionally meats with high levels of added nitrates and nitrites have resulted in life-threatening methemoglobinemia in humans, especially children. The consumption of plants high in nitrates by animals has caused significant economic loss for owners. In adult humans, however, the daily intake of nitrate and nitrite amount to less than 69 percent and 0.7 percent of the ADI of 3.64 and 0.135 mg/kg/day (48).

Nitrite reacts with secondary amines to form a variety of N-nitrosamines which are present in foods, pharmaceuticals, cosmetics, agricultural chemicals, tobacco, and tea. In vivo, nitrosamines are converted to unstable hydroxyalkyl compounds which subsequently form reactive alkyl carbonium ions capable of alkylating DNA (207). Nitrosamines are mutagens and rodent carcinogens, producing cancer in a variety of organs, including the liver, respiratory tract, kidney, urinary bladder, esophagus, stomach, lower gastrointestinal tract, and pancreas (207). Nitrite itself may promote carcinogenesis. Because they are not added to foods, however, nitrosamines are not subject to the restrictions of the Delaney Amendment. Inhibition of nitrosamine formation in foods by ascorbate, cysteine, gallic acid, tannins, sodium sulfite, and sodium erythorbate prompted the FDA to suggest that one of these compounds be concurrently added to meats during curing to reduce nitrite added from 200 to 120 ppm. Such a practice, however, is ill-advised until a suitable additive is found to deal with the threat of *C. botulinum* growth at reduced nitrate levels and while consumers accept the ensuing changes in the appearance and organoleptics properties of meat cured with this combination. Perhaps a change to lower nitrate-containing vegetables to reduce nitrate intake is a less dangerous option.

Saccharin

After having been in use since the beginning of the 20th century and surviving a ban and an attempted ban of its use due to suspected weak bladder cancer-promoting activity (142) at high doses, saccharin continues to be used as a sweetener in soft drinks and in table top uses. The average intake is 7.1

mg/day in the United States and 15.0 mg/day in Europe per capita, reaching as high as 25 mg/day in certain subpopulations (86). In 2000,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_517.html[2010/10/28 18:45:00]

Saccharin was delisted as a human carcinogen by the National Toxicology Program.

Safrole

Safrole and other alkenylbenzene compounds (β-asarone, methyleugenol, estragole, and isosafrole) are active components of many spice flavors. Sassafras, which contains high levels of safrole, has been used as a flavoring agent in sarsaparilla root beer. Safrole also is consumed in the form of sassafras oil and sassafras tea, the latter still occurring to a limited extent in the United States. A total dose of only 0.5–1.5 mg of safrole orally or intraperitoneally to infant male mice caused high liver tumor incidence. Dihydrosafrole, a synthetic safrole, caused esophageal tumors in rats, and some of the other natural alkenylbenzenes also are carcinogenic (135). These findings resulted in the FDA ban on the use of safrole, sassafras, and sassafras oil from commercial use in foods, including root beer, in 1960. Safrole continues to be used in the European Community, however. A metabolite, 1-hydroxy sulfate ester, is apparently the ultimate carcinogen, forming adducts with guanine and adenine (135).

Other chemical additives initially approved as safe by a regulatory body but now prohibited from use due to a potential risk or to lack of demonstration of safety include calamus and its derivatives in 1968 (containing aklenylbenzene flavoring agents); coumarin flavoring compounds in 1953; chlorofluorocarbon propellants in self-pressurized containers in 1978 (due to their role in the dissolution of the earth's ozone layer, which results in increased skin cancer risk from ultraviolet radiation); diethyl pyrocarbonate (DEPC), an antimicrobial agent in beers and juices (cold pasteurization) and a ferment inhibitor, in 1972, due to the presence of the carcinogen urethan in DEPC-treated products; and dulcin, a sweetener, in 1950, due to liver and bladder cancer in rats. On the other hand, the ultimate determination of the safety of recently approved additives such as the fat substitute, Olestra (long-chain fatty acid esters with sugar), must await longer-term consumer use.

Food Colors

Color is a quality of foods that makes them visually acceptable and aids in their recognition. Foods containing added colors include candy and confections, bakery goods, soft drinks, cereals, and dairy products such as butter, ice cream, and sherbet, margarine, snack foods, jams and jellies, and dessert powders. Following the passage of the Color Additive Amendment of 1960, 20 natural colors (compromising preparations such as dried algae meal, beet powder, grape skin extract, fruit juice, paprika, caramel, carrot oil, cochineal extract, ferrous gluconate, and iron oxide) were exempted from certification, whereas all the synthetic colors, including the ones approved prior to the amendment, were required to be retested if questions arose regarding their safety. A provisional certification was given to those in use that required further testing. Currently, there are seven certified synthetic colors (FD & C colors Blue No. 1, Red No. 3, Red No. 40, and Yellow No. 5 are permanently listed whereas FDB Blue No. 2, Green No. 3, and Yellow No. 6 are provisionally listed) with unlimited uses (according to good manufacturing practices) and one permanently listed color (Citrus Red No. 2) used only for coloring skins of oranges at 2 ppm. Several colors including Green No. 1, Green No. 2, Orange No. B, Red No. 2, Red No. 4, and Violet No. 1 were delisted due to concerns about their carcinogenicity and other chronic toxic effects. A controversy linking food colors to allergies and hyperkinesis in children failed to draw supportive evidence.

Packaging Materials

Packaging is an essential part of food processing that aids in the preservation of the wholesomeness of foods by preventing

(a) contamination or destruction by dirt, microorganisms, insects, and rodents,
(b) loss or gain of moisture, odors, flavors, or aroma, and
(c) deterioration from air, light, heat, and contaminating gases (69).

Other functions served by packaging include assembling a variety of items, convenient handling, labeling, and, finally, sales promotion. A variety of materials, ranging from metal foils to complex plastic substances, are in use. Examples of package modifications employing chemical additives are oleoresinous coating with or without suspended ZnO, which is used in the preservation of acid foods that do (e.g., seafood) or do not (e.g., cherries) produce sulfides; stabilizers to prevent degradation of plastic when exposed to heat and light; and hot-melt adhesives used to glue multilayered packages (tea, hydrated soups, potato chips, etc.). A complete list of additives approved for use in packaging is given by Gilchrist (69).

To approve new packaging material, FDA requires extraction studies involving one or more of aqueous (8% alcohol), alcoholic (50% alcohol), or lipid solvents (corn oil or triglycerides), followed by toxicity testing depending upon the extent of extraction, >1 ppm requiring extensive testing including chronic toxicity. The National Science Foundation (NSF) estimated that as many as 3000 chemicals may enter

foods indirectly from the process of packaging itself (75). A safety review by the FDA has resulted in banning the adhesive Flectol

H, polyurethane resins and curing agents food packaging adhesives containing 4,4-methylenebis (2-chloroanaline), and the synthetic chemicals, mercaptoimidazoline and 2-mercaptoimidazoline, used in the production of rubber articles (75). The use of polyvinylchloride for packaging liquors has been banned in the United States. Among the packaging-derived contaminants likely to be encountered in U.S. diets, benzene and vinyl chloride are known carcinogens; acrylonitrile, 1,3-butadiene, epidilorohydrin, formaldehyde, propylene oxide, and styrene oxide, are probable carcinogens; and 2,4-diaminololuene, dibutyl and diethylhexylphthalates, dimethylformamide, 1,4-dioxane, ethylacrylate, phenyl glycidil ether, styrene, and toluene diisocyanate are possible carcinogens (86, 146).

Toxic Factors Produced During Processing

Food processing is aimed at improving the quality of foodstuffs, ensuring safety, and enhancing the ease of preparation. This requires various chemical and physical treatments of food which may result in
(a) partial or complete destruction or removal of nutrients,
(b) inferior digestibility or utilization of nutrients, and
(c) generation of new, potentially harmful chemicals.

The first two effects can be overcome by nutritional supplementation. The latter represents a need for appropriate toxicological investigation. In addition, similar products can be formed during storage due to the continuous effects of heat, humidity, light, oxygen, and catalysts present in foods.

Formation of crosslinked amino acid side chains such as lysinoalanine, ornithinoalanine, and lanthionine, as well as racemization of amino acids to D-analog appear to take place during alkali treatment, for example, of soybean protein for preparing imitation meat (62). These products, especially lysinoalanine, have been shown to cause nephrocytomegaly (enlarged nuclei and cytoplasm) of the pars recta cells.

Nonenzymatic browning reactions (Maillard reactions) occurring during heating of foods (drying, frying, roasting, baking, and broiling) involve chemical interactions between amino acids and reducing sugars (aldoses and ketoses), forming mutagenic reductones, furans, amino-carbonyls, pyrazines, and other premelanoid secondary amine derivatives (Amadori and Heyns' products) which are hypothesized to inhibit growth, impair reproduction, damage the liver, cause allergies, play a role in aging, and induce lens lesions (86).

In general, high-protein foods appear to possess more mutagenic activity compared with foods rich in carbohydrates and/or fats. Pyrolysis of proteins and amino acids at high temperatures (300°C or more) yields a series of heterocyclic compounds which can be metabolized to mutagenic products were positive in one or more rodent species for carcinogenicity (86, 195). Using estimates of various heterocyclic amines ingested and cancer potencies in animal studies, Layton et al. (110) estimated that only 0.25 percent of human colorectal cancer may be due to these compounds. Certain cooking practices such as frying of high nitrite foods such as cured bacon results in the formation of nitrosamines whose carcinogenic effects have already been discussed.

A variety of polycyclic aromatic hydrocarbons (PAH) are formed in foods by pyrolysis during cooking or by their prior contact with petroleum and/or coal tar products. Although the carcinogenic effects of PAH are known, the contribution of dietary PAH to cancer in humans is likely to be insignificant.

Fats (polyunsaturated) undergo three basic changes during storage and/or heat treatments, that is, autoxidation, thermal oxidation, and thermal polymerization. Autoxidation occurs at below 100°C in the presence of enzymes (lipoxygenases) or upon exposure to light and results in the generation of hydroperoxides via a free-radical or singlet oxygen mechanism leading to rancidity (86). Hydroperoxides can be degraded into alkanes, aldehydes, and ketones, among others. Termination of peroxidative reactions generally involves scavenging of the radicals or their polymerization into nonreactive products. Lipid hydroperoxides, at subtoxic levels, can stimulate signal transduction mediated by Ca^{++} and protein phosphorylation by acting as second messengers in pathways involved in cell proliferation, chemotaxis, apoptosis, and other cellular mechanisms (196). High levels of rancid fats (5% or more of the diet) can cause decreased food consumption, diarrhea, weight loss, leukopenia, and hair loss. Hydroperoxides and/or their products (hydroxynonenal, melon-dialdehyde, etc.) can disrupt gap-junctional communication and form DNA adducts, and are mutagenic and carcinogenic, increasing the incidence of tumors and atherosclerosis (86, 221). Components of heated oils that fail to form adducts with urea, especially the cyclic monomeric fatty acids followed by polymers of fatty acids, appear to be toxic. Toxic effects include, in addition to those described above, hepatomegaly and carcinogenicity.

Yeast-fermented foods and beverages such as yogurt, cider, malt beverages, bread, soy sauce, wine, and sake, in addition to psychoactive and vasoactive amines discussed earlier, contain mutagenic and carcinogenic ethyl carbamate (urethane) derived, in the presence of heat and light, from arginine, asparagine, cyanogenic glycosides, or ethanol in the fermented commodity. Levels of <10 ppb or less

for soft drinks and <30–400 ppb for various alcoholic beverages have been recommended as acceptable by the FAO/WHO and the Canadian government, respectively (87).

The major fermentation product consumed by humans is ethanol which, in addition to death from toxic effects, contributes to human deaths from occupational as well as automobile accidents. The toxic effects of ethanol, although they can manifest themselves in many organ systems, display major CNS involvement (dependence and depression), and impact the developing fetus (fetal alcohol syndrome of mental deficiency and microcephaly) and the liver (hepatomegaly followed by cirrhosis). Mechanisms of ethanol toxicosis may involve the direct effects of alcohol, effects of its metabolite acetaldehyde, ethanol-induced malnutrition, ethanol-induced endotoxin release by intestinal bacteria that stimulate release of reactive chemicals by Kupfer's cells, ethanol-induced potentiation of other hepatotoxic agents, or a combination. An International Agency for Research on Cancer (IARC) expert panel considered ethanol a human carcinogen causing tumors of the oral cavity, pharynx, esophagus, and liver (189).

Toxic effects of processed food as a whole, however, cannot be estimated by simply adding up the toxic, mutagenic, and/or carcinogenic potential of the products present in it. This is due to the fact that chemical derivatives which both enhance as well as antagonize the myriad toxic effects of other dietary components are formed during processing (146). At present, these chemicals and their interactions with each other, for the most part, are unknown. As a result, the overall adverse effects of cooked foods can only be determined reliably based on the assessment of risk from the complex milieus of the product in question.

CARCINOGENS AND MUTAGENS IN FOODS

Cancer, a disease of most public concern for the past half a century, is, experimentally, a multistage process involving initiation (induction of DNA damage, thus resulting in a transformed cell), promotion (a nongenotoxic effect leading to a rapid multiplication of the transformed cell and, thus, establishment of a cancerous lesion), and progression. Multistage models involving a sequence of multiple genetic events with the incidence increasing in proportion to the exponent of time, however, seem to fit most human cancers (146). Naturally occurring food toxicants provide examples of both initiators and promoters, with up to 70 percent of cancer deaths being attributed to dietary factors (51). Examples of likely dietary carcinogens as reviewed by the National Research Council (NRC) (146) are provided in Table 11.5. This list includes carcinogens derived from natural products both by commercial processing (e.g., alcohol) as well as biotransformation in the body (e.g., allylisothiocyanate and nitrosamines); and initiators (e.g., aflatoxins, furocoumarins, pyrrolizidine alkaloids) as well as promoters (e.g., phorbol esters, fat, caffeine). In addition, residues of synthetic chemicals can be present in foods subsequent to their accidental contact or intentional use to increase production. An added dimension to diet is the formation of animal and possibly human carcinogens during cooking, including nitrosamines, aromatic hydrocarbons, amino acid pyrrolysates, carbolines, imidazoquinolines, quinoxalines, and fat oxidation products inducing cancer of the liver, stomach, intestines, zymbal and clitoral glands, skin, and oral cavity and others (146). Coffee, in addition to caffeine, is known to yield several animal carcinogens including caffeic acid, catechol, furfural, hydrogen peroxide, and hydroquinone during roasting and/or brewing (11). Carcinogenic natural pesticides are present in all classes of plant foods including fruits, vegetables, and spices (11).

Balancing this bewildering array of toxins and carcinogens, in almost every food item, is another group of chemicals capable of antagonizing these effects. The dietary antimutagens and anticarcinogens, whose mechanisms of action are not always understood, belong to a wide variety of chemical structures (Table 11.6). As with mutagens, multiple species of antimutagens/ anticarcinogens appear to be present in each dietary component (at least five are known in soybeans and three or more in broccoli). Interactions between carcinogens and anticarcinogens are complicated as indicated by the study of indole-3-carbinol, a component of cruciferous vegetables, known to inhibit mammary and forestomach neoplasia in rodents. When given as a pretreatment, indole carbinol reduced the carcinogenicity of aflatoxin B1, while exposure to indole carbinol after the carcinogen exposure resulted in an increase in aflatoxin carcinogenicity (17).

Natural versus Synthetic Chemicals

The widely held belief that naturally (free of synthetic chemicals) grown foods are inherently safer than those grown with the aid of synthetic chemicals is flawed. Certain natural chemicals in the human diet (such as indole carbinol in cruciferous vegetables) interact with the same receptor (Ah) as dioxin (TCDD), one of the most feared synthetic toxicants, interacts (12). An EPA reference dose, a dose estimated to produce one cancer in one million individuals (6 fg/kg/day), of TCDD is comparable to 5 mg of indole carbinol per 100 g of broccoli or cabbage, a level of exposure not unrealistic. The EPA ban on alar—using a worst-case scenario risk estimation in response to public outcry resulting from less-than-objective reporting by the media and a passive attitude by knowledgeable academicians and

researchers (168)—suggests that regulatory agencies also may subscribe to this misconception.

Page 521

The NRC (146), however, considers natural carcinogens at least as potent and, considering the extent of exposure, more potent than synthetic carcinogens. The fact that disproportionately fewer natural chemicals have been tested suggests a greater need to test natural chemicals, a daunting task considering that all toxicants in all classes of foods are not known and that exposures to those that are known are wide-ranging and not well documented.

Table 11.5 Naturally occurring carcinogens and potential carcinogens in the diet

Carcinogen/Mutagen	Major Foods Containing the Chemical
Alcohol	grains and fruits (derived from...)
Allylisothiocyanate	cabbage, collard greens, brussels sprouts, mustard (brown)
Caffeic acid, Caffeine, and Theobromine	coffee, cocoa, fruits, and vegetables
Cyclopropene fatty acids	cotton seed oil, kapok, and okra
Fat (unsaturated and cholesterol-containing)	vegetable and animal fats
Flavonoids (Quercetin, etc.)	vegetables, tea, coffee
Furocoumarins (psoralen)	celery, figs, parsley, parsnips
Gossypol	cottonseed oil
Hormones (estrogen, testosterone, progestins, and related)	meats as residues, supplements
Hydrazines (agaritine, gyromitrin)	mushrooms
d-Limonine	citrus juices
Methylazoxymethanol, cycasin	cycads
Mycotoxins (aflatoxins, fumonisins, ochratoxin A, sterigmatocystin)	corn, cottonseed, peanuts, wheat, and other grains
Nitrosamines	beets, celery, spinach, meat preserved in nitrite
Phorbol esters	croton oil, other Euphorbaceae (herbal teas)
Polyphenols (tannic acid)	beverages (tea, cider, cocoa, red wine), fruits
Ptaquiliside	bracken fern
Pyrrolizidine alkaloids	herbs, herbal teas, honey
Safrole, estragole, methyleugenol, piperine, etc.	nutmeg, other spices, black pepper
Cooked food carcinogens/mutagens	all cooked foods
Polyaromatic hydrocarbons (mono and dibenzo derivatives)	
Maillard reaction products	
Amino acid pyrrolysates (Trp-P-1-, Trp-P-2; Glu-P-1, Glu-P-2) Carbolines	
Imidazoquinolines and quinoxalines (IQ, MeIQ, MeIQx)	
Fat oxidation products	
Coffee-derived mutagens/carcinogens	

Table 11.6 Important antimutagens and anticarcinogens naturally occurring in foods

Class/subclass	Examples	Foods containing them
Alkaloids	indole-3-carbinol, caffeine	broccoli, cabbage, cauliflower, coffee
Amino acids	cysteine and tryptophan, curcumin	many plants and animals
Arylheptanoids		tumeric
Benzenoids	gingerol, paradol	ginger root and related plants
Cyclitols	myoinostol, phytic acid	wheat, other cereals, nuts, and meats?
Estrogens	sitosterol	soybeans, alfalfa, etc.
Fatty acid derivatives	conjugated linoleic and arachidonic acid	vegetable oils
Fiber	acid-soluble, neutral, etc.	fruits and vegetables, cereal bran
Minerals	Se, Ca++	crops grown on Se-containing soils, milk, meat
Phenolics		
Phenolic acids	gallic and protocatechuic acids,	many fruits and vegetables
Phenyl propanoids	caffeic, cinnamic, chlorogenic and ferrulic acids, enginol, myristicin	broccoli, other vegetables
Flavones	apigenin, myricetin, quercetin, robinetin, rutin	fruits, herbs, and vegetables soybeans and others
Isoflavones	biochanin A, genistein, daidzein, etc.	
Polyphenols		
Lignans	sesamin	sesame seed
Tannins	ellagic and tannic acids, epigallo-catechin-gallate	Chinese green tea, other teas, cereals, legumes, and fruits
Protease Inhibitors	antipain, elastatinal	
Porphyrins	chlorophyll, chlorophyllin, cytochrome C, hemin, hemoglobin, myoglobin	green leafy vegetables, meats
Sulfur-containing compounds	benzyl isothiocyanate, cysteanine, diallyl sulfide and disulfide, glutathione, isothiocyanate, phenethyl, sinigrin, sulforaphane	broccoli, cabbage, cauliflower, and others
Terpenoids		
Monoterpenes	carveol, limonene, menthols	citrus fruits, grapes, mint, other plants, wine
Diterpenes	cafestol, kahweol	coffee, variety of plants, sponges, corals, etc.
Triterpenes	glycerrhetinic acid, its glycoside, limonin, oleanolic acid, and ursolic acid	citrus fruits and a variety of medicinal plants
Sesquiterpenes	nerolidol	medicinal plants and herbs
Unidentified	unknown	in beef, cabbage, germinating wheat, mushrooms, etc.
Vitamins		
Carotenoids	canthaxanthin, α and β-carotene, fucoxanthin	fresh green, leafy vegetables
Others	vitamins A, C, E, and riboflavin	fruits and vegetables (fresh), meats, fish

Adding to this complexity is the fact that simultaneous exposure to two initiators, an initiator and a promotor, or to two promotors can lead to additive, multiplicative, and supramultiplicative carcinogenic responses in experimental settings (100). However, at exposure levels as low as those occurring in natural foods, the differences are lost so that the overall risk of a mixture becomes only additive (145). Furthermore, making the safety assessment of human dietary ingredients an almost impossible task is the presence of protective (anticarcinogens, etc.) agents in the same mixture, with interactive effects among themselves and their combined antagonistic effect against the effects of mixture of carcinogens and other toxicants present.

Testing various crude solvent extracts of each dietary ingredient or even selected total diets (composed of average daily per capita amounts of each of the common dietary ingredients in the United States, for example) may reduce the amount of testing. Interactions between components of various extracts and between extractable and non-extractable components will still need to be estimated or tested further. The best but not a perfect approach to a more realistic risk appraisal, however, may involve testing pelleted dehydrated edible whole product such as meat, fruit, or vegetable individually or in combination in animals at doses reflecting human intake. Such an approach not only reduces the cost of testing compared to an individual chemical testing strategy but, also, provides data more relevant to natural exposure to a complex diet.

At the same time, transgenic plants—with improved nutritional quality, capabilities to withstand processing, resistance to spoilage, lower levels of toxic compounds (using anti-sense or other recombinant DNA technology to inactivate gene[s] regulating biosynthesis and/or metabolism), and reduced susceptibility to fungal infestation—should be developed and the lower risk associated with consumption of such plants must be confirmed prior to extensive consumer use. Reduction in fungal susceptibility can be achieved by lowering the micro- and/or macronutrients in the plant needed for fungal growth, or other appropriate techniques (146). Success in risk reduction is also likely if preservation, processing, and storage methods to reduce the levels and/or the effects of natural toxicants in foods are developed and put in practice. Methods to process cassava root to extract/neutralize cyanide; evisceration of fugu fish to eliminate tetrodotoxicosis; waxing, heating, dipping in corn oil, spraying with lecithin, and/or immersion in dilute detergents of potatoes to reduce their glycoalkaloid content; and prudent addition of antioxidants to reduce formation of harmful agents such as lipid oxidation products and nitrosamines—all are examples of such processes. Last, but not the least, of the strategies in dealing successfully with natural dietary chemicals involves public education in avoiding/reducing exposure to natural dietary hazards.

CONCLUSION

Although there has been much progress in our understanding of identification and management of food-borne hazards, large gaps in knowledge exist in the areas of mechanisms of pathogenesis of known human intoxications associated with foods; interactions between multiple toxicants present simultaneously, between toxicants and nutritional components, and between toxicants and antitoxicants (including antimutagens and anticarcinogens) in foods; methods of realistic human health risk extrapolation from animal data; and the development of safer plant varieties and processing and cooking methodologies that minimize toxic hazards to consumers.

Considering the facts that natural dietary toxicants are, at least, as toxic as the synthetic ones and that human exposure to them is greater in quantity and consistency than to synthetic toxicants, U.S and worldwide research resources should be shifted to achieve a realistic balance, in the study of health hazards, more toward the natural dietary components. Present testing of purified individual food toxicants in animals is inadequate and must be succeeded by feeding realistic levels of such compounds in the complex milieus of the product in which the toxicant is naturally present (smoked meats, for example) or even, perhaps, in the total human diet. Realistically speaking, although this task is impossible because of the vastly variable composition of individual food ingredients as well as of the total human diet, we can edge closer to this goal by designing a diet containing various dietary ingredients (vegetables, fruits, grain, dairy products, and meats) at a level equal to percentages of their average per capita human consumption.

Education of the consumers to minimize dietary risks using practicable methods similar to those cited above and to shatter the myths that "natural is healthy" and "man made or synthetic is toxic" needs to be vigorously pursued. An educated populace is less likely to be unduly alarmed and is more likely to accept prudent regulatory actions resulting from realistic scenarios of risk estimation. Finally, application of newer molecular methodologies (such as PCR) to confirm intoxication from bacterial and other biotoxins and intensified activities by national animal health monitoring systems combined with more

rigorous application of HACCP will lead to a significant reduction in the currently widespread incidence of microbial diseases from food sources.

ACKNOWLEDGMENT
The authors acknowledge Kathy Craighead and Sarah Young for their excellent word processing skills and timely completion of this manuscript.

QUESTIONS: FOOD FOR THOUGHT

1. Design a Hazard Analysis Critical Control Point System for a food-borne microbial agent of your choice. Can this system, in principle, be used to control other toxic (both natural and synthetic) hazards? If not, is it possible to modify the HACCP system or to develop a similar system to suit such needs?
2. Using the information provided in this chapter (start with #2 of the recommended reading list) and other chapters of this book as well as other available resources (including your imagination), propose a strategy to test natural dietary toxicants in a way that allows more realistic extrapolation to humans than is currently used.
3. Do synthetic chemicals pose a greater hazard than food-borne chemicals in your informed opinion (use #3 of the recommended reading list and others)? If so, are we doing all we can to keep them out of our food supply? Is there more that can be done to achieve this goal? If not, how can we use our resources in the right context of food safety?

Solvent use by industry and the general public is widespread, encompassing numerous products and applications. As Table 12.1 illustrates, billions of pounds of organic solvents are produced annually (11, 12). Solvents may be utilized individually (e.g., acetone or toluene) or as mixtures containing several ingredients (e.g., paint thinners, cleaning agents). Alternative, nontraditional solvents, as described later, are also finding widespread applicability.

To better understand the hazards that these materials may present, we must first learn something

about their basic physical, chemical, and toxicological properties. Table 12.2 contains a list of physical properties of commonly encountered organic solvents (4, 101). This is followed by a brief explanation of the properties. For ease of comparison, inhalation, dermal, and oral toxicological data for solvents are often discussed in relation to the chemical groups to which they belong (aromatics, alcohols, halogenated hydrocarbons, etc.). Much of the text is devoted to a review of the basic toxicology of some widely used solvents as well as several alternative compounds.

Modern industrial hygiene practices have done much to characterize and minimize workplace solvent exposures. A number of these practices, such as workplace monitoring, local exhaust ventilation, and personal protective equipment are discussed in this chapter. Because solvent use in small businesses and the home is often not as well controlled as in major industrial settings, large populations may be at risk. A challenge to the health and

safety community is to help educate these groups about the safe use of solvents.

PROPERTIES OF SOLVENTS

Vapor Pressure

Vapor pressure is the amount of pressure exerted by a saturated vapor above its own liquid in a closed container. Vapor pressure increases with increasing temperature of the solvent, slowly at lower temperatures and then more rapidly at higher temperatures (85). The higher the vapor pressure, the greater the tendency for the substance to evaporate into the atmosphere. Units of vapor pressure are usually expressed as millimeters of mercury (mm Hg) at 20°C (68°F).

The vapor pressure of a mixture of two miscible solvents differs from that of the individual constituents (85). If the mixture is left open to the environment, the more volatile component evaporates first, leaving the remaining mixture rich in the less volatile solvent. This process will continue until either the more volatile solvent is gone or an azeotropic (constant boiling) mixture is formed. If the azeotrope is formed, then both vapor constituents escape simultaneously. Examples of solvents that form azeotropic mixtures are water/ethanol (95.57% by weight ethanol, boiling at 78.15°C) and chloroform/acetone (20.0% by weight acetone, boiling at 64.7°C) (85). Vapor pressure and evaporation rate (see below) can be used to estimate how quickly a substance becomes airborne and, thus, how soon an individual may be exposed to it.

Boiling Point

The boiling point of a liquid is the temperature at which the liquid's vapor pressure equals the surrounding atmospheric pressure. This is characterized by formation of bubbles of vapor within the liquid which escape into the vapor phase. The normal boiling point is measured

in degrees centigrade (°C) or degrees Fahrenheit (°F), usually at one atmosphere pressure (760 mm Hg or 14.7 psi). Generally, the solvent with the lower boiling point will have the higher vapor pressure.

Evaporation Rate

The rate of evaporation of a solvent is also an important property to consider when selecting a material for a particular process or when evaluating its fire and health hazard potential. Since evaporation rates depend on a number of intrinsic properties as well as external conditions, evaporation rates cannot be stated in absolute numbers (120). One common way of expressing evaporation rate, however, is to compare the rate for the solvent in question to a reference material under identical conditions. Such a reference is normal butyl acetate (n-BuAc), which is given an evaporation rate of 1.0, by definition. Solvents evaporating more quickly have a value greater than 1.0 (e.g., ethyl ether and hexane) and those evaporating more slowly have a value less than 1.0 (e.g., xylene and mineral spirits).

Specific Gravity

Specific gravity is the ratio of the density of a substance to the density of a reference material at a specified temperature. Water is the reference standard for liquids and solids (density 1 g/ml at 4°C). A chemical with a specific gravity greater than 1.0 (e.g., perchloroethylene), if insoluble in water, will sink. A material having a specific gravity of less than 1.0 (e.g., toluene) is lighter than water and, if not soluble, will float on it. As can be seen, specific gravity takes on special significance in fire fighting and chemical spill cleanup operations, since many flammable liquids have a specific gravity of less than 1.0 and if insoluble, will remain on top of a pool of water.

Vapor Density

Vapor density is expressed by the ratio of the mass of a vapor or gas to the mass of an equal volume of air at the same temperature (average mass for gases in air, 29 grams per mole). The density of dry air is 0.075 1b/ft3 or 1.2 kg/m3 at 70°F and 1 atmosphere (3). Materials heavier than air (e.g., carbon disulfide, perchloroethylene, and chlorine) tend to settle in low places such as sumps, manholes, and trenches. If there is little or no air movement or temperature variability that could promote mixing, then a potentially hazardous situation exists.

Flash Point

The flash point of a solvent is the lowest temperature at which vapor is given off in sufficient quantity so that the air-vapor mixture above the surface of the solvent will ignite momentarily in a flame. The flash point is determined by heating or cooling the solvent in a closed or open cup apparatus (e.g., Setaflash, Pensky-Martens, Tag, or Cleveland) and measuring the temperature at which the flash will be obtained when a small flame is introduced into the vapor above the surface of the solvent. The Occupational Safety and Health Administration (OSHA) and the NFPA (National Fire Protection Association) define a flammable liquid as a liquid having a flash point below 100°F (37.8°C).

When vapors of a flammable solvent are mixed with air in the proper proportions, ignition is possible. This proportion, called the flammable range, is also known as the explosive range. Concentrations of vapor too lean or too rich cannot be ignited. Figure 12.1 depicts the flammability characteristics of a vapor-air mixture as concentration and temperature vary (134).

Partition Coefficient

The partition coefficient (sometimes called distribution coefficient) is the ratio of the distribution at equilibrium of a solute between two insoluble solvents. This ratio is constant at a given temperature and is valid as long as the solute does not undergo a change in solution such as dissociation. For example, the partition coefficient for iodine in water and chloroform at 25°C is 0.0117 (85). In biological systems, the partition coefficient can describe the partitioning of a toxicant between other media such as air and blood or blood and fat, and so on. Lists of partition coefficients for solvents into biological media or other compounds such as olive oil have been published (44, 51, 106, 119).

CHEMICAL CLASSIFICATION FOR SOLVENTS

Most solvents fall into one of 11 chemical groups, which are characterized by a specific chemical radical that gives the individual members the properties typical of the group. Figure 12.2 presents the chemical configurations for these classifications along with examples of common solvents belonging to each group (92). Additionally, current American Conference of Governmental Industrial Hygienists (ACGIH) eight-hour time-weighted average (TWA) threshold limit values (TLVs) are given with these examples.

OCCUPATIONAL EXPOSURE LIMITS

Various organizations and governmental agencies in the U.S. and throughout the world have issued occupational exposure limits (OELs) to help protect the health and well being of the workforce. Exposure limits com

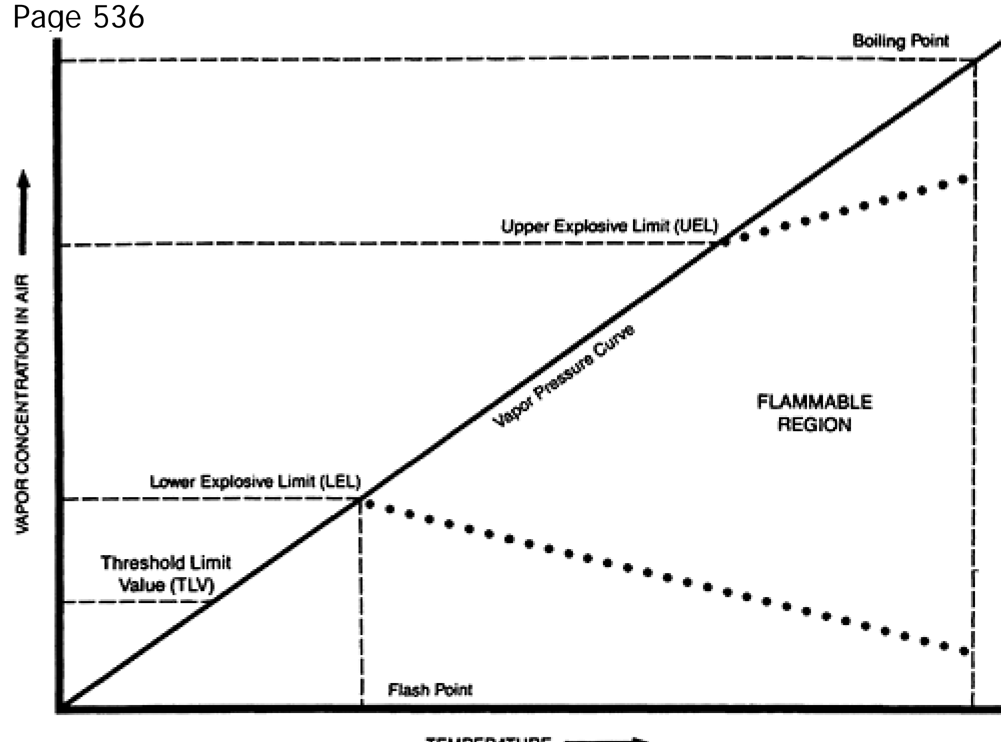

FIG. 12.1. Diagram of vapor pressure versus temperature showing relation between upper and lower flammable (explosive) limits, flammable and nonflammable regions, threshold limit value, boiling point, flash point, and vapor pressure curve. This diagram shows what happens to a vapor/air mixture as concentration and temperature vary.

monly accepted in the United States and in many parts of the world are the TLVs and the biological exposure indices (BEIs), which are updated yearly by the ACGIH. Other limits in the United States include the workplace environmental exposure level guides (WEEL) of the American Industrial Hygiene Association (AIHA), the recommended exposure limits (REL) of the National Institute for Occupational Safety and Health (NIOSH), and the permissible exposure limits (PEL) promulgated by OSHA. Exposure limits in Germany are the DFG (Deutsche Forschungsgemeinschaft) Maximum Concentration Values in the Workplace (MAKs) (2). In the United Kingdom, the COSHH (Control of Substances Hazardous to Health) Regulations mandate adherence to Maximum Exposure Limits (MEL) and Occupational Exposure Standards (OES) for protection of workers there. Additional regulations may apply for extremely hazardous substances such as carcinogens. The processes by which various occupational exposure standards are developed have been reviewed for the United States, Russia, Australia, Britain, and Norway (139). OELs are intended solely for the protection of the workforce and should not be applied to exposures unrelated to the occupational environment.

Threshold limit values are airborne concentrations of substances to which most workers may be exposed during an 8-h workday and a 40-h work week without suffering detrimental health effects (4). Most are presented as TWAs. TWAs permit excursions above the limit, provided there are compensating equivalent exposures below the limit during the workday. Importantly, TLVs are not to be considered as absolute values differentiating between hazardous and nonhazardous concentrations, nor should they be used as a relative index of toxicity. Table 12.3 presents data used by ACGIH in developing TLVs.

Table 12.3 Data used in developing threshold limit values

Physical properties
- Lipid solubility
- Water solubility
- Vapor pressure
- Odor threshold

Acute toxicity data
- Oral toxicity, LD50
- Dermal toxicity, LD50
- Dermal and eye irritation
- Inhalation toxicity, LC50

Subchronic data (oral, dermal, or inhalation)
- 14 day, NOEL[a]
- 90 day, NOEL
- 6 month, NOEL

Other data
- Developmental (teratology and embryotoxicity)
- Mutagenicity (Ames test, *Drosophila*, etc.)
- Fertility
- Reproductive (3-generation)
- Reversibility study
- Dermal absorption tests
- Pharmacokinetics
- Cancer bioassay (2-year)

Epidemiological data
- Morbidity
- Mortality
- Case reports

Industrial hygiene exposure data
- Area samples
- Personal samples

a NOEL, no observed effect level.

To illustrate the TWA concept, consider a worker who is degreasing metal parts at two different workstations using trichloroethylene (50 ppm TLV). The employee spends 240 minutes at Station 1 with an average exposure of 30 ppm, followed by 45 minutes with no exposure (lunch), then 195 minutes at Station 2 with an exposure of 60 ppm. Calculating the 8-h TWA:

$$[30\text{ ppm}\times 240\text{ min}+(0\text{ ppm}\times 45\text{ min})+(60\text{ ppm}\times 195\text{ min})]/480\text{ min}=39\text{ ppm} \qquad (1)$$

The TLV–TWA has not been exceeded. However, one may want to evaluate the employee's work practices and other aspects of the operation to reduce the exposure as much as possible (refer to sections on Exposure Controls and Personal Protective Equipment).

The TLV of a mixture is given by:

$$C1/T1+C2/T2\ldots+Cn/Tn=1 \qquad (2)$$

provided the components have similar toxicological effects and the air is analyzed for each component. The letters C and T represent the concentration and TLV of each chemical, respectively. If the calculation gives a value greater than 1, then the TLV has been exceeded.

As an example, suppose a worker was exposed to a mixture of 25 ppm trichloroethylene and 20 ppm perchloroethylene (25 ppm TLV) during the shift. The calculated TLV is:

$$25\text{ ppm}/50\text{ ppm}+20\text{ ppm}/25\text{ ppm}=0.5+0.8=1.3 \qquad (3)$$

The threshold limit has been exceeded and action should be taken to reduce this exposure. For other examples of TLVs for mixtures, refer to the most current ACGIH TLV handbook (4).

Other categories of TLVs are short-term exposure limits (STEL) and ceilings. A STEL is a 15-minute time-weighted average exposure (above the 8-h TWA) that should not be exceeded during the workday. Allowances are made for up to four STEL excursions per day as long as there are at least 60 min between exposure periods and the 8-h TLV–TWA has not been exceeded. The STEL is supplementary to the TWA limit and should not be used exclusively as an exposure limit. Methanol is an example of a solvent having both an 8-h TLV–TWA (200 ppm) and a STEL (250 ppm). A ceiling limit is an airborne

concentration that should not be exceeded, even instantaneously. Hexylene glycol is a solvent having such a limit (25 ppm).

For certain compounds a *skin* notation has been added to indicate a possible significant contribution to overall exposure from absorption through the skin, mucous membranes, or the eyes. Both methanol and propanol have skin notations.

BEIs denote levels of determinants (primarily from exhaled air, blood, and urine) likely to be found in workers exposed to the same degree as a worker with inhalation exposure to the TLV. The determinants are primarily the chemical itself or its metabolites. BEIs are a measure of the amount of chemical in the body and may be useful when evaluating the possibility of skin absorption, effectiveness of personal protective equipment, or nonoccupational exposure. BEIs are strictly related to 8-h exposures (5 days a week) and to the specified timing for the collection of the sample. A determinant for n-hexane is 2,5-hexanedione in urine (5 mg/g creatinine), measured at the end of the shift. In the case of altered work schedules, BEIs may be

Aliphatic Hydrocarbons

Straight or branched chains of carbon and hydrogen.

*Hexane — 50 ppm
Heptane — 400 ppm
VM&P Naphtha — 300 ppm

Aromatic Hydrocarbons

Contain a 6-carbon ring structure with one hydrogen per carbon bound by energy from several resonant forms.

Benzene — 0.5 ppm
Toluene — 50 ppm
Xylene — 100 ppm

Cyclic Hydrocarbons

Ring structure saturated and unsaturated with hydrogen.

Cyclohexane — 300 ppm
Turpentine — 100 ppm

Alcohols

Contain a single hydroxyl group.

Methanol — 200 ppm
Ethanol — 1000 ppm
Isopropanol — 400 ppm

Esters

Formed by interaction of an organic acid with an alcohol.

Ethyl Acetate — 400 ppm
Isopropyl Acetate — 250 ppm

Ketones

Contain a double bonded carbonyl group, C=O, with two hydrocarbon groups on the carbon.

Methyl Ethyl Ketone — 200 ppm
Acetone — 500 ppm
Methyl Isobutyl Ketone — 50 ppm

*TLV - American Conference of Governmental Industrial Hygienists (ACGIH) Threshold Limit Value (TLV-TWA), 1998.

FIG. 12.2. Classes of organic solvents.

Page 539

Halogenated Hydrocarbon

A halogen atom has replaced one or more hydrogen atoms on the hydrocarbon.

Carbon Tetrachloride	—	5 ppm
Methyl Chloroform	—	350 ppm
Chloroform	—	10 ppm

Glycols

Contains double hydroxyl groups.

Ethylene Glycol	—	100 mg/m^3 (Ceiling)
Hexylene Glycol	—	25 ppm (Ceiling)

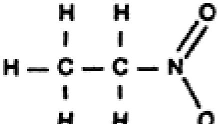
Aldehydes

Contain the double-bonded carbonyl group, C=O, with only one hydrocarbon group on the carbon.

Acetaldehyde	—	25 ppm (Ceiling)
Formaldehyde	—	0.3 ppm (Ceiling)

Nitro-Hydrocarbons

Contain an NO_2 group.



Nitroethane	—	100 ppm
Nitromethane	—	20 ppm

Ethers

Contain the C — O — C linkage.

Ethyl Ether	—	400 ppm
Isopropyl Ether	—	250 ppm

extrapolated based on pharmacokinetic and pharmacodynamic considerations (4).

The AIHA WEEL Committee develops WEELs for agents that have no current exposure guidelines established by other organizations. WEELs are expressed as TWAs; however, different time periods are specified depending on the properties of the agent. A skin notation is used in the same manner as the ACGIH TLV.

NIOSH RELs are expressed as either a TWA or a ceiling or both. These recommended limits are published as criteria documents and are periodically revised. They are established for up to a 10-h workday and are intended to provide the maximum possible protection for all workers against acute and chronic effects of exposure. Skin notations are applied.

OSHA PELs are the legal allowable concentrations of airborne contaminants. They were derived from existing standards during the enactment of the Occupational Safety and Health Act of 1970. Although the ACGIH revises some TLVs each year, the PELs remain as created unless changes are made in the law. A number of revisions

and additions have been made to the PEL list since that time. The PELs contain TWA and ceiling values and skin notations.

Immediately dangerous to life or health (IDLH) is a limit specified by NIOSH that addresses extremely hazardous conditions. It is the estimated maximum concentration of a contaminant from which a worker can escape (i.e., after failure of respiratory protection) without losing his or her life or suffering permanent health impairment. An area of concern that is becoming more and more common in today's workplace involves extended work shifts (i.e., 10-h or 12-h days). To compensate for the higher accumulated doses and reduced recovery times caused by the longer work periods, adjustments to the exposure limits need to be made. For a discussion of this subject, refer to the article by Paustenbach (104).

SAMPLING METHODOLOGY

Industrial hygiene sampling is used to characterize the concentration of a solvent in either the breathing zone of a worker or in the general work environment. There are a number of methods available to estimate solvent concentration, depending on the nature of the operation, the solvent of interest, and the objectives of the evaluation. The primary categories of industrial hygiene sampling include active sampling, direct reading, and passive dosimetry. The trend in recent years has been toward the use of direct reading instruments (e.g., colorimetric detector tubes and handheld instruments) and passive dosimetry (e.g., organic vapor badges). This is due, in large part, to the immediate feedback and/or ease of use associated with these methods. For additional information on industrial hygiene sampling, refer to the ACGIH text, *Air Sampling Instruments* (1).

Active Sampling

Active sampling involves the use of a battery-powered sampling pump to draw contaminated air onto suitable collection medium, which is then analyzed in the laboratory to determine the amount of material collected. The sampling pump requires field and/or laboratory calibration to ensure that it is pulling air at the desired flow rate. The collection medium is connected to the sampling pump via tubing and is attached to the worker in his or her breathing zone (typically the shirt collar). When completed, the medium is returned to the laboratory where the chemical of interest is extracted and analyzed. Various types of collection media are available for solvents, depending on the material being evaluated. Examples include:

(a) activated charcoal for sampling solvents such as chlorinated hydrocarbons, gasoline, many alcohols, and ketones;
(b) silica gel for amines, methanol, phenols, and aldehydes; and,
(c) chemically treated media, including filters for toluene diisocyanates, naphthylamines, and toluidines.

Direct Reading

Direct reading devices allow solvent concentrations to be measured on site with nearly instantaneous results. This approach is used in a number of applications, including identifying potential process leaks, determining peak exposure occurrences, evaluating the effectiveness of engineering controls, or in continuous monitoring applications. There are numerous direct reading devices and instruments available for measuring solvent concentrations. These include colorimetric detector (or indicator) tubes and badges, and direct reading instruments. Colorimetric detector tubes and badges contain a reagent that reacts with the solvent vapor of interest to produce a color change. This color change, or stain, is compared with a calibration scale to determine the concentration of the solvent vapor. These tubes are easy to set up, are relatively inexpensive, and may be used for short (several minutes) or longer (hours) sampling intervals. Disadvantages include possible interfering compounds, lower accuracy, and some subjectivity in the readings. Direct reading instruments are preferred over detector tubes when multiple readings are desired. Types of direct reading instruments suitable for measuring solvents include analyzers with flame ionization and infrared detectors, combustible gas/vapor meters, photoionization devices, and portable gas chromatographs. Direct reading instruments can be either hand held (for portability) or fixed (for continuous area monitoring).

Passive Dosimetry

Passive samplers (e.g., organic vapor monitors) utilize the principles of molecular diffusion rather than a sampling pump to direct samples onto a collection medium (charcoal for organic vapor monitors). This technology is particularly well suited for personal monitoring because these devices

(a) are lightweight,
(b) are unobtrusive,
(c) require no external power source,
(d) require no calibration, and

(e) can be used to obtain short-term or full-shift exposures (19).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_540.html[2010/10/28 18:45:14]

Organic vapor monitors are accurate and can be used to sample for many industrial solvents. Analysis is similar to charcoal tubes mentioned above.

EXPOSURE CONTROLS

Solvent overexposure may be avoided through proper planning, equipment design, and the use of process controls, where necessary. The approach to exposure control will depend on which route(s) of exposure are expected, primarily inhalation, skin contact, or a combination of both. Specific controls may be mandated by federal health and safety regulations (as in the case of benzene and vinyl chloride) or when exposure levels exceed established limits (such as permissible exposure limits or threshold limit values). The types of controls employed include engineering and administrative controls and the use of personal protective equipment. Control of solvent exposure is often achieved with a combination of these methods.

The preferred approach in controlling solvent exposure is through the use of engineering controls. Types of engineering controls (in order of preference) include change in a process to eliminate or reduce solvent usage; substitution with a less hazardous solvent; isolation of the process to minimize worker involvement; and ventilation to reduce the concentration of solvent vapor in the work environment. A discussion of each type of control follows.

Process Change/Solvent Elimination

Organic solvent-based processes can often be changed to eliminate or reduce solvent exposure. Eliminating the solvent is considered the best approach to controlling exposure and should be employed during the initial design of the process. Elimination has been used extensively in various organic solvent-based processes such as degreasing, cleaning, printing, painting, and metal treatment. These initiatives are the result of a combination of health and safety concerns, good business practices, and government regulations. In addition to minimizing worker exposure, elimination of organic solvents may have additional benefits as well, including the reduction of emissions into the environment and the cost savings associated with decreased waste disposal and personal protective equipment purchases. Two examples of process changes are replacing spray painting with paint dipping and replacing compressed air spray painting with electrostatic methods (less paint overspray). Examples of organic solvent elimination include: replacing chlorinated solvent degreasers with water-based detergent or subcritical carbon dioxide systems (discussed later); replacing solvent-based paints with water-based paints; improving flux application systems in circuit board manufacturing to eliminate the need for cleaning with chlorinated compounds; and using water-based or vegetable oil-based inks to eliminate solvent-based inks.

Substitution

In addition to directly eliminating solvents or using water-based materials, substitution of one organic solvent for another with lower toxicity or higher flash point is often employed. Substitutions may be made within a chemical series by retaining the active group. For example, substitution of butyl cellosolve for methyl cellosolve may be advantageous. The general group also can be retained such as in the substitution of aromatic naphtha for toluene, or toluene for benzene. Substituting a solvent with similar polar characteristics, but different toxicity, such as ethanol for methanol, may also be possible. Other examples include replacing perchloroethylene with citrus-based products in metal degreasing; substituting iosocyanate-containing coatings with toluene-based materials; and replacing formaldehyde used in preserving laboratory specimens with glycol-based compounds. Common solvents according to a group classification are shown in Table 12.4.

Isolation

A process can sometimes be enclosed and/or automated, to isolate the worker from the hazards of operation. When total enclosure of a solvent-based process is not possible, the operation can be separated from adjacent areas to minimize the number of workers exposed to the vapor. The isolation by enclosure of a solvent-based process usually requires the introduction of local exhaust ventilation (see below) to prevent the accumulation of vapors within the enclosure (fire/ explosion hazard). Examples of isolation are found in most manufacturing environments. For instance, manual painting in automotive assembly plants and manual metal plating operations have been replaced with robotic systems. These automated processes often can be operated and monitored from remote locations.

Ventilation

When the methods discussed above are not feasible or available, introducing mechanical ventilation to the process can control solvent exposure. For industrial situations, this involves the delivery of uncontaminated air into the work area (dilution ventilation) and/or direct removal of contaminated air (local exhaust ventilation).

Typical applications for dilution ventilation are heat control (as in foundries), or regulation of humidity

< previous page page_541 next page >

Table 12.4 Common solvents classified by group

Aliphatic Hydrocarbons	
Gasoline	Hexane
Pentane	Octane
Mineral spirits	Heptane
Aromatic Hydrocarbons	
Benzene	Ethylbenzene
Styrene	Toluene
Cumene	Xylene
Halogenated Hydrocarbons	
1,1,1,-Trichloroethane	Chlorobenzene
Ethylene dichloride	Perchloroethylene
Methylene chloride	Trichloroethylene
Alcohols	
Amyl alcohol	Methyl alcohol
Benzyl alcohol	Butyl alcohol
Ethyl alcohol	Isopropyl alcohol
Ketones	
Methyl ethyl ketone	Diacetone alcohol
Cyclohexanone	Acetone
Esters	
Acetates	Lactates
Alkyl formates	Propionates
Ethers	
Butyl ether	Isopropyl ether
Ethyl ether	Ethylene glycol monoethyl ether

and odor. If dilution ventilation is to be used to reduce the concentration of solvent vapors in the ambient air, at least four conditions must be met:

1. The quantity of solvent vapor generated must not be too great because the air volume necessary for dilution will become impractical.
2. The worker must be far enough away from the source of solvent vapor generation so that the TLV is not exceeded.
3. The solvent must have low toxicity.
4. The solvent vapor must be released into the work environment at a uniform rate (3).

In contrast to dilution ventilation, which dilutes vapors to acceptable levels by adding fresh air, local exhaust ventilation (LEV) removes the solvent vapors at the source. It is generally more effective than dilution ventilation and cheaper to operate since lower air volumes and smaller fans are required. LEV systems consist of a hood, ductwork, and fan, and an optional cleaner for contaminant removal prior to discharge to the outside environment. Figure 12.3 shows a typical local exhaust ventilation system (6).

The decision of whether or not to install LEV for solvent exposure control is based on a number of factors, including: the lack of more cost-effective controls, amount and toxicity of the solvent vapor generated by the process, governmental requirements, or simply good management practice (6).

In LEV systems, the air is exhausted to the outside environment either directly or by passing the airstream through a cleaner. There are three types of LEV hoods

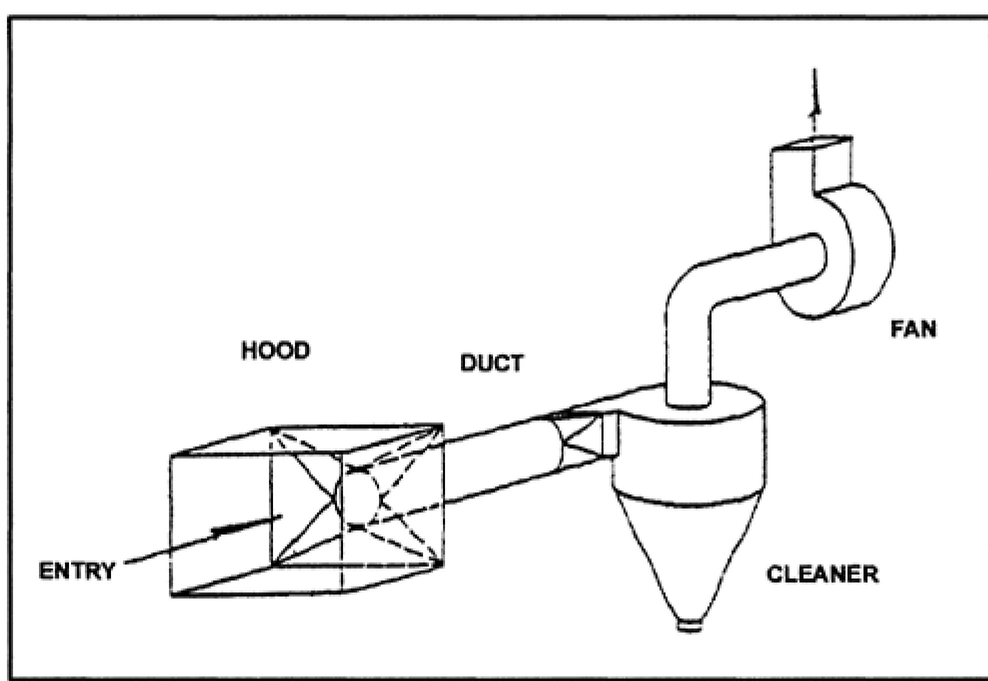


FIG. 12.3. Typical local exhaust system components. Reprinted with permission of the American Industrial Hygiene Association.

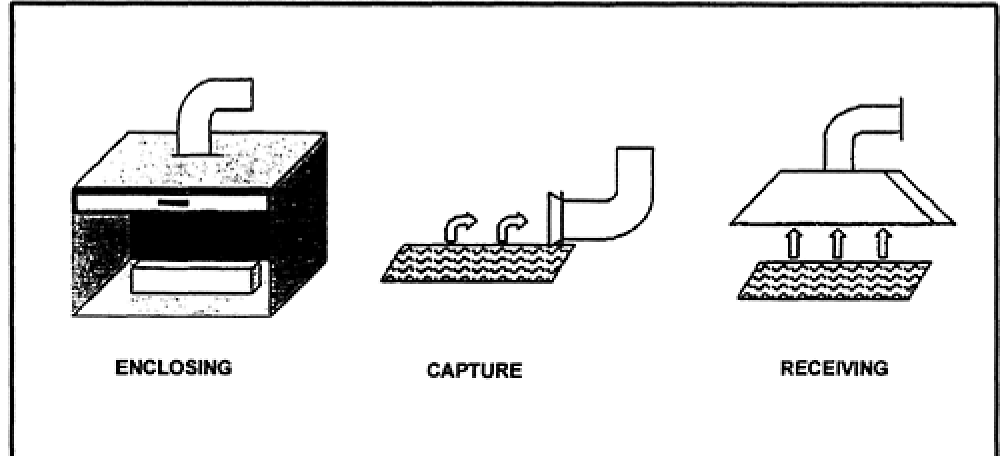

FIG. 12.4. Three types of local exhaust ventilation hoods.

used for solvent vapor control: enclosing, exterior (or capture), and receiving hoods. Figure 12.4 provides an illustration of each. Enclosing hoods are those which partially or completely enclose the process so that the point of contaminant generation is located within the hood. Enclosing the process as much as possible increases the effectiveness of LEV systems. Examples of enclosing systems include laboratory chemical fume hoods and spray paint hoods. Exterior hoods are those that are located near the point of contaminant generation, but that do not enclose it. Examples of exterior hoods are slot-type hoods used on vapor degreasing processes and flexible hoods used to exhaust solvent-based mixing processes. Receiving hoods are typically canopy-type hoods used for exhausting hot processes, for example, ovens and detergent baths. They are generally less suitable for solvent operations such as metal cleaning and degreasing.

Careful evaluation of the process should be carried out prior to selecting and designing a LEV system. Input should be provided from various disciplines, including engineering, planning, industrial hygiene, and labor. In addition to choosing the correct flow rates, designers must ensure that the arrangement of the hood and ductwork does not interfere with the work or other aspects of the facility's operation. In general, designers of LEV systems should take into account the flammability (e.g., use of approved wiring and motors) and toxicity of the solvent and the concentration generated, possible interfering air currents in the room, whether access to the work area is needed, and the amount of airflow or capture velocity required to adequately exhaust the contaminant (6).

As defined, capture velocity is the air velocity, at any point in front of the hood or at the hood opening, necessary to overcome air currents and to capture the contaminated air at that point by causing it to flow into the hood. Recommended capture velocities for solvents vary between 50 and 500 feet per minute depending on the conditions of solvent dispersion into the air (3).

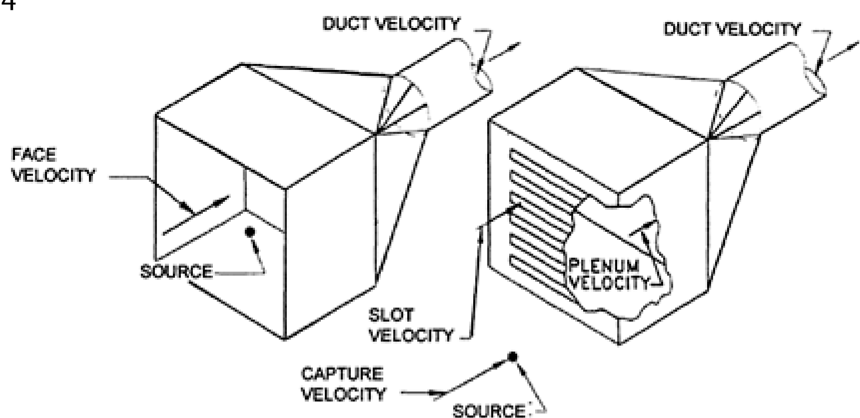
Figures 12.5–12.7 detail principles of local exhaust ventilation, including hood nomenclature and design considerations. For further reading on local exhaust ventilation systems, refer to the fundamental text, *Industrial Ventilation: A Manual of Recommended Practice*, published by the American Conference of Governmental Industrial Hygienists (3).

Administrative Controls

Although generally not the preferred approach, administrative controls may be the only feasible method to control worker exposure in certain instances or while engineering controls are being implemented. Administrative controls may include job rotation or reduction in time permitted in the area of concern. One disadvantage of limiting individual solvent exposures through job rotation is that exposures may be spread over a greater number of workers. Furthermore, administrative controls often require the continual observance of employees and additional training.

Personal Protective Equipment

If engineering or administrative controls discussed above are not feasible and/or do not provide adequate protection, personal protective equipment (PPE) must be used to minimize exposures. PPE should always be considered a last resort and managed carefully by qualified individuals. This is due to a number of limiting factors associated with PPE, which include the following:



CAPTURE VELOCITY—AIR VELOCITY AT ANY POINT IN FRONT OF THE HOOD OR AT THE HOOD OPENING NECESSARY TO OVERCOME OPPOSING AIR CURRENTS AND TO CAPTURE THE CONTAMINATED AIR AT THAT POINT BY CAUSING IT TO FLOW INTO THE HOOD.

FACE VELOCITY— AIR VELOCITY AT THE HOOD OPENING.

SLOT VELOCITY— AIR VELOCITY THROUGH THE OPENINGS IN A SLOT-TYPE HOOD. IT IS USED PRIMARILY AS A MEANS OF OBTAINING UNIFORM AIR DISTRIBUTION ACROSS THE FACE OF THE HOOD.

PLENUM VELOCITY—AIR VELOCITY IN THE PLENUM. FOR GOOD AIR DISTRIBUTION WITH SLOT-TYPES OF HOODS, THE MAXIMUM PLENUM VELOCITY SHOULD BE 1/2 OF THE SLOT VELOCITY OR LESS.

DUCT VELOCITY— AIR VELOCITY THROUGH THE DUCT CROSS SECTION. WHEN SOLID MATERIAL IS PRESENT IN THE AIR STREAM, THE DUCT VELOCITY MUST BE EQUAL TO OR GREATER THAN THE MINIMUM AIR VELOCITY REQUIRED TO MOVE THE PARTICLES IN THE AIR STREAM.

FIG. 12.5. Principles of exhaust hoods. From American Conference of Governmental Industrial Hygienists (ACGIH) (1992) (3). Reprinted with permission.

1. PPE does not eliminate the hazard. When PPE is used to control solvent exposure, the hazard continues to exist since protection is achieved by creating a barrier between the hazard and the worker. Thus, if the protection fails (such as a tear in a glove or a leak in a respirator), the worker is directly exposed to the hazard.
2. PPE requires continual worker and supervisor involvement. The effectiveness of the PPE depends not only on matching the protective device against the hazard, but, also, on the worker using the equipment properly and using it when needed. This is especially important for chemical-resistant gloves and respirator cartridges since no single glove or cartridge provides protection against every solvent.
3. Appropriate training is required. Federal regulations require that potential users be trained in the correct use and care of PPE.
4. PPE may provide a false sense of security. Some workers may believe that PPE provides complete protection, leading them to take chances when handling solvents. This is particularly true in emergency

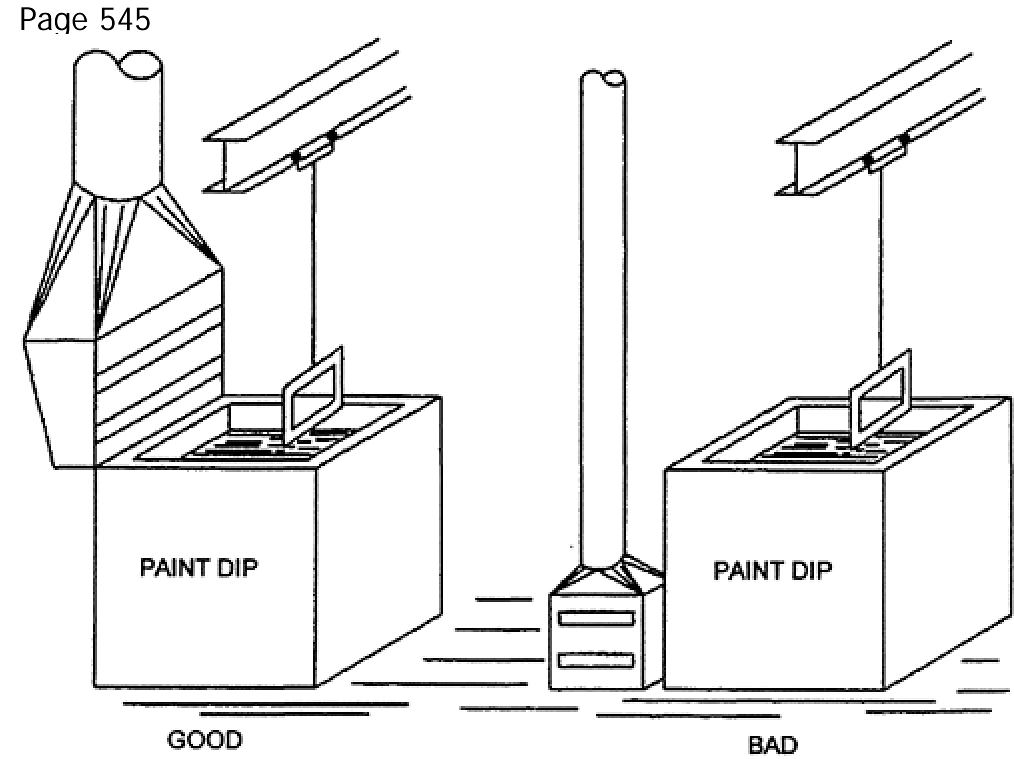

FIG. 12.6. Principles of exhaust hoods. From American Conference of Governmental Industrial Hygienists (ACGIH) (1992) (3). Reprinted with permission.

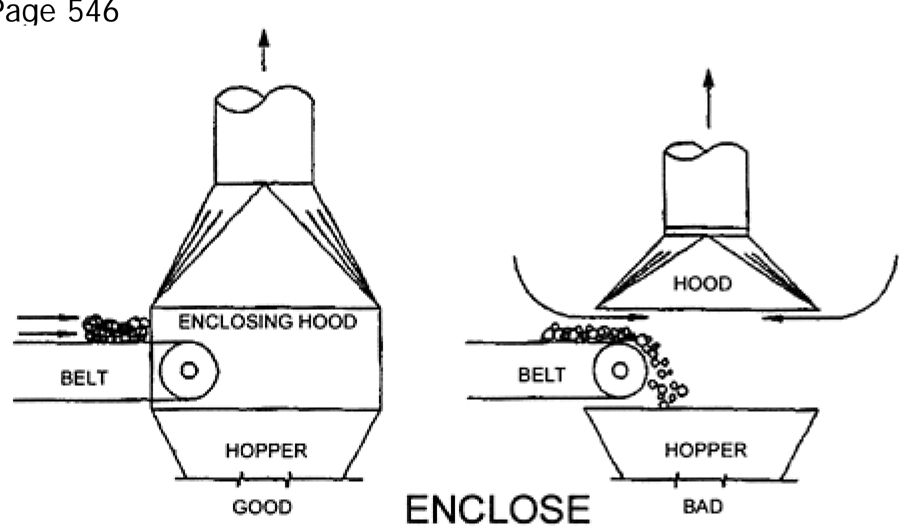
incidents where a worker may attempt to address a spill with PPE that might not be designed for the type of chemical or concentration involved.

There are various types of PPE used in the workplace, but the primary categories associated with solvent hazards are respiratory protection, protective clothing (including chemical-resistant gloves), and eye and face protection. The specific type of PPE must be carefully matched against the hazard. Often, a combination or mixture of chemicals exists, which can make PPE selection a challenge. As a general recommendation, it is always best to consult with manufacturers prior to purchasing PPE. Following is a discussion of PPE used to control solvent exposure.

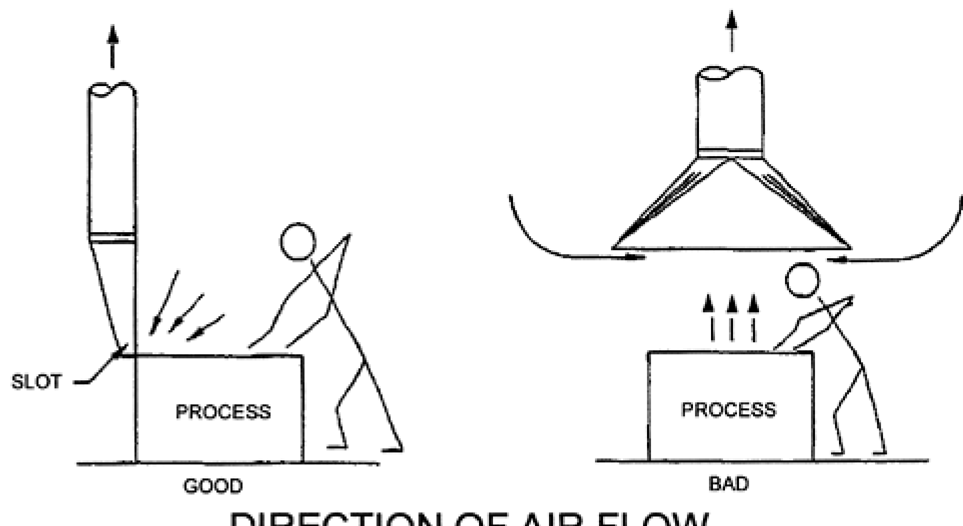
Respirators

Respiratory protection is used to prevent or reduce the level of worker exposure to airborne hazards. It is often employed to control intermittent exposures that can occur during entry into contaminated areas or during emergency repair and maintenance. However, respirators also may be the only feasible method of protection for exposures that may occur during normal work operations.

When LEV or other control methods are not feasible, the employer should provide workers with respiratory protection and implement an effective respiratory protection program. The goal is to ensure that the appropriate type of respiratory protection is selected and used correctly. OSHA has established requirements for a respiratory protection program in 29 CFR *(Code of Federal Regulations)* 1910.134. The standard instructs employers to develop written standard operating procedures to direct the respiratory protection program. Elements of the program include respirator selection, user training and fit testing, medical approval, and specific instructions for cleaning and maintenance. (See 1998 update). The two major categories of respiratory protection are air-purifying and atmosphere-supplying respirators.



ENCLOSE THE OPERATION AS MUCH AS POSSIBLE. THE MORE COMPLETELY ENCLOSED THE SOURCE, THE LESS AIR REQUIRED FOR CONTROL.



LOCATE THE HOOD SO THE CONTAMINANT IS REMOVED AWAY FROM THE BREATHING ZONE OF THE OPERATOR.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_546.html[2010/10/28 18:45:18]

Air-purifying devices for solvent exposure protect the worker by removing the contaminant from the airstream prior to its reaching the worker's respiratory system. This is accomplished by passing the contaminated air through a cartridge containing a sorbent such as charcoal. Airpurifying respirators come in various models, including half-mask, full-face, and powered air-purifying devices. Atmosphere-supplying respirators provide the user with a source of clean air separate from the local environment. Examples of atmosphere-supplying respirators include air-line devices and self-contained breathing apparatus (SCBA). Only approved respirators (i.e., by the National Institute for Occupational Safety and Health) should be worn.

Other factors that must be considered when selecting respiratory protection are the type of hazard, including oxygen deficiency, concentration of the contaminant, and adequacy of warning properties. For situations involving very high solvent concentrations and/or oxygen-deficient atmospheres, air-purifying respirators do not provide adequate protection. Thus, assessment of the hazard through industrial hygiene sampling is a key component in the selection process. Warning properties, such as odor, taste, and respiratory irritation provide an indication to the user that the device is not functioning properly (e.g., the service life of the sorbent has been reached) or the device is being worn incorrectly (e.g., leak around the face seal). Air-purifying respirators should not be worn for chemicals with poor warning properties (6). Since people vary greatly in their ability to detect odors, other methods such as cartridge replacement schedules or end-of-service-life indicators are being developed by various groups to ensure greater safety when using air-purifying equipment.

Protective Clothing

Protective clothing protects against dermal exposure by forming a barrier between the skin and the solvent. Protective clothing includes gloves, laboratory coats, rubber aprons, chemical resistant suits, and boots. Various types of chemical-resistant clothing are available, depending on the solvent of concern, the work involved, and the level of protection desired. Classifications include neoprene, nitrile, natural or butyl rubber, polyvinyl chloride, and viton. Some operations may require only partial protection (such as a rubber apron) while others may need full-body enclosures (such as those used by emergency response workers). The type of material and degree of protection chosen could affect the mobility, vision, and manual dexterity of the worker. Encapsulating suits can also present potential heat stress hazards for work conducted outdoors in the summer or work conducted indoors around heat-generating operations.

The amount of protection afforded by a given type of chemical-protective clothing is related to three primary performance factors: permeation, degradation, and penetration. Permeation is the ability of a chemical to pass through the molecules of a protective film (e.g., the clothing or glove). Degradation is a reduction in one or more of the physical properties of protective clothing or gloves due to contact with a chemical. Penetration is the flow of a chemical through physical aspects of the clothing or glove, such as zippers, seams, pores, or imperfections in the material.

Manufacturers of protective clothing determine product-specific performance data via laboratory tests conducted in accordance with methods established by the American Society for Testing and Materials (ASTM). All three factors should be considered when choosing protective clothing since data for two or three of the factors may not correlate for a given type of clothing and target chemical. For example, a glove may have acceptable degradation ratings for a chemical, but the chemical may readily permeate the material. No single glove or type of protective clothing provides adequate protection against every hazard. Furthermore, a glove type from one manufacturer often has different performance data from the same glove type produced by another manufacturer. Another general source of information is *Chemical Protective Clothing*, published by the American Industrial Hygiene Association (5). This two-volume set provides data needed to select and use chemical protective clothing. Included in the document is a discussion of permeation theory, testing methods, and available vendors.

Eye and Face Protection

Eye and face protection is used to prevent injuries that may occur while handling or transporting solvents. Two types of protective eyewear typically used to prevent exposure are chemical splash goggles and face shields. Chemical splash goggles are designed to completely enclose the eyes (as opposed to safety glasses, which are designed to prevent physical injuries that may result from an object striking the eye). Some goggles may also prevent vapor exposure to the eye in addition to contact with the liquid. Face shields are often worn in conjunction with goggles to protect the face and neck. Face shields and goggles that meet recognized safety standards bear the engraving of ANSI Z-87, which indicates that the device has passed safety performance tests conducted by the American National Standards Institute.

ABSORPTION OF SOLVENTS AND INHALATION EXPOSURE

A key factor in the absorption of solvents, whether by ingestion, dermal exposure, or inhalation, is the partitioning (solubility) of the chemical into blood and tissues.

When considering solvent exposure by inhalation, the rate of solvent uptake and subsequent equilibrium concentration in tissues are also dependent on pulmonary ventilation and the minute volume of blood flow through the lung and other organs.

Solvents that are highly soluble in blood and tissues are absorbed very readily by inhalation, and blood concentrations can rise rapidly. The driving force is the difference in concentration between inspired air and blood. The amount diffusing through the alveolar capillary membrane is dependent on the air-blood partition coefficient. Tissue equilibrium concentrations with solvents such as xylene, styrene, and acetone, which are highly soluble in blood and tissues, are not limited by pulmonary ventilation because the tissues act as a sink for the inhaled solvent. As pulmonary ventilation is increased, the blood and tissue concentrations continue to rise. The limiting factor in attaining the tissue equilibrium concentration is the blood flow through the tissues and the blood-tissue partition coefficient.

Solvents such as methyl chloroform, methylene chloride, trichloroethylene, and toluene, which have lower solubilities in blood and tissues, reach equilibrium rapidly because of low solubility or low blood-air partition coefficients. Tissue concentrations also will reach equilibrium rapidly because of low tissue-blood partition coefficients. Tissue concentration is limited, then, by tissue solubility and pulmonary ventilation. To achieve a higher concentration in tissues and blood, pulmonary ventilation must increase, allowing more solvent to enter the blood and a new blood-tissue equilibrium to be obtained (13, 14).

DERMAL UPTAKE OF SOLVENTS

The opportunity for solvents to enter the body through dermal contact is enhanced, in part, due to the large surface area of the skin (18 ft2). Fortunately, the barrier properties of the skin, which are associated with filamentous proteins and lipids of the stratum corneum, naturally inhibit penetration by harmful substances. Disruption of this barrier, however, by injury, illness, or removal of lipids, can facilitate passage of these materials. For example, treatment of the skin with polar organic solvents, detergents, and some surfactants can remove the lipids, thereby increasing the skin's permeability. Penetration of the skin also depends on a number of factors such as the thickness and integrity of the skin layer, the difference in concentration of solvent on both sides of the epithelium, and a number of physical constants. In addition, hydration can increase absorption by affecting the permeability of the skin. Movement of water-soluble compounds may be impeded, however, when the stratum corneum is highly hydrated. Although hair follicles and sweat glands comprise only a small proportion of the skin's surface area, they, too, provide pathways for solvent penetration.

Solvents can damage the skin by removing lipids, resulting in irritation, cellular hyperplasia, and swelling. For example, the careless use of solvents without proper hand and arm protection frequently leads to cases of dermatitis in the workplace. In a study of skin lipid removal by solvents, it was found that the ability of a solvent to penetrate the skin depends on the polarity of the solvent and the surface charge of the skin. Results comparing penetration or removal of lipids by several solvents showed that ethanol, the solvent with the greatest polarity, extracted the most lipids, followed by acetone and then ether (17).

Treatment of the skin with solvents can also increase the penetration rate of other compounds. In a study using excised human skin, the effect of several solvents including DMSO, dimethylacetamide, formamide, and dimethylformamide on the penetration rate of sarin was examined (86). Results showed that solvent pretreatment increased the rate of sarin transport by a factor of 10–100 over that of sarin on control skin.

Penetration of solvents by the dermal route in humans was studied for toluene, xylene, and styrene vapors. Volunteers were exposed to 300 or 600 ppm for 3.5 h in a dynamic exposure situation in which the subjects wore full-face respirators to prevent pulmonary absorption of the solvents. A 10-min exercise period was sufficient to make the subjects perspire and to raise the skin temperature about 0.5°C. Perspiration and warm skin temperature enhance the hydration of the skin and subsequent percutaneous absorption. After termination of exposure, these solvents displayed biphasic elimination from the blood into exhaled air with a short half-life of about 1 h and a much longer half-life of approximately 10 hr. Xylene and styrene had slightly delayed excretion in exhaled air after percutaneous exposure when compared with inhalation exposure. Delayed excretion after dermal exposure may be accounted for by a slow release from the skin after termination of exposure.

Overall percutaneous absorption of the compounds above corresponded to only about 0.1 percent of the amount estimated to be absorbed by the pulmonary route, thus indicating a very small absorption potential by the percutaneous route. When the percutaneous absorption of xylene vapor was compared to earlier work with xylene liquid, the vapor displayed an approximately 10-fold greater efficiency in penetrating the skin than did the liquid. According to the authors, it was not uncommon to observe

greater penetration with vapor exposure because liquid solvents removed the lipids from the stratum corneum and thus interfered with absorption. Additionally, exercise promoted the absorption of solvents because of the warm hydrated skin. In general,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_548.html[2010/10/28 18:45:19]

under reasonable exposure conditions in the workplace, percutaneous absorption of solvent vapors would not contribute significantly to the total blood concentrations of these solvents (116).

TOXICOLOGY OF SELECTED SOLVENTS

This section deals with solvents of occupational concern that have had neurotoxic, reproductive, or carcinogenic effects in humans. Examples are provided for these as well as less toxic, alternative solvents. Generally speaking, acute exposure to high levels of solvents (i.e., greater than the TLV) results in alterations of central nervous system (CNS) function. Repeated solvent exposures give rise to the organ-specific pathology described below for individual chemicals.

Effects of Acute Solvent Exposure on the Central Nervous System

Although varying widely in chemical structure and physical properties, solvents produce a rather stereotypical set of toxicological manifestations upon acute exposure (10). Most commonly these include evidence of dysfunction of the CNS and, if exposure is sufficiently severe, narcosis. Exposure to certain solvents has been associated with alterations of cognitive and psychomotor function following short-term exposures at or near the TLV. For example, controlled studies of volunteers exposed to toluene (100 ppm for about 6 h) revealed decreased manual dexterity, visual perception, and color discrimination (15). Exposure to greater concentrations may provoke symptoms including, for instance, headache, dizziness, ataxia, a sense of euphoria, drowsiness, lightheadedness, disorientation and confusion, tremulousness, and nausea. These symptoms are readily reversible under single exposure conditions upon removal of the individual to a solvent-free environment. Exposure to potentially lethal levels of solvents can result in stupor, loss of consciousness, coma, respiratory depression, and abnormal cardiac function. Information on neurotoxic symptoms associated with acute exposure to specific solvents is found in the latter portion of this chapter.

Other Toxic Effects of Solvent Exposure

Exposure to solvents at concentrations too low to induce many of the acute symptoms cited above is of special concern with regard to neurotoxicity, because the capacity of nervous tissues for post-toxicity regeneration is limited and repeated insults may lead to cumulative damage. The subtlest symptoms of chronic solvent exposure include relatively mild alterations of mood and behavior not accompanied by quantifiable evidence of dysfunction on neurobehavioral tests (18, 57). Although dose-response and causal relationships have been difficult to study in the absence of animal models, symptoms of chronic solvent exposure may include increased irritability, decreased span of attention, and loss of interest in daily activities. More severe damage to the nervous system, both central and peripheral, occurs upon repeated exposure to certain solvents such as carbon disulfide and n-hexane (discussed later). Numerous neurobehavioral and functional tests have been used to detect such changes in both clinical and experimental settings (69, 112). Whether the acute effects of solvents play a role in determining the pathogenesis of toxic lesions observed after chronic exposure to the same solvents is uncertain. However, current thought is that the acute effects on the nervous system are mediated through nonspecific interactions of solvents with the cell membrane, that is, increases in membrane fluidity or functional alteration of cell surface receptors, while the effects of chronic exposure are mediated by specific biochemical actions of solvents.

Organs that receive a high percentage of the cardiac output are exposed to greater doses of absorbed toxicants than poorly perfused tissues. A major determinant of target organ selectivity for the toxicity of solvents is xenobiotic metabolism. While pharmacokinetics defines the quantity of solvent reaching a particular organ or tissue after absorption, metabolism may yield products with increased toxic potential relative to the parent chemical. Thus, well-perfused organs with high capacities for specific types of biotransformation reactions, mainly those catalyzed by the cytochrome P450, are common targets for solvent-induced toxicity. In particular, the liver is vulnerable to the toxicity of many solvents, owing to its high capacity for xenobiotic metabolism. Many common hepatotoxic solvents yield toxic intermediates or end products upon biotransformation, for example, carbon tetrachloride (113), chloroform (109), and trichloroethylene (16). However, some solvents, such as ethanol, may exert their hepatotoxic effects indirectly by altering cellular redox balance during metabolism and thereby deranging normal liver function and structure (117).

The kidney, as a filtering and concentrating organ of excretion, receives not only untransformed solvents but also the products of hepatic metabolism of solvents. These biotransformation products—for example, conjugates of trichloroethylene—may be more toxic than the parent chemical and produce renal-specific toxicity (81). The ion transport and solute concentrating functions of renal tubules also contribute to the vulnerability of the kidney to certain chemical toxicants (82). In addition, biochemical peculiarities of certain species and genders

Page 550

may play a major role in bringing about solvent-induced renal toxicity. A notable example is the susceptibility of the male rat to renal toxicity caused by 1,4-dichlorobenzene, Stoddard solvent, VM & P naphtha, and other hydrocarbon solvents. This has been attributed to the male rat-specific abundance of the low molecular weight protein α2u-globulin, which acts as a carrier for lipophilic molecules (128). α2u-Globulin is normally degraded in renal tubule lysosomes and binding to a solvent ligand slows degradation of the protein so that the α2u-globulin-hydrocarbon complex is sequestered by lysosomes (77). The sequestered protein apparently disrupts lysosomal function and cytotoxicity results when large amounts of α2u-globulin accumulate (121). There is apparently no counterpart to this type of nephrotoxicity in species other than the rat (7).

Organs that catalyze relatively few types of chemical biotransformation reactions or have low rates of xenobiotic metabolism, such as lung, nasal mucosa, and testes, may also be target organs for the toxicity of some solvents. For example, ethylene glycol monomethyl ether and related glycol ethers are testicular toxicants (58, 95) as are hexane and the hexane metabolite 2,5-hexanedione (22). Recently, special attention has been paid to the potential susceptibility of the tissues lining the upper airways—the nasal mucosa—to solventinduced toxicity. These tissues have high levels of certain xenobiotic-metabolizing enzymes and, in addition, are exposed to high solvent concentrations relative to the lung and other organs. In particular, esters such as propylene glycol monomethyl ether acetate, dimethylphthalate, and dimethylsuccinate are enzymatically transformed by nasal carboxylesterase to yield acidic products that may accumulate to toxic levels in the nasal mucosa (95, 126, 133). Certain solvents need no metabolism to adversely affect the tissues of the upper respiratory tract; vapors or aerosols of aldehydes cause local tissue damage to the nasal epithelium (97), presumably due to the activity of these solvents in forming protein-protein and protein-DNA crosslinks (61).

It is well known that neurotoxic chemicals can have a negative impact on the sensory function. Often, the first symptoms reported following chemical exposure are those related to the senses (48). Toluene, xylene, styrene, trichloroethylene, and carbon disulfide are examples of solvents associated with adverse affects on the auditory system (98). In the industrial environment, workers are often exposed to solvents as well as high levels of noise, which is known to damage the inner ear and cause hearing loss. In recent years, evidence has emerged from workplace studies and animal experimentation that the combined effects of noise and ototoxic solvents may increase the susceptibility to hearing loss (68, 98). In one animal study, rats were exposed to toluene or noise or toluene followed by noise and then had their auditory functions tested. Results showed that rats exposed to toluene followed by noise exhibited a decrease in auditory sensitivity greater than the sum of the effects of toluene and noise alone (98). The risk for hearing loss may be increased by factors other than noise, such as drugs or other chemicals, and can also be influenced by heredity and aging (98). It is important to take all of these factors into account when addressing hearing loss in the workplace.

Solvent Mixtures

Humans are often exposed to multiple chemicals at work or in the home. An example, as reported by Worksafe Australia (the Australian National Occupational Health and Safety Commission), involved solvent exposure and health effects in spray-painter apprentices (143). Their study identified 32 different solvents contained in 20 thinner products used by the painters. The solvents represented six classes of compounds: alcohols, aromatic hydrocarbons, esters, glycol ethers, ketones, and mixtures. Of significance was the fact that the workers commonly perceived the thinners to be equivalent and safe to use. This underscores the need for chemical communication programs to inform workers about the potential hazards of working with mixtures of chemicals.

Exposure to multiple chemicals, either simultaneously or sequentially, may alter the toxicological interactions of the individual chemicals, leading to a change in the toxicity as predicted by summing their individual effects. Thus, one chemical may alter the absorption, distribution, metabolism, and/or excretion of other chemicals in a mixture (74). The study of chemical interactions has been developed most extensively for therapeutic drugs. Although some information exists on interactions of industrial chemicals, most toxicological research to date has dealt with single, pure chemicals. These single chemical studies are important because they allow researchers to gather fundamental knowledge about the mechanisms of toxicity under conditions that are well controlled. Additional research is required to examine the potential health effects associated with exposures to multiple compounds (148).

Glycol Ethers

Glycol ethers represent an important category of solvents that are widely used in mixtures for industrial and consumer applications. They are grouped as ethylene glycol, propylene glycol, or butylene glycol ethers, with the ether portion of the molecule containing methyl, ethyl, propyl, butyl, or higher molecular

weight moieties (52). Additional members of this class of compounds

are the corresponding acetate esters. The miscibility of glycol ethers with water and many organic compounds make them ideally suited as solvents in oil-water compositions. Production capacity of the ethylene-based ethers in 1992 exceeded one billion pounds, with the coatings (paint) industry being the major consumer (52). In addition to coatings, glycol ethers are found in many household goods such as brake fluids, waxes, cleaners, dyes, detergents, degreasers, and inks. 2-Butoxyethanol has been formulated into hundreds of consumer products (27).

The current ACGIH TLV–TWAs and German MAKs for three widely used glycol ethers, 2-methoxyethanol (ME), 2-ethoxyethanol (EE), and 2-butoxyethanol (BE), are 5 ppm, 5 ppm and 20 ppm, respectively. The NIOSH RELs and proposed OSHA PELs for ME and EE are significantly lower at 0.1 ppm and 0.5 ppm, respectively. All have skin notations. ACGIH based their limit for ME on possible blood, reproductive, and CNS effects. For EE and BE, effects on reproduction and the blood were considered, respectively. The TLV and REL for propylene glycol monomethyl ether (PGME) are both 100 ppm and are based on potential irritation and CNS effects (2, 4, 101).

The commonly encountered glycol ethers are colorless liquids with mild odors. The primary routes of exposure in the industrial environment are inhalation and skin absorption (52). Some cases of accidental or intentional ingestion of products containing glycol ethers by children and adults have been reported (27). In general, the ethylene glycol ethers exhibit low acute oral toxicity (52). Experiments in rats have shown that the methyl, ethyl, and butyl ethers are readily absorbed through the skin (118). As the molecular weights of the glycol ethers increase, the potential for inhalation exposure and skin absorption decreases. Because the methyl and ethyl ethers of ethylene glycol and their acetates have demonstrated adverse reproductive, embryotoxic, teratogenic, and developmental effects in animal studies (58–60, 99, 100), their use in consumer products has declined (52).

Monoalkyl ethers of ethylene glycol are converted to their respective alkoxyacetic acids via the actions of alcohol dehydrogenase (27). Many of the observed adverse effects caused by ethylene glycol ethers in animals, such as hemotoxicity (e.g., 2-butoxyethanol) and testicular toxicity, are attributed to these toxic metabolites. Whereas rat erythrocytes have demonstrated vulnerability to the hemolytic effects of 2-butoxyacetic acid (from BE), human erythrocytes have been shown to be much less susceptible to these effects (27).

PGME and its acetate (PGMEA) are relatively innocuous compounds when compared to the ethylene glycol ethers discussed above. Overexposure to PGME has been associated only with increased liver weight and CNS depression. Studies have shown that EE and PGME are metabolized by different routes and the types of metabolites produced are responsible for the marked differences in toxicity. For example, methoxyacetic acid is the primary metabolite of EE, while propylene glycol is the main biotransformation product of PGME and PGMEA (94, 96).

Investigators have studied the potential interaction of ethanol and EE because of similar metabolic pathways and the likelihood of concomitant exposure to ethanol in some individuals (100). EE, when presented to rats alone or in combination with ethanol, seemed to increase the duration of pregnancy. Exposure to EE during gestational days 7–13 caused a decrease in certain behavioral tests such as rotorod performance. However, when EE was exposed to animals that also consumed ethanol the behavioral deficit was diminished. When EE was administered alone during late gestation, motor activity of pups was depressed and performance at avoidance conditioning trials was retarded. Combined administration of EE and ethanol seemed to exaggerate the behavioral deficits induced by EE and to depress both activity and learning.

Examination of neurotransmitters in 21-day-old pups that had been whelped by dams exposed to EE alone on gestational days 7–13 revealed an increase in several neurotransmitters such as acetylcholine, dopamine, and norepinephrine. Pups that were whelped by dams that had the combined treatment displayed a decrease in acetylcholine, dopamine, and 5-hydroxytryptamine. Thus, it was observed that ethanol during late gestation altered the neurochemical effects of EE.

In summary, concomitant exposure to ethanol can have differential effects depending on the stage of gestation. Ethanol administration during the early period of gestation ameliorated both the behavioral and neurochemical effects of EE to approximately 50 percent of the response produced by EE alone. In the late stage of gestation the combination of ethanol with EE exaggerated the effects of EE alone. This indicates that the possibility exists for ethanol-induced exaggeration of the potential toxic effects of EE exposure in pregnant workers.

Retrospective epidemiological studies of workers exposed to ME and EE have reported evidence of adverse effects on the male reproductive system, with increased frequency of reduced sperm counts (145). Evaluation of sperm production in several species has shown that the output of human sperm is

about one-fourth that of other mammals when compared on a per-gram tissue basis. This finding suggests that humans may be more susceptible to occupational toxicants than predicted by laboratory animals (130). As is the case with many widely used chemicals with potentially harmful effects, substitutes are being considered. PGMEA and ethyl-3-propionate have been identified as useful and less toxic alternatives to ethylene glycol ether solvents (23).

Benzene

Benzene has been used extensively over the years as a raw material in the manufacturing of polymers, detergents, pesticides, dyes, plastics, and resins, and as a solvent for waxes, oils, natural rubber, and other compounds (93, 123). In addition, benzene is a component of gasoline and is generally present at low levels throughout the environment (64).

Exposure to benzene in the workplace is primarily through inhalation, but skin absorption may also contribute to the overall body burden. OSHA regulates benzene as a potential occupational carcinogen with a PEL of 1 ppm and a STEL of 5 ppm (102). The ACGIH TLV–TWA and STEL for benzene are 0.5 ppm and 2.5 ppm (skin notation), respectively, and ACGIH has designated benzene as a confirmed human carcinogen (4). The NIOSH REL and STEL for benzene are 0.1 and 1 ppm, respectively. NIOSH additionally lists benzene as a potential occupational carcinogen (2). The ACGIH BEI for benzene is 25 μg of the metabolite S-phenyl-mercapturic acid per gram of creatinine in urine, measured at the end of the work shift (4).

Because of its high lipid solubility, acute exposure to benzene can cause depression of the CNS to the point of narcosis. Headache, dizziness, nausea, and vomiting are all features of benzene overexposure. Exposure to benzene at high concentrations can lead to blurring of vision, unconsciousness, convulsions, ventricular irregularities, and respiratory failure. Death as a result of exposure to extremely high concentrations of benzene may occur because of respiratory failure or cardiac arrhythmias (123, 144). Concomitant exposure to benzene and high concentrations of catecholamines can sensitize the heart and lead to ventricular fibrillation.

Benzene is hematotoxic and carcinogenic following repeated exposure to high concentrations (90). There are numerous rodent studies that also show that benzene can cause cytogenetic damage in vivo (64). In addition, examination of the chromosomes of humans exposed to high levels of benzene revealed an elevated rate of chromosomal aberrations that persisted after cessation of exposure (47). Chronic exposure to benzene leads to a progressive depression of bone marrow function (83). Epidemiological studies have demonstrated that blood dyscrasias such as pancytopenia, aplastic anemia, and acute myelogenous leukemia can develop in humans as a result of this exposure (90, 123). Furthermore, clinical investigations have shown that it may take several years after the termination of exposure for benzene-induced leukemia to appear (138).

Enzymes linked to the metabolic activation of benzene and its metabolites are the cytochrome P450 monooxygenases and myeloperoxidase (90). The major metabolic pathway for benzene appears to be oxidation to a phenol, which is then converted to a sulfate conjugate and excreted in urine. Other hydroxylated metabolites include hydroquinone and catechol. Benzene metabolism can be effected by interactions of benzene with its metabolites or other compounds. For example, experiments in mice suggest that benzene can inhibit the oxidation of phenol. Furthermore, animal and human studies have demonstrated that coexposure to toluene may significantly alter the formation of benzene metabolites. Finally, treatment with ethanol induces benzene and phenol metabolism in the liver, resulting in higher levels of active metabolites (90).

The mechanism of benzene-induced leukemia is not known. Potential mechanisms for benzene-induced bone marrow disease include metabolism of the parent compound to phenols and other metabolites, in particular, quinone-type metabolites such as catechol, quinol, and pyrogallol which could react with chromosomes and interfere with mitosis. Another possibility could be the depletion of sulfur available for glutathione detoxification, thereby leading to interaction of toxic intermediates with critical elements of the bone marrow. Another suggested mechanism involves transfer of benzene metabolites from the liver to the bone marrow (123). Researchers have investigated the metabolism and binding of radiolabeled benzene in the isolated hind limb of rats in which benzene was administered directly into the bone marrow space. Metabolites of benzene were found covalently bound to macromolecules in the bone marrow, indicating that the bone marrow has the potential of metabolizing benzene to reactive intermediates (67). The fact that benzene or benzene metabolites have been shown to inhibit the multiplication of erythrocyte precursor cells in the bone marrow may imply an additional mode of action (76).

The potential for benzene to induce leukemia in experimental animals has been difficult to demonstrate. In an inhalation study involving Sprague-Dawley rats and AKR mice, benzene vapor (300 ppm) was administered for 6 h a day, 5 days a week, for the lifetime of the animals. The rats showed signs of lymphocytopenia, mild anemia, and slightly decreased survival. The mice displayed severe lymphocytopenia and anemia with significantly decreased weight gain and survival. However, no evidence of a leukemic or pre-leukemic response was observed in either species (122). In a 2-year

carcinogenicity study, rats and mice fed benzene in corn oil developed dose-related leukopenia and tumors in multiple organs, but the study failed to show benzene-associated leukemia (64).

Toluene

Toluene is a flammable solvent that has been used extensively in the chemical, rubber, paint, and drug

industries. It is also useful as a solvent for paints, inks, lacquers, dyes, and other compounds, and as an additive for gasoline. Sources of toluene in the environment include manufacturing plants, automobile emissions, gasoline evaporation, and cigarette smoke (31, 93).

Various exposure limits and biological indicators of exposure apply to toluene. The ACGIH TLV–TWA, German MAK, and NIOSH REL for toluene are 50 ppm (skin notation), 50 ppm, and 100 ppm, respectively. NIOSH adds a 150 ppm STEL and has established an IDLH of 500 ppm. The current OSHA PEL is 200 ppm with a 300 ppm ceiling limit. The ACGIH BEIs are 0.05 mg toluene per liter of venous blood, collected before the last shift of the work week, 1.6 grams of hippuric acid per gram of creatinine in the urine, collected at the end of the shift, and 0.5 mg of o-cresol per liter of urine, collected at the end of the shift (2, 4, 101). Toluene in expired air has also been evaluated to determine its usefulness as an indicator of exposure. Analysis of expired air in toluene-exposed workers revealed that the toluene concentration was correlated to the exposure environment, representing approximately 15–20 percent of the environmental concentration (28).

The principal toxic effect of toluene is injury to the nervous system. Toluene is most rapidly absorbed by inhalation, followed by ingestion and skin contact. A substantial amount of inhaled toluene is retained in the body. The toxicity of toluene is similar to that of benzene except that it does not exhibit the hematopoietic effects characteristic of benzene. Toluene is an eye and skin irritant and animal studies indicate that its acute oral toxicity is less than that of other alkylbenzenes (31). In humans, acute effects of toluene exposure can resemble alcoholic intoxication by first stimulating and later depressing the central nervous system. Groups of volunteers exposed to 100 ppm of toluene vapor for 6 hr, complained of fatigue, sleepiness, and the feeling of intoxication. Irritation of the eyes, nose, and throat was reported as well as decreased manual dexterity and accuracy in visual perception (15).

Exposure to high concentrations of toluene, as seen in cases of solvent abuse (e.g., glue sniffing), may cause death by sensitizing the myocardium (115, 144). In chronic abusers of toluene, irreversible neurological toxicity and reversible renal damage have also been reported (129, 142). Symptoms associated with intentional inhalation of high concentrations of toluene include euphoria, mild tremors, unsteady gait, and changes in behavior. Encephalographic examination of these individuals has shown abnormalities indicative of cerebellar atrophy (71). Toluene is a lipid soluble compound that readily crosses the placenta and, as such, may pose a teratogenic risk in cases of high exposure, as with intentional abuse. A pattern of teratogenicity like that of the fetal alcohol syndrome (described in the section on ethanol) is prevalent in human studies relating to excessive in utero exposure to toluene. Coabuse of alcohol and toluene may heighten the risks (142).

Toluene is metabolized to benzoic acid, which is subsequently conjugated with glycine or glucuronic acid to form hippuric acid or benzoylglucuronates, respectively. These conjugates, as well as another metabolite, o-cresol, are excreted in the urine (75). In human studies ethanol was shown to inhibit the metabolism of toluene at blood ethanol concentrations of 21 mmol/liter (42). Results indicated that the concentration of toluene in alveolar air of the toluene/ethanol-exposed group was significantly higher than that of the toluene control group. Additionally, hippuric acid and o-cresol excretion was significantly reduced as compared to controls. During the 24 hours following the last exposure, excretion of both hippuric acid and o-cresol was about 40–50 percent of that excreted by subjects who received toluene alone. These results suggest that ethanol may alter the metabolism of inhaled toluene and prolong its elimination from the body. Therefore, the possibility of ethanol consumption should be considered during biological monitoring since ethanol intake could lead to an underestimation of the actual toluene exposure (42).

In contrast to the above, pretreatment of rats with phenobarbital (PB) showed that the metabolism of toluene could be enhanced to form benzoic acid. The pretreatment did not, however, appear to effect the rate of conjugation of benzoic acid with glycine to form hippuric acid. The hippuric acid concentration in the urine of PB pretreated rats was about three times that of rats receiving toluene only. In addition, the toluene concentration in the blood of the PB pretreated group was only about one-half that in the toluene-exposed rats. Not only did the phenobarbital pretreatment enhance metabolism of toluene to benzoic acid (with subsequent conversion to hippuric acid), it also reduced the blood concentration of toluene and thus shortened the sleeping time induced by the narcotic effect of toluene (66).

The mechanism of the neurotoxic effect of toluene is not well understood. Some experimental work with rats found that exposure to 30,000 ppm toluene for a few minutes reduced the concentration of tryptophan and tyrosine in plasma by about 50 percent and 20 percent, respectively, compared to controls. Tryptophan and tyrosine are known to be precursors of the neurotransmitters noradrenaline,

dopamine, and 5-hydroxytryptamine. The reason for the decrease in the precursors was unknown, but it was speculated to be an alteration in the hepatic uptake or utilization of these amino acids (141).

A potential factor in toluene-induced neurotoxicity is production of reactive oxygen species that can cause cell damage. Experiments using rats suggested that

benzaldehyde, a metabolite of toluene, accelerates the production of these reactive oxygen species within the nervous system, and may also contribute to the overall neurotoxicity (87).

n-Hexane

n-Hexane is a flammable liquid and one of the most toxic of the alkanes. It is an excellent organic solvent that has been used in industrial applications such as printing, low-temperature thermometers, adhesives, extractions, and cleaning processes (30, 62).

The primary routes of exposure in the industrial setting are by inhalation and skin contact. The ACGIH TLV–TWA, NIOSH REL, and German MAK are all 50 ppm. ACGIH added a skin notation and NIOSH established an IDLH value of 1100 ppm (10% of the lower explosive limit). ACGIH set the TLV based on possible neuropathy, CNS effects, and irritation (2, 4, 101).

Acute toxic responses after accidental ingestion include nausea, gastrointestinal irritation, and CNS effects. Inhalation overexposure leads to dizziness, a sense of euphoria, and numbness of the extremities. Exposure to high concentrations causes vertigo and a marked anesthetic effect. Hexane is also an irritant to the skin upon dermal exposure (30).

Many cases of polyneuropathy in workers exposed to n-hexane have been noted, with the earliest occurring in Japan (147). The severity of symptoms in the Japanese workers varied directly with degree and duration of exposure and in some cases there was incomplete recovery (62). Polyneuropathy has also been reported in cases of solvent abuse (30). The neurotoxic effect of n-hexane has characteristically been a progressive motor or sensorimotor neuropathy with symptoms usually reported after several months of exposure (62). In cases from occupational exposure, symptoms have often been sensory, with numbness and paresthesia in the distal extremities, most notably the feet or hands. Improvement of symptoms is noted after cessation of exposure, and mild cases can recover completely. Hexane is readily absorbed in laboratory animals and has an affinity for tissues high in lipid content (24). It is rapidly metabolized to hydroxylated compounds prior to being converted to a keto form (72, 84). 2,5-Hexanedione and methyl n-butyl ketone are the metabolites suspected of being responsible for the production of neurotoxicity.

The mechanism of 2,5-hexanedione-induced neuropathy is not known but several hypotheses have been presented (39). These include reduction in energy production in the axon resulting in disruption of axonal transport, alteration of protein structure, and inadequate pro teolysis of neurofilaments in the nerve terminal. 2,5-Hexanedione has been shown to interact with glyceraldehyde-3,5-dehydrogenase and phosphofructokinase, inhibiting their glycolytic properties and resulting in decreased energy production and possible disruption of axonal flow. Reaction of 2,5-hexanedione with lysine amine moieties to form pyrrole adducts and modification of neurofilament or axonal skeletal proteins is also an attractive hypothesis (40). Modification of the proteins may lead to crosslinking of the neurofilaments, which could cause difficulty in neurofilament passage through narrow regions of the axon such as the node of Ranvier, and therefore an accumulation of proteins at the site of constriction. Possible biophysical membrane changes as a result of 2,5-hexanedione may influence the degeneration of the axon. 2,5-Hexanedione binding and inactivation of calcium-dependent proteases that are important for degradation of neurofilament proteins is the last mechanism mentioned that might lead to accumulation of neurofilaments. Although none of the mechanisms mentioned fully answers all of the questions concerning n-hexane-induced neurotoxicity, these hypotheses offer some contributions to the understanding of the toxic response. It may be that several mechanisms act in parallel to produce the neurotoxic effects.

Repeated exposure of rats to n-hexane not only produces the characteristic pattern of neurotoxicity but results in testicular lesions as well (146). The testicular effects are linked to disruption of the cytoskeleton of Sertoli cells. Secondary effects, caused by a loss in functional spermatogonial cells, are seen in affected tubules. Acute exposure led to reversible effects but inhalation or oral exposures of two to five weeks led to irreversible effects. Although the neurotoxic effect of n-hexane is observed in humans, the testicular effect seen in rats has not been well documented in humans.

Methyl n-Butyl Ketone

Methyl n-butyl ketone (2-hexanone, MBK) has been used as a solvent or cosolvent (e.g., with methyl ethyl ketone) for adhesives, lacquers, vinyl coatings, printing inks, oils, varnish removers, and other materials (25, 73).

Occupationally, the principal routes of exposure to MBK are via inhalation and skin contact with the liquid. The ACGIH lowered the TLV–TWA for MBK in 1998 to 5 ppm (skin notation) to protect against possible neuropathy. The German MAK is also 5 ppm. The NIOSH REL and IDLH for MBK are 1 ppm and 1600 ppm, respectively (2, 4, 101).

Methyl n-butyl ketone has low acute oral toxicity. Inhalation of high vapor concentrations causes eye and respiratory tract irritation followed by CNS depression and narcosis (131). MBK easily penetrates the skin,

and inhalation exposure yields approximately 80–85 percent pulmonary retention. In addition, MBK is widely distributed in the tissues, the highest concentrations being found in the blood and the liver (25). Chronic exposure to low doses may produce degenerative axonal changes, primarily in the peripheral nerves and long spinal cord tracts (124, 125, 131).

Depending on the route of administration, a number of metabolites in varying amounts can be detected in the blood. The primary neurotoxic metabolite, as with n-hexane, is 2,5-hexanedione. Other metabolites identified following oral, intraperitoneal, or respiratory exposures include 2-hexanol and 5-hydroxy-2-hexanediol (25).

MBK was implicated as a neurotoxic agent in the 1970s after instances of neurotoxicity were reported in the printing and painting industries (9, 91). Inhalation was the primary route of exposure, with the severity of the developed neurotoxicity proportional to the extent of exposure. The characteristic disorder caused by methyl n-butyl ketone begins several months after chronic exposure commences. Symptoms include weight loss and distal sensory neuropathy marked by a tingling sensation in the hands or feet. The muscular weakness that develops usually involves the hands and feet, but in severe cases may extend to the legs and thighs. The sensory loss is symmetrical and may progress to the legs and thighs in severe cases. There is also a moderate reduction of nerve conduction velocity in affected peripheral nerves (8, 9).

When volunteers were given MBK by inhalation, orally, or by dermal application, 2,5-hexanedione was detected in the serum. Radioactivity associated with the radiolabeled MBK was found to be excreted slowly, indicating that repeated exposures to high concentrations of methyl n-butyl ketone may lead to prolonged exposure to its neurotoxic metabolites (41).

The relative neurotoxicity of methyl n-butyl ketone, n-hexane, and their metabolites was investigated in rats. Potency was estimated by the time required to produce evidence of severe hind limb weakness or paralysis. Results showed 2,5-hexanedione to be most toxic followed by 5-hydroxy-2-hexanone, 2,5-hexanediol, methyl n-butyl ketone, 2-hexanol, and n-hexane. An examination of the data showed that the neurotoxic potency was related to the amount of 2,5-hexanedione metabolically produced (73).

Carbon Disulfide

Carbon disulfide (CS2) is a toxic and highly flammable solvent that has found extensive use in the manufacturing of rayon, soil disinfectants, carbon tetrachloride, and electronic vacuum tubes. It is commonly used as a solvent in industrial hygiene analyses. Other applications include its use as a fumigant for grain and a corrosion inhibitor (21, 93).

Inhalation and skin contact are the main routes of occupational exposure. Because adaptation to carbon disulfide's characteristic rotten egg odor occurs rapidly, the sense of smell is not useful in judging exposure. The current ACGIH, OSHA, and NIOSH exposure limits are 10 ppm, 20 ppm, and 1 ppm, respectively, all with skin notations (2, 4). The ACGIH TLV–TWA was set to protect against cardiovascular, central nervous system, and neuropathic effects. NIOSH has established an IDLH value of 500 ppm (101). In addition to these levels, there have been proposals in the literature to lower the occupational exposure limit to 4 ppm to prevent neurological sequelae (63). The Biological Exposure Index recommended by ACGIH is 5 mg of the metabolite 2-thiothiazolidine-4-carboxylic acid (TTCA) per gram of creatinine in urine, measured at the end of the work shift (4).

Acute exposure to high concentrations of carbon disulfide can result in restlessness, euphoria, nausea, vomiting, headache, mucous membrane irritation, unconsciousness, and fatal convulsions. Chronic exposure can lead to abnormalities such as irritability, hallucinations, auditory and visual disturbances, and weight loss (21, 55, 78, 93, 137). Distal sensorimotor neuropathy is the most common chronic effect associated with CS2 exposure. This has been confirmed in experimental animals as a neurofilamentous axonopathy that effects long axons in the CNS and peripheral nervous system (36, 54). Peripheral neuropathy takes place only after frequent and prolonged exposures to CS2 and is characterized by a loss of distal sensory and motor function. The condition can progress more proximally with continued exposure. Chronic exposure to CS2, as well as hexane, 2-hexanone, and their metabolite 2,5 hexanedione, results in large swellings of the distal axons which are filled with neurofilaments. Continued exposure causes axonal degeneration distal to the axonal swellings. (34, 54). In addition to these effects, encephalopathy, detected by neurological examination and neuropsychological testing, has been reported.

There is evidence that exposure to CS2 accelerates the rate of atherosclerosis (54). In addition, an investigation to determine a possible association between CS2 exposure and ischemic heart disease mortality found that the relationship is meaningful only for workers exposed to high levels for many years. Price has suggested a safe level of between 15 and 20 ppm (111).

Approximately 70–90 percent of absorbed CS_2 is metabolized and excreted in the urine. The remaining 10–30 percent is exhaled in the breath unchanged. In addition to TTCA mentioned above, other metabolites found in workers' urine include 2-mercapto-2-thiazo-lin-5-one and thiocarbamide (63, 107, 108, 135, 136).

In a study of rayon production workers with long-term exposure to carbon disulfide at concentrations well above the TLV, evidence of neuropathy was observed in a significant number of workers and consisted of distal sensory loss, altered tendon reflexes, reduced muscle power, and reduction in nerve conduction velocity. These abnormalities persisted for up to 10 years after removal from exposure and were considered to be permanent impairments in nervous system physiology (35).

Methanol

As Table 12.1 shows, synthetic methanol (or methyl alcohol, wood alcohol) production exceeded one billion pounds in 1995. Methanol's largest use is in the production of MTBE (methyl t-butyl ether), an additive in gasoline. It is also utilized as a denaturant for ethanol, a raw material in the production of numerous other chemicals such as formaldehyde and acetic acid, and as a solvent or antifreeze in paints and strippers, cleaners, and windshield washer compounds (43).

The major routes of exposure to methanol in the industrial environment are through inhalation and dermal contact. The ACGIH TLV–TWA of 200 ppm (250 ppm STEL) is based on potential ocular toxicity and CNS effects. The OSHA PEL and NIOSH REL have also been set at 200 ppm. NIOSH has further established an IDLH value of 6000 ppm for methanol, and ACGIH and NIOSH have added skin notations as indications that skin absorption can be a contributor to the overall body burden. The ACGIH BEI is 15 mg methanol per liter of urine, collected at the end of the work shift (2, 4, 101).

Most information regarding methanol toxicity in humans is gathered from acute exposures, primarily from ingestion, but there are reports of adverse health effects from inhalation and dermal exposures (80). In one NIOSH study, teachers' aides reported headaches, blurred vision, and other symptoms following inhalation exposure to methanol used in duplicating machines. Concentrations at the site were about 2–15 times the current REL. Adverse effects have also been reported following skin applications of methanol for various purposes, although inhalation may have also contributed to these exposures (80).

Methanol is readily absorbed following oral, inhalation, or dermal exposure and is distributed throughout the body according to water content of the tissues (80). Ingestion of as little as 2 teaspoonfuls may cause toxicity, whereas the fatal dose in humans is between 2 and 8 oz (53). In the absence of medical treatment, a dose of between 4 and 10 mL can lead to blindness (114), and depending on the amount of methanol ingested, mild to severe CNS depression can occur. A latent period, commonly 12 to 24 hr, usually ensues followed by severe abdominal pain, difficult breathing, blurred vision, and pain in the eyes, among other symptoms. Visual impairment or total blindness may occur within days depending on individual susceptibility and the time when treatment began (80). Metabolic acidosis due to formic acid production is thought to be the cause of the delayed symptoms and the ocular toxicity (114).

Metabolism of methanol in the liver accounts for a high percentage of absorbed methanol in both nonhuman primates and rats. Lesser amounts are excreted unchanged in the urine and breath. Metabolism is important not only because of its primary role in clearance, but because of the connection between its metabolites and the acute toxic effects mentioned above. Methanol is oxidized by a catalase-peroxidative system in rats, rabbits, and guinea pigs and an alcohol dehydrogenase system in humans and primates. The metabolic sequence proceeds from methanol to formaldehyde to formic acid (formate) and finally to carbon dioxide and water. Formic acid is metabolized in both rats and primates via a folate-dependent pathway. Rats are able to utilize this pathway more efficiently than primates, allowing for a more rapid conversion to carbon dioxide. Because the process is slower in humans and primates, high doses of methanol cause a buildup of formate in tissues, including the eye, resulting in the observed toxicity (114).

Administration of ethanol has been used in treating methanol poisoning because ethanol inhibits the oxidation of methanol by competing for the same metabolic pathway. Prompt hemodialysis (able to remove both methanol and formate), coupled with concurrent administration of ethanol and bicarbonate, has been successful in many poisoning cases (53).

Ethanol

Ethanol (ethyl alcohol, grain alcohol) is produced in large quantities (see Table 12.1) and is utilized extensively as a solvent in industry, in numerous consumer preparations, and as an additive to gasoline (gasohol). It is used industrially as a raw material in the production of drugs, plastics, perfumes, cosmetics, and other compounds. Other applications include products such as hairsprays, mouthwashes, cleaning products, and drug formulations (53, 80). Denaturants are added to the alcohol in a number of these products to discourage ingestion. Synthesis from ethylene represents the largest source of ethanol; smaller amounts are made from fermentation of natural materials (80).

Human exposure to ethanol is primarily through ingestion of alcoholic beverages and inhalation of ethanol vapors from industrial processes and consumer products. Percutaneous absorption appears to be

much less import

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_556.html[2010/10/28 18:45:24]

ant (80). OSHA, ACGIH, and many countries have established an exposure limit of 1000 ppm for ethanol (2, 4). The NIOSH IDLH of 3300 ppm was set because of safety concerns (10% of the lower explosive limit) rather than toxicological considerations (101).

Although there is no clear evidence that ethanol is carcinogenic in animals, it has been shown to be a tumor promoter. Additionally, the International Agency for Cancer Research (IARC) has classified alcoholic beverages as a Group 1 carcinogen based on the occurrence of a variety of tumors in humans that have been causally related to ingestion of these beverages (80).

An unfortunate occurrence associated with chronic maternal consumption of large amounts of alcohol is a pattern of congenital abnormalities commonly called fetal alcohol syndrome. Effects may include growth retardation, microcephaly, mental deficiency, facial abnormalities, and poor coordination. Children who have been effected may display a few or many of the features characteristic of the syndrome (33, 80, 110).

Ethanol is a CNS depressant that is capable of inducing all stages of anesthesia. It is readily absorbed by the GI tract and the lungs and is distributed throughout the body water (53). Absorption can be delayed, however, by food in the stomach. Subjects exposed to 5000–10,000 ppm of ethanol vapor experienced eye irritation and coughing (114). Individuals with tolerance to alcohol experienced headache, drowsiness, and stupor when exposed to concentrations of 9400–13,200 mg/m3 (5000–7000 ppm) for a period of 110 minutes (114). Ingestion of approximately one liter of an alcoholic beverage (40–55% ethanol) within several minutes can result in death (53). Individuals with blood alcohol levels of approximately 0.05–0.15 percent (50–150 mg/dl) may exhibit decreased inhibitions, poor coordination, blurred vision, and slowed reaction time. Increasing blood levels to 0.15–0.30 percent can result in slurred speech, visual impairment, hypoglycemia, and staggering. At 0.3–0.5 percent blood alcohol content (severe intoxication), symptoms can include muscular incoordination, hypothermia, vomiting and nausea, and convulsions. In adults, coma and death are typically associated with levels exceeding 0.5 percent (80, 114). The wide ranges reported above reflect the differences in tolerance and susceptibility of individuals to the effects of alcohol.

Like methanol, ethanol is metabolized primarily (about 90%) by the liver. Elimination from the body by urinary excretion and pulmonary exhalation is minimal (80). Oxidation of ethanol to acetaldehyde occurs via alcohol dehydrogenase within the cytosol. Acetaldehyde is then converted to acetic acid by action of aldehyde dehydrogenase. Both enzymes utilize oxidized nicotinamide adenine dicucleotide (NAD) as a cofactor (53). Following release to the blood, acetic acid is metabolized to carbon dioxide and water in the peripheral tissues (80). Alternative, but less active, metabolic pathways have been demonstrated in humans and other species. These include catalase and microsomal ethanol-oxidizing systems (26, 79). Adults metabolize ethanol at a rate of about 7–10 g/hr. This rate remains essentially constant for each individual within a wide range of exposure. Metabolic rates are higher for chronic alcoholics and children (80, 114).

The interaction of ethanol with other hepatotoxins is well known. Ethanol pretreatment has been shown to increase the toxicity of carbon tetrachloride, chloroform, trichloroethylene, dimethylnitrosamine, chlorpromazine, and other compounds (127). The induction of cytochrome P450 isozymes may be responsible for their metabolic effects (80).

Methylene Chloride

Methylene chloride (dichloromethane) is widely used in a number of diverse applications including manufacturing of polyurethane foams, production of pharmaceuticals, boat building, paint stripping, vapor degreasing, extraction of caffeine from coffee and tea, and various consumer products. Its high volatility, good solvent properties for fats, oils, and other compounds, and relatively good water solubility compared to other chlorinated compounds have made it quite valuable (103, 132).

Because of methylene chloride's high vapor pressure, the primary route of human exposure is through inhalation; however, dermal contact can be significant, depending on the application. The ACGIH TLV–TWA of 50 ppm was set to protect against CNS effects and anoxia. In addition, ACGIH has designated methlyene chloride as a confirmed animal carcinogen, but they also state that available epidemiological studies do not confirm an increased risk of cancer in exposed humans (4). NIOSH recommends that methylene chloride be regarded as a potential occupational carcinogen (101). OSHA considers methylene chloride a potential human carcinogen and has reduced the PEL for methylene chloride from 500 ppm to 25 ppm, with a STEL of 125 ppm (15 min) and an action level of 12.5 ppm that triggers certain requirements (103). The current German MAK is 100 ppm (2).

The primary acute hazards associated with exposure to methylene chloride are CNS depression and eye, skin, and respiratory tract irritation. In addition, one of the products of methylene chloride metabolism is

carbon monoxide, which can impair health in a manner similar to direct exposure to carbon monoxide. The resulting carboxyhemoglobin levels reduce the supply of oxygen

to the heart and may aggravate preexisting heart disease (103).

Metabolism of methylene chloride can proceed via two pathways, one by a route involving cytochrome P450 mixed-function oxidase (MFO) and the other by a route utilizing glutathione *S*-transferase (GST). Carbon dioxide is an end product in both systems, but carbon monoxide is only produced via the MFO route. At low concentrations the MFO system appears to dominate, but at higher concentrations (above 300–500 ppm) the glutathione pathway increases in a disproportionate manner (132).

Methylene chloride was shown in a 1986 National Toxicology Program inhalation study to produce lung and liver tumors in male and female mice and benign mammary tumors in male and female rats (56). Recent research has suggested that mice may be uniquely sensitive at high exposures to methylene chloride-induced lung and liver cancer (56). The tumors appear to be caused by a genotoxic mechanism involving metabolites of the GST pathway. The particular metabolites responsible are not found in high concentrations in lung or liver tissue in humans or rats.

In a study to determine the effects of alcohols and toluene upon methylene chloride-induced carboxyhemoglobin in the rat and monkey, it was shown that ethanol, methanol, isopropanol, and toluene inhibited the formation of carboxyhemoglobin. In addition, neither the rat nor the monkey demonstrated the methanol potentiation of carboxyhemoglobin that has been reported to occur in humans (32).

A study of the pharmacokinetics of [14C]methylene chloride in rats at 50, 500, and 1500 ppm for 6 h showed that metabolic processes were saturated above the 50 ppm exposure concentration. At 48 h postexposure, approximately 95 percent of the body burden attributable to the 50 ppm exposure was metabolized, in contrast to 69 percent and 45 percent at 500 and 1500 ppm, respectively (89). In addition, the production of carboxyhemoglobin reached a steady-state range of 10–13 percent regardless of the exposure concentration, suggesting that the CO metabolic pathway was saturated.

Tetrachloroethylene (perchloroethylene) is another solvent in which patterns of elimination are altered when metabolic pathways become saturated (105). In a study comparing oral and inhalation exposure of rats to [14C]tetrachloroethylene, it was found that with increasing dose, metabolism was saturated resulting in more of the parent compound being eliminated unchanged at 72 h after exposure (105). These results with methylene chloride and tetrachloroethylene indicate that just increasing the exposure concentration does not always increase the body burden in a linear manner. Such information may be useful for safety evaluations to avoid overestimation of body burden.

NONTRADITIONAL SOLVENTS

Given the negative health and environmental impacts created by some of the more widely used solvents, a great deal of effort has gone into finding suitable replacements. The following compounds are examples of nontraditional materials that show promise as replacement solvents.

d-Limonene

d-Limonene is a naturally occurring monocyclic terpene found in citrus peel oils, spices, evergreens, and human milk (140). It is considered to have low acute toxicity and is listed as GRAS (generally recognized as safe) as a food additive by the Food and Drug Administration (FDA) (21 CFR 182.60). It has found wide application as a solvent in numerous cleaning and degreasing applications, replacing more toxic and environmentally undesirable chlorinated solvents, glycol ethers, xylene, and chlorofluorocarbons (CFCs) (46). Skin contact with d-limonene may cause irritation and sensitization (attributed to the oxidation product d-limonene oxide) (140). d-Limonene has been shown to produce hyaline droplet nephropathy and renal tubular tumors in male rats. However, these effects are attributed to the unique presence of $\alpha 2u$-globulin in the male rat and are not deemed relevant to other species, including humans (45). Among the attributes of d-limonene are its antimicrobial, antiviral, antifungal, and antilarval properties (29). d-Limonene and related monoterpenes have also demonstrated chemopreventive and chemotherapeutic efficacy in experimental cancer-therapy models (37).

Based on similar metabolic pathways in rats and humans and the therapeutic successes in rodents, it has been suggested that d-limonene may be an efficacious chemotherapeutic agent for human malignancies (37).

Carbon Dioxide

Carbon dioxide is a gas under standard temperature and pressure conditions. It can be converted, however, to the liquid and supercritical phases by increasing pressure and temperature. The critical point of carbon dioxide is 31°C and 73 atm. Below this point, CO_2 can be maintained in a liquid state (e.g., 65 atm and 25°C), whereas above 31°C no amount of pressure can be applied to liquify it (supercritical phase) (65). In either of these dense phases, CO_2 exhibits good solvent properties. Beneficial characteristics include liquidlike density, gaslike diffusivity, and low surface tension. In

particular, liquid CO_2 acts like a hydrocarbon solvent, it has good homogenizing properties (i.e., immiscible liquids form a single phase when mixed with CO_2), and it is a good

solvent for many aliphatic hydrocarbons and most small aromatic hydrocarbons. Other chemical groups such as halocarbons, esters, ketones, and low molecular weight alcohols also exhibit good solvency in CO_2 (65). Since the mid-1970s, supercritical CO_2 technology has been employed in the food, beverage, pharmaceutical, and perfume industries. Applications include production of spice extracts, natural dyes, decaffeinated coffee and tea, plant extracts, active substances from drugs, and volatile oils (20, 38, 88). It has also been used in wastewater treatment, chemical analysis, and at times as an aerosol propellant. More recently, liquid CO_2 has found favor as an alternative for metal parts degreasing and as a solvent for dry-cleaning clothes (38, 70).

One such CO_2 degreasing system is being used in a pen manufacturing operation to replace perchloroethylene. It consists primarily of two separate systems, a hot oil pretreatment process, and an automated system that employs liquid carbon dioxide in a pressure vessel. The application is to degrease and remove chips from ball points after machining. The hot oil unit is used to displace fatty esters contained in machining oil and to remove chips in the point cavity. The automated unit then removes oil from the points using liquid carbon dioxide. The carbon dioxide and oil are separated in a recycling system and the carbon dioxide is used again during the next cleaning cycle.

Advantages of CO_2 usage over conventional solvents are numerous. Carbon dioxide is nonflammable, noncorrosive, nonreactive, nontoxic, inexpensive, and plentiful. Products obtained are solvent-free. Selective separations are possible. Finally, there are no environmental problems, since the gas is recovered for future use. One of the disadvantages of CO_2 systems involves the relatively high start-up costs for equipment. However, these may be recouped through improved productivity and reduced costs for waste disposal, for example.

Ionic Liquids

Ionic systems, which are made up of salts that are liquid at room temperature, are finding applications in a number of chemical processes. Ionic liquids have good solvent properties for many inorganic, organic, and, polymeric materials and, in some cases, these compounds can serve as both catalyst and solvent (49). Research has indicated that partitioning of organic solvents between an ionic liquid and water corresponds closely with that found for molecular organic solvents and water. Thus, ionic liquids have the potential to replace the toxic, flammable, and volatile organic compounds currently used in liquid-liquid separations (50). The room-temperature ionic compounds, such as 1-butyl-3-methylimidazolium hexafluorophosphate and 1-butylpyridinium nitrate, con sist of nitrogen-containing organic cations and inorganic anions. Their physical and chemical properties can be altered according to the choice of ions. Advantages compared to conventional organic solvents include low volatility and relative ease of recycling (50). Other potential uses include removal of organic contaminants from wastewater, soil cleanup, replacement of corrosive mineral acids in refinery processes, and spent nuclear fuel treatment (49). The safety and toxicological profiles of these compounds has yet to be thoroughly developed; therefore caution must be exercised before they are put into general use.

OPPORTUNITIES IN THE TOXICOLOGICAL EVALUATION OF SOLVENTS

Human exposure to solvents is quite common in today's society. These exposures frequently involve multiple chemicals that are found in numerous products such as cleaning agents, paint thinners, and fuels. Although most toxicological research to date has dealt with single chemicals, questions remain about the long-term health effects associated with low-level exposures to multiple chemicals and the sensitivity of the toxicological endpoints that are currently being relied upon. Development of innovative experimental protocols and new quantitative mechanistic approaches to the study of chemical interactions may be beneficial in this regard (74, 148).

Economic concerns and the desire for less toxic and more environmentally friendly chemicals have resulted in the introduction of numerous alternative compounds into the marketplace. In some cases, little may be known about the health and environmental impacts of these materials; examples include the ionic liquids discussed above. It is therefore essential that sufficient toxicological and environmental data be gathered before replacements are introduced on a wide scale.

Research has shown that many neurotoxic chemicals are capable of adversely affecting the sensory function. Minor changes in vision or hearing, for example, can dramatically alter job performance and the overall quality of life. While most reports to date have dealt with changes in the visual system, additional investigations into the effects of solvents on hearing, taste, and smell would provide important new information on this subject (48).

ACKNOWLEDGMENTS

The authors wish to thank Dr. Henry Ciuchta, Dr. Joseph Morton, and Mark Savell for reviewing portions of the manuscript and also Peter Kahla for his help

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_559.html[2010/10/28 18:45:26]

with one of the figures. The authors also gratefully acknowledge the significant contributions of the previous writers Paul H.Ayres, W.David Taylor, and Michael J.Olson.

QUESTIONS

1. You are a toxicologist with industrial hygiene responsibilities in a large manufacturing company. Your boss has just told you that the solvent the factory is using to degrease metal parts will be banned by the EPA within the next six months. Your job is to lead a team of employees, who have a vested interest in the current solvent, in coming up with a suitable alternative material. What are your considerations in recommending a replacement? Explain.
2. Assume that the solvent chosen above will be used in six locations in the factory. You surmise that some sort of ventilation will be required to protect the employees. What factors must you take into account in recommending the proper system?
3. One of your employees has begun using a solvent mixture containing xylene and toluene. To ensure the safety of the worker, you have conducted personal air monitoring throughout the day and have come up with the following sampling times and monitoring results: 0800–1000:60 ppm xylene and 25 ppm toluene; 1000–1200:92 ppm xylene and 45 ppm toluene; 1200–1300: no exposure because employee left for lunch; 1300–1600:110 ppm xylene and 47 ppm toluene. Calculate the TWA exposure for each chemical. Assume that there is no dermal exposure and that the toxic effects contributed by each solvent are additive. Has the TLV–TWA been exceeded?
4. Match each solvent or metabolite with the appropriate fact listed below.

Solvent/Metabolite	*Fact*
1. d-Limonene	a. Antidotal in methanol poisonings
2. Carbon Disulfide	b. Associated with bone marrow disease in humans
3. 2,5-Hexanedione	c. Potentially useful in cancer therapy
4. Toluene	d. Teratogen and embryotoxin
5. Methanol	e. Metabolism produces carboxyhemoglobin
6. 2-Butoxyacetic Acid	f. Frequently “sniffed” to obtain euphoric effect
7. Ethylene Glycol Monomethyl Ether	g. Used in rayon production
8. Benzene	h. A few ml can lead to blindness
9. Ethanol	i. Primary causative agent in polyneuropathy
10. Methylene Chloride	j. Produces hemolytic effects in rats

Channel Blockers, 590
Endotoxins, 599
Insect Growth Regulators, 600
Other Modes of Action, 600
Herbicides, 606
Acetyl-CoA Carboxylase Inhibitors, 606
Acetolactate Synthase Inhibitors, 606
Photosynthesis Inhibitors, 615
Protoporphyrinogen Inhibitors, 625
Bleaching Herbicides, 629
EPSP Synthase, Glutamine Synthase, and Dihydropteroate (DHP) Synthase Inhibitors, 629
Microtubule Assembly Inhibitors, 629
Cell Division Inhibitors, 629
Cellulose and Lipid Synthesis Inhibitors, 629
Synthetic Auxin Mimics (Phenoxy, Benzoic, and Pyridine Acids), 630
Herbicides with Unknown Mechanism of Action, 631
Conclusion, 631
Questions, 639
References, 639

The control of pests using chemicals dates back to more than 1000 BC by the Chinese (93). Sulfur, the first documented material, was found somewhat effective as a fumigant. However, for nearly 2500 years no additional pest control products were found. In the 16th century, the Chinese discovered arsenic could be used as an insecticide (159). Tobacco leaf (nicotine) and the seed of *Strychnos nux vomica* (strychnine) were established as possessing rodenticidal properties in 1700 (102). It was not until the mid-1800s that the insecticidally active botanicals, rotenone from the root of *Derris eliptica* and pyrethrum from the flowers of chrysanthemums, were added as insecticides. In 1880, Bordeaux mixture (copper sulfate, lime, calcium hydroxide, and water) was introduced for mildew control (93, 159). Paris

green (copper arsenite) and later calcium arsenite were used extensively at the turn of the century for Colorado potato beetle (102). The inorganic arsenicals and nature's botanicals were used for insecticides, and inorganic sulfur products for herbicides and fungicides. It was with this limited level of achievement that mankind entered the 20th century (160).

The Age of Synthetic Chemistry was ushered in with the synthetic organochlorine chemical called dichlorodiphenyltrichloroethylene or DDT (Figure 13.1). A German chemist named Zeidler (148) synthesized DDT in 1874. However, it was not until 1939 that its insecticidal properties were fully realized. DDT was developed as part of the carefully planned and targeted research of an industrial chemist, Dr. Paul Mueller (158). Despite its persistence and bioaccumulating properties, DDT has probably been responsible for saving more human lives than any other synthetic chemical in history (157).

FIG. 13.1. The structure of dichlorodiphenyltrichloroethylene (DDT).

Of all the communicable diseases, malaria has had the greatest impact on society living in tropical and subtropical areas (157). During the first half of the 20th century, every year more than 300 million people suffered from malaria. The mortality rate was estimated at 1%; 3 million people dying annually. By 1965, or less than a quarter of century after its introduction, DDT had effectively eradicated malaria as a threat to 953 million people (319). In addition to malaria, DDT controlled the outbreak of louse-borne typhus, the plague, and yellow fever, the three other most significant diseases in human history. DDT also has been credited as offering some level of control for 20 other human diseases including viral encephalitis, shigellosis, cholera, and tularemia (157).

The development and growth of the agricultural chemistry industry was rapid, particularly in regard to synthetic insect control and weed control agents, following World War II (90). Clearly, there was an intense focus on a diverse number of structures arising from the targeted application of principles of chemistry to the mechanism(s) of action toward specific and selective pest control. The use of synthetic organic crop protection chemicals grew in the United States until 1980 and then has gradually declined thereafter (98). The figures for 1992 sales were essentially the same as the 1985 number or 1.1 billion lb; 1993 sales were estimated as 1.3 billion lb (160), and 1.2 billion lb in 1995 (1).

In the United States during the last 50 years, the use of synthetic organic pesticides has enabled agriculturalists to increase crop yields as much as 50% while affording a reduction in the farm population involved by 69% (2). Despite the reduction in the number of farmers from approximately 7% to 2% of the population, the individual farmer produces enough food to feed an average of 129 people. Control of crop pests leads to healthier plants and thus reduction of mycotoxins and endotoxins, which can present significant human health risk.

Even with the extensive use of pesticides, the U.S. Food and Drug Administration (FDA) estimates that pests destroy approximately one-third of the world's food crops every year (3). The loss in the United States alone is nearly $20 billion per year. Despite the clear benefits from pesticide use, the potential hazard from their application has long been recognized and their uses are tightly regulated and monitored.

The risks associated with pesticides are evaluated by assessing the toxicity of each chemical, and estimating the magnitude of exposure from sources in the workplace, in the environment, in food, and in water. The need to balance the risk of damage to the environment and man against benefits associated with using pesticides is clear (87).

In the United States, the regulation of pesticides is covered by several legislative acts and enforced by several federal and state agencies. A brief historical review of pesticide legislation is provided as a background for current provisions for federal regulation of pesticides by the U.S. Environmental Protection Agency (EPA). Further details for the toxicology study requirements ascribed by the U.S. EPA in its guidelines (171) will be considered. In addition, guidelines, which have been generally harmonized with the U.S. EPA guidelines, are put forth by the Japanese Ministry of Agriculture, Forestry and Fisheries (MAFF), and the Organization for Economic Cooperation and Development or OECD (149, 155). Further, the U.S. EPA guidelines have been generally harmonized with those of the European Economic Community (96). This is only logical, as the United States is a member nation of the EEC and Japan belongs to the OECD. The OECD nations include Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Italy, Japan, the Netherlands, Norway, Spain, Sweden, Switzerland, Turkey, the United Kingdom, and the United States.

HAZARD CHARACTERIZATION OF PESTICIDES

Federal Insecticide, Fungicide, and Rodenticide Act

Several years after the introduction of DDT and other synthetic insecticides, the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) was passed in 1947 (169). The legislation was administered by the U.S. Department of Agriculture (USDA) and remained primarily a labeling requirement. FIFRA has been amended several times since that time and its registration provisions strengthened. Conner et al.

(89) provided a detailed review of FIFRA, with its history and regulations.
Pesticides are also regulated under the Federal Food, Drug, and Cosmetic Act (FFDCA). FFDCA was amended with Section 408 (the Miller Amendment), establishing pesticide tolerances on foodstuffs, in 1954, and Section 409, which established tolerances for food additives in processed foods, was added in 1958 (170).
Section 409 of FFDCA contains the Delaney Clause, which forbids use of carcinogens as food additives. Although Section 409 directly addresses food additives only, interpretations of this section by the U.S. EPA have

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_566.html[2010/10/28 18:45:30]

determined that pesticides, which concentrate during food processing, require food additive tolerances. Thus, the Delaney Clause applies only to pesticides, which concentrate during the processing of food. In the absence of concentration, only Section 408 applies.

Public concern for environmental and health issues as well as an interest in greater efficiency in regulations led to the formation of the U.S. EPA in 1970 (89). This new creation (162, 163) did not significantly alter the process of pesticide registration, but it did centralize it in a single agency instead of the previous two (USDA and FDA).

To protect human health and the environment, it is necessary to thoroughly evaluate health and environmental effects of all new products before manufacture and distribution. Specific toxicology study requirements for registration of pesticides around the world have been harmonized (95, 96, 149, 155, 171). As testing procedures are enhanced or new guidelines developed, these are added to the specific requirements shown in Table 13.1 (243).

Acute toxicity studies are conducted by administering the chemical orally, dermally, or by inhalation to determine the dose that causes mortality in 50% of the animals tested (LD50 or LC50). Acute studies are conducted to evaluate the irritation potential of the chemical after application to skin and eyes. Finally, the potential of the chemical to cause an allergic reaction (i.e., sensitization) is determined. Because this reaction is an all-or-nothing response, chemicals are classified as either sensitizers or nonsensitizers. Acute oral and inhalation studies are usually conducted in rats, dermal and irritation studies are conducted in rabbits or rats, and the sensitization study is carried out in guinea pigs. These tests are used to establish the product labels for all crop protection chemicals (163). The criteria used are presented in Table 13.2.

Dermal toxicity is evaluated by applying the chemical to the skin for 6 h/day for 21 days (rats) to 28 days (rabbits). Feeding studies are used to evaluate the toxicological effects of the chemical when a known dose is administered orally.

The oral feeding studies involve feeding rats, mice, or dogs diets containing the chemical for various lengths of time. Rat and mouse feeding studies are conducted for 28 days, 90 days, 1 year, and for the lifetime of the animals (24 months for rats, 18 months for mice). In dogs, the studies are usually conducted for 28 days, 90 days, 1 year, or 2 years. In all cases, animals are divided into test groups, 10 to 50 rats or mice and 4 to 6 dogs. At least four test groups are used in each study, one receiving no chemical (controls) and three groups receiving low, medium, or high concentrations of chemical in their diets. In these studies, urinalysis, hematology, and clinical chemistry parameters are evaluated, and gross and microscopic pathology examinations are performed on up to 50 tissues. Maximum tolerated doses are tested in order to demonstrate toxicity (up to 1000 mg/kg/day in the diets). In this fashion, it is possible to determine whether a chemical damages or alters any organ or tissue, and to establish levels of the chemical that produce no observable effects (no-observed effect level, NOEL) and the lowest level at which effects are noted (the lowest-observed effect level, LOEL).

Hazard testing also includes the examination of the potential of a chemical to affect the development of offspring, and to identify whether it induces birth defects in either the rat or rabbit. These tests have been described as teratology studies, but are now usually referred to as developmental toxicity studies. In addition to developmental toxicity studies, a reproduction study is conducted in rats. This study involves feeding diets containing the chemical to young adult male and female rats for approximately 3 months prior to mating. The females are allowed to produce a litter of offspring that are then reared to adulthood. The animals are fed diets containing the chemical during this entire period. After reaching sexual maturity, the second-generation animals are allowed to mate.

It was noted by Weisburger (316) that certain chemical carcinogens are capable of interacting directly with genetic material such as DNA. Based upon this association, several short-term tests to identify the alteration of genetic material or mutation were introduced into hazard testing for crop protection chemicals. These include tests to examine the possible interaction with (a) genes (gene mutation tests), (b) the chromosome (clastogenic tests), and (c) directly with DNA (classified as other tests).

Since individuals may be exposed to low levels of crop protection chemicals in their diet or water over a portion of their life span, studies to evaluate lifetime exposure are conducted in animal bioassays. An important aspect of these studies is an assessment of the potential of the chemical to cause cancer. An increase in the number of tumors or the earlier onset of tumors as a result of treatment will identify a chemical as a potential carcinogen. For laboratory studies, mice and rats are divided into at least 3 treatment groups and a control group with a minimum of 50 animals/sex/group. These groups of mice and rats are fed selected concentrations of the test chemical in their diet for 18 months and 24 months, respectively. The levels of the test chemical administered in the diet are generally selected from

repeated-dose feeding studies at least 90 days in duration, and are normally used to establish the NOEL, LOEL, and the maximum tolerated dose (MTD) (97). The MTD is defined as the highest concentration of test chemical that can be administrated that can be tolerated without causing the death of the animal; often a 10% reduction in body weight gain has been used as the criterion for establishing the MTD.

Toxicology Category	Signal Word	Oral LD50 (mg/kg)	Dermal LD50 (mg/kg)	Inhalation LC50(mg/L)	Eye Irritation	Skin Irritation
I	Danger1	Up To 50	Up To 200	Up To 0.2	Corrosive. Corneal Opacity Not Reversed In 7 Days	Corrosive
II	Warning	From 50 Through 500	From 200 Through 2000	From 0.2 Through 2.0	Corneal Opacity Reversed In 7 Days; Irritation Persisting 7 Days	Severe Irritation At 72 Hours
III	Caution	From 500 Through 5000	From 2000 Through 5000	From 2.0 Through 20	No Corneal Opacity; Irritation Reversed Within 7 Days	Moderate Irritation At 72 Hours
IV	Caution	Greater Than 5000	Greater Than 5000	Greater Than 20	No Irritation	Mild Or Slight Irritation At 72 Hours

1 The word “Poison” is used on the label if the “Danger” category is based on oral, dermal or inhalation toxicity.

Following lifetime feeding studies at the prescribed treatment levels, veterinary pathologists examine approximately 50 tissues from each animal for the presence of tumors or other evidence of tissue damage. If a statistically significant increase in the incidence of any tumor in any tissue above the incidence in the control animals is observed, then it is considered in a weight-of-evidence approach as described in the EPA cancer classification scheme (146). In a weight-of-evidence analysis, the evidence of oncogenicity in humans comes from long-term animal studies, and from epidemiology (studies of humans in exposed populations). Results from these studies are supplemented with available information from other sources that include mutagenicity and other short-term tests (for genetic effects), metabolic or kinetic studies, and other relevant toxicological studies. Using this approach, the oncogenic response is classified into one of several categories as indicated in Table 13.3.

The U.S EPA has essentially taken the approach that animal tumorigens are human carcinogens (146). This approach has been taken as a default assumption almost without regard to quality of the study, the level of test material administered, or the mechanism by which the tumor response is manifest (166). In this regard, all animal carcinogens are treated as though they have no threshold or there is a real risk at all exposure levels. The U.S. EPA has published a list identifying crop protection chemicals as known, probable, or possible human carcinogens without appropriate consideration of the mechanism by which the tumors occur or their relevance to humans (150).

However, most of the other OECD and EEC countries have long recognized that genotoxic agents exist (96, 168). For genotoxic agents, there is evidence of mutagenic and/or clastogenic responses in standard laboratory tests, and nongenotoxic chemicals are devoid of any mutagenic and/or clastogenic behavior (150). It is considered that genotoxic agents will most likely be carcinogenic in animal tests and most probably will be human carcinogens (168). These genotoxic carcinogens would be regulated as if they are devoid of a threshold, and it would be assumed that there would be a risk at all doses. On the other hand, nongenotoxic agents would be charac

Table 13.3 U.S. Environmental Protection Agency's classification of carcinogens

Carcinogen Category	Criteria for Classification	Evaluation: Uncertainty Factor	Evaluation: Mathematical Modeling
A—Human	Sufficient evidence in man		X
B—Probable Human	B1 · Limited evidence in man · Sufficient evidence in animal (two species with tumors)		X
	B2 · Inadequate human evidence · Sufficient animal evidence		X
C—Possible Human	· No evidence in man · Limited evidence in animals	X or	X
D-Not Classifiable	· Inadequate animal or human evidence	X	
E—Not a Human Carcinogen	· Sufficient animal testing with no evidence of carcinogenicity and human experience	X	

terized as having thresholds and a safety factor would be used.

Although new U.S. EPA guidelines for cancer classification based on animal data are in development (192), they have not been finalized.

Food Quality Protection Act of 1996

The Food Quality Protection Act (FQPA) amendments to the Food Drug and Cosmetic Act (170) and FIFRA (169), direct the U.S. EPA to consider a number of factors in assessing risk as part of the tolerance setting procedure (5). FQPA 1996 provides for a single, health-based standard, eliminates long-standing problems posed by multiple standards for pesticides in raw and processed foods, and requires the U.S. EPA to consider all nonoccupational sources of exposure, including drinking water, and exposure to other pesticides with a common mechanism of toxicity when setting tolerances. Most of these provisions *originally reflected* concerns that children may be especially susceptible to pesticide exposure and embodied key recommendations of a National Academy of Sciences report, "Pesticides in the Diets of Infants and Children" (153). The FQPA directs the U.S. EPA to set a tolerance for pesticide residues in food. In order to accomplish this task, the U.S. EPA uses an extra 10-fold safety factor to account for susceptibility of chil dren including effects of in utero exposure and to evaluate the cumulative effects of exposure to the pesticide. Further, the agency is directed to consider substances having a common mode of action and to consider aggregate exposure for all consumers (i.e., other routes, such as drinking water). Finally, the agency must define techniques for evaluating potential for endocrine-disrupting effects.

Unlike previous law, which contained an open-ended provision for the consideration of pesticide benefits when setting tolerances, the new law places specific limits on benefit considerations. Benefits cannot be considered for pesticides that result in reproductive or other threshold effects.

In addition, FQPA 1996 reauthorizes Federal Insecticide, Fungicide, and Rodenticide Act provisions (FIFRA) and requires tolerances to be reassessed as part of the reregistration program (5). Further, it expedites review of safer pesticides to help them reach the market sooner and replace older and potentially more risky chemicals. Minor-use pesticides and antimicrobial pesticides are given greater attention under this new law.

FUNGICIDES

The world market for agricultural and noncrop fungicides amounted to nearly $6 billion in 1995 (139). The

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_570.html[2010/10/28 18:45:32]

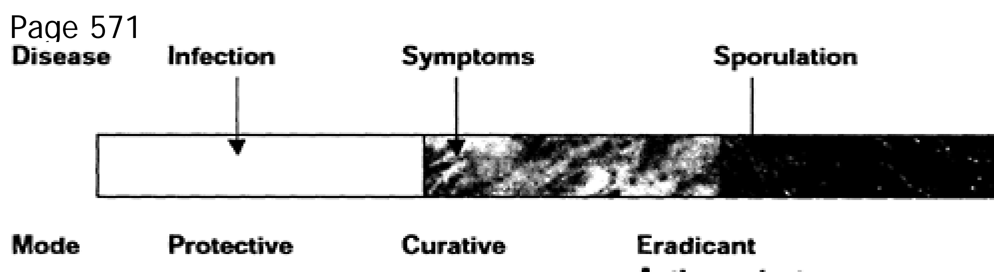

FIG. 13.2. Representation of the disease process and efficacy by mode of action.

United States, western Europe, and Japan accounted for 75% of the total world market. Tree fruits and nuts, citrus, and grapes constitute the largest market for fungicides worldwide. This sector was 28.5% of the total world market, followed by cereals, rice, vegetables, and potatoes. In western Europe, half of the $2 billion spent for fungicides was used on wheat and barley, followed by vines, tree fruits, and other crop and noncrop markets. For the Japanese market of over $1 billion, about 40% of the fungicides were applied to rice, with vegetables and tree fruits the next most important market. The U.S, market for fungicides amounted to about $800 million, with tree and vine crops accounting for 30%, followed by turf ornamentals, then vegetable crops, and finally peanuts and potatoes.

Fungicides have been classified in several different manners. Mode of action in affecting the development of fungal diseases is one of the systems used. Schematically, the disease process along with the mode of action for fungicides is presented in Figure 13.2 (91).

A *protective* or *preventative* mode of action is ascribed to fungicidal activity when the disease is prevented. *Curative* relates to activity that interrupts the development of established infection. An *eradicant,* as the name implies, stops the development of the disease after symptoms are visible in the plant, and an *antisporulant* stops or decreases spore production. Mode of action and mechanism of action determine the major classes of fungicides used in crop protection, presented in Table 13.4.

Individual fungicides representing each mode of action are discussed here. It is not feasible to discuss all fungicides within the scope of this chapter. Therefore, no attempt to consider every fungicide within a group has been made. Instead, an attempt was made to consider only those fungicides with current significant economic importance or use. Therefore, discussions focus on selected agents.

Anilinopyrimidines

The spectrum of activity for anilinopyrimidines is limited to *Ascomycetes* and *Deuteromycetes* (27). Their unique mode of action of inhibiting methionine biosynthesis as well as protease secretion necessary for infection affords both protective and curative action. The anilinopyrimidines are used to control gray mold on vines, fruits, vegetables, and ornamentals, and leaf scab on pome fruit. The anilinopyrimidines are a new class of fungicides currently represented by two commerically available products. The structures, uses, and hazard profiles of cyprodinil and pyrimethanil are presented in Table 13.5.

The profiles for the mammalian toxicity studies conducted with these fungicides suggest minimal hazard to humans from their use (224, 231).

Benzanilides

Benzanilides, which inhibit the succinate dehydrate complex in the electron transport chain and thus stop the synthesis of aspartate and glutamate, are represented by flutolanil (43). Flutolanil is a systemic fungicide with protective and curative action. It is used for control of sheath blight, white mold, and snow blight in rice, cereals, sugar beet, and other crops. The structure, uses, and hazard profile of flutolanil are given in Table 13.6.

It exhibits minimal acute toxicity and possesses a good hazard profile (186).

Benzimidazoles

The benzimidazoles have broad-spectrum activity in the inhibition of mitosis by preventing polymerization of beta-tubulin (15). Important members of this class are benomyl, thiabendazole, and thiophanate-methyl. Their structures, uses, and hazard profiles are presented in Table 13.7.

The hazards for benomyl, thiabendazole, and thio-phanate-methyl have been carefully reviewed by either the U.S. EPA or WHO (106, 132, 216). Benomyl has been classified as Category C (possible human carcinogen) based on mouse liver tumors (100).

Page 572

Table 13.4 Mode and mechanism of action for important classes of fungicides used in crop protection

Class	Mode of Action	Mechanism of Action
Anilinopyrimidines (27)	Curative and protective	Inhibition of methionine biosynthesis and protease secretion enzymes
Benzanilides (16)	Curative and protective	Inhibits fungal respiration at succinate dehydrogenase complex
Benzimidazoles (15)	Curative and protective	Inhibition of mitosis by preventing polymerization of tubulin in a broad spectrum of fungi
Phenylamides (54)	Curative and protective	Inhibition of RNA synthesis
Sterol Biosynthesis sterol Inhibitors (26)	Curative, protective, and eradicants	Interferes with biosynthesis essential for cell wall formation
Strobilurins (12)	Curative, protective, and antisporulants	Disruption of electron transport in cytochrome bc1 complex
Dicarboximides (53)	Protective, and antisporulants	Inhibition of spore germination
Dithiocarbamates (39)	Protective	Interferes with oxygen uptake and inhibits sulfur-containing enzymes
Ethylenediothio-carbamates (54)	Protective	Breaks down to cyanide which reacts with thiol compounds in the cells and interferes with sulfhydryl groups
Inorganic (23–25, 74)	Protective	Blocks enzymes and stops respiration
Organometallics (37)	Protective, some curative and antisporulant	Destroys cell membranes, and inhibits metabolism and respiration
Phenylpyrroles (35)	Protective	Interferes with membrane transport
Phthalimides (16)	Protective and curative	Inhibits enzymes by thiophosgene production
Substituted Benzenes (20)	Protective	Inhibits sulfur-containing enzymes

Phenylamides

This class of fungicides includes two products, metalaxyl and mefenoxam (55). Metalaxyl is a mixture of *R* and *S* enantiomers. Mefenoxam is the *R* enantiomer of metalaxyl. The spectrum of activity for mefenoxam is quite narrow controlling downy mildew and late blight; it is used in maize, peas, sorghum, sunflowers, and tobacco (55).

Mefenoxam is efficacious at approximately half the rate of metalaxyl; therefore, the registration of metalaxyl has been voluntarily canceled (180, 218). The structure, uses, and hazard profile for mefenoxam are presented in Table 13.8.

Table 13.5 Structures, uses, and hazard profiles for major anilinopyrimidine fungicides

Fungicide	Structure	Crops/uses	Use Rates gm (a.i.)/ha
Cyprodinil Vangard® (27)		Used on cereals, grapes, pome fruit, stone fruit, almonds, strawberries, vegetables, field crop and as a seed dressing	95–160
Pyrimethanil Mythos®, Scala ® (68, 224)		Used on pome fruit, vine crops, vegetables and ornamentals.	1000–3000

Fungicide	Irritation		LD50 (mg/kg)		LC50 (mg/L)	Sensitizing	Signal
	Eye	Skin	Oral	Dermal	Inhalation	Potential	Word
Cyprodinil (27)	Minimal Irritant	Slight Irritant	2796	>2000	>1.2	Positive	Caution
Pyrimethanil (68)	Slight Irritant	Non-irritant	>4149	>5000	>1.98	No positive	Caution

Fungicide	Species/study	NOEL1 (mg/kg/day)	Toxicity Studies	Hazard Indicator
Cyprodinil (231)	Rat/2-year	3.75	Mutagenicity	No evidence
	Dog/52-week	65.6	Developmental	Not teratogenic
	Mouse/18-month	16.1 ♂	Reproductive	No evidence
	RfD2	0.038	Oncogenicity	E(No evidence)3
Pyrimethanil (224)	Rat/2-year	20	Mutagenicity	No evidence
	Dog/52-week	30	Developmental	Not teratogenic
	Mouse/18-month	211 ♂	Reproductive	No evidence
	RfD2	0.2	Oncogenicity	C with RfD3 (thyroid tumors in rats)

1 No observable effect level
2 RfD=reference dose
3 See Table 13.3 for US EPA classification scheme

Mefenoxam is without any significant hazard to humans.

Sterol Biosynthesis Inhibitors

The sterol biosynthesis inhibitors or sterol demethylase inhibitors (DMIs) group are comprised of imidazoles, piperazines, pyridines, pyrimidines, and triazoles that produce their effect on fungi by inhibition of the synthesis of ergosterol (26). Ergosterol is essential for cell-wall integrity in fungi. The

structures and crop uses for the most prominent DMIs are given in Table 13.9.
The ability of these fungicides to inhibit cytochrome P450 demethylase required for the synthesis of ergosterol

Table 13.6 Structure, uses and hazard profile for flutolanil (Folistar®) (187)

Structure	Crops/uses	Use Rates gm (a.i.)/ha
	Used on rice, cereals, sugar beets, fruits, and vegetables	NA

Irritation		LD50(mg/kg)		LC50(mg/L)	Sensitizing Potential	Signal Word
Eye	Skin	Oral	Dermal	Inhalation		
Slight Irritant	Non-irritant	>10000	>5000	>6.0	Negative	Caution

Species/study	NOEL1 (mg/kg/day)	Toxicity Studies	Hazard Indicator

NA=Not Available

in fungi also occurs in mammalian systems and often manifests itself as an induction of liver cytochrome P450 as well as inhibiting these enzymes (31). Inherent in the chemical structure of these compounds is specificity to alter the activity of cytochrome P450 isozymes responsible for the metabolism of steroids, or xenobiotics. In some instances, these liver effects are seen following chronic feeding as liver tumors in the mouse. The hazard profiles for the selected sterol biosynthesis inhibitors are presented in Table 13.10 and 13.11.

Several fungicides produce liver tumors in mice, but all are not genotoxic. Cyproconazole (177) and triadimenol (112) elicit some evidence of developmental toxicity.

Strobilurins

The strobilurins inhibit mitochondrial respiration by blocking electron transfer between cytochrome *b* and cytochrome *c*1 (12). These materials have their origins as a natural substance derived from mushrooms and are modified synthetically. Numerous chemicals in this class are under development, but only one strobilurin is available commercially, azoxystrobin. Azoxystrobin has a broad mode of action that includes protective, eradicant, and antisporant activity. The structure, uses, and hazard profile for azoxystrobin are presented in Table 13.12.

Azoxystrobin presents a rather innocuous hazard profile (196).

Inorganic Fungicides

Inorganics, such as sulfur, were used before 1000 BC as previously discussed (102). Yet elemental sulfur and forms of copper (hydroxide, oxychloride, and sulfate) are the only commercially significant fungicides in this class remaining in use. The mode of action of the inorganic fungicides is protective or preventative; they exert their effects by blockage of enzymes and inhibiting respiration (74). These materials are cheap and are applied at high use rates, from thousands to ten thousand of grams per hectare. Severe eye irritation is seen with copper hydroxide (23); copper oxychloride and copper sulfate do not exhibit this inherent hazard (24, 25).

Table 13.7 Structures, uses, and hazard profiles for important benzimidazoles

Compound	Structure	Crops/uses	Use Rates gm (a.i.)/ha
Benomyl Benlate® (15)		Used against *Ascomycetes* and *Basidomycetes* in cereals, grapes, pome and stone fruit, rice and vegetables.	Field: 140–550 Tree: 550–1100 Storage; 25–200
Thiabenazole Mertech® (77)		Used for the control of *Aspergillus, Botrytis,* and others in vegetables, bananas, cereals, cabbage, stone fruit, citrus fruit, and hops.	~250
Thiophanate-methyl Topsin-M® (78)		Used for eyespot on cereals, scab and rot on apples and pears, powdery mildew on pome fruit, stone fruit, vegetables, strawberries, and vines	30–50

Fungicide	Irritation Eye	Skin	LD50 (mg/kg) Oral	Dermal	LC50 (mg/L) Inhalation	Sensitizing Potential	Signal Word
Benomyl (15)	Moderate Irritant	Slight Irritant	>10000	>5000	>2.0	Negative	Caution
Thiabendazole (51)	Non-irritant	Non-irritant	3100	>2000	>0.4	Negative	Caution
Thiophanatemethyl (78)	Moderate Irritant	Mild Irritant	6640 ♀	>10000	>5.0	Negative	Caution

Fungicide	Species/study	NOEL1 (mg/kg/day)	Toxicity Studies	Hazard Indicator
Benomyl (132, 173)	Rat/2-year	125	Mutagenicity	No evidence
	Dog/52-week	12.5	Developmental	Inconclusive evidence
	Mouse/18-month	40	Reproductive	Decreased fertility

Page 576

Table 13.8 Structure, uses, and hazard profile for the phenylamide fungicide mefenoxam

Fungicide	Structure	Principle Uses/Crops	Application Rate gm(a.i.)/ha
Mefenoxam (Metalaxyl-M) Ridomil Gold® (55)		Used on alfalfa, apples, asparagus, avocadoes, berries, citrus, cole crops, cotton, cucurbits, hops, peanuts, stone fruit, soybeans, sugar beets, tobacco and vegetables.	70–1680

Fungicide	Irritation Eye	Irritation Skin	LD50 (mg/kg) Oral	LD50 (mg/kg) Dermal	LC50 (mg/L) Inhalation	Sensitizing Potential	Signal Word
Mefenoxam (55)	Severe Irritant	Slight Irritant	490	>2000	>2.3	Negative	Warning

Fungicide	Species/study	NOEL1 (mg/kg/day)	Toxicity Studies	Hazard Indicator
Mefenoxam (199, 218)	Rat/2-year	13	Mutagenicity	No evidence
	Dog/52-week	8	Developmental	Not teratogenic
	Mouse/18-month	38	Reproductive	No evidence
	RfD(based on 6Month Dog)2	0.08	Oncogenicity	No evidence

1 No observable effect level

2 RfD=reference dose

Elemental sulfur is considered practically nontoxic to humans and animals (74).

Dicarboximides

The dicarboximides have a narrow spectrum of activity with strengths on *Botrytis*, *Sclerotinia*, *Monifinia*, and *Altemaria*. These fungicides appear to inhibit spore germination (51). The dicarboximides are used to treat infections in turf, strawberries, stone fruit, peanuts, and vines. Iprodione and vinclozolin represent the dicarboximide fungicides; the structures, uses, and mammalian toxicology for these agents are presented in Table 13.13.

Iprodione interferes with androgen synthesis (134); this effect results in testicular effects including interstitial-cell tumors in male rats at feeding levels of 1600 ppm and above. Vinclozolin has been shown to be metabolized to antiandrogenic metabolites, 2–1[(3,5-dichlorophenyl) carbamoyl] oxyl-2-methyl-3-butenoic acid and 3,5′-dich-loro-2-hydroxy-2-methylbut-3-enanilide, that appear to lead to infertility in male rats (140). This response is thought to be due to feminization of the outer genital organs of males exposed during development to a dietary concentration of 1000 ppm or more of vinclozolin (227).

Dithiocarbamates

The dithiocarbamates are broad-spectrum protective fungicides with multiple sites of action (39). They are use to control scab on pome fruit, blue mold on tobacco, rust on ornamentals, and diseases on vegetables. These agents interfere with oxygen uptake and inhibit sulfur-containing enzymes. The dithiocarbamates are applied at rates of 500 to over 10,000 g/hectare. Ferbam, thiram, and ziram are the commercially important chemicals in this group. Their structures, uses, and hazard profiles are given in Table 13.14.

Ferbam, thiram, and ziram have significant acute toxicity by the inhalation route. Both ferbam and ziram have been shown to alter spermatazoa in mice and thus would be placed under the endocrine disruptor category as suggested in the FQPA 1996 (5).

Table 13.9 Selected sterol synthesis inhibitors

Fungicide	Structure	Crops/uses
Cyproconazole Alto® (26)		Cereal, sugar beets, fruit trees, vines, coffee, turf, bananas, and vegetables for treatment of rust, powdery mildew, *Septoria*, *Venturia*, and others.
Difenoconazole Dividend® (31)		Seed treatment, grapes, fruit trees, potatoes, sugar beets, oilseed rape, banana, ornamentals and vegetables for treating a variety of fungal diseases.
Fenbuconazole Indar® (34)		Cereals, fruit trees, vines, beans, sugar beets, rice, bananas, ornamentals, tree nuts and vegetables
Hexaconazole Amizol® (46)		Vine, coffee, bananas, peanuts, and vegetables for treating a variety of fungal diseases.
Myclobutanil Rally®, Nova® (58)		Seed treatment, grapes, fruit trees, rice, cotton, barley, wheat, maize, grass seed, ornamentals and vegetables for treating a variety of fungal diseases
Propiconazole Tilt® (64)		Wheat, rice, coffee, bananas, peanuts, stone fruit, maize and turf for treating a variety of fungal diseases. Rates: 24 to 110 gm (a.i.)/ha
Tebuconazole Folicur® (75)		Seed treatment, cereals, coffee, fruit trees, grapes, grass seed, oilseed rape, soybeans, sugar beets, bananas, ornamentals, turf and vegetables for treating a variety of fungal diseases

Triadimefon Bayleton® (80)	Cereals, corn, fruit trees, vines, berries, sugar cane, tobacco and vegetables for treating a variety of fungal diseases
Triadimenol Baytan® (82)	Seed treatment, cereals, fruit trees, hops, vines and vegetables for treating a variety of fungal diseases
Imazalil Fungaflor® (48)	Seed, fruit trees, potatoes, bananas, vegetables, ornamentals and cereals for treating a variety of fungal diseases. Rates of 4–5 (a.i.) 100 kg seed
Prochloraz Sportak® (62)	Citrus, tropical fruit (dip), beets, oilseed rape, mushrooms, ornamentals and cereals (seed treatment). Rates: 400–600 gm (a.i.)/ha

Ethylenebisdithiocarbamates

The ethylenebisdithiocarbamates (EBDCs) have a broad spectrum of activity, although their mode of action is primarily protective. Their mechanism of action is to break down to the cyanide that reacts with thiol compounds in the cell and thus interferes with sulfhydryl groups (53).

The structures of mancozeb, maneb, and zineb, the three most important members of this class, are presented

Table 13.11 Hazard profile for more sterol synthesis inhibitor fungicides

with their toxicologically significant metabolite, ethylen-ethiourea, in Figure 13.3.
The hazard profiles for mancozeb, maneb, and zineb are presented in Table 13.15.
Both mancozeb and maneb are classified as B2, probable human carcinogens (100), based on the formation of mouse liver tumors and/or thyroid follicular cell tumors in rats. Although zineb was not found to be oncogenic in the rat or mouse, it was observed to produce nonneoplasic hyperplasia of the follicular cells of the thyroid in rats (217). All three fungicides are metabolized to ethylenethiourea. This is known to inhibit thyroid peroxidase and to cause progressive lesions in the thyroid follicular cells, often leading to tumor formation (126, 127, 129). The U.S. EPA has regulated the risk associated with the EBDCs using a cancer slope factor of 0.06 $(mg/kg/day)^{-1}$ (216).

Organometallic Fungicides

The organometallic fungicides are limited in spectrum of disease control, but are effective as protective, curative, and antisporulants in early and late blight, scab, leaf blotch, and powdery mildew (37).
Triphenyltin, whose structure, uses, and hazard profile are presented in Table 13.16, works through destruction of cell membranes and inhibition of respiration (37).
Triphenyltin hydroxide has been classified by the U.S. EPA as category B2, probable human carcinogen, based on mouse liver and pituitary and testicular tumors in rats (100).

Phenylpyrroles

The phenylpyrrole fungicides are a recent entry into the marketplace. They represent a new mechanism of action through interference with membrane transport (35). The structures, uses, and hazard profiles of these two new fungicides, fenpiclonil and fludioxonil, are presented in Table 13.17.
Both of these products are not acutely toxic, and do not exhibit remarkable toxicity profiles. Fludioxonil represents an exception as it has been classified as a category D or nonclassifiable in regard to carcinogenicity. This conclusion is based on the statistically significant increase in liver tumors in female rats for combined adenoma/carcinoma only. Despite the lack of a tumorigenic response in male rats or in either sex of the mouse, additional mutagenicity studies have been required (202).

Phthalimides

The phthalimide fungicides represent a relatively old group of synthetic chemicals. Of this group of fungicides, only captan remains significant in regard to use. Captan has a broad spectrum of activity that owes its action to degradation to thiophosgene (16). The structure, uses, and hazard profile of captan are given in Table 13.18.

Captan has been shown to bind to DNA in vitro but not in vivo. Further, captan is classified by the U.S. EPA as category B2, probable human carcinogen, based on gastrointestinal-tract tumors in the mouse (100).

FIG. 13.3. Structures for ethylenedithiocarbamate fungicides.

Substituted Benzenes

The substituted benzene fungicides have a broad spectrum of activity and are considered protective. Chlorothalonil, in this class, controls fungal infection by inhibiting sulfur-containing enzymes (20). The structure, uses, and hazard profile of chlorothalonil are given in Table 13.19.

The U.S. EPA has classified chlorothalonil as B2, probable human carcinogen, based on kidney and forestomach tumors in both rats and mice (100, 201).

INSECTICIDES

In 1995, insecticide worldwide sales represented $3.5 billion and 13.7 million lb of product (1). Discussion of insecticides here emphasizes the major classes of commercial compounds by mode of action. Discussion of insecticide mode of action focuses on their interactions with cell-membrane proteins and the resulting expression of toxicity in the insect (8). No attempt is made to include all the important compounds within a group.

The modes and mechanisms of actions for these major groups of insecticides are included in Table 13.20.

Many of these classes are newly discovered and often originate from nature (8).

Acetylcholine Mimics

Nicotine has been used as an insecticide since the middle of the 18th century (102). Nicotine exhibits contact activity in insects and across phyla including humans (264). Nicotine mimics the action of acetylcholine, which is a major excitatory neurotransmitter in the insect central nervous system (CNS). After the presynaptic cell releases acetylcholine, it binds to the postsynaptic nicotinic acetylcholine receptor and activates an intrinsic cation channel. This results in depolarization of the postsynaptic cell due to an influx of sodium and calcium ions. The synaptic action of acetylcholine is terminated by the enzyme acetylcholinesterase, which rapidly hydrolyzes the ester linkage in acetylcholine. This activity is depicted in Figure 13.4.

A newer compound in this class is the nitroguanidine, imidacloprid. Imidacloprid generally works best as a stomach poison, and has plant systemic activity (50). Nicotine and imidacloprid activate the nicotinic acetylcholine receptors. This persistent activation leads to an overstimulation of cholinergic synapses, and results in hyperexcitation, convulsions, paralysis, and death of the insect (152). The structures, uses, and hazard profiles of these products are presented in Table 13.21.

Imidacloprid is much less toxic to mammals than nicotine (214).

Carbamates

In contrast to the nicothinoids, the carbamate insecticides inhibit acetylcholinesterase (AChE) so that acetylcholine is not destroyed, resulting in continued stimulation of cholinergic receptors. Carbamates behave in biological systems almost identically to the organophosphate insecticides. Carbamate insecticides exist as esters of carbamic acid, typically having an aryl (ring) substituent as the leaving group. The interaction of the carbamate insecticide with acetylcholinestherase (AChE) is depicted in Figure 13.5.

Carbamates react with the serine group on acetylcholinesterase to yield a carbamylation of the serine hydroxyl group. A hydoxylated leaving group is also

generated. The central nervous system is the site of action of carbamates, and the signs of intoxication are similar to those of the organophosphates. The carbamylation of AChE is reversible, unlike the phosphorylation of the AChE by organophosphate insecticides. The carbamylated complex will typically hydrolyze in minutes (8).

The structures and uses of some representative members of this class are given in Table 13.22.

The carbamates are often highly toxic to mammals and must be handled carefully. The hazard profiles of these selected carbamates are presented in Table 13.23.

Aldicarb is the most acutely toxic of the selected carbamates, with an oral LD50 below 1 mg/kg as well

as a dermal LD50 of 20 mg/kg. Aldicarb, carbofuran, methomyl, and propoxur have been classified as category C (possible human carcinogens) or D(aldicarb) by the U.S. EPA (100). These four materials elicited liver tumors in mice in the 18-month studies.

Organophosphorus Insecticides

Organophosphorus insecticides (OPs) vary tremendously in chemical structure and chemical properties (8).

These chemicals are classified into groups depending on the positioning of the central phosphorus—hence their classification as phosphates, phosphonates, phosphorothionates, phosphorodithioates, and phosphoroamidothioates. Selected examples representing these different groups are presented in Table 13.24.

The OPs react with acetylcholinesterase at the serine hydroxyl group within the enzyme active site. In this reaction, this hydroxyl group is phosphorylated, yielding a leaving group (Figure 13.6).

FIG. 13.6. Representation of the interaction of organophosphate insecticides with acetylcholinesterase. The phosphorylated acetylcholinesterase is inactivated, blocking acetacholine degradation in the synapse. This results in a buildup of this neurotransmitter and central nervous system hyperstimulation. The signs of intoxication include restlessness, hyperexcitability, tremors, convulsions, and paralysis. Reactivation of the enzyme can take many hours or even days. The toxicologic profiles for selected OPs are presented in Table 13.25.

GABA Agonists (Avermectins)

The avermectins are a group of closely related macrocyclic lactones isolated from the fungus *Streptomyces avermitilis* (Turner and Schaeffer, 1989). The structures of abamectin and emamectin-benzoate, the commercially available insecticides in this class, are shown in Figure 13.7. In addition to the avermectins,

Table 13.20 Mode and mechanism of action for important classes of insecticides used in crop protection

Class	Mode of Action	Mechanism of Action
Acetylcholine Mimics (50, 59)	Systemic acting as a contact and stomach poison	Bind to acetylcholine receptor
Cholinesterase Inhibitors (10, 11)	Systemic acting as a contact and stomach poison	React with a serine hydroxyl group within the enzyme active site and inactivates the enzyme blocking the degradation of the neurotransmitter acetylcholine.
GABA (γ-amino-butyric acid) Agonists (9)	Systemic acting as contact and stomach poison	Act by stimulating the release of GABA, an inhibitory neurotransmitter, by increasing chloride ion flux at the neuromuscular junction.
GABA Antagonists [Channel Blockers] (33)	Non-systemic acting as contact, stomach, and respiratory poison	Act antagonistically at the GABA receptor-chloride channel complex
Compounds Affecting Voltage-Dependent Sodium Channels (36)	Non-systemic acting as contact and stomach poison	Prolong the current flowing through sodium channels by slowing or preventing the shutting of the channels
Juvenile Hormone Mimics (32)	Insect growth regulator preventing metamorphosis to viable adults	Mimic the action of the juvenile hormones and disrupts molting and reproduction
Molt Inhibitors (76)	Systemic acting to inhibit molting and feeding	Inhibit chitin synthesis
Ecdysone Agonists (249)	Lethally accelerates the molting process	Act by binding to the receptor site for ecdysone
Larvicides (28)	Insect growth regulator with contact action	Inhibit embryo development interfering with molting and pupation
Pheromones (147)	Modifies the behavior of other individuals of the same species	Volatile chemicals, natural or synthetic, act for signaling and homing
Respiratory Inhibitors and Uncouplers (19)	Non-systemic acting against all stages of insect development	Inhibit mitochondrial electron transport

spinosad is derived from the fungus *Saccharopolyspora spinasa* (Figure 13.7).

The mode on action of these three products in insects is paralysis. The avermectins stimulate the release of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) at the neuromuscular junction (88, 167). The agonistic release of GABA evokes an electrical activity in vertebrate and invertebrate nerve and muscle by increasing the membrane conductance to chloride ions. The ionic concentration within the neuron increases continuously until a trigger level is reached and the action potential is produced. This activity is depicted in Figure 13.8.

Table 13.21 The hazard profile for the acetylcholine mimic insecticides

Fungicide	Structure	Principle Uses	Application Rate gm (a.i.)/ha

NA=Not Available

Avermectin intoxication in mammals begins with hyperexcitability, tremors, and incoordination, and later develops into ataxia and coma-like sedation (141). The toxicity profiles of abamectin, emamectin-benzoate, and spinosad are given in Table 13.26.

Both abamectin and emamectin benzoate have the propensity to produce neurotoxicity. This toxicity is reduced or prevented in test animals having a fully intact P-glycoprotein blood-brain barrier. Much of the early testing of the hazards of these avermectins was performed in the CF-1 mouse. The CF-1 mouse has been found to be heterozygous for P-glycoprotein and has been ruled out as an experimental model for human risk assessment (122, 142, 143, 251).

Channel Blockers

Organochlorines

The channel-blocking convulsants represent one of the oldest groups of synthetic organic insecticides, dating back to the early 1940s (148). These lipophilic compounds were found to be environmentally stable and persistent, and many, like dieldrin, endrin, and DDT, have been

Table 13.22 Structures and uses of selected carbamate insecticides

Insecticide	Structure	Principle Uses/Crops	Treatment Rate gm (a.i.)/ha
Aldicarb Temik® (11)	$H_3C{-}S(CH_3)_2{-}CH{-}N{-}C(=O){-}N(CH_3)H$	Controls chewing and sucking insects in vegetables and crops.	350–5600
Carbaryl Sevin® (17)	$OCONHCH_3$	Controls chewing and sucking insects in vegetables and various crops	250–2000
Carbofuran Furadan® (18)	$OOCNHCH_3$, O, CH_3, CH_3	Controls soil dwelling and foliar feeding insects in food crops	260–2050
Methomyl LanoxC® (56)	$CH_3C(SCH_3){=}NOC(=O)NHCH_3$	Controls chewing and sucking insects in vegetables, food crops and turf.	120–2000
Propoxur Aprocarb® (65)	$OOCNHCH_3$, $OCH(CH_3)_2$	cockroaches, flies, fleas, ants, and mosquitoes	NA

banned in the United States. However, some of the more biodegradable materials like lindane and endosulfan still find use today. Fipronil is an aryl heterocycle with a similar mode of action, but improved selective toxicity toward insects.

In both insects and mammals, chloride channelblocking insecticides cause hyperexcitability and convulsions (7). These effects occur via poisoning of the CNS through antagonism of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Normally, when GABA is released from the presynaptic nerve terminal, it binds to a postsynaptic receptor protein containing an intrinsic chloride ion channel. When GABA binds to the receptor, the channel is opened, and Cl ions flow into the postsynaptic neuron (see Figure 13.8). This chloride permeability can significantly hyperpolarize the membrane potential and has a dampening effect on nerve impulse firing. The structures, uses, and toxicology profiles for selected channel blockers are given in Table 13.27.

The organochlorine channel-blocking insecticides are generally not mutagenic, developmental, or

reproductive toxins or oncogenic.

Pyrethroids

The pyrethroid insecticides, typically esters of chrysanthemic acid, were isolated from the flowers of

Page 592

chrysanthemums (160). Synthetic pyrethroid chemistry and action are classified as Type 1 or Type 2, depending on the alcohol substituent (6). The members of the Type 1 group are generally unstable in the environment, which has prevented their use in row crops. The Type 2 pyrethroids are more narrowly defined in terms of their chemical structure. They specifically contain an α-cyano-3-phenoxybenzyl alcohol, which increases insecticidal activity about 10-fold.

The signs of intoxication by pyrethroids develop rapidly, and there exist different poisoning syndromes for the two types of compounds (6). Type 1 pyrethroids

cause hyperexcitability and convulsions in insects and a whole-body tremor in mammals. Type 2 pyrethroids cause ataxia and incoordination in insects, and writhing and salivation in mammals.
Pyrethroid intoxication results from their potent effects on nerve impulse generation within both the central and peripheral nervous systems. The nerve impulse or action potential consists of a transient depolarization driven by an influx of Na^+ ions, followed by the efflux of K^+ ions. This activity is depicted in Figure 13.9.

Type 1 compounds induce multiple spike discharges in peripheral sensory and motor nerves, as well as interneurons within the central nervous system (CNS). Type 2 pyrethroids depolarize the axon membrane potential, which reduces the amplitude of the action potential and eventually leads to a loss of electrical excitability. These effects occur because pyrethroids prolong the current flowing through sodium channels by slowing or preventing the shutting of the channels.

The structures and uses of some of the economically important representatives of both types of pyrethroids are given in Table 13.28.

All of these synthetic pyrethroids are generally used in the low grams per hectare range because of their toxicity to insects. The mammalian toxicity profiles of these materials are given in Table 13.29.

Both fenvalerate and lambda-cyhalothrin are acutely toxic by the oral and inhalation route. Lambda-cyhalothrin and permethrin have some potential to produce neurotoxicity, and both exhibit some weak oncogenic potential in animal models.

Endotoxins

Bacillus Thuringiensis

Bacillus thuringiensis (Bt) is an aerobic spore-forming gram-positive, rod-shaped bacterium. At sporulation, Bt forms a crystalline inclusion body that contains a number of insecticidal protein toxins (13). When consumed by the insect, the inclusion is dissolved in the midgut and releases δ-endotoxins. The toxin proteins contain a few hundred to over 1000 amino acids. After they are ingested, the δ-endotoxins are cleaved to an active form by proteases within the midgut. The active toxins bind specifically to the membranes of the midgut epithelia and alter their ion permeability properties by forming a cation channel or pore. Ion movements through this pore disrupt potassium and pH gradients and lead to lysis of the epithelium, gut paralysis, and death (99).

Bt has been used directly as a preparation created from grinding up insects infected with Bt or genetically engineered into plants. In regulating this insecticide, the U.S. EPA considered that microbial preparations

of Bt have been commercially available for the last 30 years. As these bacterial strains are found in nature, the mammalian hazard test requirements are not as extensive as for synthetic pesticides (197, 229). Generally, the hazard tests performed are acute oral toxicity, in vitro digestibility under gastric conditions, and amino acid homology evaluations and comparisons.

Insect Growth Regulators

Juvenile Hormone Mimics

The juvenile hormone mimics (JHMs) are compounds bearing a structural resemblance to the juvenile hormones of insects. Juvenile hormones are lipophilic sesquiterpenoids containing epoxide and methyl ester groups. The JHMs mimic the action of the juvenile hormones on a number of physiological processes, such as molting and reproduction. Exposure to these compounds at molting results in the production of insects containing mixed larval/pupal or larval/adult morphologies. The efficacy of these compounds is greatest when normal juvenile hormone titers are low, namely, in the last larval or early pupal stages (8, 263). Thus, timing of application is important for successful control. Another useful property of these compounds is that, in adults, they disrupt normal reproductive physiology.

The structures, uses, and hazard profiles of three of these compounds are presented in Table 13.30. All three of these compounds have excellent acute and repeated-dose hazard profiles.

Molt Inhibitors

These compounds are classified as benzoylphenylureas and possess a number of halogen substituents. Insects exposed to these compounds are unable to form normal cuticle because the ability to synthesize chitin is lost. Fifty percent of the cuticle is comprised of chitin, which is a polysaccharide of *N*-acetylglucosamine. In the absence of chitin, the cuticle is unable to support the insect.

The compounds are generally not very toxic to mammals but exhibit a high degree of lipophilicity and are stored in the fat. The structures, uses, and hazard profiles of diflubenzuron and teflubenzuron are presented in Table 13.31.

Diflubenzuron and teflubenzuron have excellent hazard profiles with no evidence of significant developmental or reproductive toxicity; neither is carcinogenic.

Molt Accelerators or Ecdysone Agonists

The ecdysone agonist tebufenozide acts upon ingestion, causing the larvae to cease feeding and successfully molt. This compound is also selective, bringing a quick kill to lepidoptera pests (263). The structure, uses, and hazard profile of tebufenozide are presented in Table 13.32.

Tebufenozide is not acutely toxic and does not produce a hazard in regard to repeated-dose toxicity or developmental, reproductive, and oncogenic potential.

Other Modes of Action

Larvicides

The larvicidal agents do not all belong to the same class of chemistry as characterizes some of the previously described mode of action groups. Clofentezine is used as an acaricide/ovicide for deciduous fruits, citrus, cotton, cucurbits, vines, and ornamentals. Cyromazine, an insect growth inhibitor with contact poison features interfering with molting and pupation, is used as a foliar spray, for fly control on treated surfaces, and as a feed premix. Hexythiazox acts as an acaricide, larvicide, and nymphicide. It is used to control eggs and larvae on fruits, vines, vegetables, and cotton. The exact mechanism of action of these three chemicals is not well understood. The structures, principle uses, and hazard profiles for these novel insecticides are given in Table 13.33.

The larvicides possess limited mammalian toxicity. Although cyromazine has not been shown to have any carcinogenic potential in animal studies, both clofentezine and hexythiazox have been classified as category C carcinogens. Clofentezine is to be managed using a reference dose (RfD), whereas, hexythiazox's is regulated using a cancer slope factor value.

Pheromones

Pheromones are common chemical sex attractants secreted by special glands of one or both sexes in insects. These chemicals work to identify and/or locate insects of the opposite gender (147). A pheromone (including an identical synthetic compound) is defined by the U.S. EPA as a compound produced by an arthropod (insect, arachnid, or crustacean) that modifies the behavior of other individuals of the same species (179).

Lepidopteran pheromones, produced by a member of the order Lepidoptera, including butterflies and moths, share a physicohemical feature common to all pheromones: their volatility, which is the basis for the signaling and homing mechanism. The U.S. EPA has registered 17 arthropod pheromones active ingredients, 11 of which are lepidopteran pheromones (179). The information submitted covered compounds that were from 6- to 16-carbon unbranched alcohols, acetates, and aldehydes. The structure

for the major lepidopteran pheromone, tetradecenyl acetate, is shown in Figure 13.10.
The U.S. EPA has assumed that pheromones and other similar natural chemicals are different from conventional

synthetic pesticides. Therefore, there are fewer data requirements for registering pheromones. In fact, most of the hazard data for these pheromones are anecdotal. The data available on both lepidopteran and other arthropod pheromones, including several aromatic pheromones, have indicated no acute mammalian toxicity at the limit dose levels tested. The acute toxicity profile generally reveals oral and dermal LD50 values of greater than 5000 mg/kg and 2000 mg/kg, respectively (226). The acute inhalation LC50 value is generally >5 mg/L. Eye and skin irritation potential fall in the mild or not irritating range, with no evidence of sensitization potential. Since a miniscule amount of the pheromone will be adsorbed to the inside of the bait station, there is practically no human contact with the pheromone. Therefore, the full data package required for conventional pesticides is waived by the U.S. EPA (226).

Respiratory Inhibitors and Uncouplers

Compounds that disrupt energy metabolism have been identified from both natural and synthetic sources. An important natural product is rotenone, which is derived from cube or derris root (160). The synthetic compounds in this group include a number of nitrogen-containing heterocycles, such as pyridaben (144). Disruption of energy metabolism occurs in the mitochondria and usually takes the form of either an inhibition of the electron transport system or an uncoupling of the transport system from ATP production. Inhibition of the electron transport system blocks the production of ATP and causes a decrease in oxygen consumption by the mitochondria. These uncouplers act on coenzyme Q oxidoreductase in the electron transport chain or the cytochrome b–c1 complex (103). The electron transport system functions normally, but the production of ATP is uncoupled from the electron transport process due to a dissipation of the proton gradient across the inner mitochondrial membrane. In the presence of uncouplers, oxygen consumption increases, but no ATP is produced (104). The disruption of energy metabolism and the subsequent loss of ATP results in a slowly developing toxicity, and the effects of all these compounds include inactivity, paralysis, and death.

The structures, uses, and hazard profiles of three compounds in this group registered in the United States are given in Table 13.34.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_603.html[2010/10/28 18:45:55]

Page 606
All of these materials possess low to moderate toxicity to mammals. The U.S. EPA has classified hydramethylnon as category C (possible human carcinogen) based on lung tumors in mice.
HERBICIDES
Herbicides are the leading type of pesticides, in terms of both user expenditures and amount used (1). In 1995, approximately $6.25 billion (United States) and $16.25 billion (worldwide) were spent by users on herbicides; this constitutes 55% and 45% of the U.S. and worldwide markets, respectively. Quantity-wise, 556 (46%) and 2210 (39%) million lb of active ingredient were purchased in the U.S. and worldwide markets, respectively. This market has been significantly impacted with the introduction of new chemistry, such as, the sulfonylureas (active in the grams per acre range), and new technology such as corn bioengineered against the phytotoxicity of the nonspecific herbicide glyphosate (198).
As the sheer number of herbicides available is significant, the number of herbicides presented here is limited with a focus on those considered to have economic and high agronomic value. There is an attempt to cover all the different mechanisms of actions in this process. The modes and mechanisms of action for important classes of herbicides used in crop protection are presented in Table 13.35.
Acetyl-CoA Carboxylase Inhibitors
Herbicides that act via inhibition of acetyl coenzyme A (acetyl-CoA) carboxylase alter lipid biosynthesis in weeds. The lipid inhibitors include the aryloxyphenoxypropionate and cyclohexanedione herbicides. These herbicides prevent the formation of fatty acids, components essential for the production of plant lipids. Lipids are vital to the integrity of cell membranes and to new plant growth. The lipid inhibitor herbicides inhibit a single key enzyme involved in fatty acid synthesis (154). Broadleaf plants are tolerant to these herbicide families, but many of the perennial and annual grasses are susceptible. Injury symptoms are slow to develop (7 to 10 days) and appear first on new leaves emerging from the whorl of the grass plant. These herbicides are taken up by the foliage and move in the phloem to areas of new growth (92).
Aryloxyphenoxypropionates
The structures, uses, and hazard profiles for six acetyl-CoA carboxylase-inhibiting aryloxyphenoxypropionate herbicides are presented in Tables 13.36 and 13.37.
These materials are generally not acutely toxic. Clodinafop-propargyl and haloxyfop have been identified as peroxisomal proliferators (pp) in the rodent. The relevance of peroxisomal proliferation to humans is still unresolved. However, studies involving the peroxisomal proliferator response element upstream of the human acyl-CoA oxidase gene as well as in rats showed that the rat gene responded to peroxisomal proliferators; whereas, the human gene was unresponsive (318). Additional work with the new gene technologies that are currently available may afford an opportunity to put this apparent species specific phenomenon into proper perspective.
Cyclohexanediones
The cyclohexanedione herbicides inhibit acetyl-CoA carboxylase, producing the same effects on susceptible perennial and annual grasses as noted with the aryloxyphenoxypropionates. The structures, uses, and hazard profiles of clethodim and sethoxydim are presented in Table 13.38.
Both cyclohexanedione herbicides have excellent acute and repeated-dose hazard profiles, which do not trigger any mammalian toxicology concerns.
Acetolactate Synthase Inhibitors
The sulfonyureas, imidazolinones, triazolopyridimidines, and pyriidinyl thiobenzoates constitute acetolactate synthase (ALS) inhibitors. The ALS inhibitors interact with the acetolactate synthase enzyme, inhibiting biosynthesis of an essential amino acid (297).
Sulfonylureas
Sulfonylurea herbicides belong to a class of compounds comprised of three distinct components. These are an aryl group linked to a nitrogen-containing hetrocycle via a sulfonylurea bridge. Sulfonylurea herbicides inhibit root and shoot growth in rapidly growing plants by suppressing cell division (4). Initial research conducted on *Escherichia coli* and *Salmonella typhimurium* and latter confirmed in plants and yeasts indicate that the herbicidal activity is due to the inhibition of acetolactate synthase (ALS), an enzyme necessary for the biosynthesis of branched chain amino acids in bacteria, fungi, and higher plants.
A large number of sulfonylurea herbicides have been developed for commercial use in North America and Europe (Tables 13.39 and 13.40).
Sulfonylurea herbicides generally are not acutely toxic or irritating to the skin and eye, nor are they mutagenic, developmentally toxic, or oncogenic (203). Their hazard profiles are given in Tables 13.41 through 13.43.

Table 13.35 Mode and mechanism of action for important classes of herbicides used in crop protection

Class	Mode of Action	Mechanism of Action
Acetyl CoA Carboxylase (ACCase) Inhibitors (41)	Systemic grass herbicides	Inhibit ACCase lipid biosynthesis.
Acetolactate Synthase (ALS) Inhibitors (297)	Selective systemic herbicides	Normal function of the ALS enzyme is blocked, inhibiting biosynthesis of essential amino acids.
Photosynthesis Inhibitors (268)	Selective systemic herbicides	Block the photosynthetic reaction, and disrupt cellular membranes so that captured light cannot be converted to chemical energy.
Protoporphyrin Inhibitors (265)	Selective contact herbicides	Inhibits the enzyme protoporphyrinogen oxidase.
Bleaching Herbicides (301)	Selective systemic herbicides	Disrupt synthesis of carotenoid pigments which protect chlorophyll pigments in light. Lack of carotenoids lead to chlorophyll destruction and white, bleached appearance.
EPSP Synthase Inhibitors (287)	Non-selective systemic herbicides	Inhibit 5-enolpyruvlshikimate-3-phosphate synthase preventing the biosynthesis of essential amino acids.
Glutamine Synthase Inhibitors (286)	Non-selective contact herbicides	Inhibit glutamine synthase leading to accumulation of ammonium ions, and inhibition of photosynthesis.
Dihydropteroate (DHP) Synthase Inhibitors (267)	Selective systemic herbicides	Inhibit DHP synthase involved in folic acid synthesis needed for the formation of purine nucleotides required for cell division.
Microtubule Assembly Inhibitors (14)	Selective systemic herbicides	Affect seed germination and prevents weed growth.
Mitosis Inhibitors (303)	Selective systemic herbicides	Affect cell growth and cell elongation.
Inhibitors of Cellulose Synthesis (294)	Selective systemic herbicides	Inhibit cell wall biosynthesis through inhibiting the formation of cellulose.
Membrane Disruptors (302)	Non-selective contact herbicides	Disrupt internal cell membranes by formation of a superoxide preventing the cell from manufacturing energy.
Inhibitors of Lipid Synthesis (308)	Selective systemic herbicides	Block formation of lipids in the shoot (meristem) and roots of grass plants.
Synthetic Auxins (Mimic or Inhibit Indoleacetic Acid) (82)	Selective systemic herbicides	Affect growth in the meristems and leaves by affecting protein synthesis and normal cell division.

Various target organs have been identified at high doses in chronic studies in rodents and dogs, including bone marrow, liver, kidney, testes, and the peripheral and central nervous systems. Tumor incidence was elevated above control levels in the liver (primisulfuron) and heart (oxasulfuron) at doses that exceed the maximum tolerated dose. An earlier appearance of mammary tumors has also been observed in female Sprague-Dawley rats (prosulfuron, tribenuron).

A unitary mode of action underlying effects of this class of chemical on mammalian systems is not discernable. The diversity of the effects observed in various target organs is attributed to specific functional groups and not to the defining characteristic of the class, the sulfonylurea bridge.

Imidazolinones

There are a restricted number of registered chemicals in this class of ALS-inhibiting herbicides. They include imazameth and imazamethabenzmethyl. The hazard profiles for these chemicals (Table 13.44) indicate that this class of herbicide is relatively nontoxic, even at high doses, with no evidence of mutagenic, developmental, or oncogenic effects.

Triazolopyrimidines

The triazolopyrimidine class of ALS inhibitors registered for herbicidal use includes imazamox, imazapyr, imazaquin, and imazethapyr. As with the imidazolinones, these chemicals also have excellent hazard profiles (Table 13.45). No evidence of significant target organ toxicity or mutagenic, developmental, or oncogenic potential has been realized even at doses that approximate the limit dose of 1000 mg/kg.

Pyrimidinylthiobenzoates

The members of this class of ALS-inhibiting herbicides, flumetsulam and pyriminobac-methyl (Table 13.46), are less well tolerated in mammalian systems than for other ALS inhibitors as evidence by lower no observed effect levels. However, the hazard profile for these chemicals is still favorable since no mutagenic, developmental, or oncogenic effects have been reported.

Photosynthesis Inhibitors

The photosynthesis inhibitors include triazines, phenylureas, uracils, benzothiadiazoles, nitriles, carbamate, and dicarboxylic acid. Photosynthesis inhibitors shut down the photosynthetic (food-producing) process in susceptible plants by binding to specific sites within

NA=Not Available

the plant chloroplast. Inhibition of photosynthesis could result in a slow starvation of the plant; however, in many situations rapid death occurs, perhaps from the production of secondary toxic substances (101). The triazines, uracils, substituted ureas, benzothiadiazoles, and phenylpyridazines inhibit electron flow in Photosystem II, leading to destruction of cellular membranes and plant death. The bipyridyliums inhibit Photosystem I electron flow.

Injury signs include yellowing (chlorosis) of leaf tissue followed by death (necrosis) of the tissue. Three of the herbicide families (triazines, phenylureas, and uracils) are taken up into the plant via the roots or foliage and move in the xylem to plant leaves. As a result, injury signs will first appear on the older leaves, along the leaf margin. Foliar-applied photosynthetic inhibitors generally remain in the foliar portions of the treated plant, and movement from foliage to roots is negligible.

Triazines and Triazinone

The triazine herbicides inhibit the Hill reaction in the process of photosynthesis (161). This unique mechanism of action is specific to photosynthesizing plants. Therefore, the triazines do not exhibit significant mammalian toxicity but rather target-species selectivity. The structures and uses of the symmetrical triazines and an asymmetrical triazine or triazinone, metribuzin, are presented in Table 13.47.

The hazard profiles of these agents are presented in Tables 13.48 and 13.49.

These triazines are generally not acutely toxic, nor do they cause a significant repeated dose toxicity. The one exception appears to be the symmetrical chlorotriazines, atrazine, cyanazine, propazine, and simazine, which in lifetime feeding studies in Sprague-Dawley female rats induce an earlier onset and/or an increase in the incidence of mammary tumors (161, 176). The relevance of these tumors to humans has been the subject of intense research and evaluation (94, 164, 317).

Recently, the International Agency for Research on Cancer reexamined atrazine and simazine (105). Both were classified as "not classifiable as to carcinogenicity

Page 619

Table 13.47 Structures and uses of selected photosynthesis-inhibiting herbicides: Triazines and triazinones

Herbicide	Structure	Principle Crops/uses	Use rates
Atrazine Aatrex® (268)		Pre- and post-emergence control of annual broadleaved and annual grasses in corn, sorghum, sugar cane, and pineapple	1.5 to 2.5 kilograms (a.i.)/hectare
Cyanazine Bladex® (276)		Pre-emergence in broad beans, corn and peas; and post-emergence in barley and wheat	1 to 3 kilograms (a.i.)/hectare 0.26 to 0.33 kilograms (a.i.)/hectare
Propazine Milo-Pro® (222)		Pre- and post-emergence control of annual broadleaved and annual grasses in sorghum, carrots, chervil, and parsley	0.5 to 3 kilograms (a.i.)/hectare
Simazine Princep® (309)		Pre- and post-emergence control of annual broadleaved and annual grasses in pome fruit, stone fruit, citrus, vines, corn, sorghum, sugar cane, and pineapple	1.5 to 3 kilograms (a.i.)/hectare
Ametryn Evik® (266)		Pre- and post-emergence control of annual broadleaved and annual grasses in bananas, citrus fruit, corn, coffee, sugar cane, and pineapple	2 to 4 kilograms (a.i.)/hectare
Prometryn Caparol® (244, 306)		Pre-emergence in vegetables, cotton, sunflower, and peanuts and post-emergence in cotton and vegetables	0.8 to 2.5 kilograms (a.i.)/hectare 0.8 to 1.5 kilograms

			(a.i.)/hectare
Prometon Pramitol® (305)		Control of most annual and many perennial broadleaved weeds, grasses and brush weeds in non-crop areas	10 to 20 kilograms (a.i.)/hectare
Metribuzin Sencor® (296)		Pre- and post-emergence control of annual broadleaved and annual grasses in soya beans, potatoes, corn, cereals, sugar cane, alfalfa, and asparagus	0.35 to 0.7 kilograms (a.i.)/hectare

to humans" when mechanistic data were taken into account in making the overall evaluation.

Uracils and Pyridazinones

The structures, uses, and toxicity profiles for two uracils and a pyridazinone herbicide are given in Table 13.50.

The acute hazard associated with bromacil, terbacil, and norflurazon is unremarkable. None of these products have been found to represent a mutagenic, teratogenic, or reproductive hazard. However, bromacil and norflurazon have been classified as category C (possible human carcinogen), based on mouse liver tumors.

Ureas

Three ureas of this older class of photosynthesis-inhibiting herbicides are considered. The structures, uses, and toxicity for diuron, flumeturon, and linuron are provided in Table 13.51.

The acute and repeated-dose toxicity of these three ureas is nonproblematic until the oncogenic potential of these compounds is examined. Both diuron and linuron

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_620.html[2010/10/28 18:46:06]

4 UF=Uncertainty factor

have been classified by the U.S. EPA with the known or likely designation as defined in the EPA 1996 classification scheme (192) or as category C (possible human carcinogen) based on the earlier scheme (146). The classification of flumeturon is still pending.

Amides and Nitriles

The structures of two nitriles, dichlobenil and ioxynil, and one amide, isoxaben, are presented along with their uses and toxicology profiles in Table 13.52.

Ioxynil's profile suggests minimal hazard. Dichlobenil is flagged for its oncogenic potential and received a category C designation based on mouse liver tumors. Isoxaben represents a bit more concern as it has been found to be weakly mutagenic and elicits liver tumors in the mouse and adrenal tumors in the rat.

Benzothiadiazoles and Phenylpyridazine

One example of a benzothiazole and a phenylpyridazine photosynthesis inhibitor are presented in Table 13.53.

Bentazon and pyridate have been found to have acute and repeated-dose profiles that suggest minimal hazard to humans.

Bipyridyliums

Diquat and paraquat, bipyridylium photosynthesis inhibitors, are unlike the triazines, uracils, substituted ureas, benzothiadiazoles, and phenylpyridazines in that they inhibit electron flow in Photosystem I. The structures, uses, and hazard profiles for diquat and paraquat are provided in Table 13.54.

Diquat is less acutely toxic than paraquat. Neither bipyridylium is mutagenic, teratogenic, or carcinogenic, nor have they been demonstrated to be reproductive toxicants.

Protoporphyrinogen Inhibitors

The mode of action for this class of herbicides is to interfere with critical enzymes needed in the biosynthesis of chlorophyll in plants. Unfortunately, mammalian systems possess a similar chromophore, namely, heme, that relies on a similar set of enzymes that are also affected by these chemicals. Therefore, it is not uncommon to find evidence of anemia in mammals exposed to protoporphyrinogen-inhibiting chemicals and other photobleaching herbicides (145, 151, 321). In addition to effects on heme synthesis, it is theorized that light(phorryhia) and oxygen-dependent peroxidation of cell membrane lipids may lead to cell lysis and death, particu

Page 626

larly in organs where these metabolites form or bioconcentrate. Such a theory is consistent with the experimental observation that liver damage and liver tumor formation, particularly in mice, are often a consequence of exposure to these chemicals. An alternate viewpoint is that liver damage and subsequent tumor response may result from peroxosome proliferative effects of chemicals in this class.

Diphenyl Ethers

Acifluorfen, formesafen, lactofen, and oxyfluorfen represent the diphenyl ether protoporphyrin inhibitors. The structures, uses, and toxicity profiles for the products are presented in Table 13.55.

Lactofen is a severe eye irritant; otherwise, the acute hazards associated with these protoporphyrin inhibitors are not remarkable. These diphenyl ethers are classified as B2 (probable human carcinogens) in the case of acifluorfen and lactofen (liver and stomach tumors), or C (possible human carcinogens) in the case of oxyfluorfen and formesafen (liver tumors).

N-Phenylphthalimides, Thiadiazoles, and Triazolinones

Only one representative for each of these chemical groups is featured in Table 13.56.

Page 627

Table 13.55 Structures, uses, and hazard profiles for selected protoporphyrin inhibitors: Diphenylethers

4 Proposed 1996 US EPA classification scheme
NA=Not Available

Flumiclorac-pentyl is applied in the 30 to 90 g/hectare range and has an acute and repeated-dose hazard profile that should not evoke concern in regard to human health. The thiadiazole, fluthiacet-methyl, which is applied at a remarkable low rate of 4–15 g/hectare, exhibits an unremarkable acute hazard, but has been found to produce liver tumors in mice and pancreatic tumors in the rat. Carfentrazone-ethyl, which is applied at the very low rate of 9–35 g/hectare, incurs little concern based on the acute or repeated-dose hazard evaluation.

Bleaching Herbicides

The bleaching herbicides disrupt the synthesis of carotenoid pigments, which protect chlorophyll pigments in light. In the absence of carotenoids, chlorophyll is destroyed and turns white, thus having a bleached appearance. The pyridazinones, triketones, and isoxazoles bleaching herbicides are considered here. The pyridazinones, triazoles, and isoxazolidinones inhibit carotenoid biosynthesis at the phytoene desaturase step, whereas, the triketones and isoxazoles inhibit the 4-hydroxyphenylpyruvate dioxygenase enzyme (156).

Pyridazinones

The structures, uses, and hazard profiles for norflurazon and fluridone are given in Table 13.57. Neither norflurazon nor fluridone is acutely toxic; the repeated-dose profile for fluridone is unremarkable. Norflurazon is classified as category C (possible human carcinogen) based on mouse liver tumors.

Triazoles and Isoxazolidinones

Amitrole (triazole) and clomazine (isoxazolidinone) are presented with regard to their structures, uses, and toxicity profiles in Table 13.58.

These compounds are not acutely toxic. Clomazone has an unremarkable repeated-dose hazard profile. Amitrole has been classified as category B2 (probable human carcinogen) based on thyroid tumors in rats and liver tumors in mice.

Triketones and Isoxazoles

The structures, uses, and hazard profile for sulcotrione (triketone) and isoxaflutole (isoxazole) are presented in Table 13.59.

Although the acute toxicity information for sulcotrione does not suggest that it represents a hazard, the available data for its repeated-dose profile are inadequate for full hazard assessment. Isoxaflutole does not represent an acute hazard but has been shown to be a potential developmental toxin, a neurotoxin, and potential carcinogen.

EPSP Synthase, Glutamine Synthase, and Dihydropteroate (DHP) Synthase Inhibitors

A single member of each of these classes of synthase inhibitors was selected for this review. The inhibition of 5-enolpyruvlshikimate-3-phosphate (EPSP) synthase prevents the biosynthesis of essential amino acids (287). The inhibition of glutamine synthase leads to an accumulation of ammonium ions, and inhibition of photosynthesis (286). Inhibition of DHP synthase inhibits folic acid synthesis, which is needed for the formation of purine nucleotides required for cell division (267).

The structures, uses, and hazard profiles for representative ESSP synthase, glutamine synthase, and dihydropteroate synthase inhibitors are given in Table 13.60.

It can be seen that glyphosate, glufosinate-ammonium, and asulam are not acutely toxic. Both glyphosate and glufosinate-ammonium have excellent repeated-dose toxicity profiles. Asulum is also not mutagenic, teratogenic, or a reproductive toxin, but does produce tumors in male rat.

Microtubule Assembly Inhibitors

The structures, uses, and hazard profiles of three commercially important dinitroaniline microtubule assembly inhibitors are given in Table 13.61.

Benfluralin, pendimethalin, and trifluralin are not acutely toxic. There are inadequate data to access the repeated-dose hazards for benfluralin. Both pendimethalin and trifluralin were classified as category C (possible human carcinogens) by the U.S. EPA (100).

Cell Division Inhibitors

The structures, uses, and toxicology profiles for four chloracetamide inhibitors of cell division are provided in Table 13.62.

All four chloracetamide herbicides are potential sensitizers. Alachlor and acetochlor both exhibit mutagenic potential and significant oncogenic potential in both rats and mice. Dimethenamid also has exhibited weak genotoxiciy and a tumor response in the female rat. Metolachlor showed a weak oncogenic response in the liver of the female rat.

Cellulose and Lipid Synthesis Inhibitors

The structures, uses, and hazard profiles of the cellulose synthesis inhibitor isoxaben and of the lipid

synthesis inhibitors butylate and molinate are given in Table 13.63.
Isoxaben exhibits a low acute toxicity hazard. Butylate is a potential sensitizing agent, and molinate has signifi

< previous page page_629 next page >

Table 13.57 Structures, uses, and hazard profile for selected bleaching herbicides: Pyridazinones

Chemical/ Common Names	Structure	Principle Uses/Crops	Application Rate gm (a.i.)/ha
Norflurazon Evital® (220)		Fruit Tree, Nut, & Vine crops, Soybean, Ornamentals, Peanut, Cotton, and IWC,	500–3360
Fluridone Sonar® (285)		Aquatic herbicide	2240 (0.075–0.15 mg/L)

Herbicide	Irritation Eye	Skin	LD50 (mg/kg) Oral	Dermal	LC50 (mg/L) Inhalation	Sensitizing Potential	Signal Word

NA=Not Available

cant acute inhalation toxicity. Isoxaben has some mutagenic, developmental, and oncogenic potential. The lipid synthesis inhibitor butylate appears not to exhibit significant repeated-dose toxicity. Much of the critical assessment data for molinate is not available, making full evaluation impossible; however, from the available data, molinate appears to have reproductive toxicity and oncogenic potential.

Synthetic Auxin Mimics (Phenoxy, Benzoic, and Pyridine Acids)

The synthetic auxins alter growth in the meristems and leaves by affecting protein synthesis and normal

cell division. 2,4-D (phenoxy), dicamba (benzoic), and clopyralid and picloram (pyridine acids) represent this

Page 631

NA=Not Available

class. The structures, uses, and hazard profiles of these synthetic auxins are provided in Table 13.64. Dicamba and clopyralid were found to exhibit sensitization potential. Dicamba was shown also to have some mutagenic and weak, questionable carcinogenic potential.

Herbicides with Unknown Mechanism of Action

The structures, uses, and hazard profiles of two of these products are presented in Table 13.65. Monosodium methanearsonic acid (MSMA), an organic arsenical, has a rather unremarkable acute toxicity profile; it has, however, been shown to decrease fertility in rats and is classified as category B2 (probable human carcinogen) based on bladder tumors in the rat. Difenzoquat is labeled as a danger because of its corrosive effects on the eyes; however, it possesses a nonproblematical repeated-dose hazard profile.

CONCLUSION

Although older products, like the practically irreplaceable DDT and chlordane, have been banned because of their persistence in the environment, their replacements, the organophosphate insecticides, currently are under fire by the U.S. EPA. Therefore, this

overview of crop protection chemicals and modalities has focused primarily on the newer products used for disease control, insect control, and weed control.

Besides the movement toward more natural chemistry, such as with the avermectins, the chemicals of the late 1980s and 1990s are efficacious at a low grams per acre rate with pest-specific toxicity and limited mammalian toxicity, such as for the ALS sulfonylurea herbicides. In order to reduce the area of exposure due to application, applying materials directly to the seed to be planted is

NA=Not Available

being used extensively. More recently, seeds have been genetically engineered to incorporate the natural insecticide control stock of *Bacillus thuringiensis*. Most recently, a gene has been installed in crop seed to protect the crop from a nonspecific herbicide. It can be seen that crop protection chemicals are evolving to superefficacious agents. In most cases, this enhanced efficacy for the target pest did not come at the expense of human or environmental safety.

The crop protection industry has become a significant business during the last 50 years. However, with the harvest reaped by this industry, there have been substantial benefits provided to society. Looking beyond the lives saved by DDT from its use in disease control, the agriculturist's ability to produce food and fiber have significantly increased and labor costs have significantly decreased. Despite a 69% decrease in the number of U.S. farmers from the 1930s to the 1990s, the individual farmer can now feed an average of 129 people; this is up from 19 in the 1930s. Currently less than 2% of our population now grows enough food to feed the entire U.S. population, with surplus.

The average life expectancy has increased from 60 years in 1930 to in excess of 75 years today, primarily due to the availability of an adequate and healthy supply of food. It has been less than 60 years since DDT was first used as an insecticide, and we have learned a lot about the need to develop chemicals that do not disturb our environment.

Page 639

We are also learning that nature itself may provide us with better ways of achieving that objective. The challenge is ours. In the next 60 years, world agriculture must be able to provide food for more than 11 billion people. This means that we must triple our output over the next six decades while eliminating any impact on the environment.

QUESTIONS

1. Farmers must contend with some 80,000 plant diseases, 30,000 species of weeds, and 1000 species of nematodes and more than 10,000 species of insects. Today, national and international agricultural organizations estimate that as much as 45% of the world's crops continue to be lost to these types of hazards. In the United States alone, about $20 billion worth of crops (one-tenth of production) is lost each year. What do you think would be the status of our national food production capacity without the use of pesticides?
2. Who assures that pesticides can be used without unacceptable hazard to the consumer to protect food crops and maximize yields?
3. How stringent are the testing requirements for the registration of a pesticide when compared to those for products used in the household and yard, industrial chemicals, or even pharmaceuticals?
4. Has the introduction of pesticides into your food supply had a positive or negative impact on the quality of your life?

Metals are elements generally characterized by ductility, luster, being electropositive with a tendency to lose electrons, and having the property of conducting heat and electricity. However, a number of the elements individually discussed in the body of the chapter are not true metals (e.g., arsenic, fluorine). The attempt was made to include elements that have physiological actions (both beneficial and toxic) by virtue of their chemical ionic form. Elements such as oxygen and sulfur, which are essential to life in some forms (e.g., water,

amino acids) but which also exist in forms that are chemically reactive and hence toxic (e.g., hydroperoxide, sulfuric acid), are not covered in this chapter.

Metals can have a variety of physiological effects, and it is often possible to demonstrate the toxicity of any given metal in any given organ, provided that the dose is both high and prolonged (but not so high and prolonged that the primary target organ receives a fatal dose). Essential elements may be toxic at a dose that overwhelms homeostatic controls on absorption and excretion, and the mechanism of toxicity is commonly related to an essential physiological role of the metal (e.g., control of osmolarity for sodium consumption in excess of water intake, neurotransmission for potassium consumption in excess of water intake; redox reactions for iron intake in excess of protein binding capacity). Physiological actions of nonessential elements include substituting for essential elements in enzymatic reactions, energy metabolism, neurotransmission, structural components (bone), reacting covalently or noncovalently with enzymes, membranes, DNA, and stimulating the production of active oxygen species (223). The variety of physiological effects makes it difficult to determine which action is responsible for toxicity in the most sensitive target organ. In some cases, organs are most sensitive for a biochemical reason (e.g., thallium interferes with energy metabolism, and target organs are those with the highest energy requirement); in other cases, the most sensitive organ is simply the organ in which the accumulation is greatest (e.g., cadmium and uranium accumulate in the kidneys, which are the target organs). Metals can interact with each other either to enhance toxicity (e.g., by affecting the same target organ) or to reduce toxicity (e.g., by stimulating defense mechanisms); this must be particularly kept in mind for the interpretation of animal experiments (e.g., levels of calcium, iron, and zinc should be controlled in investigations of cadmium toxicity) and epidemiological studies (e.g., fluoride reduces the incidence of dental caries: therefore, a population with the lowest fluoride exposure is likely to have the highest exposure to mercury and other metals used in dental restorations). The number of combinations of metals that could potentially be investigated is huge, and such studies are most useful either when a sensitive subpopulation is identified (e.g., individuals with insufficient intake of specific nutrients) or when a specific mechanism is revealed. Few treatments for metal toxicity are based on interfering with the mechanism of action; rather, measures are designed to reduce gastrointestinal absorption (from acute poisoning) by removing or binding the metal or are designed to speed elimination from the body (e.g., chelation therapy) (172). Prevention of excessive exposure is generally the best way to reduce the potential for metal toxicity.

The variety of physiological effects that metals can have is also the reason that adverse effects can often be demonstrated in most organ systems. Reproductive, developmental, immunological, and neurological toxicity, which are often not investigated in routine bioassays, are endpoints of increasing concern. For metals in particular, which on general principles would be expected to at least have the potential for these types of toxicity, toxicological understanding should not be considered complete without some information on whether these systems might be the most sensitive.

QUANTIFICATION OF TOXICOLOGICAL EFFECTS OF METALS

Consideration of the toxicity of metals must be quantitative because of the need to identify the most sensitive organ among all the systems that can be affected by the metal, and also because metals are naturally occurring and ubiquitous. Exposure to any metal cannot be banned the way exposure to, for example, an organic pesticide or food additive can be banned; some elements are essential to life, and even for those that are not, with sufficiently sensitive analytic techniques their presence can be demonstrated in any given sample of food, water, soil, or air. The quantification of the toxic effects of metals must attempt to precisely identify the highest level that is not expected to cause undue adverse effects because in many cases the traditional approach of using a safety/uncertainty factor of 10 would quickly lead to calculated levels that are below those essential for health (e.g., zinc, molybdenum) or levels that are below background exposures from food or water and hence extremely costly to achieve (e.g., cadmium, arsenic).

An example of the need to quantify toxicity is in the U.S. Environmental Protection Agency (U.S. EPA) program to address abandoned hazardous waste sites. For each site, a quantitative risk assessment is performed to determine the need for and extent of remediation (583). Essentially this risk assessment calculates doses of contaminants based on the concentration in a medium (air, soil, food, water) and the intake of that medium (e.g., adults are assumed to ingest 100 mg of soil per day). This dose to the maximally exposed person is then compared to two quantitative toxicological values. The first is the reference dose (RfD) or reference concentration (RfC), which is the highest dose or concentration not thought to be associated with adverse noncancer health effects (the "threshold"). The derivation of RfDs and RfCs is described in the chapter by Beck et al. (chapter 2) in this volume. RfDs quantify oral (and

potentially dermal) toxicity, and RfCs quantify inhalation toxicity; separate values may be derived for acute, intermediate, and chronic exposure duration. The second toxicological

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_650.html[2010/10/28 18:46:26]

value is the slope factor, which quantifies the cancer risk corresponding to a given lifetime dose (see Chapter 2). There are commonly separate slope factors for the inhalation and oral routes; risks from less-than-lifetime exposure are evaluated by dividing the duration of exposure by an (assumed) 70-year lifetime. Cleanup standards for a site are commonly set as the concentrations that would deliver a dose to the most exposed individual that is less than the RfD for each chemical, and that results in an "acceptable" cancer risk (e.g., 10^{-4} to 10^{-6} incremental lifetime cancer risk). For metals, one important issue is whether they are present at the hazardous-waste site at levels exceeding the natural background level (which are not necessarily below what would pose an unacceptable risk to the most exposed individual). Another issue that arises is incorporation of uncertainty into derivation of cleanup standards. One example is chromium, commonly measured as total chromium, which leads to uncertainty because only the rarer hexavalent form, not the more common trivalent form, is considered a carcinogen (589); considering all chromium detected at a hazardous to be hexavalent will lead to an overestimate of the risk and the need for cleanup, by an unknown amount. Another example is antimony, which has an oral RfD derived with a safety factor of 1000 (589); it is likely that this safety factor is too conservative and that cleanup standards will be more stringent, and therefore more expensive, than needed. For both chromium and antimony, additional information (speciation at the site for chromium; better toxicology data for antimony) would allow risk assessments to determine more precisely acceptable levels, which would prevent the setting of potentially unnecessarily strict standards. On the other hand, there may be situations where current standards of exposure are not strict enough. Human activities such as mining and smelting, fossil fuel burning and incineration, fertilizer-intensive agriculture, and other industrial processes have increased human exposure to many elements to levels far above those of the preindustrial environment. Lead and cadmium are two examples of metals for which the level of exposure deemed acceptable has dropped many times over the years, as concern about frank toxicity among workers was replaced by concern about more subtle signs of toxicity in workers, which was in turn replaced by concern about even more subtle adverse effects in the general population exposed through environmental (including dietary) routes (94, 108). There are numerous examples of metals for which our knowledge of toxicology primarily consists of information on frank toxicity in exposed workers and a few animals studies, very similar to the extent of information that was used to derive standards for lead and cadmium that we now know could cause substantial toxicity in the general population. One of the major reasons for the advances in knowledge about lead, cadmium, and a few other metals was the development of biomarkers of exposure (blood lead levels and urinary cadmium levels) that provide a way to quantify environmental exposure and thus allow studies linking exposure to health effects in the general population. Biomarkers of exposure commonly provide much more precise quantification of exposure than is possible by traditional means, particularly for the general population that may be exposed by several routes (food, air, water), all of which are variable in time and location. One important future direction for investigation of metals toxicology is developing and validating biomarkers of exposure, and using these biomarkers to investigate potential adverse effects in the general population.

For most metals, quantification of toxicological effects has not been done using human studies with validated biomarkers. Instead, the traditional methods are used (discussed in more detail in Chapter 2): assembling the entire data set, surveying the data to determine the most sensitive target organ (the organ exhibiting an adverse effect at the lowest dose), identifying the no-observed-adverse-effect level (NOAEL) or the lowestobserved-adverse-effect level (LOAEL), and applying safety or uncertainty factors to derive a threshold below which no noncancer effects are expected to occur. For cancer risk assessment, the process involves determining a weight-of-evidence judgment as to whether the element has the potential to cause cancers in humans (the U.S. EPA uses classifications of group A, known human carcinogen; group B, probable human carcinogen; group C, possible human carcinogen; and group D, not classifiable as to human carcinogenicity); a separate step is to quantify the cancer risk associated with a given dose, on the no-threshold assumption that any exposure carries some cancer risk, with a safety margin built in by using the most sensitive sex/species/organ carcinogenic response and by using the upper 95th percentile confidence limit of the slope (583).

Several issues for the qualitative and quantitative evaluation of toxicity pertain particularly to metals.

Essentiality

Recommended dietary allowances (RDA) are defined as "the levels of intake of essential nutrients that, on the basis of scientific knowledge, are judged by the National Research Council's (NRC) Food and Nutrition Board to be adequate to meet the known nutrient needs of practically all healthy persons" (420). They are revised and published periodically by the NRC, which convenes expert committees to

estimate the mean dietary requirement for the population based on deficiency studies, balance studies, nutritional intakes, bioavailability, interactions, and homeostatic regulatory mechanisms

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_651.html[2010/10/28 18:46:27]

(446). A normal Gaussian distribution for the range of requirements within the population and a coefficient of variation of 15% are generally assumed. The RDA is then set at two standard deviations above the mean. Statistically, the RDA represents the 97.5th percentile of the nutrient requirement in the healthy population (86). The first RDAs were set during World War II, when food was rationed, and it was important to set minimum requirements to prevent frank deficiency diseases. Today, although preventing nutrient-deficient diseases is still important, public health concerns are directed toward defining the amounts of nutrients needed to ensure optimum health, provide excellent physiological and mental function, and prevent degenerative diseases (291). For example, the 1989 recommendation for selenium is based on the amount needed to support maximal activity of the selenium-dependent enzyme glutathione peroxidase and prevent cardiomyopathy (420); however, recent epidemiological studies suggest selenium has cancer preventive activity at levels significantly higher than that needed to support maximal activity of glutathione peroxidase (125, 126, 627). A higher recommendation for selenium might be set if a reduction in cancer risk were chosen instead of preventing the disease process associated with frank selenium deficiency, cardiomyopathy (135). This will require a "reconstructed," trilevel RDA, tentatively named the dietary reference intake (DRI) (397), which will address (a) the amount needed to prevent the deficiency disease, (b) the amount needed to provide specific health benefits, and (c) the amount associated with health hazards. The Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, has formed the Committee on the Scientific Evaluation of Dietary Reference Intakes to address these issues.

Route of Exposure

Two major routes of exposure to metals are by inhalation and oral exposure. Inhalation of metals, particularly as fumes or dusts, commonly causes systematic effects on the lung, ranging from mild, self-limiting metal fume fever from acute exposure and benign pneumoconiosis from chronic exposure for some metals to severe chronic obstructive lung disease for others (254, 430). Standards for inhalation exposure to metals are developed by the American Conference of Governmental Industrial Hygienists (ACGIH), based primarily on occupational data; the highest allowable standard, 10 mg/m3, pertains to dusts that are not chemically reactive but present a cumulative, physical burden on the lung that can be harmful from long-term exposure (31). Oral exposure to many metals with known lung toxicity often has no adverse effects (although at high enough oral doses, most metals cause acute gastrointestinal irritation and distress) (172), possibly due in part to the faster turnover of gastrointestinal versus lung cells. Another important route distinction has to do with carcinogenicity. Several metals are considered to be carcinogenic by the inhalation route, but not by the oral route (e.g., cadmium, chromium, nickel). This classification is based on the observation of an increased rate of lung but not other forms of cancer among workers and experimental animals exposed by inhalation, and on no observed increased rate among experimental animals exposed orally. However, these metals could have weak rather than no oral carcinogenicity; on theoretical grounds, it could be argued that most mechanisms by which an element is carcinogenic to lung tissue could operate in other tissues as well, and certain metals such as arsenic are known to be both lung carcinogens and systemic carcinogens. The potential human oral carcinogenicity of metals, particularly those known to be inhalation carcinogens, is an area deserving further study, and again, valid biomarkers of exposure would be very valuable for such studies. Another point concerning route of exposure is that some metals, such as cadmium, are known to have very different toxicokinetic and toxicological properties by parenteral routes than by oral or inhalation routes. For cadmium at least, this is most likely due to the binding to metallothionein as a required step in oral or inhalation absorption, which is bypassed by parenteral exposure (16). Cancers can be induced in experimental animals by implantation of solids (metals as well as other solids); this "solid-state" carcinogenicity is typically considered to be only marginally relevant to human exposures. However, solid-state carcinogenesis may be relevant in humans with implanted metal-containing prosthetic devices (605). In general, studies using parenteral routes of exposure are often of limited use, unless the goal is to evaluate human parenteral exposure from medical procedures. A final point with respect to route of exposure is that most metals are considered not to be absorbed through the skin (with certain exceptions such as mercury and thallium); however, few data actually exist to substantiate this assumption, and further studies would be useful to quantify the dermal absorption of metals.

Form

Some metals, such as mercury, exist in elemental, ionic, and organic forms, and each of these forms has a unique toxicity. Other metals, such as chromium, may exist in two or more valence states with different effects. Still others, such as nickel, may be primarily protein bound in food sources but primarily free ions in water, which may affect absorption. Finally, there are some metals, such as

cadmium, that appear to have similar toxicological effects regardless of their form. Ideally, in

< previous page page_652 next page >

formation would be available to do a separate quantification for each toxicologically distinct form; this would only be useful, of course, in situations where the form to which humans are to be exposed is actually known. Failing this ideal, the attempt is made to derive a standard for the most toxic form of a given metal; however, in many cases this leads to overly stringent standards, and in some cases lack of information on the most toxic form of a metal may lead to standards that are too lax.

Duration of Exposure

The influence of duration of exposure on the quantitative, and even qualitative, toxicology of a metal depends on its toxicokinetics. Cadmium is an example of a cumulative toxin. To a relatively good approximation, the same total dose given over a week, a month, or a year will accumulate in the kidneys to the same extent and have the same physiological effect (16). Other metals, particularly essential elements, are excreted so efficiently that any dose that can be tolerated for a day can also be tolerated for a lifetime (420). For well-studied metals, information is generally available to account for duration of exposure. One example is that ACGIH commonly derives threshold limit values (TLVs) as time-weighted averages (TWAs), but may also derive a short-term exposure limit (STEL) or a TLV ceiling (TLV-C) for substances that have acute as well as chronic effects (31). For less studied metals, many standards are derived based on animal data with very little information on toxicokinetics, which means that extrapolation to durations of exposure other than those used in the study at hand are quite uncertain.

Age at Exposure

Infants and young children may be particularly sensitive to toxic effects of metals both because they often absorb a greater fraction of ingested metals than older children or adults and because some developing systems (particularly the nervous system) are more sensitive to toxic effects than mature systems. Lead is an example of a metal that is known to be most deleterious to fetuses, infants, and toddlers (108, 109). The elderly are another group that may be more sensitive than healthy adults to the toxic effects of metals due to diminution of homeostatic and adaptive mechanisms. Definition of a safe level of exposure has an inherent uncertainty for metals lacking data on effects on infants and the elderly.

Animal Versus Human Data

For well-studied metals, animal and human toxicity appear to be in general qualitative agreement, although there are some exceptions, such as the difficulty in demonstrating that arsenic is carcinogenic to experimental animals. However, quantitative differences do occur; for example, gastrointestinal absorption of cadmium is about two to three times lower in experimental animals than humans (16). Use of a 10-fold safety factor for animal-to-human extrapolation in this case would yield a toxicological value about 3 times more stringent than necessary. This emphasizes the importance of using human data whenever possible for quantification of toxicity.

Toxicokinetic Modeling

Toxicokinetic modeling is very useful for evaluating the toxicity of well-studied metals. Good models can integrate information on the effects of routes of exposure, chemical forms, age at exposure, duration of exposure, and interindividual variation on absorption, distribution, excretion, and target-organ sensitivity. The toxicokinetic model developed for quantifying the systemic toxicity of cadmium is discussed later in this chapter. In addition, toxicological modeling is used in the quantification of the cancer risk from exposure to radioactive elements. Principles of radiological toxicity are covered in detail in the chapter on radioactivity (Chapter 15); the following is a brief description highlighting the use of toxicokinetic modeling for radioactive elements. Radioactive elements can cause damage at levels of exposure many orders of magnitude below those at which their nonradioactive forms cause chemical damage because radioactive decay involves the release of a large amount of energy in the form of alpha particles, beta particles, and/or gamma rays. A single radioactive decay can initiate a cascade of events that creates a huge number of active oxygen species, which are thought to be the ultimate cause of radioactive damage. This damage can cause cell death at high levels of exposure; of greater concern is the possibility of mutations that can initiate or promote cancer or result in hereditary defects (582).

Quantification issues are addressed for individual metals in the remainder of this chapter. The reader should recognize that the U.S. EPA continually reviews and revises toxicity values, and that the numbers presented here are simply the values that were specified in December 2000.

Sources of Information

There are numerous sources of information on toxicity of metals, many of which are updated on a regular basis. The U.S. EPA maintains the Integrated Risk Information System (IRIS), which has a summary of information (including RfD and RfC values) on numerous toxic

chemicals, including a number of metals (589). This database is regularly updated, and is available on the EPA web site (http://www.epa.gov). The American Conference of Governmental Industrial Hygienists (ACGIH) publishes annually a listing of all chemicals for which threshold limit values (TLV) and biological exposure indices (BEI) exists (32). The documentation for the development of these values is also available, with the latest update of this publication occurring in 1996 (31). The U.S. Agency of Toxic Substances Disease Registry has published many documents that summarize the toxicological effects of elements and chemicals; documents exist for many of the elements discussed in this chapter. Finally, the series *Patty's Industrial Hygiene and Toxicology* contains a vast amount of information on the toxicity of metals and other elements and compounds, with the major emphasis being on industrial exposures and effects (63, 64, 142, 460). Treatments for exposures to metals and other compounds are described in detail in *Clinical Toxicology of Commercial Products* (222) and in *Diagnosis and Treatment of Human Poisoning* (172).

ESSENTIAL ELEMENTS

Calcium

Calcium is essential both for the physical structure of bone and for normal physiological function (e.g., nerve conduction, muscle contraction, blood clotting, membrane permeability, enzyme activation, acetylcholine synthesis) (27). The average healthy adult body contains about 1200 g of calcium, 99% of which is found in bone and teeth, with the remaining 1% in extracellular fluids, intracellular structures, and cell membranes. The average calcium content of the blood ranges from 9.0 to 10.5 mg/dl with tight physiological controls. Decreased body calcium leads to loss of bone mineral, reduction of bone strength, increased susceptibility to fractures (479), and may increase blood pressure (382), particularly among pregnant women (65). Calcium deficiency is also associated with convulsions and tetany. The RDA for calcium is derived from the need to maintain skeletal calcium, using an estimated 200–250 mg/day obligatory loss and an oral absorption fraction of 30–40%, leading to a recommendation of 1200 mg/day for ages 11–24 years and 800 mg/day for older age groups, except that 1200 mg/day is recommended throughout pregnancy and lactation (420). In 1994 a National Institutes of Health Consensus Conference on Optimal Calcium Intakes recommended all Americans over 5 years of age consume levels of calcium higher than the current RDA, with the greatest change in calcium intake being for elderly persons, who should consume 1500 mg/day (419).

Calcium is not a very toxic metal, but adverse effects may occur at intakes greater than 2000 mg/day (419). Intestinal absorption of calcium decreases as intake increases; however, very large intakes of calcium can increase the calcium body burden (420) as well as interfere with the absorption of magnesium (515), zinc (195), and iron (240). Very large chronic intakes are associated with hypercalcemia and/or hypercalciuria. Other symptoms of calcium excess include renal failure and soft tissue calcification. High-calcium diets could increase the risk of kidney stones in susceptible individuals and reduce the biovailability of zinc and iron. Although excessive calcium intake from food and municipal water was previously seen mainly in individuals with conditions predisposing them to increased calcium absorption, such as parathyroidectomy (379), the consumption of calcium-fortified foodstuffs (e.g., sparkling water, breakfast cereal, orange juice) in addition to a diet containing generous amounts of dairy products could theoretically reach levels of concern (615). Education of health-care professionals and the general public is needed to prevent both overconsumption of calcium in one population and the risk of calcium deficiency in another. A potential adverse effect associated with habitual intake of calcium supplements is ingestion of heavy metals, such as arsenic, cadmium, and lead, which have been found to contaminate some calcium supplements (84, 614). With the increased interest in daily calcium supplementation as a preventive measure for colon cancer, osteoporosis, and hypertension, the possible contaminants of these supplements warrant further investigation. The Food and Drug Administration (FDA) does not regulate nutritional supplements; the amount of trace metal contaminants is variable.

Chlorine

Chloride is the principal extracellular inorganic ion. It is required for maintenance of fluid and electrolyte balance and for the production of gastric acid (420). Dietary chloride deficiency is rare, but prolonged loss of electrolytes from vomiting, diarrhea, heavy sweating, and so forth can lead to hypochloremic metabolic alkalosis. The minimum requirement of chloride, based on its close association with sodium in both dietary sources and physiological losses, is 750 mg/day (420).

Reactive chlorine compounds (chlorine gas, hydrochloric acid, hypochlorite, chlorine dioxide, etc.) are irritating to the tissues they contact, but neutral chloride solutions are nontoxic (179). Habitual excess intake of table salt may contribute to hypertension in susceptible individuals, and animal data suggest that the chloride ion may play a role as well as the sodium ion (410). This question has more than

theoretical implications because

potassium chloride is widely used as a salt substitute by individuals seeking to restrict their sodium intake. However, the sparse human data on the association between chloride intake and blood pressure are generally negative, and more studies are needed before restriction of chloride intake, independent of sodium intake, could be suggested to have a beneficial effect in the general population. The U.S. EPA has not derived any toxicity values for chloride (589).

Chromium

Chromium is a first series transition metal, with its name derived from the Greek word for color, because most chromium compounds are brightly colored. The only important chromium ore is chromite. Chromium is used as an alloy with other metals, and is also used for plating of metals (63). Although chromium can have valences from −2 to +6, the most important valences are +3 and +6 (31). Trivalent chromium is the most abundant form of chromium in the environment. Chromium(III) is an essential nutrient that plays a role in glucose metabolism (35, 63). Although Cr3+ is poorly absorbed orally (158), absorption is greatly enhanced by the presence of the "glucose tolerance factor," which forms a complex with Cr3+ (513). Chromium(III) is considered to be relatively nontoxic in vivo (63). Mice exposed to chromium(III) acetate in drinking water for over 2 years did not show an increased incidence of tumors (502).

Hexavalent chromium is the most important valence from a toxicity standpoint. Unlike chromium(III), chromium(VI) is readily absorbed by all tissues. Because chromate (CrO_4^{2-}) is structurally similar to phosphate and sulfate (139), it readily enters all cells via the general anion channel protein. Chromium(VI) is acutely toxic, with most reports of human toxicity occurring as a result of accidental or intentional ingestion. The lethal oral dose of soluble chromates in humans is estimated to be in the range of 50–70 mg/kg. Symptoms of acute toxicity include vomiting and generalized gastrointestinal tract damage, with gastrointestinal bleeding leading to cardiovascular shock. If the victim survives the initial toxic effects, liver necrosis, tubular necrosis of the kidney, and damage to the blood-forming tissues can occur (63). Long-term occupational exposure to chromium has been associated either with low-molecular-weight proteinuria, or with elevated levels of proteins normally found in the urine (63, 139). Although animal studies have shown that parenteral administration of 15 mg/kg potassium chromate (+6) is nephrotoxic, chronic renal disease due to occupational or environmental exposure has not yet been reported (63).

Dermal exposure to potassium dichromate and other chromium compounds can lead to the development of a sensitization reaction. The resulting hypersensitivity results from chromium binding to proteins and becoming a hapten (151). Prior to the implementation of appropriate industrial hygiene precautions, occupational inhalation exposure to Cr6+ was associated with changes in the septal mucosa, ranging from irritation to septal perforation (63). However, inhalation exposure rarely causes asthma (430).

The carcinogenicity of chromium in the respiratory tract has been well established, beginning when the first nasal tumors were described among Scottish chrome pigment workers in the late 19th century (432), and has been reviewed in the recent literature (63, 130, 139). The mechanism of action believed to be from a direct modification of DNA (444). After hexavalent chromate enters a cell, it is rapidly reduced to Cr3+. During the reduction process, unstable and reactive intermediates, including Cr(IV), Cr(V), hydroxide, thiyl and organic (RS and R) radicals, and active oxygen radicals are formed, and it is believed that these moieties are responsible for chromium carcinogenicity (130). Because Cr6+ is readily absorbed by all tissues, one could postulate that chromium-induced cancers should be noted in other organs. Although the evidence is not as strong, exposure to hexavalent chromium is associated with an increased incidence of may types of cancers (139).

The U.S. EPA has established an oral RfD for chromium(III) of 1.5 mg/kg/day, an oral RfD for chromium(VI) of 5 μg/kg/day, an inhalation RfC for chromic acid mists and dissolved Cr(VI) aerosols of $8.6\times10-3\mu$g/m3, and an inhalation RfC for Cr(VI) particulates of $1\times10-1\mu$g/m3. The U.S. EPA has classified chromium(III) as a group D (not classifiable) carcinogen and chromium(VI) as a group A (human) carcinogen.

Cobalt

Cobalt is an essential component of vitamin B12, which is involved in intermediary metabolism, nucleic acid synthesis, and single-carbon metabolism, and is required to prevent macrocytic megaloblastic anemia, atrophic gastritis, achlorhydria, neurologic degeneration, and dementia (27). Vitamin B12 is synthesized by bacteria, fungi, and algae, but not by yeasts, plants, or animals (420). Cobalt deficiency may develop in animals dependent on gut microflora for their vitamin B12, such as ruminants, and in strict vegetarians consuming no animal products. The RDA for vitamin B12 is 2 μg/day, and although

cobalt is known to activate the enzyme arginase (554), the only recognized requirement for cobalt is as a component of vitamin B12. Cobalt is a hard, silvery metal widely distributed in rocks and soils and always occurs with nickel and usually with arsenic (13). It is primarily used in the production of superalloys, as a drier in paints,

and in magnets, and in the production of prosthetic devices. Occupational exposure occurs in the hard metal industry, among cobalt blue dye plate painters, and in coal miners, and this exposure is reflected in elevated levels of cobalt in tissues and body fluids.

Cobalt can be toxic. For the general population, ingestion is the primary route of exposure (13). Oral exposure to cobalt caused cardiomyopathy among individuals who drank excessive amounts of beer (8–25 pints/day) containing cobalt as a foam stabilizer (405). This effect may have been potentiated by a combination of alcohol, preexisting heart damage, and/or poor diets associated with heavy alcohol consumption, because anemic individuals have been exposed to higher levels of cobalt without a similar effect (405, 516). Cobalt can cause allergic dermatitis (eczema and urticaria, mainly of the hands) (28, 598), and cross-reaction with nickel is frequent (595, 493). Inhalation exposure to cobalt alloyed to tungsten carbide (hard metal) is associated with hard metal disease, which is characterized by interstitial fibrosis and restrictive respiratory impairment (352). The toxic mechanism of hard metal particles is thought to involve both cobalt sensitivity and the generation of oxygen radicals by the carbide particles (352, 431). Cobalt by itself has caused occupational asthma in diamond polishers, and the effect has been attributed to an immunologic mechanism with cobalt acting as a hapten (207).

The carcinogenicity of cobalt is uncertain. Animal studies are positive only for subcutaneous, intramuscular, or intratracheal administration, but not for inhalation, and the excess rates of lung cancer observed in men occupationally exposed to cobalt dust could be explained by simultaneous exposure to nickel, arsenic, and/or tobacco (338, 439).

The U.S. EPA has not derived toxicity values for cobalt. The ACGIH has adopted TLV-TWA values for cobalt carbonyl and cobalt hydrocarbonyl of 0.1 mg Co/m3 (32).

Copper

Copper occurs naturally as the free metal and occurs in compounds in +1 or +2 valence state. Copper is incorporated into several enzymes involved in hemoglobin formation, carbohydrate metabolism, catecholamine biosynthesis, and cross-linking of collagen, elastin, and hair keratin (6). These enzymes include cytochrome *c* oxidase, dopamine β-hydroxylase, ascorbic acid oxidase, and superoxide dismutase, as well as interaction with ceruloplasmin and metallothionein. Copper deficiency causes anemia, neutropenia, and impaired growth, particularly in children (420). The ingestion of copper in foods is the primary source for copper intake. The intake from copper plumbing and unpolluted fresh water is not significant. The estimated safe and adequate daily dietary adult intake is 1.5 to 3.0 mg/day (420). The U.S. EPA action level for copper in tap water is 1.3 mg/L (129).

Copper is readily absorbed following oral ingestion, but homeostatic mechanisms limit further intake once requirements are met. Copper overload is normally further controlled by binding to metallothionein. Copper is either active or in transit, with little or no excess copper being normally stored (350). Following absorption, copper is bound to albumin and transcuprein, and is mainly deposited in liver hepatocytes with lesser amounts in the kidney. Biliary excretion is the major route with small amounts secreted in the urine. Considering these homeostatic mechanisms following oral intake, absorption through the inhalation or dermal routes may allow toxic levels to pass unimpeded into the blood.

The consumption of water containing high levels of copper or suicide attempts with copper sulfate can result in vomiting, diarrhea, nausea, abdominal pain, hemolytic anemia, hepatic and renal neurosis, and death. Industrial exposure may occur to copper fumes resulting in metal fume fever with dyspnea, chills, headache, and nausea (63). The ACGIH has adopted TLV-TWA values for copper of 1 mg Cu/m3 for dusts and mists and 0.2 mg Cu/m3 for fumes (32). The OSHA PEL differs with 0.1 mg/m3 for copper fume. Copper can be dermally absorbed from copper-containing topical products (335, 465, 466). Dermal irritation and contact allergic dermatitis have been associated with copper jewelry, intrauterine contraceptive devices, and through occupational exposure to electroplating and copper containing agricultural products (335).

Wilson's disease is one of several examples of toxicity involving copper in humans. This disease is due to an autosomal recessive disorder that affects normal copper homeostasis. There is an excessive retention of hepatic copper, decreased concentration of plasma ceruloplasmin, impaired biliary copper excretion, and hypercupremia, resulting in hepatic and renal lesions and hemolytic anemia (6). Menkes's disease is a multisystemic lethal disorder characterized by neurodegenerative symptoms and connective tissue manifestations. The disease is attributable to a deficiency of one or more copper-dependent enzymes (571).

Fluorine

Fluorine, the most reactive of the elements, is a pale yellow gas with a pungent odor. The chief fluoride sources are fluorspar (CaF2) and cryolite (Na3AlF6). Fluorine, hydrogen fluoride, and other fluorine

compounds are used in a wide number of applications in the nuclear (in the

synthesis of uranium hexafluoride), agrochemical (pesticides), drug (anticaries agents), and other industries (31, 63). Fluorine gas is a severe eye, mucosal, and skin irritant (31).

Hydrogen fluoride (HF) is a weak acid that causes severe burns on the skin and in the eye, either in aqueous solution or as the anhydrous acid (63). In addition to causing dermal and ocular damage, hydrogen fluoride is readily absorbed through the skin. Once absorbed, fluoride complexes with calcium and causes hypocalcemia. If the hypocalcemia is severe, death can occur via cardiac arrhythmia. Hydrogen fluoride burns over as little as 2.5% of the body surface have caused fatalities, depending on the concentration of HF (113, 118, 318).

Fluoride is incorporated into bones and tooth enamel, making teeth more resistant to caries, but fluoride deficiency has never been conclusively demonstrated in humans or animals, although goats fed <1 mg F/kg dry ration had reduced growth and survival (40). The NRC classifies fluoride as a beneficial but not an essential element (420). Fluoride replaces hydroxyl ions in enamel, yielding an apatite crystal that is more resistant to acid. Some studies suggest that fluoride supplements may also increase bone strength (452). Fluoride in aqueous solutions is virtually 100% absorbed, while absorption of fluoride in bone meal may be as low as 40% (420). The estimated safe and adequate daily dietary intake for fluoride from both food and water is set equal at 1.5–4 mg/day, based on the range of fluoride composition of diets in the United States (420). Although serious complications are rare (because of limitations set by the U.S. Food and Drug Administration on the total amount of fluoride in an over-the-counter anticaries drug product), acute fluoride toxicity can occur from accidental ingestion of fluoride containing products. In his review of reported accidental fluoride poisoning cases, Whitford (612, 613) proposed a "probably toxic dose" of 5 mg/kg, although toxicity has been reported at doses as low as 0.1 mg/kg (23).

Doses of fluoride above 2 mg/day can cause mottled teeth in children, doses over 8 mg/day can cause osteosclerosis, and doses of 20 mg/day for 10–20 years can cause hypermineralization of bone leading to crippling skeletal fluorosis and renal toxicity (378, 420). Fluoride increases bone mass but decreases its tensile strength, and is apparently not a treatment for osteoporosis (55). Case reports indicate that administration of sodium fluoride for treatment of osteoporosis can exacerbate rheumatoid arthritis, possibly by stimulating leukocytes and other mediators of the acute inflammatory response (163).

Human epidemiological studies have found no evidence that fluoride causes gastrointestinal, respiratory, reproductive, or developmental toxicity (92). Skeletal and dental changes can be seen in rodents exposed to fluoride, as well as chronic stomach inflammation and ulcers (92, 378). The U.S. EPA has derived an oral RfD for fluorine based on a no-observed-effect level (NOEL) for objectionable mottling of the teeth (dental fluorosis), which may occur in children drinking water with more than 1 ppm fluoride, leading to a NOEL of 0.06 mg/kg/day in a 20-kg child drinking 1 L/day and ingesting 0.1 mg/kg/day of dietary fluoride (589). The endpoint of dental fluorosis is not considered toxic or adverse. The ACGIH has adopted a TLV-TWA value for fluorides of 2.5 mg F/m3, with carcinogenicity classification A4 (not classifiable as a human carcinogen) (32).

The potential carcinogenicity of fluoride is debatable. No increase in tumors was found among mice exposed to 1.75 mg/kg/day of sodium fluoride in water for 30 months (297). Sprague-Dawley rats had no statistically significant increase in tumors following 2 years of exposure to doses up to 25 mg/kg/day (378). The National Toxicology Program 2-year drinking water study of sodium fluoride at doses up to 10 mg/kg/day found no evidence for carcinogenicity in female rats, male mice, or female mice, and equivocal evidence of carcinogenicity in male rats (92). The evidence in male rats consisted of an increase in bone osteosarcomas with a dose-response trend that was statistically significant but an incidence in the highest dose group that was not significantly elevated compared to controls (92). Also, no osteosarcomas were found in female rats even though they accumulated fluoride in bones to the same extent as the male rats and they exhibited fluoride-induced osteosclerosis (92). The U.S. EPA has not yet evaluated fluoride for potential human carcinogenicity (589). While human epidemiology studies have generally been negative, the question of whether fluoride is a potential human carcinogen is still open, and more studies are needed to resolve this question of some public health importance (55, 92, 378).

Iodine

Iodine is the heaviest of the halogens that are of industrial interest. In solid form, iodine takes the form of gray-black plates or granules. It volatilizes at room temperature, yielding a violet vapor (460). The major sources of iodine are oil and natural gas brines, with Japan's natural gas-well brines being credited with as much as four-fifths of the world's iodine reserve (460). Topical iodine solutions (2% iodine and 2% NaI in 50% alcohol, USP) have been used for decades as germicides and antiseptics (31). When inhaled, iodine vapor can be intensely irritating to mucous membranes and affects the upper

and lower portions of the pulmonary tract (30). Flury and Zernik (194) reported that humans could work undisturbed at 0.1 ppm, work with

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_657.html[2010/10/28 18:46:30]

difficulty at 0.2 ppm, and could not work at 0.3 ppm. Topical application of iodine solutions can cause irritation, and strong solutions can cause burns (31).

Iodide is required for the synthesis of the thyroid hormones thyroxine and triiodothyronine. Iodide is efficiently absorbed, and excess iodide is excreted in the urine (420). Deficiency of iodide causes hypothyroidism and goiter, and severe deficiency in the newborn may cause cretinism and mental retardation (183). The RDA for iodine is 150 μg/day for adults, with an extra 25 μg/day during pregnancy and 50 μg/day during lactation (420). Chronic absorption of high levels of iodide can lead to a condition known as iodism. This condition is characterized by sleeplessness, tremor, rapid heart rate, diarrhea, weight loss, conjunctivitis, rhinitis, and bronchitis. This syndrome is usually associated with long-term ingestion of iodide containing medications (31). The U.S. EPA and ACGIH have not derived toxicity values for iodide (32, 589).

Iron

Iron is a silver-white solid metal found mainly in combination with other elements as oxides, carbonates, sulfides, and silicates (63). It exists in two stable oxidation states, oxidized ferric (Fe^{3+}) and reduced ferrous (Fe^{2+}), which accounts for its essentiality as a trace element and its crucial role in the oxygen and electron transport reactions of all living cells. Dietary iron is available as either heme or nonheme (27). Heme iron is found in meats and is relatively well absorbed compared with nonheme iron, which is also found in meats, grains, and vegetables. Intestinal absorption of iron depends on iron status, with 10% of the total (heme plus nonheme) being absorbed when iron status is normal, but up to 20% in deficiency states. Adequate intakes of vitamin C increase the intestinal absorption of nonheme iron by two- to fourfold (138), which may be of significance to the iron status of vegetarians. Iron is lost through the shedding of cells, sweat, nails, hair, blood loss, menstruation, and in the urine. Early symptoms of iron deficiency are nonspecific and include fatigue and weakness. This progresses to iron-deficiency anemia, which is characterized by small red blood cells with low hemoglobin content (microcytic hypochromic anemia). These symptoms resolve after administration of iron. The RDA for iron is derived using an adequate body store of 300 mg, estimated losses of 1 mg/day in men and 1.5 mg/day in women, and an oral absorption fraction of 10–15%, leading to a recommendation of 10 mg/day for adults males and 15 mg/day for adults females, with an additional 15 mg/day recommended during pregnancy (420).

Free iron is an oxygen-reactive substance, highly toxic to cells, and will enhance the formation of free radicals and peroxidation of membrane lipids (49, 50, 491). Humans are unable to eliminate excess iron and regulate body iron stores by limiting absorption (381). Divalent iron is taken up by intestinal mucosa and converted to the trivalent form. The trivalent form is bound to transferrin (63, 247), a glycoprotein with two iron-binding sites (363). Iron is transported as transferrin to the liver or spleen, where it is stored as ferritin, which has a high iron storage capacity and prevents iron from participating in the Fenton reaction (59, 389). Of the typical 4-g body iron stores found in adults, 66% is bound as hemoglobin, 10% as the protein myoglobin, with a minute amount in iron-containing enzymes, and the rest as intracellular storage proteins. The physiological controls on this essential but potentially toxic metal can be overwhelmed, either by an acute large intake (accidental ingestion of dietary supplements by children) or by chronic excessive intake (endogenous sub-Saharan African populations with a probable genetic defect who consume beverages brewed in steel drums may develop pancreatic, hepatic, and/or renal toxicity from their accumulation of excessive iron) (221). Inhalation exposure to iron dust or fumes has resulted in pulmonary siderosis; fibrosis does not develop and the clinical course is benign (430). Hepatotoxicity is typically seen in patients with iron overload and can progress from portal fibrosis to cirrhosis (541). A gray-bronze hyperpigmentation of the skin caused by increased melanin and iron deposition usually resolves after iron removal. Free radical stress and lipid peroxidation have both been suggested as factors in the etiology of diabetes (443), and increased iron stores have been reported to contribute to the development of non-insulin-dependent diabetes (495). An increased risk of infection by a number of microorganisms, including *Vibrio vulnificus, Listeria monocytogenes, Yersinia enterocoloitica, Eschericia coli,* and *Candida* species, may result from excessive iron intake, due to direct effects on the immune system and/or enhanced bacterial growth due to the increased availability of iron (220, 249). Epidemiologic evidence suggests excess dietary iron is a coronary risk factor (494, 573, 574) and regular blood donation in middle-aged males is associated with a reduced risk of myocardial infarction (496).

Iron poisoning is the most common fatal poisoning in children reported to poison control centers in the United States (354, 610). Despite supplements being packaged in child-resistant packages and carrying warning labels, the public perception of their potential danger is low (274) and fatalities in children have

recently increased (34, 68, 610). Iron poisoning is characterized by four distinct clinical stages, but individual patients do not always demonstrate each stage (172, 228, 385): Stage I (initial period) occurs 0.5–2 h postingestion and is characterized by the onset of acute gastrointestinal symptoms (vomiting and diarrhea), but central nervous system (CNS) symptoms (lethargy and coma) may be present in severe cases;

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_658.html[2010/10/28 18:46:31]

stage II (quiescent period) occurs 6–24 h postingestion and the victim may be asymptomatic or appear to have improved; stage III (recurrent period) occurs 12–48 h postingestion and is characterized by gastrointestinal perforation, coma, convulsions, cardiovascular collapse, hepatic and renal failure, and metabolic acidosis; and stage IV (late period) occurs 3 to 4 weeks postingestion with the appearance of gastrointestinal scarring. The failure to recognize a patient in stage II iron poisoning has been noted as a "pitfall" in the medical management of iron poisoning (396) and has resulted in premature discharge (172). Gastrointestinal symptoms typically occur following the ingestion of 20 mg elemental iron/kg body weight, and doses greater than 60 mg/kg are often lethal. Treatment involves stabilizing vital functions, removing unabsorbed iron from the gastrointestinal tract, and intravenous administration of deferoxamine if symptoms are severe (34, 385, 396). Deferoxamine is an iron chelator produced by *Streptomyces pilosus* and removes iron from transferrin and ferritin, but not hemoglobin (359, 555). Current research is directed toward the design of an orally active, nontoxic, selective iron chelator (258, 320). The FDA recently issued regulations requiring all iron-containing products to carry a label stating the dangers of iron overdosage and unit-dose packaging for products containing 30 mg or more per dosage unit (591). The U.S. EPA has not derived any toxicity values for iron (589); the ACGIH has adopted TLV-TWA values for iron of 5 mg Fe/m3 for iron oxide dust and fume and 1 mg Fe/m3 for soluble iron salts (32).

Magnesium

Magnesium is essential to a large number of biochemical and physiological processes including neuromuscular conduction in skeletal and cardiac muscle (63). It is also an important structural component of bone (420). Plasma concentrations of magnesium are regulated within a narrow range (0.65–1.0 m*M*), primarily by adjustments in the reabsorption of filterable magnesium in the loop of Henle, and also by the passive buffering by bone magnesium (420). Magnesium deficiency can occur secondarily to general malnutrition, alcoholism (480), or other disease states that affect gastrointestinal electrolyte absorption or excretion or renal cation reabsorption. Magnesium deficiency results in reduced levels of potassium and calcium, as well as symptoms of nausea, muscle weakness, irritability, and mental derangement (525). The RDA for magnesium is derived from balance studies indicating that magnesium balance can be maintained in healthy men at intakes of 3.0–4.5 mg/kg/day, leading to a recommendation of 350 mg/day for men and 280 mg/day for women, with an extra 20 mg/day during pregnancy and 75 mg/day during lactation (420). Average intakes of U.S. adults are not much above the RDAs; however, there is no definitive evidence of effects attributable to magnesium deficiency (420). Vitamin D facilitates the absorption of magnesium (398).

Oral exposure to magnesium is not toxic except in individuals with impaired renal function, who may experience nausea, vomiting, and hypotension, followed by CNS depression accompanied by a sharp drop in blood pressure and respiratory paralysis (63, 420). Magnesium salts are poorly absorbed orally and are commonly used as antacids or cathartics. Inhalation exposure to magnesium oxide can cause metal fume fever (19, 63, 430). The U.S. EPA has not derived toxicity values for magnesium; the ACGIH has adopted a TLV-TWA value for magnesium oxide fumes of 10 mg/m3 (nuisance dust) (32).

Manganese

Manganese is a silver-gray soft metal and occurs in ores mainly as oxides (63). Manganese and its compounds are used in numerous products and applications including iron and steel alloys, dry cell batteries, paints, inks, fertilizers, and fungicides (208). Manganese is an essential trace metal that is a component of several mitochondrial enzymes, pyruvate carboxylase and superoxide dismutase, and activates a wide variety of enzymes (decarboxylases, transferases, hydrolases). It occurs in meats, poultry, nuts, grains, green leafy vegetables, and tea. Although outright manganese deficiency has not been observed in the human population, suboptimal manganese intake may be a concern (589). In animals, manganese deficiency can cause impaired growth, skeletal abnormalities, and altered metabolism of carbohydrates and lipids (22). The estimated safe and adequate daily dietary intake for manganese is set equal to current U.S. dietary intakes, based on a lack of evidence for human manganese deficiency, yielding a range of 2–5 mg/day (420). The U.S. EPA has reviewed numerous human and animal studies and related information and concluded that an appropriate chronic oral reference dose for manganese is 10 mg/day (0.14 mg/kg/day) (589). Only between 3 and 10% of dietary manganese is absorbed in normal adults, and total body stores are controlled by a complex homeostatic mechanism regulating absorption and excretion. Calcium, iron deficiencies, age, and other factors may increase manganese absorption (22, 589).

Occupational inhalation exposure is the primary route for manganese toxicity. The primary toxic effect of occupational inhalation exposure is neurological damage (483); however, inhalation exposure to

manganese can also affect the lung directly, causing metal fume fever, pneumonitis, chronic obstructive lung disease, and pneumonia (22, 430). Occupational exposure to manganese

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_659.html[2010/10/28 18:46:32]

Page 660
at levels of about 1 mg/m3 may decrease male fertility (205, 337). The neurological effects of inhalation of manganese dusts, termed manganism, typically begin with weakness and lethargy, and may progress to disturbances in speech and gait, a mask-like face, tremor, and possibly hallucinations and psychosis (483). Symptoms may resemble Parkinson's disease, but there is only minimal response to L-dopa therapy. The pathobiochemical aspects of manganism involve the striatum and globus pallidus. Cell damage may be due to the auto-oxidation of dopamine with the formation of free radicals (596). Manganese applied to the nasal cavity in rats is taken up in the olfactory receptor cells and transported along the primary neurons to the olfactory bulbs, with subsequent migration into most parts of the brain. This route circumvents the blood-brain barrier (559). More subtle nonclinical neurological damage can be identified by neurobehavioral tests (reaction time, finger tapping, hand steadiness, etc.) in men chronically exposed to levels as low as 0.14mg/m3 for 1–35 years (283). Impairment of speed and coordination of motor function are noted.

The U.S. EPA has derived a recent inhalation RfC of 0.05 μg/m3 based on studies of Roels et al. (483, 589). The previous RfC was 0.4 μg/m3. The ACGIH has also lowered the TLV-TWA value to 0.2 mg Mn/m3 for elemental and inorganic compounds (32). Manganese cyclopentadienyl tricarbonyl (MMT) is a gasoline octane enhancer in use since 1970. The major combustion products of MMT are manganese particulates of manganese phosphate with some sulfates and a small amount of oxides. The TWA-TLV for MMT is 0.1 mg Mn/m3, with a notation noting the potential for dermal absorption (32). Little evidence exists to suggest that manganese has carcinogenic potential. A 2-year bioassay of manganese sulfate monohydrate in the diet found no evidence of carcinogenicity to rats and equivocal evidence of carcinogenicity to mice (22). The U.S. EPA has classified manganese as a group D carcinogen (not classifiable as to human carcinogenicity), based on inadequate evidence in humans and animals (589).

Molybdenum

Molybdenum is a silver-white metal of the second transition series. The primary molybdenum-containing ore is molybdenite (MoS_2), with minor ores being powellite ($CaMoO_4$) and wulfenite ($PbMoO_4$). Metallic molybdenum is used in a number of important applications, such as in high temperature and tool steel alloys, and in missile and aircraft parts. Molybdenum disulfide is used as a dry lubricant or as a component in lubricants (31).

Molybdenum is a constituent of several enzymes, including aldehyde oxidase, xanthine oxidase, and sulfide oxidase (420). Deficiency is extremely rare; one patient on total parenteral nutrition had disturbed sulfur and uric acid metabolism that resolved after molybdenum supplementation (420). The estimated safe and adequate daily dietary intake for molybdenum is set equal to the current U.S. dietary intake for molybdenum, based on the lack of evidence for human molybdenum deficiency, yielding a range of 75–250 μg/day (420). High levels of molybdenum in herbage eaten by cattle caused diarrhea in cattle (186), which could be alleviated by the administration of copper salts (429). Further study has shown an inverse relationship between molybdenum and copper. When molybdenum intake in cattle is increased, the concentration of utilizable copper in the liver decreases (63).

The acute oral toxicity of molybdenum compounds is related to their solubility. Molybdenum trioxide, calcium molybdate, and ammonium molybdate caused fatalities in rats when administered at doses from 1.2 to 6.0 g Mo/kg. Conversely, administration of insoluble molybdenum disulfide to rats at concentrations as great as 6.0 g Mo/kg did not cause any fatalities (182). The U.S. EPA derived an oral RfD for molybdenum of 5 μg/kg/day (250 μg/day for a 70-kg adult) based on an increase in urinary uric acid levels in humans exposed to 10 mg Mo/day in the diet with an uncertainty factor of 30 (589). Rodent bioassays of molybdenum trioxide indicate that this compound is carcinogenic in rats and mice, causing an increased incidence of alveolar/bronchiolar adenoma or carcinoma (combined). Male rats and mice appear to be more sensitive to the carcinogenic effects of molybdenum trioxide (114).

Dental technicians exposed to dust of vitallium alloy, which contains chromium, cobalt, and molybdenum, can develop pneumoconiosis that is clearly different from hard-metal lung disease associated with cobalt exposure (430), and there are some data to suggest that molybdenum inhalation can cause pneumoconoiosis (31). The ACGIH has adopted TLV-TWA values of 10 mg Mo/m3 for insoluble compounds and 5 mg Mo/m3 for soluble compounds (32).

Phosphorus

Phosphorus is an essential component of bone and also participates in many important biochemical reactions (420). Approximately 85% of the body store of phosphorus is in bone, with the rest as soluble phosphate ion and a component of a variety of biomolecules. Absorption of phosphate ranges from 50–70% when intake is adequate, to 90% when intake is low (420). Dietary phosphorus deficiency is rare but can occur following prolonged use of the antacid aluminium hydroxide, which binds phosphorus into

an unavailable form. Symptoms of

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_660.html[2010/10/28 18:46:32]

phosphorus deficiency include bone loss, weakness, anorexia, and pain. The RDA for phosphorus is set equal to the RDA for calcium, based on a lack of evidence for either phosphorus deficiency or toxicity at usual U.S. intakes, yielding 1200 mg/day for ages 11–24 years, 800 mg/day for older age groups, with an extra 400 mg/day throughout pregnancy and lactation (420).

High-level phosphate intake in the forms of phosphate-fortified infant formulas, phosphoric acid in carbonated beverages, or purified amino acids may cause calcium loss, which can be adverse in situations of inadequate calcium intake; however, phosphorous in the form of complex proteins does not seem to have this effect (420, 537). Certain reactive forms of phosphate may be chemically irritating, but neutral phosphate solutions are essentially nontoxic (304). Phosphorus as the free element does not occur in nature. It exists either as relatively nontoxic red phosphorus or toxic yellow (or white) phosphorus (150). Toxic exposure to yellow phosphorus can occur through the oral, dermal, or respiratory routes. Rodenticides and insecticides containing yellow phosphorus have accounted for poisonings characterized initially by gastrointestinal burning and severe abdominal pain, vomiting, and diarrhea. Acute cardiovascular collapse may occur (276, 463). If survived, a second stage of symptoms may occur up to several weeks later, resulting in systemic toxic effects on the liver, heart, kidneys, or central nervous system. Phosphorus can cause necrotic skin burns. The fumes are irritating to the respiratory tract, eyes, and skin. Phosphorous is converted to phosphates and excreted in the urine. The U.S. EPA has derived a chronic oral RfD for elemental phosphorus based on studies of Condray (137), which found increased mortality in pregnant rats near the end of gestation at a dose of 0.075 mg/kg/day for 80 days prior to mating and during gestation. A NOAEL of 0.015 mg/kg/day was converted to an RfD of 0.02 μg/kg/day (1.4 μg/day for a 70 kg adult) with low confidence, using an uncertainty factor of 1000 (a factor of 10 for interspecies variation, 10 for intraspecies variation, and 10 for incomplete reproductive/developmental data and a less-than-adequate lifetime study), and a modifying factor of 1 (589). The ACGIH has adopted TLV-TWA values for phosphorus of 0.2 ppm for phosphorus trichloride, 1 mg/m3 for phosphorus pentasulfide, 0.1 ppm for phosphorus pentachloride, 0.1 ppm for phosphorus oxychloride, and 0.02 ppm for yellow phosphorus (32). No data exist to suggest that phosphorus may have carcinogenic potential.

Potassium

Elemental potassium is a highly reactive soft metal with a silver-colored appearance and is not found in nature. Potassium compounds are common. Elemental potassium is even more reactive than sodium and must be stored under airtight anhydrous conditions, such as under xylene. Oxidation on the surface of the metal may form highly reactive superoxides, which can detonate the bulk, causing spattering and skin and eye penetration (326). Autoignition can occur at room temperature. Dermal and ocular thermal burns and liquefaction necrosis due to the formation of potassium hydroxide are the primary effects following exposure. Imbedded particles require surgical debridement. Water irrigation is contraindicated.

Potassium is the principal cation of intracellular fluid, accumulating to a concentration about 30 times higher than in plasma. Potassium in plasma is involved in nerve transmission, muscle contraction, and blood-pressure homeostasis. The gastrointestinal absorption of potassium is nearly complete; plasma concentrations are kept within a narrow range by regulation of urinary excretion, and by depletion of body stores in cases of low potassium intake (420). Dietary potassium deficiency is rare, but prolonged vomiting, diarrhea, or diuretic use may deplete potassium enough to cause weakness, anorexia, nausea, drowsiness, irrational behavior, and, in severe cases, potentially fatal cardiac arrhythmias (420). Potassium appears to moderate the effect of increased sodium intake on elevating blood pressure, probably by affecting renal sodium excretion (410). The minimum requirement for potassium is based on the need for 1600 mg/day to maintain normal body stores and plasma levels (420). Dietary potassium is not toxic if sufficient water is ingested and renal function is adequate to maintain homeostasis; symptoms of hyperkalemia from dehydration or acute renal failure are similar to those of hypokalemia, including muscle weakness, fatigue, and paralysis (74). The U.S. EPA has not derived any toxicity values for potassium.

Selenium

Selenium is widely distributed in nature and found in combination with sulfides and other minerals (20, 64). It has semiconducting properties and is used in photocopying machines, light meters, and rectifiers; cadmium selenide is a pigment used for car taillights; and it is used in agriculture and personal care as a component of fertilizers, pesticides, animal feeds, and antidandruff shampoo (20, 31, 196). Although selenium has long been known to protect vitamin E-deficient rats from liver necrosis (512) a specific biochemical role was not elucidated until Rotruck et al. (487) demonstrated it to be an essential constituent of glutathione peroxidase. This enzyme protects polyunsaturated fatty acids in the cell

membrane from oxidative damage caused by free radicals. Its identification in human erythrocytes established selenium as an essential trace element in human nutrition (46). Selenium deficiency has been ident

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_661.html[2010/10/28 18:46:33]

ified as the major causal factor in the potentially fatal cardiomyopathy affecting young children and women of child-bearing age in the Keshan region of the People's Republic of China (303). A diet based primarily on local produce grown in the selenium-poor soil resulted in a selenium deficiency, alleviated by supplementing the diet with selenium-fortified table salt (123). Additional evidence for essentiality in humans is provided by the observed cardiomyopathy seen in patients maintained on long-term total parenteral nutrition (292, 355, 594). Selenium also plays an important role in the control of thyroid hormone (70), which is essential for normal growth, development, and metabolism. The selenoenzymes, iodothyronine deiodinases, are responsible for the activation of thyroxine (T4) to triiodothyronine (T3), and a selenium deficiency may cause reduced growth rates. The RDA for selenium was derived from the intake associated with a plateauing of plasma glutathione peroxidase activity in Chinese adult males (40 μg/day) (625), adjusted for differences in body weight between the reference Chinese and North American male, with an additional safety factor of 1.3 to account for individual variation (346, 420). The RDA for selenium is 70 and 55 μg/day in males and females, respectively with additional recommendations of 10 μg/day during pregnancy and 20 μg/day during lactation. Selenium is readily absorbed from the gastrointestinal tract, and the average U.S. diet typically provides 60–150 μg/day (539), which should be adequate to prevent cardiomyopathy in the general population.

Selenium toxicity has long been observed in cattle grazing on milk vetch (legumes of *Astragalus* species) grown in the seleniferous soils of Wyoming and South Dakota (246, 299, 374, 408). Acute intoxication in livestock is known as "blind staggers" and is characterized by signs of CNS impairment (ataxia, impaired vision, disorientation), and respiratory distress. Chronic exposure to moderately toxic selenium levels is known as "alkali disease" and results in skin lesions with alopecia, hoof necrosis and loss, growth retardation, anemia, and cardiac atrophy. In humans, chronic sublethal selenium toxicity has been observed in individuals living in seleniferous areas and is characterized by hair or nail loss, thickened or brittle nails, garlicky breath, tooth decay (235, 236), skin lesions, gastrointestinal disorders, and CNS abnormalities including peripheral anesthesia, acroparesthesia, and pain in the extremities (503, 534, 625). It has also been reported following the ingestion of superpotent selenium dietary supplements, and consumers need to be aware of its potential for toxicity (253, 289). The deterioration of keratinized tissue is thought to result from the replacement of sulfur with selenium in methionine, cystine, and other sulfurcontaining amino acids. Acute selenium intoxication resulting from ingestion is rare in humans (204), but has been reported following suicidal, accidental, and homicidal exposure (102, 323, 364, 490). Symptoms include gastrointestinal disturbances due to the irritative properties of selenium, a characteristic garlicky breath from the exhalation of dimethyl selenide (384), formication of the nose, signs of rhinitis, neurological symptoms ranging from mild tremors to myoclonic jerks, and cardiovascular shock. Acute inhalation of hydrogen selenide has been reported to cause severe dyspnea with abnormal pulmonary function tests (501), and chronic inhalation of the gas leads to garlicky breath, gastrointestinal disturbances, dental caries, nail deformities, and conjunctivitis (24). Chronic overexposure to selenium has been associated with the motor neuron disease amyotrophic lateral sclerosis (329, 599). Although selenium is known to be an avian teratogen (198, 264, 408) there is inconclusive evidence linking it to mammalian teratogenesis (287, 521); Yang et al. (624, 625) did not observe teratogenesis in babies during epidemiological studies in seleniferous regions where malformed chicks hatched from local eggs.

The U.S. EPA has established a chronic oral RfD for selenium using the study of Yang et al. (624) and corroborated by Longnecker et al. (357). The NOAEL of 0.85 mg Se/day was converted to a dose of 0.015 mg/ kg/day (based on an average adult body weight of 55 kg), and an RfD of 5 μg/kg/day was derived using an uncertainty factor of 3 (less than a full factor of 10 was used to account for sensitive individuals because of the availability of epidemiological data from two independent studies of moderate size) (589). Confidence in this RfD is considered high (589). The U.S. EPA has not derived RfCs for selenium. The ACGIH has adopted a TLV-TWA value for selenium of 0.2 mg Se/m3 (32).

Various animal models report a protective effect of pharmacologic levels of selenium against chemical carcinogenesis (127, 282, 473, 557). In 1969, Shamberger and Frost (520) reported an inverse relationship between cancer mortality rates in the United States and plant selenium levels as mapped by Kubota et al. (328). Subsequent epidemiological studies have reported promising but inconclusive findings (136, 273, 319). A recent randomized cancer prevention trial reports that 200 μg selenium daily did not protect against the development of recurrent skin cancers, but was inversely associated with mortality from total prostrate, lung, and colorectal cancers (125, 126). Another study reports an inverse relationship between advanced prostrate cancer and toenail selenium concentration (627), an indicator of past selenium intake. One of the authors, Gerald Combs, pointed out that "the greatest value of

epidemiology is in generating hypotheses, not testing them" (184), and stressed the requirement for further research before a beneficial effect of increased selenium intake can be established.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_662.html[2010/10/28 18:46:33]

Selenium sulfide has been shown to be a rodent carcinogen by the oral (417) but not dermal (416, 418) route. A 2-year gavage bioassay of selenium sulfide by the National Toxicology Program produced evidence of carcinogenicity in male rats (liver), female rats (liver), and female mice (liver and lung), but not in male mice (417). The U.S. EPA classifies selenium sulfide as a group B2 carcinogen (probable human carcinogen), based on inadequate data from human studies and sufficient evidence from rodent studies; no quantitative risk assessment was performed (589). Other selenium compounds are classified as group D carcinogens (not classifiable as to carcinogenicity in humans) based on inadequate evidence in both humans and animals (589). The suggested beneficial antioxidant effects of selenium and the potential widespread use of selenium supplements make it important to gain a fuller understanding of selenium toxicology.

Sodium

Sodium is a highly reactive soft metal with a silver appearance that is not found in the elemental form in nature (326). Sodium compounds are ubiquitous in nature. Elemental sodium must be stored under airtight anhydrous conditions, such as under oil, to prevent oxidation, which can produce autoignition at room temperature. Superoxides may form resulting in a violent explosion. Dermal and ocular thermal burns and liquefaction necrosis due to the formation of sodium hydroxide are the primary effects following sodium exposure. Explosion may cause particles to imbed in the skin and eye requiring surgical debridement. Water irrigation is contraindicated.

Sodium is the principal cation of extracellular fluid and the primary regulator of extracellular fluid volume. Sodium also regulates osmolarity, acid-base balance, and membrane potential, and participates in active transport across cell membranes. Renal excretion of sodium maintains homeostasis over a wide range of intakes and losses, via aldosterone control of tubular excretion. Sodium deficiency is very uncommon but may occur after heavy and prolonged sweating, chronic diarrhea, or renal disease, and constitutes a medical emergency. Dietary sodium is not toxic if sufficient water is ingested and renal function is adequate to maintain homeostasis (420). Lifelong excess intake of sodium may predispose sensitive individuals to hypertension, and individuals diagnosed with high blood pressure are commonly advised to limit sodium intake to 1–2 g/day or less (410). At present, the public health benefit of restricting sodium intake in the general population is not firmly established (420). The U.S. EPA has not derived any toxicity values for sodium.

Zinc

Zinc is a bluish-white, soft metal extracted from ore and is used in alloys, for galvanizing iron to prevent corrosion and oxidation, and in numerous compounds including use in cosmetics, pharmaceuticals, and dry-cell batteries (190). At temperatures approaching its boiling point, zinc volatilizes and oxidizes to the white fume of zinc oxide (31). Zinc is an essential trace element and is a required component of many enzymes (420). Zinc is stored in bone and muscle, but is not readily released from these stores during deficiency. Gastrointestinal absorption of zinc is higher when body stores are lower, and is also higher from more refined diets. Zinc deficiency causes loss of appetite, growth retardation, and slow wound healing; no single enzyme function has been identified as associated with these signs of zinc deficiency. Severe zinc deficiency causes hypogonadism and dwarfism, which are alleviated with zinc supplementation. The RDA for zinc is derived from an estimated 2.2–2.8 mg daily loss and an oral absorption fraction of 20%, plus a 20% safety factor, leading to a recommendation of 15 mg/day for adult men and 12 mg/day for adult women, with an additional 3 mg/day during pregnancy and 7 mg/day during lactation (420).

Inhalation exposure to zinc oxide fume can cause metal fume fever (31). Zinc chloride fume is a corrosive material that has caused chemical pneumonitis, alveolar and bronchial obliteration, and death (21). Zinc compounds are absorbed orally and excreted primarily in the feces. Zinc has low human toxicity by the oral route, but high levels can cause gastrointestinal (GI) distress (21). Long term oral intakes of zinc at levels of 18.5–25 mg/day can interfere with copper absorption, and intakes 10–30 times the RDA can impair immune responses and decrease serum high-density lipoprotein (420). The U.S. EPA has derived an oral RfD for zinc of 0.3 mg/kg/day (589). No inhalation RfC has been derived for zinc. The U.S. EPA has classified zinc as a group D carcinogen (not classifiable as to human carcinogenicity) based on inadequate evidence in humans and animals. The ACGIH has adopted TLV-TWA values for zinc of 10 mg/m3 for zinc dust, 5 mg/m3 for zinc oxide fume, and 1 mg/m3 for zinc chloride fume (32).

A summary of quantitative values for essential elements is given in Table 14.1. Elements are listed in the order of highest to lowest dietary requirement.

MAJOR TOXIC METALS

Arsenic
Arsenic is a Group VA element of the periodic table, the 52nd most abundant element in the earth's crust.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_663.html[2010/10/28 18:46:34]

a For a 70-kg adult; see text for actual values.
b RfD, reference dose.
c RfC, reference concentration.
d Group A, known human carcinogen; group B2, probable human carcinogen; group D, not classification as to human carcinogenicity.
e Chromic acid mists and soluble Cr(VI) aerosols
f Chromium(VI) particulates
g Based on cobalt content of vitamin B12.

Arsenic is refined from the minerals arsenopyrite and loellingite, or it can be prepared from the reduction of arsenic trioxide. The main use of arsenic in the United States is in the production of herbicides and other agricultural chemicals. Arsenic is also used in the semiconductor industry (32). Although arsenic can exist in several valence states, the +3 and +5 states are the most prevalent, with arsenic (+3) being more toxic than arsenate (+5) (172). Dietary consumption of arsenic is generally low; the typical daily American intake is 145 μg/day from both food and water (60). However, consumption of seafood can increase the amount of arsenic ingested (278, 570).

Arsenic is readily absorbed via the gut (63), and excretion occurs primarily in the urine (93, 141, 369, 549). Two processes are involved in the metabolism of arsenate and arsenite; the interconversion of arsenate and arsenite, and the conversion of these moieties to monomethyl arsenic acid and dimethyl arsenic acid. Because the meth ylated forms of arsenic are less toxic and because methylation results in lower tissue retention of inorganic arsenic, the methylation process is viewed as a detoxification mechanism (15).

Arsenic is believed to exert its toxic effects through at least two mechanisms, depending on its valence state. Arsenate inhibits ATP synthesis by uncoupling oxidative phosphorylation, whereas arsenite reacts with thiol groups on the active sites of many enzymes and tissue proteins, such as keratin (i.e., skin, nails, and hair) (550). Because of this reactivity with thiol groups, arsenic concentrates in the skin, hair, and nails. Mee's lines (horizontal white lines on the fingernails) appear in exposed individuals after the exposed nail bed grows to the exterior (390). At one time, inorganic arsenic was widely used as a "criminal poison" because it was odorless and nearly tasteless. The lethal dose of arsenic trioxide can be as low as 0.2 g (222). Acute toxicity is characterized by severe gastrointestinal symptoms, which

occur from 30 min to several hours after ingestion. Eventually, severe gastrointestinal hemorrhaging occurs, leading to profound losses of fluid and electrolytes, resulting in collapse, shock, and death (222). If the victim survives the initial toxic sequelae, jaundice, renal failure, and peripheral neuropathology can develop (172, 222).

In cases of acute intoxication, chelation therapy can be very effective in reducing or preventing symptoms. The agent of choice is British anti-lewisite (BAL), which is dimercaptopropanol (620). D-Penicillamine is also effective as a chelating agent, but nephrotoxicity and optic neuritis can result from long-term use (172). Therefore, BAL remains the treatment of choice in arsenic poisoning (222).

Chronic ingestion of arsenic can be difficult to diagnose. Diarrhea and abdominal pain can occur, as well as hyperpigmentation, hyperkeratosis, and numerous other skin- and hair-related disorders (48, 101, 172, 267, 553). Peripheral vascular occlusive disease has also been linked to chronic exposure to high levels of arsenic in drinking water in Chile (Raynaud's phenomenon) (83) and in Taiwan (blackfoot disease) (566). Neurological changes have been associated with occupational inhalation exposure to inorganic arsenic by smelter workers (81, 185, 257). Neurologic changes included peripheral neuropathy of sensory and motor neurons, as measured by motor and sensory deficits (406) and encephalopathy, as evidenced by hallucinations and other psychological disturbances (61).

Chronic exposure to arsenic in drinking water is associated with an increased incidence of cancer. Numerous studies have been conducted in Taiwan, comparing residents in the blackfoot disease endemic area with residents in areas with low levels of arsenic in drinking water. These studies have consistently shown an increase in the incidence of skin cancer and several internal cancers in areas with high arsenic consumption (119–122, 566, 567, 621). A similar study was conducted in Japan, which showed an association between high levels of ingested arsenic and lung and urinary-tract cancer (569). Chronic exposure to arsenic via the inhalation route is also associated with the development of tumors. Studies of smelter worker populations have shown strong associations between exposure and an increased incidence of lung cancer (47, 175, 341, 476, 560), as have studies of pesticide manufacturing workers (362, 451) case reports of lung cancer in arsenical pesticide applicators (486). Although the carcinogenicity of arsenic is well established in humans, carcinogenicity in animal models has been more difficult to establish. Of the many animal carcinogenicity studies reviewed by the IARC in 1980 (570), only two gave positive results: one with subcutaneous/intravenous administration of sodium arsenite in mice in a multigenerational study (450), and one with intratracheal installation of copper and calcium arsenate in rats (285). Later studies showed that both calcium arsenate and arsenic trioxide are carcinogenic when administered intratracheally to Syrian golden hamsters (284, 461, 462). The mechanism of carcinogenicity is postulated to be related to the multistep metabolism of pentavalent arsenic to dimethyl arsenic acid, during which free radicals are produced (63, 550).

Arsine, AsH3, is a gaseous form to arsenic that is formed whenever arsenic is in the presence of hydrogen (222) and as such can be generated in metal tanks storing acids that contain arsenic impurities (63). The toxicity profile of arsine is different from all other arsenic compounds. The hallmark of arsine toxicity is hemolysis, sometimes followed by acute renal failure (222). BAL and D-penicillamine are not effective treatments for arsine poisoning (222).

The U.S. EPA has established the following RfDs for arsenic compounds: inorganic arsenic, 0.3 μg/kg/day (group A (human) carcinogen); arsine 0.05 μg/m3 (589). The ACGIH has adopted the following TLVs for arsenic compounds: arsenic, elemental arsenic, and inorganic compounds, as As, 0.01 mg/m3 (A1 carcinogenicity notation; confirmed human carcinogen); arsine, 0.05 ppm (32).

Cadmium

Cadmium is a soft silver-white metal, often found in association with zinc and obtained primarily as a by-product of zinc preparation (63). It is used primarily in the production of nickel-cadmium batteries (35%), but also for metal plating (30%), pigments (15%), plastics and synthetics (10%), and miscellaneous uses (10%) (16). The toxicity of cadmium has been widely investigated, and cadmium has been shown to affect nearly every organ system if the dose is high enough (71). Acute effects of cadmium depend on the route of exposure. Symptoms of acute inhalation exposure to cadmium develop 4–10 h postexposure and initially simulate metal fume fever (fever, nausea, vomiting, headache, cough, dyspnea, nasopharyngeal irritation), but with progression to chemical pneumonitis and a potentially fatal pulmonary edema (71, 76, 79, 164). A fatal dose can be inhaled by exposed individuals who are unaware of either the presence of cadmium or its inhalation hazard (71, 360). Cadmium absorption following inhalation exposure is dependent on particle size and solubility and ranges from 20 to 50% of the amount inhaled (200). Fatal doses have been estimated at 50 mg/m3 for 1 h (57, 96) and 9 mg/m3 for 5 h (71). Recovery following acute high-level exposure or chronic exposure at lower levels may be

accompanied by pulmonary fibrosis (56, 144, 562). Oral exposure to cadmium is rarely fatal because the gastrointestinal irritation leads to vomiting, eliminating most of the dose before absorption (52, 95, 361, 440, 526). Gastrointestinal

absorption is about 5%, but can reach 20% with concurrent calcium or iron deficiency (192, 200). Rats exposed by intravenous injection to 4 mg Cd/kg developed a potentially lethal hepatic necrosis (162, 213).

Chronic inhalation or ingestion of cadmium results in kidney damage, characterized by tubular and/or glomerular dysfunction with proteinuria, low concentration capacity, and decreased inulin clearance (200). Increased urinary excretion of β2-microglobulin, a low-molecularweight protein normally reabsorbed in the proximal tubule, is an early indicator of renal dysfunction and should be regarded as an adverse effect because it is predictive of an increase in the age-related decline in the glomerular filtration rate (484). Absorbed cadmium is first transported to the liver, where it stimulates the synthesis of metallothionein and is sequestered as cadmium-metallothionien. Small amounts of liver cadmium-metallothionein are released into the plasma following normal cell turnover, filtered with the primary urine, and reabsorbed into the proximal tubular cells, where lysosomes degrade the metallothionein portion, with the release of cadmium, which then induces renal metallothionein synthesis. Renal damage results when the kidneys can no longer produce sufficient metallothionein to sequester the cadmium ion and prevent its interaction with critical macromolecules (224). Free cadmium may inactivate metalloenzymes, activate calmodulin, and/or damage cell membranes through activation of oxygen (602). This threshold level is commonly called the *critical concentration*. Kjellström et al. (314) proposed the term *population critical concentration* (PCC), where a PCC-10 indicates the cadmium concentration in the renal cortex that is likely to result in renal dysfunction in 10% of an exposed population—that is, 10% of the exposed population will have exceeded their individual critical concentrations. They estimated the PCC-10 to be 180–220 μg/g and the PCC-50 to be 25% higher. Excess inhalation or ingestion exposure to cadmium leads to abnormalities of calcium metabolism, and susceptible individuals may develop a painful bone disease as first discovered in a cadmium-contaminated area in Japan (Toyama Prefecture) and termed itai-itai (ouch-ouch) disease (412, 568). The disease is characterized by osteomalacia and osteoporosis with an increased tendency to spontaneous fracture and is associated with bone pain and renal tubular dysfunction. Cadmium has been shown to increase bone resorption and inhibit bone formation in both in vivo and in vitro systems (73). Current knowledge suggests that bone changes associated with pregnancy, lactation, and menopause may enhance cadmium's effect on bone. There is conflicting evidence concerning cadmium exposure and the risk of developing hypertension, with human studies reporting either positive, negative, or no effect (16, 413). This suggests that a cadmium effect on blood pressure is small to nonexistent compared to other established risk factors. Cadmium-exposed populations are not reported to have elevated death rates associated with cardiovascular disease. Maternal and fetal toxicity of cadmium is well documented in rodents (16, 453). Elevated levels of cadmium in neonates are associated with a decreased birth weight (271), but further research is required to determine if developmental effects of cadmium are of concern at environmental levels. Tobacco plants are known to concentrate soil cadmium, and it is estimated 1-pack/day smokers can absorb 1–3 μg cadmium/day (347). Pregnant smokers have an increased cadmium concentration in both maternal and cord blood (117), and cadmium-metallothionein mobilized into the serum has been suggested to be the toxic serum factor associated with preeclampsia (124). High doses of parenteral cadmium will induce testicular necrosis in male rodents, and this effect is thought to be related to cadmium inhibition of a testes-specific enzyme (16). Pretreatment or concurrent treatment with various substances, including zinc and selenium, will inhibit the acute toxic effect of cadmium, but the precise protective mechanism is unknown (527).

The U.S. EPA has derived a chronic oral RfD for cadmium based on an early version of the toxicokinetic model for cadmium (201). Separate values were derived for food and water exposure, assuming 2.5% absorption of cadmium from food and 5% from water with a 0.01% per day excretion, and a kidney concentration of 200 μg Cd/g wet human renal cortex is considered the NOAEL (589). An uncertainty factor of 10 was used for intrahuman variability, and the resulting RfD values are 0.001 mg Cd/kg/day (food) and 0.0005 mg Cd/kg/day (water); confidence in these values is considered high. No reference concentration values for chronic cadmium inhalation exposure were calculated. The Agency for Toxic Substances and Disease Registry (ATSDR) has calculated chronic minimal risk levels (MRLs) for cadmium based on human studies with measured exposures (16). The inhalation MRL was calculated from a NOAEL for renal effects in workers exposed to 0.0016 mg/m3 (288); adjusting for continuous lifetime exposure and using an uncertainty factor of 10 to account for sensitive members of the population, the chronic inhalation MRL is 0.0002 mg/m3. A chronic oral MRL of 0.0007 mg/kg/day was calculated from a study in a Japanese population exposed to cadmium in rice (438). The average nonsmoking American absorbs approximately 1–3 μg Cd/day from the diet (16), which is only 2 to 4 times lower than the oral

MRL, indicating that there is not a large margin of safety with respect to cadmium toxicity, particularly given evidence that postmenopausal women and diabetics may be more sensitive to cadmium toxicity than members of the general population (94).

The carcinogenicity of cadmium is the subject of much discussion. In animals, inhalation exposure causes lung cancer in rats but not in mice or hamsters (211, 252, 547). In humans, increases in lung cancer rates were associated with cadmium exposure in one cohort (558), but not in three others (4, 170, 535); in these same cohorts, early indications of an increase in prostate tumors were not borne out by longer term follow-up. The role of arsenic and/or smoking in the cohort with the increased rate of lung cancer is controversial (156, 331, 542). Studies investigating environmental cadmium and its role in prostate cancer have been hampered by a lack of dose quantification (2, 53, 611), and results from studies with occupational exposure have been mixed (315, 536). In animals, older studies found no significant increase in tumors following lifetime oral exposure to cadmium, but the doses in these studies were relatively low and histological examination was limited compared to present standards (133, 358, 502). A more recent study reports prostate tumors in male rats after oral cadmium exposure (603). Further research is required to establish the role of cadmium in human prostate cancer (604). Cadmium is genotoxic (248); it has been reported to induce apoptosis, which may serve to remove critically damaged cells (234, 241). The International Agency for Research on Cancer (IARC) accepts cadmium as a category 1 (human) carcinogen (281) based primarily on its role in lung cancer (542). The U.S. EPA classifies cadmium as a group B1 carcinogen (probable human carcinogen) (589) based on evidence in humans and animals (547, 558). An inhalation unit risk of 1.8×10^{-3} per ($\mu g/m^3$) was calculated from the study of Thun et al. (558).

If future research were to establish that present levels of exposure to cadmium carry an unacceptable risk of either noncancer or cancer effects, difficult questions would arise. The primary difficulty would be how to reduce exposure; the main source of cadmium exposure is the diet, but reducing this exposure, by removing cadmium from fertilizer, would be costly and difficult. Another policy issue is whether cigarette smokers should be considered a sensitive subpopulation deserving extra protection, so that exposure must be controlled to levels that would be safe for smokers, or whether smokers should be considered individuals with a demonstrated lack of concern for, and need for protection from, adverse health effects.

Lead

Lead is a heavy, bluish-gray metal and, although it serves no biological purpose, is the most widely used nonferrous metal (17, 187). Lead and/or lead compounds have been used in many industrial applications, including batteries, ammunition, paints and varnishes, gasoline, pigments, radiation shields, medical equipment, solder, glass, and ceramic glazes (17). Inhalation and ingestion are the main routes of exposure for inorganic lead (261). Adults are primarily exposed occupationally (17), and this occurs by inhalation with 35–40% of inhaled lead dust or fumes deposited in the lungs with extensive (95%) blood absorption (342). Children are primarily exposed by ingestion and absorb 50% of an ingested dose through the gastrointestinal tract. In contrast, adults absorb 10% of an ingested dose, but gastrointestinal absorption will vary with particle size (inverse proportion), solubility, nutritional status, and fasting. Excretion is mainly in the urine, with lesser amounts in the feces, sweat, hair, and nails.

In adults, early symptoms are often nonspecific (fatigue, depression, sleep disturbance, anorexia, intermittent abdominal pain, nausea, constipation, diarrhea, and myalgia) (261). Blood lead level (PbB) is the single best diagnostic test for lead exposure (261). Epidemiologic studies and animal experimentation suggest PbB levels as low as 14 μg/dl may elevate blood pressure (245, 510), but the results are not definitive (256). A recent study (269) suggests that long-term lead accumulation—measured as bone lead, as opposed to PbB, which reflects recent exposure—is associated with developing hypertension. However, other researchers report no consistent effect (540), and the subject remains controversial. Reversible slowing of nerve conduction velocity has been observed at PbB as low as 30 μg/dl (519), and adverse effects on reaction time, mood, and visual-motor coordination at 30–50 μg/dl (51, 544). Anemia is not seen until PbB are in excess of 50 μg/dl (270). Overt neurotoxicity (wrist drop) is reported at levels in excess of 80 μg/dl (219). Chronic irreversible nephropathy requires high and sustained PbB exposure (225), but recent evidence suggests low-level lead exposure (PbB<10 μg/dl) is associated with renal impairment, as measured by an increase in serum creatinine (308). Morphological alterations and decreases in sperm count, density, and motility have all been reported in heavily exposed males (PbB>40 μg/dl) (42, 45, 345, 572). Paternal occupational lead exposure has been reported to increase the risk of low birth weight and prematurity (349). Lead readily crosses the placenta to the fetus (305, 482), and maternal PbBs in excess of 15 μg/dl are associated with low birth weights and preterm delivery, and PbB in excess of 30 μg/dl with spontaneous abortions (176, 180, 485).

Lead poisoning in children caused by ingestion of lead paint was first noted in Australia and became

recognized as a public health problem in the United States in the 1920s (351). Early symptoms of chronic poisoning in children are often nonspecific, including headaches, anorexia, vomiting, and constipation, progressing to anemia with

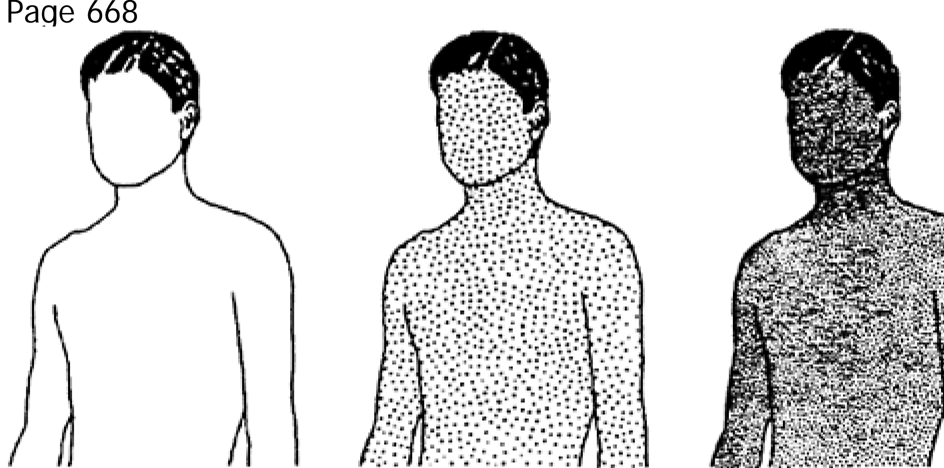

FIG. 14.1. Comparison of lead body burden (from left to right): ancient people uncontaminated by industrial lead (1 dot); typical American (1000 dots); level associated with clinical lead poisoning (4000 dots). Each dot represents 40 μg Pb/70 kg person. Reprinted from Patterson et al. (455), *Sci. Total Environ.*, copyright 1991, pp. 205–236, with permission from Elsevier Science.

basophilic stippling of red cells, Burton's line, chronic nephritis, peripheral neuropathy (manifested as wrist and/or foot drop), and radiographs of long bones revealing lead deposits (442, 459). Frank encephalopathy (PbB>80 μg/dl) is characterized by ataxia, coma, convulsions, cerebral edema, and even death. The long-term neurologic consequences of childhood lead poisoning were recognized in 1943 when Byers and Lord follow up 20 "cured" cases and found poor academic performance in all but 1 (98). In 1975, de la Burde and Choate (147) reported school failure due to learning and behavioral problems in asymptomatic lead-exposed children. Asymptomatic children with elevated dentine lead levels in first and second grade scored lower on standardized tests, especially in areas measuring verbal performance and auditory processing, and were more likely to exhibit disruptive behavior relative to controls (152, 427). Reexamined 11 years later as adolescents, those with greater lead exposure were more at risk for dropping out of school, reading disability, absenteeism, poor hand-eye coordination, and low scholastic class standing (66, 428, 511, 561).

Since 1970, the CDC has repeatedly lowered the level of concern for PbB from 70 to 10 μg/dl, and the following federal laws have been enacted to reduce lead exposure: the 1971 Lead-Based Paint Poisoning Prevention Act (575); the U.S. EPA phaseout of lead in gasoline, starting in 1973 (581) with completion in 1995 (587); the U.S. EPA ban on lead in plumbing, fixtures, fittings, and solder (576); the Consumer Product Safety Commission (CPSC) 1978 ban on the use of paint containing more than 0.06% lead by weight for interior/exterior residential surfaces, toys, and furniture (579); the FDA ruling to eliminate lead-solder in food cans by December 1995 (590); and the Residential Lead-Based Paint Hazard Reduction Act of 1992 (577). Results of two National Health and Nutrition Examination Surveys, NHANES II (1976 to 1980) and NHANES III (phase I, 1988 to 1991; phase II, 1991 to 1994), indicate a substantial decline in PbB (111, 216, 464). Since the late 1970s, the average PbB in children 1–5 years of age has declined from 15 μg/dl to 2.7 μg/dl, and the reduction of lead in gasoline and dietary sources (primarily through the former use of lead-soldered cans for food and beverages) is believed responsible for this effect (88, 464). Although this decline is substantial, Patterson et al. (455) estimate today's average American has a mean body burden of 40 mg industrial Pb/70 kg, whereas analysis of pre-Columbian American Indian skeletons indicates their mean body burden was 40 μg Pb/70 kg (Figure 14.1). Based on bone: blood lead ratios, this equates with a PbB of 0.016 μg/dl, which is 600-fold lower than the current level considered acceptable for children (i.e., 10 μg/dl) (193) and places current guidelines much closer to lethal Pb levels than natural (529). It is estimated that 890,000 (4.4%) U.S. preschool children have a PbB of 10 μg/dl or higher (111). Further reductions in PbB will require primary prevention efforts to reduce exposure to lead remaining in housing and soil (334, 464, 530). The Centers for Disease Control and Prevention (CDC) 1997 lead poisoning prevention program recommends targeted screening and follow-up care for high-risk children (i.e., children who live in older-homes, children from low-income families) (111). Although controversial (367), it reserves universal screening of young children to those meeting at least one of the following criteria: (a) child resides in ZIP code where at least 27% of the housing predates 1950; (b) child receives public assistance for the poor; or (c) caretaker's response to a risk assessment questionnaire suggests child is at risk.

The use of car radiators containing lead solder for the illegal distillation of alcohol (moonshine) has long been associated with lead poisoning (178), and recent reports suggest middle-aged men in rural settings continue to be at risk (173, 456). Excessive PbB (>40 μg/dl) have been reported in automobile radiator repair mechanics, and "take-home" lead is a potential source of elevated PbB in their children (217), as has been reported in other lead-related industries (300). Apart from congenital intoxication, lead poisoning in infants has been reported from the use of traditional folk remedies, which are often known by their common names of azarcon, greta, and ghasard (104–107); the use of lead-contaminated water to prepare formula (523); use of a lead-soldered samovar (urn) for formula preparation (522); and household renovation (110). Lead as galena (PbS) was the main constituent of eye cosmetics (kohls) in Oman (243) and may contribute to lead poisoning in households with children practicing pica. Lead poisoning in children with pica has been reported following the ingestion of foreign objects including an imported clothing accessory (177), fishing sinkers (407), and curtain weights (77). The dissolution of retained lead gunshot has resulted in lead poisoning (306, 368), with rapid onset when the bullet lodges in contact with synovial fluid (392). Lead in crystal leaches into alcoholic beverages, and lead contents as high as 21.5 mg/L have been reported in beverages stored in crystal decanters (227). The lead content of various calcium supplements (bonemeal, dolomite, calcium carbonate) has been tested, and levels of supplementation providing 800 mg calcium would also contain over 6 μg lead in over one-quarter of the 70 different brands tested (85, 614). Although cases of lead intoxication by this route have not been reported, pregnant women and children are the populations most at risk from this source. Lead-contaminated heroin has been reported as a source of lead intoxication, and physicians need to be aware of this possibility (454).

The primary treatment for lead poisoning is to identify and eliminate exposure. For children with venous PbB >45 μg/dl the CDC (108) currently recommends chelation therapy. In 1991 the U.S. FDA approved the use of *meso*-2,3-dimercaptosuccinic acid (DMSA, Succimer), which is an effective oral chelating agent and is more specific for lead than CaNa2EDTA, the use of which is associated with urinary loss of essential trace elements. PbB ranging from 20 to 44 μg/dl is treated with chelation therapy if a provocative test indicates substantial lead can be mobilized. Pharmacological treatments are not currently available for PbBs<20 μg/dl. Iron deficiency is associated with increased lead absorption (365) and should be treated in all cases (36).

The adverse health effects associated with lead occur at PbBs so low as to be without a threshold, and the U.S. EPA considers it inappropriate to derive RfD values for lead (589). The U.S. EPA classifies lead as a group B2 carcinogen (probable human carcinogen) based on sufficient evidence in animals with dietary and subcutaneous exposure and inadequate evidence in humans. The U.S. EPA considers it inappropriate to quantify the carcinogenic risk from oral exposure because toxicokinetic differences between humans and animals cannot be taken into account using the standard procedures.

Mercury

Mercury is a silver-white fluid trace metal found in igneous and sedimentary rocks and in the form of the ore cinnabar (mercury sulfide) (63). It is biologically nonessential and toxic to all organisms. Mercury may occur in the elemental form, or as inorganic and organic compounds. Mercury and its compounds are used in electrical meters, chloralkali production, thermometers, and as antimicorbial preservatives in paints, cosmetics, and pharmaceuticals. Use in dry-cell batteries is now restricted due to environmental toxicity concerns following disposal (578, 588). Use in interior latex paints is prohibited (584). Toxicity is related to the covalent binding of mercury to sulfhydryl groups, as well as to carboxy, amide, amine, and phosphoryl groups, thereby inactivating cellular functions (100).

Acute elemental mercury ingestion is usually of no significance due to poor absorption from the GI tract. Acute exposure to high concentrations of elemental mercury vapors are irritating to the respiratory tract. Chronic exposure to the vapors produces CNS toxicity, which includes muscle weakness and tremors, nervousness, memory loss, and anorexia. Inorganic mercury compounds generally demonstrate local irritant or corrosive activity. Acute ingestion may result in necrosis to the GI tract and renal tubular necrosis. Chronic effects produce CNS toxicity similar to that noted for elemental mercury. Organic mercury compounds have been used for treatment of syphillis and as diuretics, but have been replaced by less toxic drugs. Organic mercury compounds, such as phenylmercuric acetate, thimerosal, and mercurochrome, are primarily used as antimicrobial preservatives in ophthalmic preparations, vaccines, and nasal sprays (100). Contact dermatitis may occur to both inorganic and organic mercurials, with cross-sensitivity to each being reported (18, 188). Elemental mercury and its compounds are excreted in urine, feces, and through respiration.

Dietary intake, from agricultural products treated with mercurial fungicides and fish from mercury-

polluted water, is the major route for toxicity of organic mercury compounds. Metallic and inorganic mercury can enter the air and water from rock and ore deposits, burning of fossil fuels, industrial and agricultural emissions,

Table 14.2 Major toxic metals

Metal	Chronic oral toxicity		Chronic inhalation toxicity		Carcinogenicity		
	RfD[a] (mg/kg/day)	Confidence	RfC[b] (μg/m3)	Confidence	Oral slope factor [risk/(mg/kg/day)]	Inhalation slope factor [risk/(μg/m3)]	Classification[c]
Lead	–[d]	–	–	–	–[e]	–	B2
Cadmium	1×10^{-3} (food) 5×10^{-4} (water)	High	–	–	–	1.8×10^{-3}	B1
Mercury	–	–	3×10^{-1}	Medium	–	–	D
Arsenic	3×10^{-4}	Medium	–	–	1.5	4.3×10^{-3}	A

a RfD, reference dose.
b RfC, reference concentration.
c Group A, known human carcinogen; group B1, B2, probable human carcinogen; group D, not classifiable as to human carcinogenicity.
d U.S. EPA quantifies lead toxicity using a biokinetic model; threshold is equivalent to intake of about 5×10^{-3} mg/kg/day.
e U.S. EPA has not quantified lead carcinogenicity; slope factor would be in the range of $1–4\times10^{-3}$/(mg/kg/day).

and trash disposal and incineration. Atmospheric fallout adds to water pollution. Inorganic mercury compounds may be methylated by the microflora of soil and water to form methylmercury. Through the food chain, edible fish can concentrate methylmercury to levels a thousands times greater than in the environment (100). Methylmercury is neurotoxic, and the effects are both dose and time dependent (63). Ataxia is an early symptom, followed by slurred speech, weakness, vision and hearing loss, tremors, coma, and death. Well-documented poisonings from contaminated fish and grains occurred in Japan and Iraq (63, 100). Additionally, methylmercury is a well-known neuroteratogen (18).

Recently, the use of dental amalgam fillings has generated concern, both because exposure of dental workers may exceed occupational standards and because a variety of illnesses (multiple sclerosis, rheumatoid arthritis, leukemia, etc.) have been attributed to dental mercury exposure in the general population (41, 203, 330, 601). Contact dermatitis is experienced by some dental patients, and for those in which symptoms do not quickly subside with antihistamine treatment, replacement of fillings with nonmercury materials may alleviate immunological and dermatological symptoms (203, 330). However, other diseases have not been firmly linked to mercury exposure, and at present replacement of mercury-containing fillings cannot be justified in nonallergic individuals, while the issue of whether mercury should continue to be used for new dental fillings is more controversial (41, 203, 330). Additional research is needed before the potential for dental amalgams to cause harm, and the benefit of substituting more costly or less durable materials, can be reasonably evaluated. Concern must include the potential risk of effects on the fetus (18).

The U.S. EPA has derived a chronic inhalation exposure RfC for elemental mercury (vapor) of 0.3 μg/m3 based on critical effects of hand tremor, memory disturbances, and autonomic dysfunction (acrodynia) with a medium level of confidence (589). There is no current chronic oral exposure RfD pending further review (589). The ACGIH has adopted TLV-TWA values for inorganic forms and metallic mercury of 0.025 mg/m3, for aryl mercury compounds of 0.1 mg/m3, and 0.01 mg/m3 for alkyl compounds (32). These TLV-TWA values carry a skin notation that points out the potential for dermal absorption. The ACGIH and EPA consider mercury as not classifiable as to human carcinogenicity, based on no evidence of carcinogenicity in humans and inadequate evidence in animals (32, 589).

A summary of some quantitative toxicity values for these four major toxic metals is given in Table 14.2. Metals are listed in approximate reverse order of toxicity (least toxic first).

MINOR TOXIC METALS WITH RfDs

Antimony

Antimony is a brittle silver-colored metal extracted from ores (63). Compounds of antimony cover the full range of toxicity. Less toxic compounds have found use in cosmetic pigments (antimony sulfide) and medicinals (antimony potassium tartrate; tartar emetic). Stibine, the metal hydride of antimony, is a colorless

highly toxic gas used in the manufacture of semiconductors (63). Ingestion of antimony compounds can cause gastrointestinal, cardiac, dermatological, hepatic, and neurological toxicity in humans and animals (9). Mechanisms for these effects include binding to sulfhydryl groups and inhibiting protein and carbohydrate metabolism (380). Acute inhalation exposure to antimony trichloride or antimony pentachloride may cause pneumonitis, but the injury may be caused by the chloride rather than by the antimony itself; acute exposure to antimony hydride can cause hemolysis, but, again, the antimony itself may not be responsible (430). Long-term inhalation exposure to antimony can cause benign pneumoconiosis (430) and may raise blood pressure (9). Dermatological reactions to antimony (eczema, pustules) exhibit signs of an acute inflammatory response but do not appear to be an allergic reaction (380). The U.S. EPA has derived a chronic oral RfD for antimony based on the study of Schroeder et al. (508), which found changes in blood glucose and cholesterol levels in rats exposed to antimony in drinking water at a dose of 0.35 mg/kg/day. This LOAEL was converted to an RfD of 0.4 μg/kg/day using an uncertainty factor of 1000 (10 for interindividual variation, 10 for interspecies variation, and 10 for use of a LOAEL rather than a NOAEL). Confidence in the RfD was considered low (589). However, a recent study of potassium antimony tartrate in rats following 90-day exposure via drinking water gave a NOAEL level of 0.06 mg/kg/day (467). Using a 100-fold safety factor, as just described, 0.6 μg/kg/day approximates the RfD. The U.S. EPA has not derived an inhalation RfC for antimony (589). The ACGIH has adopted a TLV-TWA value for antimony of 0.5 mg Sb/m3 (32).

The carcinogenicity of antimony is uncertain. Mice given antimony potassium tartrate in drinking water at a dose of 0.88 mg/kg/day for 33 months had no increased incidence of lung, liver, or total tumors (297). Workers exposed to antimony concentrations well over 5 mg Sb/m3 had an increased risk of lung cancer (155); however, exposure to arsenic may have caused the excess (380). Female rats exposed to >30 mg Sb/m3 had an increased incidence of lung tumors (433). A chronic inhalation oncogenicity study in rats of antimony trioxide dust at doses less than 30 mg Sb/m3 did not show carcinogenicity (233). Antimony has not been evaluated for human carcinogenic potential by the U.S. EPA (589). The ACGIH has classified antimony trioxide production as a suspect human carcinogen for which exposure levels should be as low as reasonably achievable (31, 32).

Barium

Barium is a silvery-white alkaline earth metal and is found in nature in combination with other elements (10). The barium ion is highly reactive and its toxicity is dependent on the solubility of the specific compound, with water-soluble forms (i.e., chloride, hydroxide, nitrate) being more toxic than insoluble forms (i.e., sulfate, carbonate). Barium compounds are used primarily as lubricating agents in drilling muds, but also in the manufacture of paints, bricks, tiles, glass, rubber, and pesticides. Barium sulfate is used medically as a contrast agent in x-ray diagnosis. Hospital staff familiar with this use may fail to recognize barium as a potential toxic agent, and this has contributed to at least one fatality (159). The general population is exposed by ingestion (i.e., food, drinking water) and inhalation. Some plants bioconcentrate barium from the soil, with brazil nuts having very high concentrations (3000–4000 ppm) (62).

Occupational exposure to inhaled barium sulfate can cause a benign pneumoconiosis (baritosis) (154), which resolves with cessation of exposure. Acute ingestion of soluble Ba2+ salts acts as a muscle poison characterized by stimulation followed by paralysis (475). Symptoms of poisoning start with the gastrointestinal muscles (gastric pain, vomiting, diarrhea) and progress to skeletal and cardiac muscle with ventricular fibrillation followed by death due to respiratory muscle paralysis (5, 153, 475, 488). The barium ion is thought to act as a potassium antagonist, producing an extracellular hypokalemia (488) relieved by intravenous infusion of potassium salts (5, 153, 475). However, potassium infusion does not relieve the hypertension (153, 488, 589). Prompt oral administration of sodium sulfate to form the highly insoluble barium sulfate (1 g dissolves in 400,000 parts water) has been used to prevent absorption (5, 475). The U.S. EPA has derived an oral RfD for barium based on two studies involving humans, one experimental (618) and one epidemiological (87), and the subchronic and chronic rodent studies performed by the National Toxicology Program (NTP) (423). Wones et al. (618) found a NOAEL of 0.21 mg Ba/kg/day (the highest dose tested) in healthy male volunteers exposed to barium in drinking water. Brenniman and Levy (87) found no convincing evidence of a difference in hypertension or other effects between 2 communities, one exposed to <0.2 mg Ba/L and the other to a mean of 7.3 mg Ba/L (0.20 mg Ba/kg/day). These very similar NOAELs were converted to an RfD of 0.07 mg/kg/day using an uncertainty factor of 3 (to account for database deficiencies and to protect sensitive individuals; a factor lower than 10 was considered appropriate because the supporting studies considered adult males, those likely to be most sensitive to barium's hypertensive effects) (589). Confidence in the RfD was considered

medium. The ACGIH has adopted a TLV-TWA value of 0.5 mg Ba/m3 for soluble barium compounds and 10 mg Ba/m3 for barium sulfate (32).

The National Toxicology Program (NTP) performed a 2-year rodent bioassay with barium chloride dihydrate in drinking water and found no carcinogenic effects in either rats or mice (423). The U.S. EPA classifies barium as group D (not classifiable as to human carcinogenicity) (589). The carcinogenic potential of inhaled barium cannot be determined due to the lack of adequate animal inhalation studies.

Beryllium

Beryllium is an alkaline earth metal that is the lightest of the structural metals. Beryllium is a rare metal, and is extracted primarily from bertrandite (beryllium-silicate ore) and beryl (beryllium-aluminum oxide-silicate ore). The primary uses of beryllium are as a structural metal in lightweight applications, in metal alloys, and in nuclear reactor technology, as beryllium is an excellent neutron reflector and moderator (31, 63).

As beryllium is a rare metal, its toxic effects were not completely recognized until it became widely used in the 1940s. Although beryllium and its compounds can cause contact dermatitis, the primary target organ is the lung. Two types of beryllium-induced lung injury can occur, acute and chronic. The acute and frequently fatal syndrome resembles chemical pneumonitis and is associated with exposure to soluble forms of beryllium (e.g., beryllium sulfate and beryllium fluoride), where the concentration of airborne beryllium is greater than 0.1 mg/m3 (168). First reported in the early 1930s (63, 593), this syndrome has been virtually eliminated in the workplace after 1950, because of controls limiting the concentration of these beryllium compounds in the air (11, 169).

Chronic beryllium disease was first reported in 1946 as a delayed pneumonitis (244). The disease (also known as berylliosis) is characterized by granuloma formation, fibrosis, emphysema, and reduction in vital capacity of the lung, and total lung capacity (11). The chronic disease has two forms, one that occurs during exposure, and a second where the disease becomes evident 10 or more years after the cessation of exposure (63). The mechanism of the delayed onset of the condition is not known. The disease has a strong immunological component; chelation treatment has little effect on the course of the disease, whereas corticosteroid treatment has been effective in disease suppression (63).

Beryllium dermatitis is a hypersensitivity reaction that is usually noted 1 to 2 weeks after exposure to soluble beryllium salts. Patch tests of individuals with soluble beryllium salts provoke a positive response. Beryllium can also induce dermal ulceration if particles of beryllium salts become imbedded in the skin (63). The ulceration can be long-lasting, and surgical intervention can be required to resolve the condition (556).

Beryllium compounds are also carcinogenic. The IARC reviewed the available literature and in 1993 published its findings that there was sufficient evidence in humans and animals for the carcinogenicity of beryllium (281). In several retrospective epidemiologic studies conducted in the 1970s and 1980s, a consistent (but small) increase has been noted in the incidence of lung cancer in workers exposed to beryllium. The decade of hire was one of the strongest correlates of lung cancer mortality.

The U.S. EPA has established the following toxicity values for beryllium: oral, RfD, 2 μg/kg/day; inhalation, RfC, 0.02 μg/m3 and has classified it as a group B1, probable human carcinogen (589). The ACGIH has adopted TLV values for beryllium of 0.002 mg Be/m3 as an 8-h TWA and 0.01 mg Be/m3 as a STEL/C. An A1 carcinogenicity notation (confirmed human carcinogen) is present (32).

Boron

Boron is a metalloid. It is a solid element and, because of its high affinity for oxygen, always occurs in nature bound to oxygen in the form of inorganic borates (12, 167, 400). Boron and associated compounds have many industrial applications, including the production of borosilicate glass, laundry bleaches (sodium perborate), wood preservatives, fire retardants, pesticides (cockroach control), cosmetics, and pharmaceuticals (12). In 1875, Lister used boric acid as an antiseptic (353), but its effectiveness has since been discredited. The world's two largest borate deposits occur in the Mojave Desert (near Boron, California) and in Western Turkey (167). Borates have long been known to be essential for plants, but a specific biochemical role remains to be determined (80). Although boron deficiency has been reported in rats, chickens, and humans, as yet no requirement has been established in humans (420). Nielsen in 1996 (436, 437) classified it as an ultratrace element, and the World Health Organization (WHO) Expert Committee on Trace Elements in Human Nutrition came to the conclusion that it is "probably essential" in human nutrition (140). Biochemical and physiological consequences of boron deprivation in humans suggest it affects calcium and magnesium metabolism (435). Inadequate dietary boron (<0.2 mg B/day) has been suggested as a factor contributing to osteoporotic bone loss (434).

Inorganic borates exhibit a low order of acute toxicity in mammals, with the oral LD50 for boric acid in male rats being 4.5 g/kg body weight (142). However, inadvertent use of a 2.5% boric acid solution in

preparation of infant formula has resulted in toxicity and death (619). The oral lethal dose in adults has been reported as 15–20 g (528), but 80–297 g has been tolerated in a single ingestion (600). Nausea with vomiting and diarrhea, both

a characteristic blue-green color, are common. Frequently the skin shows signs of erythema, desquamation (boiled lobster appearance), and exfoliation. Death generally occurs several days after ingestion and results from renal injury, circulatory collapse, and shock. Although the use of boric acid solutions as an antiseptic is now obsolete, concentrated boric acid is still readily available as a household pesticide, and householders, particularly those with young children, need to be familiar with symptoms of poisoning (528, 532). Borates are not absorbed through intact skin (166), including that of newborns (202), unless the skin is damaged, abraded, or otherwise compromised (161). The use of boric acid as a dusting power during diapering has resulted in fatalities (215). The Cosmetic Ingredient Review Expert Panel (72) reviewed the use of borates in cosmetics and concluded that "cosmetic formulations containing free sodium borate or boric acid at this concentration (5%) should not be used on infant or injured skin". Animal experiments indicate that chronic oral exposure to boric acid or borax is toxic to the male reproductive system, with testicular lesions being observed in rats, dogs, and mice (181, 422, 609), and boric acid is a developmental toxicant in all three mammalian species tested (rat, mouse, rabbit) (251, 469, 470). The rat was the most sensitive species for developmental effects, with a NOAEL of 9.6 mg B/kg/day (469). The effect of boron on male fertility has been investigated indirectly in an occupationally exposed population using a questionnaire to determine the standardized birth ratio (SBR; ratio of the observed number of births to the expected); no adverse reproductive effects were reported (617).

The U.S. EPA has derived a chronic oral RfD for boron (589) using the study of Weir and Fisher where dogs were exposed to boric acid in the diet for 2 years (609) as the pivotal study. Testicular atrophy occurred at a dose of 29 mg/kg/day, whereas no effects were noted at 8.8 mg/kg/day. This NOAEL was converted to an RfD of 90 μg/kg/day using an uncertainty factor of 100 (a factor of 10 each for both inter- and intraspecies variation); confidence in this RfD was considered medium. Other risk assessments of boron (411, 616) considered the 1972 Weir and Fisher dog study (609), which predated Good Laboratory Practices, to be of insufficient power and design for use as a pivotal study, using instead the rat developmental study of Price et al. (469), where decreased fetal body weight occurred in a dose-dependent manner. No inhalation RfC has been derived for boron. The ACGIH has adopted several TLV values for boron compounds: TWA values of 10 mg/m3 for boron oxide, 5 mg/m3 for sodium tetraborate decahydrate, and 1 mg/m3 for sodium tetraborate pentahydrate and anhydrous, and ceiling values of 1 ppm for boron tribromide and boron trifluoride (32). NTP conducted a 2-year carcinogenesis biosassay in male and female B6C3F1 mice and reported testicular atrophy and interstitial-cell hyperplasia in males receiving 201 mg B/kg/day, but found no evidence of carcinogenicity (422). The U.S. EPA has not evaluated the potential human carcinogenicity of boron, but classifies it as group D (not classifiable as to human carcinogenicity) (589) based on lifetime studies conducted in mice (422) and rats (609).

Nickel

Nickel is member of the Group VIIB series of transition metals. There are three principal classes of nickel ores: sulfide, silicate, and arsenide. Nickel is used in a wide variety of applications, with 80% of the nickel in the United States being used in the production of nickel metal and alloys (63). The essentiality of nickel in humans is debatable. Nickel deficiency can be experimentally induced in rats and larger mammals (38, 420). There is some evidence that nickel is essential for methyl metabolism and iron, calcium, and zinc absorption (38, 457), but that if essential, the amount of nickel required would be amply met by the amount of nickel in a typical American diet (457).

Animal experiments have indicated that nickel compounds can be nephrotoxic, hepatotoxic, immunotoxic, and teratogenic (546). In humans, nickel can cause allergic contact dermatitis, particularly in young women using nickel-containing earrings in pierced ears (97), and is the most frequent disease among nickel workers. Statistical evaluations showed that up to 17% of all occupational allergies may be related to nickel occupational exposure (63). Allergic asthma is rare (430), but case reports have been published (63). Acute inhalation exposure to metallic nickel can cause metal fume fever (430). Nickel carbonyl is a colorless, volatile liquid that is particularly hazardous. It has been estimated that exposure to 30 ppm nickel carbonyl for 30 min may be lethal in humans (33). Acute inhalation exposure to this material can cause immediate and delayed toxic effects. Headache, dizziness, and nausea are the immediate manifestations. Ten to 36 h after exposure, substernal pain, coughing, and dyspnea, consistent with chemical pneumonitis, are observed (31, 63). Sodium diethyl-dithiocarbamate (dithiocarb—a chelating agent) has been employed in the therapy of nickel carbonyl-exposed workers (33). Recovery is protracted and is characterized by fatigue upon slight exertion (63). Short-term exposure to 150 ppb Ni(CO)4 can cause immediate but not delayed symptoms, whereas short-term exposure to

concentrations on the order of a few parts per million can cause the more severe, delayed-type reactions (63). The U.S. EPA has derived a chronic oral RfD for soluble salts of nickel of 20 μg/kg/day. Neither oral nor inhalation

RfDs have been established for nickel subsulfide, nickel refinery dust, nor nickel carbonyl (589). Inhalation of nickel compounds can cause lung cancer. The initial observation of excessive lung cancer and nasal tumors among nickel refinery workers was made as early as 1932 (63, 404). Since the initial observation, numerous epidemiologic studies have been conducted that show conclusively the association between occupational exposure to nickel refinery dust and nickel subsulfide and lung and nasal cancer (63). The latency period for nickel-induced lung cancer was 13 to 14 years and that for nasal cancer was 15 to 24 years after first employment (31). Nickel exposure has not been clearly associated with respiratory cancer in any of the industries using nickel (31). The U.S. EPA has classified nickel subsulfide and nickel refinery dust as group A carcinogens (human carcinogen) on the basis of animal and epidemiologic carcinogenicity data; nickel carbonyl has been classified as a group B2 carcinogen (probable human carcinogen) (589). IARC has classified nickel compounds as carcinogenic to humans (280). The National Toxicology Program published results on the carcinogenicity of inhaled nickel oxide (424), nickel subsulfide (425), and nickel sulfate hexahydrate (426) in rats and mice. There was no evidence of carcinogenicity of nickel sulfate hexahydrate in either species, clear evidence of carcinogenicity of nickel subsulfide in both species, and either no, equivocal, or some evidence of carcinogenicity of nickel oxide, depending on species and sex. The ACGIH has adopted the following TLVs for nickel compounds: elemental/ metal, 1.5 mg/m3; soluble compounds, 0.1 mg/m3; insoluble compounds, 0.2 mg/m3; nickel carbonyl, 0.05 ppm; nickel subsulfide, 0.1 mg/m3 (32).

Silver

Alloys of silver are used in jewelry, tableware, photographic materials, electronics, dental products, and as topical antibacterial agents for the treatment of burn wounds (63, 266). Silver is generally low in toxicity. It is absorbed following inhalation, ingestion, or topical application (31). Accumulation of silver results in argyria, a blue-gray discoloration of the skin, mucous membranes, and eyes. Silver sulfadiazine used in the management of burn wound sepsis has resulted in argyria, ocular injury, leukopenia, and toxicity in kidney, liver, and neurological tissues. Silver may affect the immune system, and contact dermatitis has been observed following exposure to various silver compounds (7). Toxicity has been attributed to the free silver ion released into solution and interaction with sulfhydryl, amino, carboxyl, and other groups on membrane or enzyme proteins (266). Excretion from oral, respiratory, or topical exposure is primarily through the GI tract (7). Mucociliary escalator activity accounts for removal of silver following respiratory exposure. Silver is not considered to be a carcinogen or a reproductive or developmental toxicant (7, 589). The U.S. EPA has derived a chronic oral RfD for silver of 5 μg/kg/day (589). No inhalation RfC has been derived for silver. The ACGIH has adopted TLV-TWA values for silver of 0.1 mg Ag/m3 for the metal and 0.01 mg Ag/m3 for soluble compounds (32). The ionic form is highly toxic to fish, but is found at extremely low concentrations in the aquatic environment, and other more common forms of silver show only low to moderate toxicity (265).

Strontium

Radiotoxicity is beyond the scope of this chapter and the following discussion pertains to stable strontium. Strontium is a soft silvery metal that turns yellow upon formation of the oxide (63). Its salts are used in the manufacture of color television screens, pyrotechnics (metal and salts impart a characteristic red color to flames), and electrical materials (586). Over 99% of the typical body burden of 320 mg is found in bone, and there is no conclusive evidence it is an essential trace element in mammals (63). Epidemiologic data suggest drinking water containing strontium in the presence of fluoride (5–6 mg Sr^{2+} and 1 mg F^{-}/L) decreases the incidence of dental caries in children (143). The gastrointestinal absorption of the strontium ion is poor (586) and acute strontium toxicity is low, with an oral LD50 of 2250 mg/kg body weight reported for strontium chloride in rats (99). Acute lethality is due to respiratory failure (132). In contrast, bone is the target organ following chronic strontium exposure. High doses inhibit calcification of the epiphyseal cartilage and cause deformities of long bones (533). Strontium causes these effects by substituting for calcium in the hydroxyapatite crystal during calcification or displacing calcium from existing calcified bone. The metabolic basis of strontium's effect on calcium metabolism is thought to be inhibition of the renal synthesis of 1,25-dihydroxyvitamin D3 (447). Young animals (still growing) are more susceptible to the toxic effects of strontium than adults, with widening of the epiphyseal cartilage being observed at lower levels of dietary strontium (545). Dietary calcium plays a protective role in strontium toxicity. Weanling rats maintained on diets containing 950 mg Sr/kg and 0.69% calcium for 4 weeks exhibited rachitic changes that were not seen in rats supplemented with 1.6% calcium (174). In contrast to these toxic effects, pharmacologic treatment with low doses of strontium suppresses bone resorption (372), and low-dose strontium lactate has been used to treat osteoporosis (383). The U.S. EPA has derived an oral RfD for strontium of 0.6

mg/kg/day, and confidence in this value is medium (589). Stable

< previous page page_674 next page >

strontium has not been adequately evaluated for carcinogenic potential.

Thallium

Thallium is a soft bluish-white metal, widely but sparingly distributed in the earth (63). Historically it has been used to treat gput, venereal disease, dysentery, ringworm, and tuberculosis (115). Thallium sulfate was widely used as a rodenticide, but its use was banned in the United States in 1972 (63). It is still used as a rodenticide in other parts of the world, and rodent resistance to warfarin may cause this use to increase (301). Thallium intoxication from contaminated heroin, presumably imported from areas where thallium is still used as a rodenticide, has been reported (472). It is currently used in the electronics industry and in the manufacture of prisms, imitation jewelry, low-temperature thermometers, and infrared spectrometers. Thallium is well absorbed following oral ingestion and causes severe gastrointestinal symptoms followed by painful paresthesia of the extremities, motor paralysis, and death from respiratory failure (255, 316, 366, 393, 409). Individuals surviving the acute phase suffer characteristic scalp alopecia about 10 days postingestion (255, 409, 592). For an adult the LD50 has been calculated to be 8 to 12 mg Tl/kg (409). Treatment involves the use of activated charcoal and oral Prussian blue (ferric ferrocyanide, C.I. 77510), which prevents enterohepatic recirculation and enhances fecal elimination, hemodialysis, and forced diuresis (316, 391, 409, 592). The FDA has yet to approve the human use of Prussian blue (391, 409), making suitably pure material difficult to obtain, although it is used as a diagnostic agent in pathology laboratories. The effectiveness of Prussian blue in thallotoxicosis is dependent on the size of the crystal lattice (325). Chelating agents (dithiocarb) have caused a redistribution of thallium to target organs, with an increase in toxicity (172, 295). The precise mechanism of toxicity is unknown, but likely involves the substitution of the thallous ion for potassium in the sodium/ potassium ATPase pump and/or interference with sulfhydryl enzymes (409). Interference with tissue riboflavin with subsequent effects on metabolic pathways has also been suggested (103). The U.S. EPA has derived a chronic oral RfD for thallium based on its own 90-day study of rats exposed to aqueous thallium sulfate by gavage at doses up to 0.20 mg Tl/kg/day (589). Treatment-related effects of serum chemistry changes, alopecia, and lacrimation without histopathological changes were not considered adverse, and 0.2 mg/kg/day was considered the NOAEL (589). This NOAEL was converted to an RfD of 0.09 μg/kg/day using an uncertainty factor of 3000 (10 for intraspecies extrapolation, 10 for interspecies variation, 10 for less than chronic exposure duration, and 3 for lack of reproductive and chronic toxicity data). Confidence in the RfD was considered low. No inhalation RfC has been derived for thallium. The ACGIH has adopted a TLV-TWA of 0.1 mg Tl/m3 for elemental and soluble thallium compounds (32). Thallium is classified as group D (not classifiable as to human carcinogenicity), based on two inadequate negative studies in humans and a lack of animal studies designed to examine carcinogenic endpoints (589). Existing data do not indicate thallium is mutagenic (343).

Uranium

Uranium is a soft, malleable metal of the actinide series in the periodic table. The primary uranium ores are pitchblende (uranium oxide) and carnotite (uranium/ vanadium-containing mineral). Uranium is primarily used as nuclear fuel, but there are some minor uses, such as a colorant in ceramics or glass, or in armor-piercing projectiles (31). Occupational exposure occurs in mining operations and in uranium enrichment (uranium hexafluoride).

Acute inhalation exposure to uranium hexafluoride can cause pneumonitis, but the injury may be caused by the fluoride rather than the uranium itself (430). Chronic inhalation exposure of uranium dioxide dust at concentration of 5 mg U/m3 produced no observable adverse effects in rats, dogs, or monkeys (339). The kidney is the main target of uranium's chemical toxicity, with the targets being the pars recta of the proximal tubules, the ascending limb of the loop of Henle, and collecting tubules (31). Attempts have been made to define a "critical concentration" of uranium in the kidney that constitutes a threshold for renal damage (197). Experimental evidence clearly indicates that the "consensus value" of 3 μg/g is above the level shown to produce toxic effects by a factor of 5–10; however, studies of workers exposed to uranium at levels derived from this consensus value have shown no evidence of chemical toxicity (197). This may reflect differences between animal and human metabolism (e.g., binding of uranium to metallothionein or other detoxifying proteins) or differences between the route and duration of the animal and human exposures. The U.S. EPA developed a chronic RfD of soluble salts of uranium of 3 μg U/kg/day; no inhalation RfC has been derived for uranium (589).

Uranium isotopes are radioactive, but only weakly due to their extremely long half-lives. Natural uranium has a radioactivity of about 0.7 pCi/μg (585). No direct evidence exists that uranium is carcinogenic to humans or animals. However, based on the fact that uranium does emit ionizing radiation as it decays, the U.S. EPA has classified uranium as a group A carcinogen (known

human carcinogen) and has proposed to quantify the cancer risk of uranium in drinking water using toxicokinetic modeling (585).

Vanadium

Vanadium is a white to gray common trace metal that does not occur in nature but occurs in combination with oxygen, sodium, sulfur, and chloride. Vanadium deficiency can occur in laboratory animals on a very strict diet (39, 420), and there is evidence that vanadium helps regulate some phosphoryl transfer enzymes (457). A requirement for vanadium extrapolated from animal experiments is 10–25 μg/day, whereas typical intake is 8–18 μg/day (457); however, the National Research Council believes that there is only weak evidence that vanadium is essential and that any vanadium requirement would be met by naturally occurring levels (420).

Inhalation exposure to vanadium pentoxide can cause tracheobronchitis with persistent bronchial hyperreactivity and inflammation (14, 31, 430). A greenish-black discoloration of the tongue, gastrointestinal symptoms, neurotoxicity, and renal toxicity have also been reported in workers exposed to vanadium pentoxide. The short term repeated inhalation in rats of vanadium metavanadate (8 h/day for 4 days) at a concentration encountered by humans over a typical work week altered pulmonary immune cell function and produced significant changes in the lungs themselves (131). Oral exposure to vanadium can be toxic to the gastrointestinal, renal, and neurological systems. Vanadium is rapidly excreted in feces and urine following termination of exposure. The U.S. EPA has derived a chronic oral RfD for vanadium pentoxide of 5 μg V/kg/day (9 μg VO5/kg/day), which was derived using an uncertainty factor of 100 (10 for interindividual variation and 10 for interspecies variation); confidence in this RfD was considered low (589). The U.S. EPA has not derived an inhalation RfC for vanadium compounds. The ACGIH has adopted TLV-TWA values for vanadium of 1 mg/m3 for ferrovanadium dust and 0.05 mg/m3 for vanadium pentoxide (32).

The results of behavior testing show that oral sodium metavanadate in rats resulted in significant reductions in both general activity and learning (498). Mice given vanadyl sulfate in drinking water at doses up to 1 mg/kg/day for up to 33 months had no significant increase in tumor incidence (296, 505). The U.S. EPA has not evaluated the potential human carcinogenicity of vanadium (589).

Table 14.3 presents the quantitative toxicity values derived by the U.S. EPA for the metals listed in this

Table 14.3 Minor toxic metals with RfDs

	Chronic oral toxicity		Chronic inhalation toxicity		Carcinogenicity		
Metal	RfD*a* (mg/kg/day)	Confidence	RfC*b* (μg/m3)	Confidence	Oral slope factor [risk/(mg/kg/day)]	Inhalation slope factor [risk/(μg/m3)]	Classification
Boron	9×10−2	Medium	–	–	–	–	–
Barium	7×10−2	Medium	–	–	–	–	D
Nickel	2×10−2	Medium	–	–	–	2.4×10−4	A

section, with metals listed in reverse order of toxicity (least to most toxic).

MINOR TOXIC METALS WITHOUT RfDs

Aluminum

Aluminum is the third most abundant element in the earth's crust, and is extracted from bauxite ore. Although aluminum is not an essential element, humans consume a substantial amount in the diet and are exposed to aluminum from a number of nondietary sources. On average, American adults consume 2 to 25 mg A1 daily from food and beverages (230), with average amounts being 8.2 mg/day for males and 7.1 mg/day for females (458). Aluminum is naturally present at low levels in most foods, but the primary source of dietary aluminum is from food additives. Over-the-counter antacids contain large amounts of aluminum hydroxide, and millions of consumers are dermally exposed to aluminum salts from the use of antiperspirants and deodorants (230).

Aluminum is generally considered to have a low order of toxicity, but it can cause reproductive toxicity when administered in high doses to experimental animals (218). The potential role of aluminum in either causing Alzheimer's disease or speeding its progression is highly controversial. Aluminum is certainly neurotoxic. In renal dialysis patients, excessive parenteral exposure to aluminum can cause a progressive, fatal neurological syndrome known as dialysis dementia (26). In addition, injection of aluminum salts into the brain of rabbits leads to the development of neurofibrillary tangles, but not *β*-amyloid plaques, which are also indicators of Alzheimer's disease (317). Some studies have found elevated levels of aluminum in some regions of the brain (327, 564, 606, 622, 626), whereas others have found no difference in aluminum levels between Alzheimer's and control brain tissue (286, 373, 565).

Epidemiologic studies do not show an association between aluminum exposure and the incidence of Alzheimer's disease. Canadian miners, between 1944 and 1979, were exposed to high concentrations of aluminum and aluminum oxide powder (McIntyre Powder) preceeding each shift as a prophylactic treatment against silicotic lung disease. In an initial study of this population, there was no increased incidence of neurological disorders in exposed miners, but there was an increase in neurological impairment as measured by cognitive testing (478). A follow-up study was conducted to address several methodological weaknesses in the initial study. No statistically significant differences were noted between exposed and nonexposed miners in either neurological disease or cognitive impairment incidence (477). Similarly, an association was noted with aluminum in drinking water and the incidence of Alzhemier's disease (376). A follow-up study (with methodological improvements) found no evidence of such an association (375). Another recent study has shown no association between occupational exposure to aluminium and the incidence of Alzheimer's disease (226).

The ACGIH has adopted TLV-TWA values for aluminum of 10 mg Al/m3 for metal dust and aluminium oxide, 5 mg Al/m3 for pyro powders and welding fumes, and 2 mg Al/m3 for soluble salts and alkyls (32).

Bismuth

Elemental bismuth is a soft lustrous metal and can occur naturally or in combined forms in ores. Bismuth is used in low-melting alloys. Insoluble bismuth salts are poorly absorbed orally or dermally. Excretion is primarily through the GI tract. Bismuth compounds demonstrate a low order of toxicity (63). They are used as coloring agents in cosmetics, and in pharmaceuticals, including use for diarrhea, gastroesophageal reflux, and in ulcer therapy. Bismuth subsalicylate used in ulcer therapy has no substantial capacity to neutralize gastric acid, but rather provides cytoprotection involving enhanced secretion of mucous and HCO_3^-, inhibition of pepsin activity, and the formation of bismuth protein complexes that may afford a protective barrier against peptic digestion. Primary activity may be due to the antibacterial effect of bismuth compounds against the bacteria *H. pylori* in the gastrointestinal mucosa (90). Toxic bismuth levels are not reached with normal use, although salicylism has been reported following use of bismuth subsalicylate (597). Rats exposed to bismuth oxychloride in the diet for 2 years at doses up to 2.0 mg/kg/day were found to have no increased incidence of tumors (468). The ACGIH has adopted a TLV-TWA value for bismuth telluride of 10 mg/m3 (32).

Bromine

Bromine is a reddish-brown, noncombustible liquid. Although the earth's crust contains a vast amount of bromine, the most readily recoverable sources of bromine are in salt lakes and brines. The largest use of bromine is in the production of fire retardants, gasoline antiknock agents, and in the agricultural chemical industry (460). Bromine vapors are highly toxic; exposure to 1000 ppm bromine is rapidly fatal in humans, and exposure to 40–60 ppm is dangerous for brief exposures (460). The symptoms of

inhalation exposure include coughing, nosebleed, dizziness and headache, and abdominal pain and diarrhea; sometimes a measles-like eruption on the trunk and extremities can occur (460). Bromine vapor is extremely irritating to the eyes, skin, and mucous

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_677.html[2010/10/28 18:46:43]

membranes and produces inflammatory lesions in the upper respiratory tract (25). Prolonged contact with the skin causes ulceration (460).

Bromine may be an essential element. A brominedeficient diet impaired the growth and reproductive success of goats; however, the evidence for the essentiality of bromine is weak, and no cases of human deficiency are likely to occur, due to the widespread distribution of bromine in foods (37).

Excessive oral intake of bromide can cause neurological symptoms in humans (headache, lethargy, ataxia, disorientation, etc.), and high levels of bromine in the diet (400–1200 mg/kg) can cause CNS depression in mice (543). Potassium bromate is a widely used form of bromine. Its primary use is as a conditioner for flour and dough (460). Potassium bromate has been investigated for possible carcinogenic activity. Renal and other tumors were induced in male and female Fischer 344 rats exposed to potassium bromate in drinking water in a 2-year bioassay; tumor formation was dose dependent (279). The IARC has classified potassium bromate as a group 2B (possibly carcinogenic to humans) carcinogen. Conversely, mice and rats fed diets high in bread containing up to 75 mg/kg potassium bromate showed no increase in tumor incidence (191, 210). The lack of a carcinogenic effect could be attributable to the degradation of potassium bromate during the baking process (279).

The ACGIH has adopted TLV values for bromine gas of 0.1 ppm as an 8-h TWA and 0.2 ppm as a STEL/C (32). Although the U.S. EPA has established a number of toxicity values for bromine-containing compounds, the U.S. EPA has not derived any toxicity values for bromine (589).

Cerium

Cerium is a lanthanous rare earth metal and is used in fireworks and cigarette lighter flints, self-cleaning ovens, and as an abrasive for polishing glass (63). Occupational inhalation exposure has been reported to cause a pneumoconiosis without pulmonary functional impairment (275). Intravenous administration of cerium chloride produces severe hepatotoxicity in rats (414). The U.S. EPA has not derived toxicity values for cerium (589).

Gallium

Gallium is a relatively rare metal that has found uses in diagnostic radiology (63), as an antineoplastic agent (82), and for the control of cancer-related hypercalcemia (157, 607). It is used in the manufacture of alloys and semiconductor electronic devices. There are limited indications of occupationally related toxicity. Occupational exposure to GaF3 fumes resulted in a rash with sub sequent reversible neurological effects consisting of muscular weakness (63). Gallium is excreted in urine. Renal toxicity is noted in rats with the formation of precipitates of gallium complexed with calcium and phosphate (63). No adverse effects were noted in a reproduction study conducted in male mice (134). There are no occupational health standards for gallium or its compounds (63). The U.S. EPA has not derived toxicity values for gallium.

Germanium

Germanium is a Group IVA semiconducting metal. The pure metal has a metallic appearance, but is very brittle, much like glass. Germanium is not found in the free state, but always in combination with other elements, such as silver, copper, and arsenic. Germanium is used in the semiconductor industry (germanium was used in the first transistor), and it is often used in combination with other materials, such as arsenic and antimony, and alloyed with aluminum, gallium, and indium. It is also used in certain optic applications, as the pure metal is transparent to infrared radiation. Industrial exposures are to the dusts and fumes of germanium metal during extraction from ore and metal fumes from welding operations (63). Germanium oxide and germanium sesquioxide have been used in "elixirs" for the treatment of cancer and AIDS (552).

In longer term oral animal studies, germanium and germanium oxide have been shown to be nephrotoxic (497), neurotoxic (309, 377), and myotoxic (377). The potential for germanium to induce lung injury is unclear; in one 4-week inhalation toxicity study of germanium powder in rats, histopathologic changes consistent with pulmonary toxicity were present (43), but a follow-up study using germanium dioxide showed no treatment-related histopathologic effects (44). Germanium does not appear to be carcinogenic; in fact, certain germanium compounds appear to have antineoplastic activity (206). In a lifetime feeding study in rats, animals receiving 5 ppm sodium germanate in water had a significantly lower incident of tumors than the control animals (297).

Because of this anticancer activity, germanium-containing elixirs have been sold, first in Japan, and then in other countries as a treatment for cancer and other diseases. To date, there have been at least 31 reported cases of toxicity associated with oral intake of germanium compounds, of which 9 were fatal (552). Nephrotoxicity is the primary manifestation of germanium intoxication, although neurotoxicity and myotoxicity have been reported (548, 552).

No TLV has been set for germanium or germanium oxide, but a TLV-TWA of 0.2 ppm has been set for germanium tetrahydride (32).

Gold

Gold is a soft yellowish metal and belongs to Group IB of the periodic table. Its excellent heat and electrical conductivity and malleability have made it important in industrial applications (62). Medically, it is used either orally or by intramuscular injection to slow the progression of rheumatoid arthritis, but treatment is associated with a high incidence of toxicity (277). Adverse skin and mucous membrane effects (dermatitis, stomatitis, pruritus) are most frequent, with incidence and severity less for oral as opposed to parenteral treatment (563). A mild proteinuria is the most common renal effect, but gold-induced nephrosis may occur. Aplastic anemia is relatively rare and has been associated with poor prognosis (623), which may improve with bone marrow transplantation (293). Although traditionally regarded as inert, gold is being recognized as a common contact allergen (268). In Sweden it is second only to nickel (91), and results from the North American Contact Dermatitis Group rank it among the 10 most common allergens in the United States (386). Gold hypersensitivity is characterized by late reactions, and failure to monitor the test site for a minimum of 3 weeks may result in false negatives. The U.S. EPA has not derived toxicity values for gold (589).

Hafnium

Hafnium is a gray metallic element having a silverlike luster and is found in association with zirconium ores (31, 171). It has outstanding corrosion resistance and is used for this characteristic in atomic reactors, in electronic components, and in alloys. Hafnium compounds show moderate toxicity in acute animal tests by several routes of administration (239). Studies indicate concentration in the liver and skeleton. Hafnium is poorly absorbed orally (313) and the dust is considered to have relatively low toxicity. Workers exposed to 150 mg/m3 of hafnium- and zirconium-containing dusts showed no adverse effects after 2–6 years (165). The ACGIH has adopted a TLV-TWA value for hafnium of 0.5 mg/m3 (32).

Indium

Indium is a Group IIIA metal that is widely distributed in the earth's crust. It is not found in the free state, but most commonly in association with copper, zinc, and sulfur. Indium is used in surface protection of metals, and in many alloys because of its ability to increase hardness. Indium compounds are also used in the photovoltaic and semiconductor industry. Industrial exposures to indium occur during extraction and purification, and in plating and the manufacture of cer tain electronic instruments (63). Absorption of indium compounds is highly dependent on form; insoluble indium compounds are poorly absorbed and distributed, whereas soluble compounds, such as InCl3 and In2(SO4)3, are rapidly absorbed and distributed (63, 628). Consistent with these findings, soluble indium compounds are also more toxic than their insoluble counterparts. The acute lethal dose range for the soluble compound indium chloride in rabbits, rats, and dogs was 0.33 to 3.6 mg/kg (160), whereas the minimum lethal dose for insoluble indium oxide in rats was 955 mg/kg (3), and the oral and intraperitoneal LD50 for insoluble indium phosphide was greater than 5 g/kg (294).

Indium compounds are toxic when inhaled. Copper indium diselenide and indium trichloride, when acutely administered intratracheally to rats at high doses (higher than would be expected in an industrial exposure), induced a persistent inflammatory response (78, 402). Copper indium diselenide was only slightly fibrogenic to the lung, and this corresponds with the limited solubility of this compound (403). Subchronic inhalation of indium sesquioxide in rats induced a persistent inflammatory response; no fibrosis was noted (31). Hamsters were treated once per week for 15 weeks with either indium arsenide or indium phosphide (dose=7.5 mg arsenic or phosphorus) by intratracheal installation and were examined at the end of their lifespan. Adverse histopathologic findings were significantly higher in the treated groups (551).

Several studies have investigated the reproductive and developmental toxicity of indium compounds. Indium arsenide, administered intratracheally, reduced epididymal sperm counts in rats (449) but not hamsters (448); intratracheal instillation of indium chloride in mice did not affect reproductive performance of either males or females, but it was fetotoxic (116).

The ACGIH TLV-TWA for indium and its compounds is 0.1 mg In/m3 (32).

Lithium

Lithium is a silvery-white metal and the lightest solid element. Although it is used in batteries, organic synthesis (Grignard reagent), the space industry, as a swimming pool sanitizer, and in air conditioners, industrial intoxication has not been reported (344). Lithium hydride in contact with water releases hydrogen gas (flammable), and it must be stored under air-tight anhydrous conditions (63). Inhalation exposure to lithium hydride can cause pulmonary edema, but the hydride rather than the lithium is likely responsible (430). The ACGIH has adopted a TLV-TWA value for lithium hydride of 0.025 mg/m3 (32).

Oral lithium salts are widely used in the treatment of manic-depressive disorders, but fre

quent individual monitoring of serum concentrations is required because of the narrow therapeutic index (232, 371). The same levels of lithium are devoid of psychotropic effects in individuals not suffering manic-depressive disorders (371). Effective treatment generally requires levels between 0.8 and 1.2 mEq/L, and toxic effects have been seen at serum levels above 1.5 mEq/L. Signs of lithium toxicity are primarily neurologic and range from fine tremors and muscle weakness in mild cases, to dysarthria, hyperreflexia, coma, and collapse. Lithium therapy may produce lasting neurologic consequences (231). Lithium has properties similar to sodium, and substitution for body cations (sodium, potassium) may account for these effects (592). There is no specific antidote. Renal symptoms of intoxication include polyuria, polydipsia, and renal failure (445). Lithium therapy during pregnancy has been associated with an increase risk of cardiac anomalies, and there are sufficient animal and human data to indicate lithium can cause developmental toxicity (399). The U.S. EPA has not derived toxicity values for lithium (589).

Niobium

Niobium is a white, soft metal found in ores in combination with tantalum and other elements (63). Niobium is used in alloys and may find use in surgical implants and dental applications (63, 69, 518). Organometallic niobium compounds have shown antitumor and anti-HIV activity in vitro and in mice (321, 322, 507). Acute and chronic animal tests have been conducted on several niobium compounds (238, 307, 508). Niobium is poorly absorbed from the GI tract. Parenteral administration of niobium pentachloride results in decreased respiration, lethargy, and death. The compound is a moderate to severe skin irritant, with less irritation noted in rabbit eyes. Life-term studies of sodium niobate in mice and rats did not show carcinogenicity (297). Occupational or general health standards have not been established for niobium in the United States. No reports of occupational health hazards from dust or fumes associated with forging or other fabrication techniques of niobium metal and alloys have been reported (63).

Osmium

Osmium is a platinum-group metal. Osmium tetroxide is a noncombustible, colorless to pale yellow solid, with a disagreeable chlorine-like odor. Osmium tetroxide is apparently formed quite readily from finely divided osmium metal by heating in air, or even at room temperature (242). Osmium is found in combination with platinum and nickel-bearing ores. The major use of osmium is as osmium tetroxide, which is used as a biological stain for adipose tissues (31).

Metallic osmium and most of its other compounds are not considered highly toxic (31); however, osmium tetroxide has been shown to be toxic in animals and in man. The oral LD50 for osmium tetroxide has been reported to be 14 mg/kg in the rat and 162 mg/kg in the mouse; the intraperitoneal LD50 for the mouse was 14 mg/kg (63). The reported LC50 for the rat and mouse is 400 mg/m3 (31). Additionally, rabbits exposed for 30 minutes to osmium tetroxide at a concentration of 130 mg/m3 died after 4 days from pulmonary edema (89). Application of a drop of a 1% solution of osmium tetroxide to the rabbit eye caused severe corneal damage, permanent opacity, and superficial vascularization (89). Toxic effects have also been reported on guinea pig bone marrow, although the route of administration, dose, and duration were not reported (242).

Osmium tetroxide-induced toxicity in humans has been reported in the early toxicology literature. Inhalation exposure to OsO_4 can cause irritation of the nose and throat, which can persist for at least 12 h (242). Industrial exposure to osmium tetroxide concentrations ranging from 0.1 to 0.6 mg/m3 induced lacrimation and disturbances in vision (i.e., the appearance of rings around lights). Other complaints included conjunctivitis, cough, and headache. Recovery usually occurred within a few days (387). One human fatality has been reported, resulting from inhalation of osmium tetroxide (387). The exposure concentration was not reported; death was attributed to capillary bronchitis and pulmonary edema.

The ACGIH has adopted a TLV-TWA of 0.0002 ppm and a STEL/C of 0.0006 ppm for osmium tetroxide, both measured as osmium (32).

Platinum

Although platinum is relatively rare, it is found both as the pure metal and in combination with nickel, copper, and gold (63). Platinum is used as a catalyst in the automotive, chemical, and pharmaceutical industries, and its nobility (resistance to oxidation) makes it important in the manufacture of laboratory equipment (481). Metallic platinum is relatively inert, but the complex salts are frequent sensitizers, producing conjunctivitis, urticaria, dermatitis, and eczema following inhalation and/or dermal exposure (212). A syndrome formerly known by the misnomer "platinosis" is characterized by lacrimation, sneezing, rhinorrhea, cough, dyspnea, bronchial asthma (from chloroplatinates), and cyanosis (212). This term suggests a pneumoconiosis and fibrosis, which are not a part of platinum allergy syndrome,

and the condition is more accurately known as "allergy to platinum compounds containing reactive halogen

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_680.html[2010/10/28 18:46:44]

ligands" (272). The mentioned symptoms are elicited by either an immediate (type I) or delayed (type II, within 24 h) hypersensitivity reaction (212). The platinum analogue cisplatin has been used as a chemotherapeutic agent against various cancers, especially testicular and ovarian tumors, despite nephrotoxicity at therapeutic doses (212). More recently, carboplatin has been used with comparable efficacy (for many types of cancer) and less toxicity, with thrombocytopenia being the major side effect (212, 356). The ACGIH has adopted TLV-TWA values of 1 mg/m3 for platinum metal and 0.002 mg/m3 for soluble salts (32). The TLV for platinum salts protects against sensitization, but does not offer protection to a previously sensitized individual. No increased risk of cancer has been reported from occupational exposure to platinum (212). The U.S. EPA has not evaluated the toxicity of platinum (589).

Rhodium

Rhodium is a silver-white, hard metal that can form highly corrosive resistant alloys and coatings used in electrical contacts, reflectors, and jewelry (31, 212). Unlike the related platinum compounds, rhodium compounds have not been found to be clinically active in cancer therapy. Antimalarial activity is reported for a rhodiumchloroquine complex (499). Only a limited toxicity profile has been developed for rhodium and its compounds. Intravenously administered rhodium trichloride was moderately low in acute toxicity in rats and rabbits (~200 mg/kg), with death possibly due to central nervous system depression (333). Oral rhodium trichloride was low in toxicity (LD50>500 mg/kg) (212). A chronic feeding study showed slight carcinogenic activity in mice (504). Rhodium has been reported to cause allergic contact urticaria (189). The ACGIH has adopted a TLV-TWA of 1 mg Rh/m3 for elemental and insoluble compounds, and 0.01 mg Rh/m3 for soluble rhodium compounds, concurrent with the determination that elemental and rhodium compounds are not classifiable as human carcinogens (31, 32). The OSHA PEL values for elemental, insoluble, and soluble rhodium compounds are one-tenth these levels (31).

Tantalum

Tantalum is a gray, hard metal found in ores in combination with niobium and other metals. It is used in electric capacitors, as the carbide for tools, and has found a wide range of use in medical diagnostic and surgical implant applications (31, 63, 75). Elemental tantalum and its principal oxide are essentially nontoxic in vitro and in vivo. Occupational exposure to tantalum and its oxide has shown no overt adverse health effects (31). Medical uses include tantalum gauze in the repair of hernias, implant plates and screws, and radiographic lung and bone markers (75). The TLV-TWA for tantalum metal and oxide as dust is 5 mg Ta/m3 (32).

Tellurium

Tellurium is placed in Group IVA of the periodic table. Tellurium has a number of industrial uses and is also found in a variety of food products (e.g., condiments, dairy products, nuts, fish) in high concentration. Pneumonitis and hemolytic anemia are prominent features of acute tellurium intoxication (29). Tellurium hydride has been shown to be highly toxic, causing pulmonary irritation and intravascular hemolysis (608). Acute oral or parenteral tellurium intoxication resulted in numerous symptoms, with hematuria noted in all animals treated (29, 388). Weanling rats fed 1% tellurium in the diet developed a peripheral neuropathy characterized by a transient demyelinating/remyelinating event (67, 332).

There have been no reports of serious illness or death in workers exposed to tellurium and its compounds. However, absorbed tellurium is slowly metabolized to dimethyl telluride and is excreted in urine, sweat, and breath (149). It is dimethyl telluride that is responsible for the "garlic breath" that is associated with tellurium exposure (336). Two fatalities occurred after unintentional treatment with 2 g sodium tellurite by ureteral catheter (302). Autopsy revealed acute fatty degeneration and edema of the liver. The ACGIH has adopted a TLV-TWA value of 0.1 mg Te/m3 for tellurium and compounds (32).

Tin

Tin is a soft, white metal that occurs in combination with other chemicals (e.g., chlorine, oxygen) (8). It is alloyed with other metals to make pewter, solder, bronze, and a special cast bronze termed bell metal (up to 24% tin), which is noted for its tonal quality (63). Most of the tin used in the United States is for plating steel cans. The fluoride is used in toothpaste, and the chloride is used to make frost-free windshields (500). Organotins function as antimicrobials in agriculture and industry, as stabilizers in polyvinyl chloride (PVC) plastics, and as marine antifouling agents (63). Although Schwarz et al. (514) in 1970 reported a significant growth effect of dietary tin in weanling rats maintained on purified diets, this has not since been independently confirmed and tin is not considered to be essential. Inorganic tin compounds are poorly absorbed from the gastrointestinal tract [i.e., rats dosed orally absorbed 2.8% of Sn(II) and less than 1% of Sn(IV) (260)] and are therefore relatively nontoxic; acute oral LD50 for SnCl2 in rats is

700 mg/kg (99), but after intravenous administration it is reported as 100 mg Sn/kg (517). Soluble salts of inorganic tin are gastric irritants producing nonspecific signs of nausea, vomiting, and diarrhea. Rats maintained on diets containing 0.3% or more as soluble inorganic tin salts (i.e., stannous chloride) experienced growth retardation and anemia (146). Injected stannous chloride is a potent inducer of rat renal microsomal heme oxygenase, enhancing heme breakdown (298). Diets supplemented with high levels of iron and copper protected rats from the anemia, but did not alleviate growth depression (145). Tin has adverse effects on the absorption and metabolism of the essential elements iron, copper, and zinc (145, 146, 229). In contrast, organotins, especially the trialkyl derivatives, are highly toxic [i.e., rat acute oral LD50 of 10 mg/kg (310)]. Triethyltin compounds are skin irritants and potent neurotoxins, producing a decrease in myelin content of the CNS and edema of the white matter (492). Uncoupling of oxidative phosphorylation has been proposed as the mechanism of action (401). Acute inhalation exposure to tin can cause metal fume fever and chronic exposure can cause a benign pneumoconiosis, stannosis (430). The ACGIH has adopted TLV-TWA values of 2 mg/m3 for the inorganic compounds (except tin hydride, SnH_4) and a TLV-TWA of 0.1 mg/m3 for organic tin compounds (32). Although the U.S. EPA has not evaluated tin and tin-containing compounds for carcinogenicity, the NTP has performed a 2-year bioassay for stannous chloride in rats and mice with negative results in all but male rats, where the results were equivocal for thyroid C-cell tumors (421).

Titanium

Titanium is a silver-gray metal that can occur naturally in several forms including titanium dioxide. Titanium is a component of several alloys, and is used in surgical implants where it is considered nontoxic (250). Titanium dioxide, the most common oxide of titanium, is extensively used as a white pigment in paints, plastics, inks, and cosmetics (63, 209). Titanium dioxide is generally considered to be essentially nontoxic by the oral, dermal, and inhalation routes. A 2-year feeding study of titanium dioxide at maximum doses of 2.5 g/kg/day in rats and 6.4 g/kg/day in mice found no evidence of carcinogenicity (415), although the dose-response relationship was statistically significant for thyroid tumors in female rats and keratoacanthomas in male rats (214). Toxicity from the more prevalent respiratory exposure to titanium dioxide has been investigated. A 2-year inhalation study was conducted in rats with acceptable results at a level of 10 mg/m3; high levels produced squamous-cell carcinomas, which are postulated to be the result of saturation of normal pulmonary clearance mechanisms (31, 340). Epidemiological findings and related information do not conclusively support a relationship between occupational exposure to titanium dioxide and pulmonary fibrosis, cancer, or other adverse health effects (31). The ACGIH has adopted a TLV-TWA value of 10 mg/m3 for titanium dioxide (32).

Tungsten

Tungsten is a member of the third series of transition metals and occurs in nature in combination with iron, manganese, and calcium. The major use of tungsten is in cutting and wear resistant materials (63). The bulk of inhaled tungsten oxide is rapidly excreted in dogs (1). Although exposure to soluble tungsten compounds can be toxic in experimental animals (311, 531), insoluble tungsten compounds have a low order of toxicity (148, 199, 312, 395). Male and female rats given sodium tungstenate in water for $2\frac{1}{2}$ years at doses of 0.25 and 0.29 mg/kg/day had no significant increase in tumor incidence (506).

Pulmonary fibrosis observed in men with inhalation exposure to cobalt-cemented tungsten carbide (394) has been attributed to cobalt (63). Evaluation of workers with long-term exposure to tungsten or its insoluble compounds showed no development of pneumoconioses (31).

The tungsten ion antagonized the normal metabolic action of the molybdate ion, and therefore can inhibit molybdate-dependent enzymes (259, 290, 441). The ACGIH has adopted TLV-TWA values of 5 mg W/m3 for insoluble compounds and 1 mg W/m3 for soluble compounds (32).

Yttrium

Yttrium has a silvery luster and is used primarily as the matrix producing the red color in television tubes (63). Yttrium chloride has been reported to cause granulomatous changes in the rat lung following intratracheal instillation (262), and the liver and spleen are reported to be the primary target organs following intravenous injection (263). Despite a long history of industrial use, there are no definitive reports of adverse effects in workers (63). The LD50 for yttrium chloride following intraperitoneal injection in rats is 132 mg Y/kg body weight (128). The U.S. EPA has not derived toxicity values for yttrium. The ACGIH had adopted a TLV-TWA value of 5 mg Y/m3 but reduced this to 1 mg Y/m3 (31, 32) based on a report that yttrium inhalation caused severe lung damage (63).

Zirconium

Zirconium is a grayish-white element of the second series of transition metals. The metal is produced from

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_682.html[2010/10/28 18:46:46]

two main sources of ore, zircon ($ZrO SiO_2$), and baddeleyite (ZrO_2); hafnium is always associated with zirconium (32). Zirconium is used for the cladding in nuclear fuel rods, and zirconium compounds are also used in foundry and sandblasting applications. Industrial exposure occurs during mining and purification operations, and in foundry and other industries. A significant percentage of the general population is exposed (dermally) to aluminum zirconium chlorohydrate complexes in commercially marketed antiperspirant products.

Zirconium oxide has a low order of toxicity via the inhalation route in animals (538); slight toxicity was noted in dogs when exposed to an airborne mist of zirconium chloride at 6 mg Zr/m^3 for 2 months. Zirconium oxide and zirconium chloride exposure at 3.5 mg Zr/m^3 for 1 year had no measurable adverse effect on the animals exposed (63). Similarly, in most studies of industrially exposed workers, no adverse effects have been associated with inhalation exposure to zirconium fumes or other zirconium compounds (237, 370, 474). However, several cases of either fibrotic (58) or granulomatous (324, 348) changes in the lung associated with inhalation exposure to zirconium compounds have been reported. Long-term exposure of mice to zirconium sulfate was not associated with increased tumor incidence (297).

Certain zirconium compounds, such as zirconium lactate, when applied to human skin (54, 63, 489, 524) or the skin of experimental animals (471), can produce dermal granulomas of allergic origin. Aluminum zirconium chlorohydrate complexes, used as active ingredients in antiperspirants, do not appear to cause these granulomatous reactions, but because of risk/benefit considerations, the U.S. Food and Drug Administration banned the use of these materials in aerosolized drug and cosmetic products (580). The ACGIH has adopted a TLV-TWA value of 5 mg Zr/m^3 and a STEL/C value of 10 mg Zr/m^3 for zirconium compounds (32).

ACKNOWLEDGMENTS

The authors gratefully acknowledge the significant contributions of the previous author, Fanny K.Ennever.

QUESTIONS

1. Margins of safety are normally calculated by determining a no-observable-adverse-effect level (NOAEL) in an animal species and modifying the value by factors to account for inter- and intraspecies variability. U.S. EPA reference doses (RfD) are calculated using a similar approach. How does the oral RfD for the essential metal mol ybdenum show the limitations of this approach for calculating margins of safety?

Answer: The estimated safe and adequate daily dietary intake for molybdenum is set at the current U.S. dietary intake of 75–250 μg/day, whereas the oral RfD for molybdenum is 350 μg/day, a value very close to the current dietary intake. In fact, the U.S. EPA had initially derived an RfD of 280 μg/day, essentially the same as current U.S. dietary intake levels. These calculations show that the indiscriminate use of safety factors (without consideration of other relevant information) can lead to overestimation of the toxicity of a substance.

2. Your 15-kg patient has ingested 10 tablets, each containing 324 mg ferrous sulfate. How much elemental iron did the child ingest? (Ferrous sulfate contains 20% elemental iron.)

Answer: $10\times324\times0.20=648$ mg elemental iron. Then $648/15=43.2$ mg Fe/kg body weight. Inaccurate calculation of the dose of elemental iron ingested is a known pitfall in the management of iron poisoning.

3. Why is toenail selenium used instead of blood or hair selenium concentrations for estimating past selenium intake?

Answer: Hair selenium content is difficult to accurately measure because of the common use of selenium-containing antidandruff shampoos. Blood selenium is not a good indicator of past selenium intake because the life of an erythrocyte is only 120 days.

4. Some metals elicit clinical neurotoxicity at certain workplace exposure levels. For example, manganism is often characterized by Parkinson-like symptoms. Describe tests useful in determining neurotoxicity prior to clinical symptoms in order that safe exposure levels may be established and corrective action taken.

Answer: Nonclinical neurological injury can be evaluated by controlled neurobehavioral tests that evaluate reaction time, eye-hand coordination, and hand steadiness.

The increasing use of radiation in the modern world and recent incidents of massive radiation exposure dictate that certain basic elements of radiation toxicity be addressed.

Radiation toxicology is the study of the adverse effects of radiation on living organisms. It is a multidisciplinary science, borrowing freely from several of the basic sciences. The cytopathological consequences of radiation exposure are similar to those induced in other types of cellular injury. Radiation-induced cell changes may result in death of the organism, death of the cells, modulation of physiological activity, or cancers that have no features distinguishing them from those induced by other types of cell injury.

Electromagnetic radiation is divided into nonionizing and ionizing radiation according to the energy required to eject electrons from molecules (575). Ionizing radiation, which may exhibit the properties of both waves and particles, has sufficient energy to produce ionization in matter. The ionizing radiations

that exhibit corpuscular properties include alpha and beta particles whereas those that behave more like waves of energy include x-rays and gamma rays.

Radiation exposure comes from many sources and may be *directly ionizing* or *indirectly ionizing*. Directly ionizing radiation carries an electric charge that directly interacts, by electrostatic attraction or repulsion, with atoms in the tissue or medium exposed. Indirectly ionizing radiation is not electrically charged, but results in production of charged particles by which its energy is absorbed. A characteristic of charged particles produced directly or indirectly is *linear energy transfer* (LET), the energy loss per unit of distance traveled, usually expressed in kiloelectron volts (keV) per

micrometer (μm). The LET, depending on the velocity and charge of the particle, may vary from about 0.2 to more than 1000 keV/μm.

DOSIMETRY AND EXPOSURE

Système Internationale

The International Commission on Radiological Units and Measurement (ICRU) introduced the "Système Internationale" or SI units in 1980 to express radiation dose (268). The gray (Gy), the SI unit for absorbed dose, corresponds to an energy absorption of 1 joule/kg or 100 rads. This concept of energy absorption is useful for determining absorbed doses of x-rays and gamma rays. However, determination of the absorbed dose in tissues exposed to fast neutron radiation involves more elaborate calculations. The absorbed dose of neutron radiation depends on the transfer of energy from neutrons to directly ionizing particles in the tissue and is described by the kinetic energy released in the material.

For general use, a quantity different from the rad or gray has been introduced, the dose equivalent. The dose equivalent allows for the relative effectiveness of a particular type of radiation. Gamma rays and x-rays are regarded as the standard and a quality factor of 1 is multiplied by the dose to compute the dose equivalent. Therefore, the dose equivalent (Seiverts, Sv) for x-rays and gamma rays is equal to the dose (grays). However, neutrons are thought to be roughly 10 times more effective in producing tissue damage than x-rays and therefore are assigned a quality factor of 10.

Exposure Factors

Before discussing the effects of ionizing radiation, some of the factors that influence the toxicity of radiation should be reviewed. One of the major factors related to the exposure is the dose or total amount of radiation received (Table 15.1). The absorbed dose of radiation is the quotient dE/dm where dE is the differential energy deposited into a differential mass, dm (268). The unit of absorbed dose, in the CGS (centimeter-gram-second) system, is the rad (radiation-absorbed dose) and 1 rad=100 ergs/g (a dose of 1 rad of ionizing radiation has been absorbed when 100 ergs of energy have been deposited in each gram of material) (555). Another term commonly used, particularly in the field of radiation protection, is the rem (roentgen equivalent man). This unit was developed to enable radiation protection personnel to set standards of exposure (rem=rad×quality factor×distribution factor). The quality factor is a unit to equate the relative biological effectiveness (RBE) of one radiation to another and the distribution factor

Table 15.1 Radiation quantities and units used in radiobiology[a]

Unit or quantity	Symbol	Application
Becquerel	Bq	SI quantity of radioactivity Bq=1 disintegration/s Bq=2.7×10^{-11} Ci
Curie	Ci	Quantity of radioactivity 1 Ci=3.7×10^{10} dps 1 Ci=3.7×10^{10} Bq
Gray	Gy	SI unit of absorbed dose 1 Gy=100 rad=1 J/kg
Rad	rad	Unit of absorbed dose 1 rad=0.01 Gy=100erg/g
Rem	rem	Unit of dose equivalent rad×Q×other modifying factor 1 rem=0.01 Sv
Sievert	Sv	SI unit of dose equivalent rad×Q×other modifying factor 1 Sv=100 rem
Linear energy transfer	LET	Energy deposition per unit of path length Usually in eV/micron
Relative biological effectiveness	RBE	Same effect from same dose of reference radiation Used in radiobiology
Quality factor	Q	Biological effectiveness of radiations
Working level	WL	1.3×10^{-5} MeV α-energy/L air
Working level month	WLM	1 WL×170 h
Electron volt	eV	Unit of energy; 1 eV=1.6×10^{-12} ergs 1 eV=1.6×10^{-19} J

attempts to compensate for the varying sensitivity of the different parts of the body. The roentgen, the amount of radiation required to produce one electrostatic unit of charge per cubic centimeter of air, is an older radiation exposure term that may still be seen in literature. This is a measure of only the actual ionizations produced by x-ray or gamma ray irradiation in air.

A second factor influencing the toxicity of radiation is the dose rate, $D = dD/dt$, the differential dose with respect to time; when there is no variability in dose dE/dm, $D = D/t$. When reviewing experiments in radiation toxicology, the variables, total dose, dose rate, type of radiation, and variability of the model, must be considered.

The exposure to radon (^{222}Rn) and radon daughters may be expressed, by convention, as the concentration of radon daughters measured in working levels (WL), and cumulative exposures over time are measured in working level months (WLM) (49). The WL is defined as any combination of radon daughters in 1 liter of air that results in the ultimate release of 1.3×10^5 MeV of potential alpha energy. This is approximately the alpha

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_700.html[2010/10/28 18:46:57]

Table 15.2 Average annual effective dose equivalent of ionizing radiations[a]

Source	Dose equivalent		Effective dose equivalent	
	mSv	mrem	mSv	%
Natural				
Radon	24.0	2400	2.0	55.0
Cosmic	0.27	27	0.27	8.0
Terrestrial	0.28	28	0.28	8.0
Internal	0.39	39	0.39	11.0

energy emitted by the radon daughters in equilibrium with 100 pCi of radon. The WLM is defined as exposure to this concentration for a working month of 170 h.

SOURCES

The quantity of radiation present could range from the irreducible natural background levels to large scale releases such as occurred at Chernobyl and Chelyabinsk in Eastern Europe. Biological damage may be detected at levels only slightly above the former, whereas the latter would result in extreme biological toxicity of unknown proportions. The sources of radiation may be broken into two major components: technologically induced or man-made radiation and natural radiation (Table 15.2).

Technologic or Man-Made Radiation

Health Sciences

The use of man-made radiation in the health sciences is normally divided into three areas: (i) diagnostic x-ray examinations, (ii) nuclear medicine, and (iii) therapeutic radiation. In the more highly developed countries, exposure from medical sources may equal or exceed natural background radiation, but in undeveloped countries, the relative contribution of medical irradiation may be only about 5% of the total exposure (437).

The use of x-rays in diagnostic examinations, including dental, represents the single largest man-made source of radiation exposure in the U.S. population. The Bureau of Radiological Health, Food and Drug Administration (FDA), estimated that approximately 65% of the people in the United States were exposed to x-rays for medical and dental diagnostic examinations in 1970. The mean active bone marrow dose to adults was 103 mrads with the 65 and older age group receiving the highest per capita dose (48). Dental x-ray examinations are the most common of the diagnostic examinations and approximately 30% of the total diagnostic examinations are received on an outpatient basis (437).

The use of radiopharmaceuticals in nuclear medicine has almost doubled over a 10-year period. It is estimated that up to 12 million doses of radiopharmaceuticals are given each year in the U.S. for diagnostic purposes (48). However, the per capita effective dose equivalent from these procedures in the United States is only about 140 μSv (437).

Radiation therapy has been used almost exclusively for the treatment of malignant neoplasms. The high absorbed dose, 50–70 Gy, required in most malignant conditions, leads to *nonstochastic* or direct effects such as cell death.

Therefore, some of the normal tissue surrounding the neoplasm may be exposed and incur some long-range risk. The risk, however, is usually eclipsed by the immediate benefits normally associated with increased life expectancy.

Nuclear Weapons

The first atomic weapon was detonated in 1945 on a New Mexico desert north of Alamagordo. Since that day hundreds of test explosions have been conducted by the United States, the Soviet Union, the United Kingdom, India, France, and the People's Republic of China. Between 1945 and 1984, the total estimated yield of all atmospheric nuclear explosions was approximately 546 megatons (437). A one-megaton (MT) explosion equals the explosive force of 1 million tons of 2,4, 6-trinitrotoluene (TNT).

The radioactive fallout from nuclear explosions may be divided into three portions depending on the yield and height of the burst. The larger, intensively radioactive particles fall out close to the site within hours. Slightly smaller particles behave somewhat like aerosols and are dispersed into the troposphere where they will stay for a matter of months. The fallout from this portion remains in bands around the earth at the latitude of the detonation. The third portion penetrates the strato sphere and its particles are deposited worldwide over a period of months to years (196). Most of the radioactive fallout is downwind from the explosion and up to 70% is in the larger particle portion, returning to the earth close to the detonation site within hours. The intensity of the radioactivity varies inversely with distance from the site of explosion. With a steady wind, the pattern of accumulated dose of radioactivity assumes nested cigar-shaped contours, each contour denoting a particular dose.

A one-MT thermonuclear weapon detonating at ground level with a steady wind of approximately 15 miles per hour would produce a fallout radioactivity dose rate of 400 rem in 24 h in an area of approximately 400 square miles. At a dose rate of 2 rem per year, more than 20 times the maximum recommended by the U.S. Environmental Protection Agency (EPA), an area of 1200 square miles would remain unfit for use for a year and more than 20,000 square miles would be uninhabitable for a month (201).

In a nuclear explosion over 400 radioactive isotopes are released into the biosphere. Among these, about 40 radionuclides are considered potentially hazardous. Of particular interest are those isotopes whose organ specificity and long half-lives present a danger of irreversible damage or induction of malignant alterations. Both early and delayed fallout result in the deposition of radioactive material in the environment (102). The annual average whole-body fallout rate in the United States is now approximately 45 μSv (4.5 mrem) and is projected to stay at this level through the year 2000 (48, 437).

Nuclear Power Production

When radiation exposure from nuclear power production is mentioned, most persons immediately think of nuclear power reactors and the environmental dispersion of radionuclides, particularly krypton 85, tritium, carbon 14, and iodine 129. However, exposure from nuclear power production should also include mining, uranium fuel fabrication, and waste storage and disposal (437).

Although uranium mines increase the amount of uranium and its decay products, along with radon and its daughters, the environmental risks from the radioactive emissions from uranium mines is insignificant (196, 290). However, mill tailings may represent a significant source of environmental radiation due to the emanation of ^{222}Rn, dispersion of the tailings by wind and water, and by the use of mill tailings in building construction.

About 1000 land-based nuclear reactors have been constructed and operated at some time throughout the world. Some of the reactors were built for research, or the production of radioisotopes and plutonium. Approximately 200 naval vessels throughout the world are powered by nuclear reactors. Yet, the environmental release from nuclear operations in the United States results in a dose rate for the average person of less than 1 mrem/year (48).

Accidents

Although the environmental release of radionuclides from nuclear reactor operations is approximately 1 mrem/year per person, malfunctions can develop and accidents can happen (48). The contents of the reactor at the time of an accident, the amount of contaminant, including its physical and chemical properties, depend on the reactor type, its application, and the duration of operation (596). Not all of the nearly 800 nuclides produced in reactors are radioactive and of these only 54 are considered significant in risk assessment (196). With core damage, the severity of the accident and therefore the risk, depends on the radioactivity, mainly as ^{131}I and ^{137}Cs, being released to the environment.

Since 1952, there have been 14 reactor accidents that involved core damage. One, the Windscale, U.K. Atomic Energy Works accident, was the first time radioactive material was released from a reactor accident. In October 1957, a plutonium production reactor located on the coast of Cumbria in northwest

England released approximately 740 TBq ^{131}I, 22 TBq ^{137}Cs, 8.8 TBq ^{210}Po, and 3 TBq ^{89}Sr (122, 196). The core in the No. 1 Pile of the two air-cooled, graphite-moderated, natural uranium reactors was partially consumed by fire, releasing the fission products onto the seashore and foothills southwest

of the Cumbrian Mountains, over much of England, and parts of northern Europe. As an aftermath of this accident, the village of Seascale has had four fatal leukemia cases in children who were under 20 years of age between 1950 and 1980. Based on statistics, only 0.5 cases would have been expected (617).

On March 28, 1979, the worst accident in the history of U.S. commercial nuclear power generation occurred on Three Mile Island (TMI) in Pennsylvania (290). Even though the accident at TMI-2 released the radionuclides ^{131}I, ^{133}Xe, and ^{135}Xe into the environment, the collective dose equivalent to the population from the release was less than 1% of the dose accrued from natural background radiation in a year (596). As with the Windscale accident, the radionuclide identified as principal concern was ^{131}I, but in this case, only 1 TBq ^{131}I was released and the fission products at TMI were retained within the vessel (121, 122). Although radiation exposure to the plant workers and the public was insignificant, the nuclear power industry was set back almost a decade. Even orders for the construction of new nuclear plants were canceled (196).

The largest airborne dispersion of radionuclides thus far occurred from the explosion and ensuing 10-day fire of the graphite-moderated reactor of Unit No. 4 of the Chernobyl nuclear power station in the former Soviet Union (now Ukraine) on April 26, 1986. It has been estimated that this has been the single most costly industrial accident in history (122, 196, 310, 596). One revealing evaluation of the economic loss from this accident has been the estimate that from 8 to 10 annual budgets for the Republic of Belarus will be consumed in order to appropriately address the effects of this disaster, just for the needs generated in that country alone (91). Another more conservative estimate puts the costs of modestly dealing with the Chernobyl nuclear accident at 45 billion dollars, not including, of course, the human and ecological toll (594). The health care needs, for instance, are only now becoming apparent (154).

Fallout from the Chernobyl nuclear disaster was very widespread, with a large amount of a variety of radionuclides distributed throughout the northern hemisphere (20, 214, 355, 661). In Eastern Europe and Scandinavia, it has been estimated that approximately 4×10^{18} Becquerels (Bq) were dispersed by the accident (315, 534, 608). The radioactive cloud moved outside of the area of the Soviet Union in the first few days after the accident, and the event only became publicized when radioactive levels in Sweden became elevated, reaching 14 times background levels (121). The importance of meteorological conditions at the time and place of nuclear accidents or thermonuclear detonations was clearly evidenced in the dispersion patterns of the fallout. The majority of the ensuing environmental radioactivity now resides in the newly created nation of Belarus (immediately north of the Chernobyl nuclear complex), which now has the distinction of having approximately 30% of its territory with a significant contamination from the accident, including 20% of the forests and 18% of the farmland (315). Ukraine and Russia have most of the remainder of the inventory that was released. The most prominent radionuclides released, in terms of quantity and widespread geographic dispersion, were ^{137}Cs, ^{90}Sr, and ^{131}I. Although less widespread, significant levels of ^{239}Pu and various transuranics were also distributed in the areas around the reactor complex.

The International Atomic Energy Agency (IAEA) report published by the Soviet Union in 1987 determined a radiation dose for the two most highly contaminated areas as (i) a 106,340-man-Sv collective 50 year dose for a population of 10.1 million in Belarus, and (ii) a 80,660-man-Sv collective 50 year dose for a population of 29.8 million in Ukraine (664). Although many east European scientists in post-Soviet scientific circles challenge these estimates as too low, they do indicate a significant radiation dose to a large number of people in the contaminated areas of these two countries. Indeed, newer estimates are that the one million people in the most contaminated areas of Belarus and Ukraine will accumulate between 150,000 and 200,000 Sv (as much as the total dose for both countries in the 1987 report), with the total population dose approaching 1,000,000 Sv (429). Many villages surrounding the Chernobyl reactor area had to be abandoned, along with the entire city of Pripyat, formerly housing over 50,000 people. This made Pripyat the first sizable city in history to be abandoned solely on the basis of radioactive fallout. Some of the inhabitants of the abandoned villages were calculated to have been expected to accumulate at least 35 rem per person (429). In Belarus alone, approximately 2.2 million people live in the areas significantly contaminated by the accident, including 800,000 children (154). At least 135,000 people were evacuated just from the Chernobyl exclusion zone, now established in the areas immediately around the reactor complex (613, 699).

One result of the Chernobyl accident has been that the people and the ecosystem of the contaminated areas of Belarus, Ukraine, and Russia have become a living laboratory of the consequences of widespread radioactive contamination. In the ecosystem, deposition of the radionuclides from the reactor

fire and dispersion tended to be very "patchy," with variation of over 100% in soil and sediment samples even taken only meters apart (318). Uptake of radionuclides into wildlife around the reactor was very high, with radiocesium concentrations averaging 18,000 Bq/g in one rodent species (363) and up to 200 Bq/g in fish (318). Food contamination from environmental radioactivity resulted in leafy vegetables reaching 10 μCi/kg and iodine levels in milk commonly measured at 1 μCi/L (196).

Page 704
The ecotoxicological effects from the Chernobyl accident have also provided an unprecedented observation recently of the widespread dispersion of radionuclides in the environment. Evaluations of the blood cell DNA of fish from the radioactively contaminated aquatic habitats near the reactor revealed abnormal DNA distributions, hyperdiploidy, and cell cycle perturbations, though there were no gross physical malformations (155, 156, 386, 628). An even more extensive evaluation of rodents in Chernobyl-contaminated areas has been published in the last few years. A reduction in fertility and various other physiological disorders were reported in some mammalian species in the years immediately following the accident (223, 365). Cytogenetic and other mutagenic effects were observed in rodents from sites ranging from the Chernobyl power plant vicinity to Sweden (142, 143, 250, 603). At least some of the variation in response observed can be attributed to a species difference in sensitivity, such as the high radioresistance reported for *Clezhrionomys glareolus* from Chernobylcontaminated areas (308, 363). Species differences in oxidative stress enzyme response were also found in rodents from these areas, with *C. glareolus* showing radioresistance relative to another species (298), despite a much higher deposition of radionuclides measured internally (114). There was sufficient radioactivity released in the accident to kill about 400 hectares of pine forest, and more than one million square meters of ground was bulldozed and buried (430).
The human health effects of the Chernobyl nuclear accident are only now becoming evident, with additional reports appearing each year. A relatively high incidence of thyroid cancer has been documented in Belarus, Ukraine, and Russia (66, 232, 517). The incidence of leukemia is still under investigation, but a statistically relevant increase related to the accident has not yet been substantiated (249, 334, 604, 703, 712). An increased frequency of chromosomal aberrations have been detected in the blood cells of people living in the contaminated areas, or those who worked as liquidators in the cleanup after the accident (582, 618). An increased mutation rate at human minisatellites was found in children born in a contaminated region of Belarus relative to a control population (187, 188). These minisatellites provided perhaps the only currently available system for the efficient monitoring of germline mutation in humans, and it was concluded that the damage was probably not due to DNA damage induced directly at the minisatellites, but from radiation-induced damage at other sites in the genome (188). Somatic minisatellite mutation events were present in a subset of radiation-induced, but not sporadic, thyroid cancers, suggesting that this type of genomic instability may play a role in radiation-induced tumorigenesis in the thyroid gland (496). There was an increased frequency in both lymphocyte micronuclei (an assay of chromosomal integrity) and somatic mutations in erythrocytes at the glycophorin A locus of residents of Chernobyl-contaminated cities in Belarus, and these effects were significantly correlated with radiocesium content (391, 537). Somatic mutation responses were also found in the glycophorin A locus of erythrocytes from Chernobyl workers from the Baltic countries (61, 62) and in immigrants to Israel (707). There has been some indication that children exposed to low LET radiation due to Chernobyl may have an increase in cataract formation (166). Among children in Belarus, it was also reported that after the accident there were increases in endocrine and dermatologic diseases, digestive organ diseases, autoimmune thyroiditis, and chronic tonsillitis and adenoiditis (393).
Another serious radiation accident occurred in the central Brazilian plateau state of Goias and went virtually unnoticed by most of the world (144). The Instituto Goiano de Radioterapia, a private radiotherapy clinic in Goiânia, Brazil, ceased operation in 1985, leaving a 137Cs radiotherapy unit in an insecure situation in an abandoned treatment room. In September 1987, the 50.9-TBq 137Cs source was removed from the protective housing of the therapy unit. With the later rupture of the container, the 137Cs became widely dispersed throughout the city's one million population. Exposure to the 137CsCl resulted in 4 deaths, 28 other cases of acute radiation sickness, and 3500 m3 of radioactive waste. The four persons who died received estimated doses ranging from 4.5 to 6.0 Gy. Other than massive accidents with widespread contamination such as occurred at Chernobyl, this is one of the most serious radiation accidents that has ever occurred.
Nuclear Waste Management
The disposal of radioactive waste is part of a dilemma facing a technologically advanced society. One of the basic demands of such a growing society is availability of convenient and inexpensive sources of energy. As the demand for energy increases, the reliance on nuclear power will increase, as will the production of radioactive waste.
Radioactive waste is classified by its physical and chemical properties as well as its source (196, 236). Three general categories of radioactive waste are: (i) low level, (ii) transuranic, and (iii) high level. Low-level radioactive waste (LLRW) includes residues from laboratory research, medical institutions, uranium mill tailings, and waste generated in the cleanup of uranium, radium, and thorium processing plants.

LLRW is further subdivided into classes A, B, and C, depending on the concentration, energy levels, half-life and the sources of the radionuclides in the waste. Radionuclides found in LLRW include 241Am, 14C, 242Cm, 60Co, 137Cs, 129I, 241Pu, 226Ra 90Sr, 99Tc, 230Th, and 235U. Because the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_704.html[2010/10/28 18:47:00]

national inventory of LLRW waste is growing at 105 m3/year (30% from medical institutions), management of the waste is facing a crisis in storage and disposal.
Transuranic (TRU) wastes are materials containing radionuclides with atomic numbers greater than uranium, such as americium, curium, and plutonium. These wastes originate mainly as by-products in the production and fabrication of plutonium for military purposes. Resulting from an industrial process involving transuranic materials, the TRU wastes are predominantly contaminated with 238Pu and 239Pu. These wastes tend to be water-soluble and pose a distinct health hazard because they can contaminate a variety of physical forms ranging from absorbent papers and rubber to discarded tools.
The most radioactivity and the highest concentration of radionuclides associated with nuclear wastes is found in spent fuel from civilian nuclear power reactors, and the reprocessing of civilian and military spent fuel. Typical radionuclides found in this high-level radioactive waste (HLRW) are: 60Co, 137Cs, 239−242Pu, 106Ru, and 90Sr. Because of the high hazard duration (>105 years) associated with these nuclides, large quantities (80 million gallons in 1982) (196, 236) of highly toxic liquid and solid HLRW must be isolated from the environment for thousands of years.
At present much of the HLRW is stored at temporary sites in concrete-encased steel tanks a few meters below the surface of the ground. Considering the finite lifetime of the steel tanks (15–40 years), it becomes clear that these wastes must be transferred to other containers or sites in the future. Several options for the permanent repository of radioactive waste have been considered (196, 251) and the method currently in favor is in deep underground mined cavities.
The worst example of nuclear waste management has been the experience of the Soviet nuclear weapons production complex, MAYAK, which started in 1948 on the Techa River in the Ural mountains of the Soviet Union (about 60 miles from the city of Chelyabinsk). The city constructed nearby to support the facility was originally called Chelyabinsk-65 (it is now called Ozersk), and this nuclear contamination area is now usually referred to simply as Chelyabinsk. Over 2×107 Ci were released over time into the surrounding area, making this the largest release of radionuclides at a single site in history (428, 652). Most of this inventory was released in 1957 in an explosion in a fuel reprocessing plant, referred to afterwards as the Kyshtym accident. The workers in the MAYAK facility were reported to have had high levels of radioactive exposure, exceeding 1 Gy annually for 25% of the radiochemical workers in the first 5 years of operation, with 11% of the workers overall receiving 6.3 Gy over the first decade (249). This resulted in some deaths from chronic radiation lung injury (359) and elevated lung cancer deaths and leukemia in the workers (360). In the people living in the villages along the Techa River and in the areas contaminated by the Kyshtym accident, there were also reports of high internal radionuclide doses (249) and an increased incidence of leukemia (361).
Natural Environmental Radiation
Natural background radiation is the greatest contributor to radiation exposure in the world. In most countries natural background radiation contributes slightly more than half of the absorbed radiation dose (437). Relative contributions to the total absorbed dose may range from 42% in highly developed countries to 94% in most developing countries. Exposure to natural sources of irradiation is unavoidable and life has evolved under a continuous exposure of ionizing radiation. This background radiation has three components: (a) cosmic radiation (external), (b) terrestrial radiation (external), and (c) naturally occurring radionuclides (internal).
Cosmic and Solar Radiation
Cosmic and solar radiation originate predominately from galactic sources and consist mostly of high-energy protons and alpha particles (48, 437, 555). Cosmic radiation at the earth's surface varies with altitude, geomagnetic latitude, and solar modulation (214, 290). For instance, in the United States, 48% of the population lives at sea level to 152.5 m and receives a dose rate of approximately 27 mrem/year (0.27 μSv/year), whereas in Leadville, Colorado (altitude 3200 m), the residents receive about 125 mrem/year. This effect of altitude becomes increasingly important to passengers and crews of high-flying aircraft. It is estimated that cabin attendants and crew members receive approximately 160 mrem/year above that received at sea level (196). The cosmic rays are reduced by the earth's atmosphere, resulting in a shielding effect. This shielding effect decreases with altitude, with cosmic ray exposure doubling every 1500 m above the earth's surface (437).
Above the earth's atmosphere the radiation consists of two main components. One is the dose from highly energetic cosmic radiation geomagnetically trapped in the earth's magnetic field. The second component is received beyond the earth's magnetic field and is due to background cosmic radiation of about 85% protons and 14% alpha particles. Astronauts traveling into outer space must traverse two belts of geomagnetically trapped radiation, the primary cosmic radiation, radiation from solar flares, and

directed beams of gamma rays emitted by certain quasars and pointed directly at Earth (206).
Within the United States the effect of latitude on cosmic radiation dose rate is less than 10%, with an average dose rate at sea level of about 270 μSv/year (437).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_705.html[2010/10/28 18:47:00]

However, in the United Kingdom the annual dose rate varies from about 280 μSv a year in the south of England to 310 μSv a year in the north of Scotland (214). The dose rate variation with latitude depends primarily upon the variations in the earth's magnetic field, with which cosmic radiation interacts (48).

Terrestrial Radiation

Terrestrial radiation levels and rates from natural background sources are functions of geographic location and living habits. In most areas on earth the terrestrial radiation level varies within relatively narrow limits, but in certain regions of Brazil, China, France, Italy, Madagascar, and Nigeria, the terrestrial radiation substantially exceeds the normal range (196, 398, 437). For instance, a person suntanning on some beaches along the Atlantic coast of Brazil may receive as much as 17.5 cGy/year from the sand alone (437). Meanwhile, the exposure from the fine monazite particles of the soil in the Donganling and Tongyou regions of China would run between 18 cGy and 20 cGy per year (398).

The conterminous United States may be divided into three general radiation regions (48). The Atlantic and gulf costal plains receive an average of 23 mrems/year whereas the range in the Colorado plateau area may be as high as 140 mrems/year. The average terrestrial level for the remainder of the United States is only 46 mrems/year, with an estimated national average of 40 mrems/year.

The terrestrial radiation rate varies with the type of soil in the area and the naturally occurring radionuclide content of the soil. Approximately 70 of the 340 nuclides found in nature are radioactive (196). These radionuclides have existed on the earth's crust since its formation and are known as *primordial radionuclides*. These primordial radionuclides have half-lives comparable to the age of the universe and are the source of terrestrial radiation (437).

Three distinct chains of primordial radioactive elements are found in the earth's crust and account for much of the terrestrial radiation exposure (437). These are: (i) the uranium series, (ii) the thorium series, and (iii) the actinium series. Uranium, the origin of the actinium series, is found in various quantities in rocks and soils. The uranium isotopes are alpha emitters and therefore do not contribute to the gamma background radiation. The presence of uranium in soils and in fertilizers leads to its presence, via the food chain, in plant and animal tissues. At equilibrium, an adult human male may be expected to have a uranium content of 100–125 μg. The thorium (232Th) decay series may also move through the food chain, but, due to its relative insolubility and low specific gravity, it is present in biological materials only in insignificant amounts (196). Thorium may be found in silty clay and peaty soils, and in such vegetables as potatoes, corn, carrots, beans, and squash. However, the principal source of human exposure is inhalation of soil particles. Thorium is removed very slowly from bone and its concentration increases with age.

Radium 226 (226Ra), an alpha emitter originating in the uranium decay series, is present in varying amounts in all rocks, soils, and water, and is of special importance, along with its daughter products (437). 226Ra, with a half-life of 1622 years, decays to radon (222Rn), a noble gas radio-nuclide with a half-life of 3.8 days. Radon, to be discussed later, also emits alpha particles but adds to the gamma radiation level of the environment through its gamma-emitting descendants.

Radium is very similar to calcium and is absorbed by plants from the soil like calcium. It then passes through the food chain to humans, where 70–90% is concentrated in bone. The amount of 226Ra moving through the food chain depends upon its content in the soils and its rate of absorption by plants. This rate of absorption by plants is related to the amount of exchangeable calcium in the soil. Brazil nuts, because of their tendency to concentrate barium, another chemical very similar to radium, may have a 226Ra content approximately 1000 times greater than the average diet.

Radionuclides

Internal radiation results from naturally occurring radionuclides contained within the body, and contributes approximately 11–17% of the average radiation exposure of the population (50, 614). Although some of the radio-active emitters may be freely dispersed throughout the body, others are concentrated in specific organs and all of the emitted decay energy is absorbed locally (555, 716). The deposition of naturally occurring radionuclides such as bismuth, carbon, hydrogen, lead, polonium, potassium, radium, radon, thorium, and uranium results primarily from the inhalation and ingestion of these materials in air, food, and water (48).

In a terrestrial ecosystem, radionuclides such as 210Ra, 226Ra, and 222Rn that occur in the soil, or are deposited in the soil, are incorporated metabolically into plants (196). In addition to root absorption, plants are contaminated by direct foliar deposition. Foliar deposition is potentially a major source of food chain radionuclide contamination because the radionuclide may be absorbed metabolically by the plant or transferred directly to animals consuming or coming in direct contact with the foliage. Individual radionuclides pass from the roots or the leaves to the remainder of the plant. Mean 232Th

concentrations of 0.018±0.022 Pci/kg have been found in the edible portions of 25 vegetables, including beans, carrots, corn, potatoes, and squash. Flora near the summit of the Morro do Ferro, a hill in the state of Minas Gerais, Brazil, have absorbed so much ^{228}Ra that they can easily be autoradiographed (196).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_706.html[2010/10/28 18:47:01]

Atmospheric radionuclides are eventually deposited on surface waters as well as on the soil. Therefore, the atmosphere is coupled to soils, surface waters, and subsurface aquifers. Radionuclides are eventually transported into streams or subsurface aquifers. Those that appear in deep underground aquifers may eventually reach surface waters and become incorporated into the biosphere again.

Rivers, estuaries, and coastal waters are major receptors of effluent radionuclides from industrial plants and cities. These waters are of special importance because of their high biological activity and productivity. Phytoplankton in these relatively shallow waters convert mineral resources in the aquatic environment into food for higher organisms. Zooplankton, the basic food of several higher trophic levels, use phytoplankton as their source of nourishment. Certain bottom-dwelling fish and animals also use phytoplankton as a source of nourishment.

Once the radionuclides have settled in an aquatic system over time, they tend to accumulate in the bottom sediments. In a collection pond built to contain a significant radioactive spill, 85% of the primary radionuclide present (radiocesium) was irreversibly bound up in the sediments, with some of the rest of the radionuclides available for remobilization from the sediment and subsequent exchange with the water column (700, 701). This accumulation in the sediments is an important factor in determining uptake and deposition in various aquatic species, with bottom-dwellers tending to accumulate more radionuclides than some other organisms in the water column.

The importance of radionuclides in marine and fresh water foods depends, in part, on where the radionuclide is located in the organism. A radionuclide is a higher risk if it concentrates in an organ consumed by higher organisms, such as humans, than if it is deposited in a portion that is not eaten. The radionuclides of cobalt (^{60}Co) and zinc (^{65}Zn) concentrate in edible tissues whereas those of radium (^{226}Ra) and strontium (^{90}Sr), although concentrated by clams, oysters, scallops, and certain crabs, are stored in the shell, which is not ordinarily consumed (196).

Uptake and retention of radionuclides is influenced by the portal of entry, chemistry and solubility, metabolism, and particle size. Internal contamination normally occurs via three principal routes of entry: inhalation, ingestion, and skin absorption. Of the three, inhalation is the biggest problem.

Direct ingestion from contaminated food is also a problem. Gastrointestinal exposure depends upon transit time through the gut, whereas absorption depends upon the solubility of the radionuclide.

Contamination of skin with radionuclides is of less consequence because the skin forms a formidable barrier. However, contamination of an open wound may result not only in continuous radiation of the surrounding tissue, but in the introduction of the radionuclide into the rest of the body.

Regardless of the portal of entry, the radionuclide passes throughout the body of the animal and into the milk, flesh, internal organs, and eggs. When the radio-active material enters the body it becomes an internal emitter. It will continue to radiate the body until it is excreted by some physiological process, mainly through urine and feces, or until its radioactivity decays (102). The time it takes an organism to eliminate half of the radionuclide is known as the *biologic half-life* and the time necessary for a radionuclide to decay to half of its activity is the *physical half-life* (Table 15.3). If the biologic and physical half-lives are known for a particular radionuclide, the *effective half-life* may be calculated (437).

Radon

Radon (^{222}Rn), the short-lived radionuclide decay product of ^{226}Ra, accounts for approximately 60% of the effective dose equivalent from internal emitters (437). As seen in Table 15.2, radon and its decay products or progeny (^{222}Rn, ^{214}Bi, ^{214}Pb, ^{214}Po, ^{218}Po) contribute 55% of the total average annual effective dose equivalent of 3.6 mSv.

Since 1974, international concern has centered upon radon, with radon progeny as indoor air pollutants that concentrate in nearly airtight homes and office buildings, resulting from efforts directed toward energy conservation. These energy-efficient homes cause exposure to all segments of the population in which much lower air concentrations of radon progeny may be inhaled during life-span exposures (that is, at much lower dose

Table 15.3 Half-lives of some biologically significant radionuclides[a]

b Whole body.

rates than those that have occurred in uranium mining populations). In addition, the low dust concentrations in such buildings with very low air changeover rates result in greatly increased fractions of radon progeny that are unattached to air carrier aerosols, causing proportionately higher radiological doses in the basal-cell epithelium of the conducting airways of the lungs. Measurements of air concentrations in Colorado Plateau uranium miners showed less than 2% unattached radon progeny, but in regions of quiet air such as in private homes, levels became an order of magnitude higher; 81% of the attached RaA may become unattached upon decay (275). During the years 1940 to 1988, many models were developed to calculate the radiation dose to the lungs as a whole or to selected regions of the respiratory tract. Dose conversion factors of rad/WLM show considerable increases above unity as the unattached fraction of radon progeny increases.

In order to define the role of attachment of radon progeny to aerosols and the incidence and site of radon progeny-induced respiratory carcinoma, a series of experimental studies used specific pathogen-free Wistar rats (627). Groups of 32 rats received inhalation exposure during 84 hours per week to 900 WL radon progeny attached to 15 mg/m3 carnotite uranium ore dust. Exposures lasted for 150 days and the animals were then held for life-span carcinogenesis studies. These animals showed 60% incidence of squamous carcinoma or adenocarcinoma in the periphery of the respiratory tract following these prolonged inhalation exposures to radon progeny that were 98–99% attached to uranium ore dust aerosol, but the animals showed no tumors of the nasal pharynx. In marked contrast, matched groups of rodents that received exposure to radon progeny with only room-air aerosol (from 10–25% unattached, as likely to occur in private homes) displayed less than 6% squamous carcinoma in the peripheral lung but 100% nasal squamous metaplasia and several cases of squamous carcinoma in the nasal pharynx, plus 22% squamous metaplasia in the major conducting airways such as the bronchi and first generations of secondary bronchi (627). Additional studies in the same laboratory involved rats exposed to several concentrations of radon progeny attached to uranium ore dust, designed to determine the effect of exposure rate and unattached fraction of radon progeny on the nature and incidence of pulmonary carcinoma (147). Groups of 32 or 48 male specific pathogen-free Wistar rats received inhalation exposures to radon progeny in groups having unattached percentages of 1.6 and 10, the latter representing exposure conditions that might occur in minimally ventilated dwellings. Pulmonary neoplasms included epidermoid carcinoma, adenocarcinoma, adenosquamous carcinoma, mesothelioma, and adenoma. Exposure regimes included background level, 250, 500, and 1000 WL, with total exposures of 640 or 2560 WLM. Percentages of lung tumors resulting from these exposures ranged from none in the case of animals receiving background exposures to laboratory air to 47% in those animals at the 500 WL dose rate, with the total received exposure of 2560 WLM. Pathological evaluation resulting from the dose rate exposure study indicated an increase in the risk of pulmonary lung tumors as the exposure rate *decreased*.

Epidemiological studies of the incidence of bronchio genic carcinoma among uranium miners in the Colorado Plateau, as well as in several European uranium mining studies, show considerable consistency in the relationship of the risk of bronchial carcinoma *per* WLM (275). Studies using human volunteers that inhaled significant concentrations of radon progeny attached to uranium mine aerosols in the Colorado Plateau underground mines showed 90–100% attached radon progeny that were deposited in the regions of bronchi and subsegmental bronchi (146). Because of the efficient deposition of unattached RaA in the brachia and major bronchi, the dose to bronchial epithelium from unattached RaA can be greater than three times that of unattached progeny per unit concentration in the atmosphere. Values for the dose conversion factor of rad/WLM in this region of the respiratory tract are 0.5 for underground miners. Analyses of exposures of individuals in the general population indicate values of 0.7 rad/WLM for men, 0.6 for women, 1.2 for children, and 0.6 for infants (275). The unit WLM is defined only in terms of potential alpha energy from radon progeny per liter of air. There can be very significant changes in the magnitude of this dose, with factors of up to twofold higher, due to differing characteristics of inhaled atmospheres. These significant differences are not accounted for when using WLM alone as a unit or exposure.

In 1984, the focus of attention of carcinogenesis resulting from radon progeny inhalation by humans shifted from the miners of the Colorado Plateau to the discovery of unusually high radon levels in a home built upon a geological formation called the Reading Prong in Pennsylvania. It soon became evident that each state had different problems associated with radon exposure to the general population. Whereas Pennsylvania had about 22,000 homes on its section of the Reading Prong, more than 250,000 homes were located on the New Jersey Reading Prong (495).

In order to explain the current concern concerning radon/radon progeny levels in the home, a further

definition of the working levels is necessary. Because it is far simpler to measure radon, the parent, rather than the individual radon progeny, even though the latter contribute 95–98% of the dose to the respiratory epithelium, the "working level" can be defined according to its original estimate, that is, 100 pCi of radon per liter of air, which at 100% equilibrium with its progeny will give,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_708.html[2010/10/28 18:47:02]

by definition, 1.0 working level. In 1984, the National Council on Radiation Protection and Measurement Report No. 74 recommended an action level of 8 pCi per liter environmental exposures, that is, exposures to the general population. Because only 50% of equilibrium is generally assumed for radon progeny 218Po, 214Pb, 214Bi, and 214Po (i.e., one-half the concentration of the parent 222Rn), this corresponds to an equivalent of 0.04 working level.

In 1986, in order to provide a more conservative position, the EPA issued a citizen's guide to radon recommending 4 pCi/L as an action level (663). The recommended caution level by the EPA is based upon linear extrapolations of high-dose level exposure over 5–30 years of a small mining population on the Colorado Plateau (663); the equating of lung cancer risk from a specified level of radon progeny to a given level of cigarette smoking is particularly difficult in that there is a close synergism between incidence of bronchogenic carcinoma in the uranium miner population and high levels of cigarette smoking by these men. The wide limits of uncertainty found in the lung cancer risk estimate associated with a given total exposure level and the importance of dose rate factors, demonstrated by recent animal and epidemiological studies, have resulted in risk estimate calculations by agencies within the United States as well as in Canada and Europe, that suggest possible lower risk per WLM or pCi/L exposure level. The action level for homes recommended by the EPA of 4 pCi/L is low when compared with that recommended by Canada and Finland (110). It is likely that countries of the European Union will follow the example of these two countries with action levels at 8 or 20 pCi/L.

RADIATION BIOCHEMISTRY

Radiation toxicity represents a dynamic interaction between radiation physical constraints and molecular damage, which are further amplified by biological processes resulting in injury (Figure 15.1). Biochemistry provides this important link through which a quantity of energy sufficient to raise the temperature of a liter of water by 0.1°C, an amount less than the caloric energy of a candy bar, can elicit toxicity resulting in death, or the beneficial therapy of a malignant tumor, diverse extremes, and yet mechanistically similar at the molecular level, the initial injurious events that occur in 10−17–10−5 s, may be irreversible and may require seconds to years for expression. The expression of injury for some cancers is so slow that it may not be observed over the individual's lifetime. The four processes mediating and amplifying radiation toxicity, ionization and excitation, molecular injury, biochemical damage, and amplification and expression of injury, are illustrated in Figure 15.1. The first three will be discussed in this section, followed by amplification and expression of biological injury in the remaining sections. The latter sections emphasize the important roles of biological mediators and hormones in this process, as well as delineating specific risk concerns such as cancer.

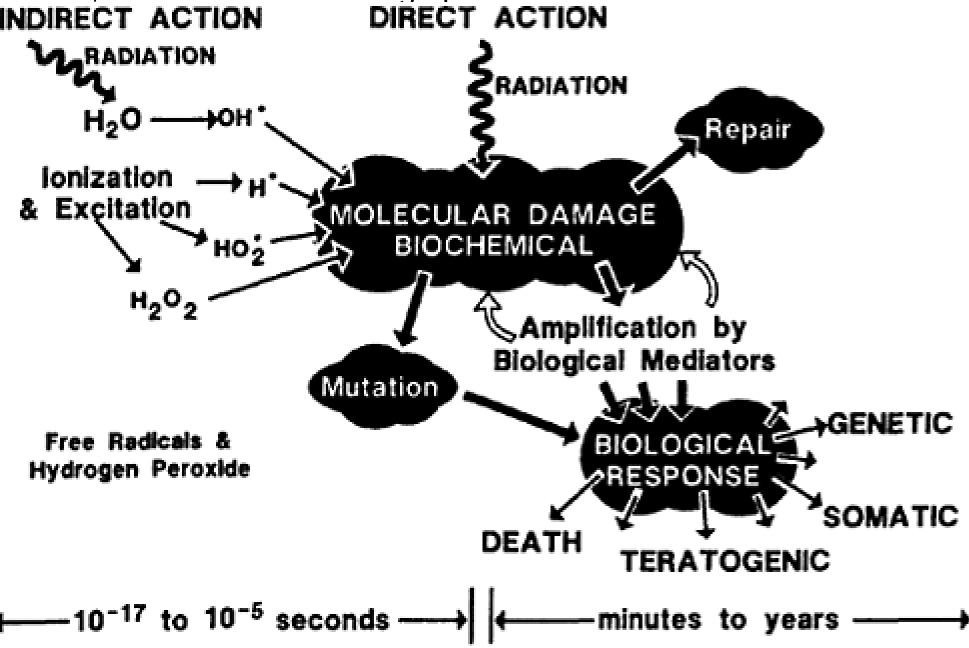

FIG. 15.1. Schematic for radiation injury to biological systems. The small quantity of radiation interacts with matter by ionization and excitation, producing both direct and indirect damage; the latter occurs primarily through free-radical attack. Because free radicals induce chain reaction of free-radical injury, the initial event is magnified. The molecular and biochemical damages in turn stimulate further

amplification through the release of biological mediators and hormones. At each of these points, actions can be taken (i.e., radioprotection, radiosensitization) that will enhance or suppress the biological expression of injury. (From References 296 and 685. Used with permission.)

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_709.html[2010/10/28 18:47:03]

Page 710

There are four basic possibilities for the interaction of ionizing radiation with an atom: direct and indirect ionization, excitation, and pair production. Ionization occurs through the impartation of sufficient energy to eject an electron out of its orbit, resulting in formation of an ion pair, the positively charge atom and the negatively charged electron. If the ejected electron is also imparted with additional energy, then it too may interact with other atoms to produce additional ion pairs, and this is an indirect ionization process. With excitation, the energy imparted to the electron is sufficient to raise it to a higher electron orbital, but not to escape. Ionization does not occur, but the energy may be sufficient to break chemical bonds. Between 20 to 35 electron volts (eV) are required to produce an ion pair, whereas hydrogen bonds can be broken by 5 eV (686, 692). Lastly, photon radiation with energies greater than 1.02 MeV are capable of interacting with the electromagnetic field of the nucleus to convert the energy into the formation of positron and an electron, *pair production*. Neutrons, alpha particles, and other particulate radiations also produce ionization and excitation. Further, in the process of nuclear activation, the neutron is absorbed by the nucleus, forming a radioactive isotope.

Although differing types of radiation may be equal in their initial energy, they differ in the pattern in which the radiation is imparted to matter and, as a result, differ in their biological responsiveness. These differences are quantified for their *relative biological effectiveness* (RBE), determined as the dose of a given type of radiation (neutron, gamma, x-ray, etc.) to produce a reference biological effect divided by the dose of a standard radiation, usually 250 kilovolt potential (kVP) x-rays, to produce the same effect. This is illustrated by the threshold for cataract formation in humans of 2 Gy for x-rays and 0.2 Gy for neutron exposures, resulting in a RBE of 10 (48). This RBE applies only to this particular effect; for a different response the RBE might be 1 or even 50. Differences in effectiveness arise because the amount of energy transferred by a unit dose of radiation per unit pathway traveled through matter, the LET, varies with the type of radiation. Neutrons, protons, alpha and beta particles, and atomic nuclei are high LET radiations, whereas gamma and x-rays are low LET radiations. The depth of penetration is determined by the total energy and the LET factor. High LET radiations produce many ionizations per distance traveled, dissipate energy quickly, and have low depths of penetration. In fact, alpha particles dissipate all of their energy before they can transverse through a sheet of paper, a layer of paint, or the stratum corneum of the skin. The consequence of such a concentrated delivery to a biological system is that more ionizations and therefore more damage is concentrated in a smaller area, making it more difficult to repair the damage (49, 686, 687, 692). Higher RBEs for neutrons (up to 46 for life shorting and 80 for cancer transformation) are elicited when lower doses and dose rates are used because of the better ability of cells to repair injury due to low LET radiation (115, 269, 493). Low dose neutron exposure is more carcinogenic for mammary tissue than x-rays, and a low environmental or accidental exposure to neutron could therefore be more damaging than the total exposure dose alone might indicate (50). In general, the LET increases from electrons to neutrons to alpha particles. The RBE increases with increasing LET up to 100–125 keV/μ (50, 269). Of particular concern, low dose and dose rate exposures to high LET neutron radiation may be more effective at causing cancers than similar exposures to low LET radiation.

Radiation interacts with matter by direct and indirect processes to form ion pairs, some of which may be free radicals. These ion pairs rapidly interact with themselves and other surrounding molecules to produce free radicals. Both the indirect and direct activities of ionizing radiation lead to molecular damage which is then translated to biochemical damage. Biochemical damage may then be amplified and expressed as biological injury in one of three basic processes, including damage to the DNA which may become expressed, stimulation and release of biological mediators, and alteration of nutritional vascular support.

Radiolysis of Water

Radiation may impart energy to matter in one of two primary ways, either directly through ionizations or indirectly by transfer of energy and formation of free radicals. The most abundant molecule in living systems is water. It accounts for about 55% of the mass in humans. Ionizing radiation interacts with water molecules to form an ionized pair consisting of a free electron (e−) and an ionized water molecule (H2O+) in a process termed radiolysis. The free electron rapidly interacts with water to form the hydrated electron (H2O−) which decomposes to OH− and H· The dot (·) designates a free radical, a molecule having an unpaired electron in the outer electron shell. The free radical may also be electrically neutral but remains highly reactive because of the unpaired electron. The second ion from the ion pair, (H2O+), decomposes to H+ (hydrogen ion) and OH· (hydroxyl radical). The ionic designation depends on the molecular charge, so it is possible for a molecule to be a free radical and an ion. The hydroxyl radical contains nine protons and nine electrons, and is electrically neutral.

The end products of the radiolysis of water without oxygen are H·, OH·, H+, and OH−. Of these, H· and OH· are the most important, and comprise 55% of the initial relative yield (49). Both are highly reactive and have half-lives of 10^{-11} s. This allows for the initial

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_710.html[2010/10/28 18:47:03]

impact of the radiation ionization event, which may have missed the biological target, membrane or DNA, etc., to diffuse away from the initial site and produce damage by free-radical attack of a nearby molecule. The two primary factors influencing the formation of free radicals are the presence of oxygen and the LET. Radiolysis in the presence of oxygen produces the hydroperoxy radical ($HO_2\cdot$), the hydroperoxy ion (HO_2^-), and hydrogen peroxide (H_2O_2). These chemical entities are powerful oxidizing agents with longer half-lives on the order of 10^{-10} and may diffuse even farther from the initial site of ionization (49, 296, 692). The type of radical species formed is also governed by how closely or how rapidly radicals are formed, because they may interact to form H_2, H_2O, and H_2O_2, neutralizing the radical attack before reaching the biological target. For example, H· reacts with OH· to form H_2O. High LET radiations produce more ionizing events closer together, with a greater chance of free-radical neutralization. Hence, direct effects tend to predominate with high LET. The net effect of the above processes is that biological material irradiated in a dry state and in the presence of oxygen, is more resistant to injury than when the reverse conditions are present. Interaction of a free radical with a biological molecule (RH) results in the formation of an organic free radical and stabilization of the initial radical:

$$OH\cdot + RH \rightarrow H_2O + R\cdot$$

The Oxygen Effect

The most effective sensitizer of biological tissues is oxygen (269). Biological material and living systems irradiated in the presence of oxygen are more susceptible to injury than when irradiation occurs without oxygen. This response, known as the *oxygen effect* was first observed in 1909 by Gottwald Schwartz who noted that pressure applied to the forearm during irradiation reduced the resulting erythema (686). He was not aware that lack of oxygen per se was responsible. The effectiveness of oxygen in modifying the response to radiation is expressed as the *oxygen enhancement ratio* (OER), the radiation dose in the absence of oxygen to observe a given response divided by the radiation dose required to observe the response in the presence of oxygen. OERs for low LET radiations are generally 2.8 to 3, and tend to decrease as the RBE increases, up to a point, between 100 to 200 keV/μ. The radiosensitizing effects of oxygen are particularly important in radiotherapy because tumors may have hypoxic centers either because of poor vascular supply, tumor compression from the outer cells, or altered metabolism. Therapeutic attempts to address this issue have tried to increase tumor oxygenation (through increased vascularization, vasodilation, hyper baric oxygen, or increased oxygen delivery to tissues using intravascular perfluorocarbons) or to use electronegative compounds that mimic oxygen (269). Hypoxia decreases the radiosensitivity of tissues, but increases the sensitivity to hyperthermic treatments. The oxygen concentration must be reduced below 2.0% to see any appreciable protection, which increases rapidly with decreasing oxygen concentrations below 0.5% (3 mm partial pressure of oxygen, compared to 40 mm in venous blood and 60–80 mm in oxygenated arterial blood), at which point the OER is about 2 (269). Oxygen results in the formation of hydroperoxy and hydrogen peroxide radicals that are more damaging because of their longer half-life. Free radical damage is "fixed" through reaction of oxygen leading to formation of peroxy and hydroperoxy organic products that are more resistant to biochemical repair processes (263, 269). The presence of oxygen can also enhance the therapeutic efficacy of some chemotherapeutic agents, whereas some agents including misonidazole, mitomycin C, doxorubicin, and tirapazamine are more effective in hypoxic environments (269, 640, 641). Ethanol, narcotics, leukotrienes, and some thiols are radioprotective in part through their ability to induce hypoxia (238, 686). Ethanol and narcotics suppress the respiratory center in the central nervous system, resulting in hypoxia.

Effects of Radiation on Macromolecules

Radiation-induced modification of biomolecules can be divided into structural degradation and decomposition, cross-linking of molecules, and breakage of chemical bonds (12, 263, 296, 680, 685, 686, 692). The individual responses for the different classes of macromolecules are presented in Table 15.4. Bond breakage occurs through energy transfer, ionization transfer, or electron transfer. Cross-linking can occur between similar and also different classes of molecules: protein-protein, lipid-lipid, protein-DNA, etc. Structural and conformational changes may alter or eliminate biochemical activity directly and expose internal sites to radical attack (117, 233, 692). The DNA bases are protected from free-radical attack because of their position in the center of the helix, but are exposed by strand breaks, breakage of hydrogen bonds, and unwinding processes. Conformation is also critical for enzyme activity and structural proteins. The response of macromolecules in vitro may vary from the effects in vivo due to molecular interaction and biological repair processes.

Lipid Peroxidation

Radiation injury of lipids in vitro and in vivo occurs primarily through peroxidation by free radical attack at the double bonds and carbonyls (543, 685, 686). Lipid

Table 15.4 Effects of ionizing radiation on macromolecules

Amino acids	Liberation of ammonia, hydrogen sulfide, pyruvic acid, carbon dioxide, and hydrogen.
Carbohydrates	Cleaveage of glycosidic bonds, depolymerization of individual monomers, oxidation of terminal alcohols to aldehydes.
DNA	Degradation with base loss or modification; breakage of hydrogen bonds or sugar-phosphate bonds; cross-linking of DNA-DNA or DNA-protein; strand breakage; formation of guanyl, thymidyl, and sugar radicals.
Lipids	Peroxidation; bond rearrangement—conjugated diene formation, aldehyde formation, β-scission, cross-linking; increased microviscosity.
Proteins	Degradation and modification of amino acids, chain scission, and cross-linkage. Denaturation and changes in molecular weight, and solubility.
Thiols	Oxidation, reduction, radical formation, cross-linkage.

a From References 357 and 543.

peroxidation, as illustrated in Table 15.5, consists of three phases: initiation, propagation, and termination. Lipid peroxidation is important to homeostasis and is associated with the formation of lipid mediators, including the prostaglandins and leukotrienes, as well as lipid degradation (Figure 15.2). Peroxidation may be mediated by three possible initial events (543, 686) (Table 15.5). Initiation may occur enzymatically, as with cyclo-oxygenase and lipoxygenase enzymes, and requires molecular oxygen and ferric cofactors. Radiation-induced lipid peroxidation is initiated by direct or indirect ionization, or by free-radical attack. The primary radical species involved are the hydroxyl radical and superoxide (193, 543).

Lipid peroxidation is affected by the lipid structure and composition, the presence of oxygen and antioxidants, pH, temperature, and the conditions of irradiation (193, 543, 686). Increasing the number of double bonds in the lipid carbon backbone enhances its susceptibility to free-radical oxidation in solution. For example, arachidonic acid possesses four double bonds and is more sensitive than linoleic acid which has three double bonds (477). The greater the lipid concentration, the greater the likelihood that the free radicals propagate the chain reaction by attacking another lipid molecule. On the other hand, with increased rate of radical formation, the risk of radical interaction and neutralization increases. Therefore, unlike other radiation-induced molecular injury processes, greater lipid peroxidation product yield is obtained with lower radiation doses and exposure rates.

Lipid peroxidation is a chain reaction in which interaction of the lipid radical with another organic molecule results in conversion of that organic molecule to the free-radical state and propagation of damage. Alternatively, the lipid radical may terminate the reaction by one of several different processes as outlined in Table 15.5. It may react with another free radical or with a free-radical scavenger. The primary free-radical scavengers in biological systems are vitamins A and E and the thiols, and their membrane concentrations influence cellular radiosensitivity (357, 686, 687). In addition, at least eight enzyme systems are associated with detoxification and repair of free-radical injury, not including DNA-specific repair enzymes (368, 686). These include glutathione transferase, NADPH-dependent glutathione reductase, selenium-dependent glutathione peroxidase, selenium independent glutathione

peroxi

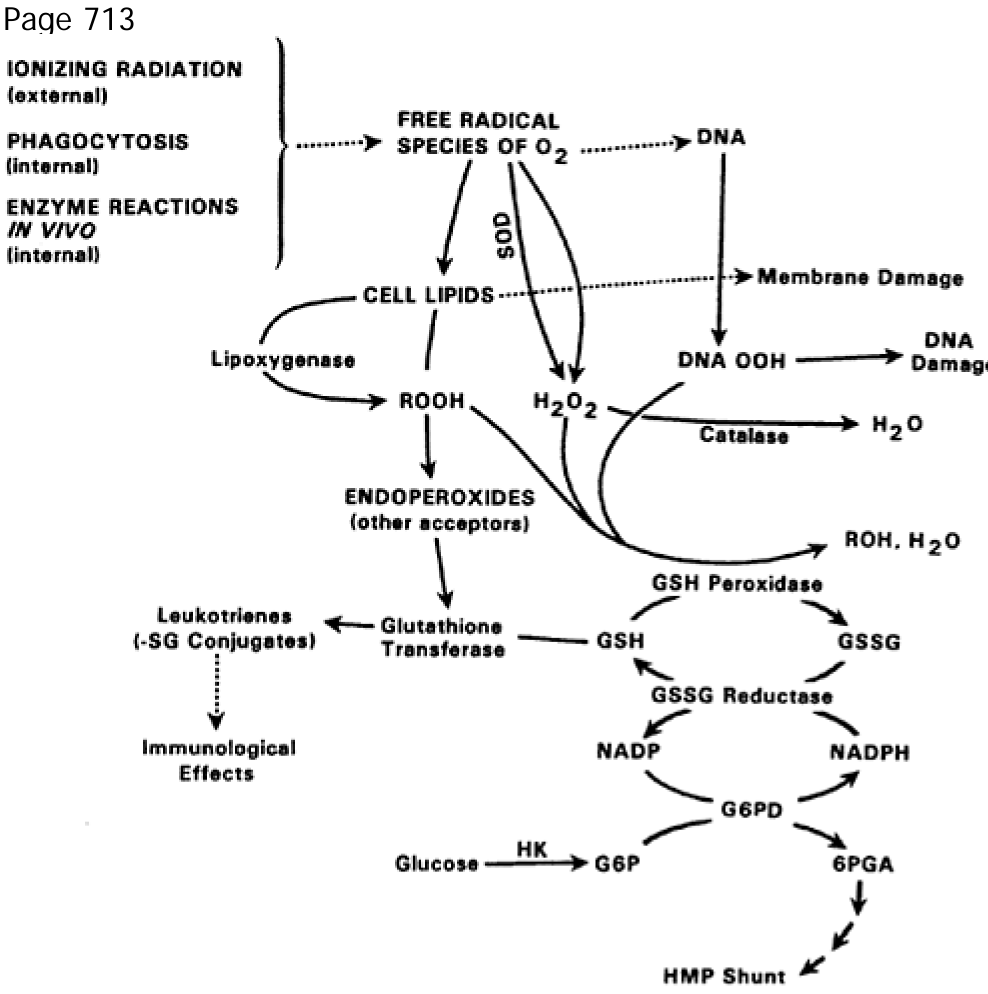

FIG. 15.2. Enzymatic repair of peroxide damage. Reactive oxygen species formed by enzymatic and nonenzymatic processes may induce oxidative attack of DNA, lipids, and other biomolecules. Repair of this damage can be mediated by glutathione (GSH-reduced glutathione) or glutathione dependent peroxidases. As shown, oxidized glutathione (GSSH-glutathione disulfide) can be reduced/renewed, and most of the system can be maintained as long as a sufficient supply of reducing power (NADPH-nicotinamide adenosine diphosphate) generated by the metabolism of glucose is available. DNA-deoxyribonucleic acid; G6PD-glucose 6-phosphate dehydrogenase; HK-Hexokinase; HMP-hexose monophosphate shunt; ROOH-organic peroxide; SOD-superoxide dismutase. (From Reference 368. Used with permission.)

dase, ferric superoxide dismutase, manganese superoxide dismutase, copper-zinc superoxide dismutase, and catalase. Metallothionein is another protein with free-radical scavenging ability, because one third of its amino acids are cysteine residues. Synthesis of this protein is enhanced under stress situations, including lipid peroxidation and radiation injury (686), and can be induced by zinc supplementation. Another thiol-containing protein, thioredoxin, participates in the reduction of a number of important DNA enzymes and transcription factors, including ribonucleotide reductase (225), and is a radioprotectant. It is itself reduced by NADPH-dependent thioredoxin reductase, a selenoprotein. Vitamin E is an important free-radical scavenger that is located primarily in the cell membrane. Once modified or activated by free-radical attack, it is detoxified and renewed by specific enzymatic pathways. Vitamin E interacts with organic radicals to form a stable organic alcohol (357). In this process, vitamin E is con verted to an excited state that is restored by interaction with vitamin C. Vitamin C, in turn, is renewed through the action of an NADH-dependent enzyme. Interestingly, melatonin, the pineal gland hormone, has been demonstrated to scavenge free radicals (546), and pretreatment of human lymphocytes irradiated in vitro reduced subsequent micronuclei damage (678).

Thiols are molecules containing free or potential sulfhydryl groups (SH−) in their structure. Examples include the amino acids methionine and cysteine, and the complex lipid thiol ether, leukotriene C4. The most abundant nonprotein thiol, the tripeptide glutathione (GSH), is present intracellularly at 1–3 mM. Thiols act as cofactors for some enzymatic processes and participate in radical scavenging and

detoxification processes. Their activities are dependent on cellular concentration, location, synthesis, and catabolism. During the reaction of a thiol with a free radical, donation of hydrogen by the reduced sulfhydryl of the thiol to the organic radical

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_713.html[2010/10/28 18:47:05]

results in a form of chemical repair:

$$GSH+R\cdot \rightarrow RH+GS\cdot$$

Two glutathione radicals (GS·) may then react to form a disulfide (GSSG), terminating the radical chain reaction. This disulfide, or oxidized glutathione, is regenerated to yield two GSH molecules by the action of NAPDH-dependent glutathione reductase (Figure 15.2). Thiols may also affect responses to irradiation through formation and destruction of disulfide bridges. Glutathione may form a disulfide bridge with the free sulfhydryl group of another molecule, perhaps in an enzyme active site, masking and protecting the sulfhydryl from radical injury. Organic peroxides are repaired through the actions of selenium-dependent and -independent glutathione peroxidases (368, 686).

Hydrogen donation reducing power for these processes is provided by NADPH generated through the hexose monophosphate shunt. Therefore, anything interfering with the hexose monophosphate shunt, glucose utilization, or synthesis of NAD+, NADP+, or glutathione may ultimately influence free-radical scavenging and tissue injury (59, 368). In fact, hypoxic cells depleted of glutathione become more sensitive to radiation (59, 463, 686). This has implications for the radiotherapy of tumor cells, although sensitization has not been consistently observed for aerobic cells (686). The difficulty arises in that glutathione concentrations must be reduced below 5% for sensitization to be observed (463, 686). Yet, even at these low levels, glutathione-dependent enzymes usually maintain activity because they retain glutathione. The depletion of glutathione levels by use of specific glutathione synthetase inhibitors, such as buthionine sulfoximine, may have a greater effect on DNA damage, because glutathione synthesis does not take place in the nucleus (29). Glutathione must diffuse into the nucleus. As a result, glutathione depletion in the nucleus would subject the DNA to greater free-radical damage. The participation of other non-glutathione-dependent enzyme systems for modification of oxidative damage also limits the significance of glutathione during irradiation under aerobic conditions. Under aerobic conditions, the electron transport chain ensures a steady supply of NADPH to drive the glutathione-dependent repair enzymes. Because of their roles in free-radical scavenging, chemical repair, and, in some instances, the induction of hypoxia, thiol compounds have been studied extensively as potential agents for radioprotection.

Amifostine (WR-2721) is an organothiophosphate initially developed through the Antioxidation Drug Development Program of the Walter Reed Army Institute of Research, and is approved by the Food and Drug Administration for chemoprotection of the kidneys in patients receiving cisplatin therapy. Amifostine is such a potent radioprotective agent when given prior to radiation exposure that it raises (protects) the necessary hematopoietically lethal dose of radiation by 2.5- to 2.7-fold (724). This compound has also been used in clinical trials to minimize radiation injury to normal tissues of patients receiving radiation therapy (115, 178, 269, 353). It is administered intravenously; potential side effects include hypotension, nausea, vomiting, and hypocalcemia. Studies demonstrate that amifostine is preferentially taken up by and therefore protects normal tissues, as opposed to tumor tissues (725). There is minimal central nervous system protection, because it does not cross the blood-brain barrier.

Superoxide is produced physiologically by several enzyme systems, is released by activated neutrophils, and is formed during the radiolysis of water in the presence of oxygen (686). It is removed through conversion to hydrogen peroxide by the action of superoxide dismutase (SOD):

$$2H^{+}+2O_2\rightarrow H_2O_2+O_2$$

Treatment with SOD has been shown to protect macromolecules, cells in vitro, and animals. Hydrogen peroxide is itself a potent oxidizing agent that can also be converted, in the presence of ferric compounds, to yield hydroxyl radicals. Hydrogen peroxide is decomposed by catalase:

$$2H_2O_2\rightarrow 2H_2O+O_2$$

Nitric oxide, NO, is a neurotransmitter and also acts as endothelial cell relaxation factor, a vasodilator. Superoxide interacts with nitric oxide to form NO_2 and NO_3, processes that are inhibited by SOD. As such, SOD potentiates the response to nitric oxide. Peroxynitrite ($ONOO^-$) is a toxic oxidant product from superoxide and nitric oxide interaction that can breakdown to hydroxyl and nitrous oxide radicals that participate in lipid peroxidation (203). There is much interest in the biological roles of nitric oxide, with as yet little information on modification by ionizing radiation. There are three isozymes of nitrite synthetase, one of which is an inducible form, which has been shown to stimulated in the rate colon and ileum (401). The increase in nitric oxide is thought to be associated with radiation-induced ileal dysfunction (401). Exposure of mice to 7 Gy of gamma irradiation has been shown to stimulate the L-arginine-dependent production of nitric oxide from the terminal guanidine group in mouse liver, lung, brain, and spleen (679). Treatment of mice with a specific inhibitor of nitric oxide synthetase, or with DEA/NO, a nitric oxide-releasing agent, results in increased animal survival of the irradiated mice.

Interestingly, both agents have

< previous page page_714 next page >

been shown to increase the hypoxic fraction of the mouse bone marrow, and this may be related to alterations in regional blood flow (induction of acute hypoxia). Protection is most effective when these compounds are given close to and before irradiation.

Because of its similarities to oxygen, nitric oxide has also been evaluated as a radiosensitizing agent to hypoxic cells in vitro, with a sensitization enhancement ratio of 2.4 (464). It is thought that under hypoxic conditions, the free radical, nitric oxide, interacts with carbon-based free radicals to "fix" radiation-induced free-radical injury in a manner similar to oxygen.

Effects on Amino Acids, Peptides, and Proteins

The primary effects of radiation on amino acids and proteins in solution are provided in Table 15.4 (12, 384, 686). Radiation-induced breakage of hydrogen bonds and disulfide bridges, or cross-linkage formation, can affect conformation and therefore activity/function. The radiation dose to inactivate proteins in the dried state is proportional to the molecular weight, that is, a larger target requires more radiation. This relationship has established radiation-inactivation of proteins as an accepted method of determining molecular weights. Further alterations may occur from moderation of radiation synthesis, although, in general, protein synthesis is not affected by radiation doses within the lethal range for humans (12, 507). RNA synthesis usually decreases following irradiation of radiosensitive tissues (12, 686). Radiation effects on inducible enzyme systems depend on the particular system and vary between species and sexes. Some drug detoxification enzymes are reduced in males in association with decreased testosterone synthesis. Chronic radiation exposure has been shown to induce the hsp 70 heat shock protein (hsp) in mouse lung (436), whereas 0.25 Gy to cells in vitro induces PBP74/mortalin/Grp75, another member of the heat shock protein family (571). Induction of heat shock proteins have been related to increased radioresistance.

Effects on Carbohydrates

The basic effects of carbohydrates in solution are shown in Table 15.4. Radiation may cause depolymerization of glycogen, because the α-glycosidic linkages found in glycogen and cellulose are more radiosensitive than *β*-glycosidic linkages that might be found in bacterial cell walls (686). In vivo, the effects of radiation on carbohydrates are dominated by alterations in metabolic processes. Radiation promotes glycogenesis and gluconeogenesis during the first several days post-irradiation primarily as a result of hormonal influences and alterations in metabolic enzymes (12, 113, 686). Insulin and adrenocorticoid release stimulates an increase in blood glucose, providing a source for the glycogen synthesis which is further supplemented by shunting of amino acids released by tissue injury. Decreases in hexokinase, aldolase, and pyruvate kinase and an increase in transketolase are observed (113, 686). Additional NAPDH reducing power is obtained by shunting of carbohydrates through the pentose phosphate pathway.

Effects on Nucleic Acids and DNA

Ionizing radiation exposure of DNA may cause degradation of bases and sugars, breakage of hydrogen or sugar phosphate bonds or cross-linking (Table 15.4, Figure 15.3) (117, 233, 263, 296, 680, 692). The incidences for the individual types of damage is base damage >single-strand breaks >DNA-protein cross-links >double-strand breaks (692). In base damage, sensitivity is thymine >cytosine > adenine >guanine (263). At radiation doses of 200 kGy, it is proposed that the two primary radicals formed in DNA are the thymine anion and the guanine cation (295, 680, 681). Radicals may be of a charged anion,

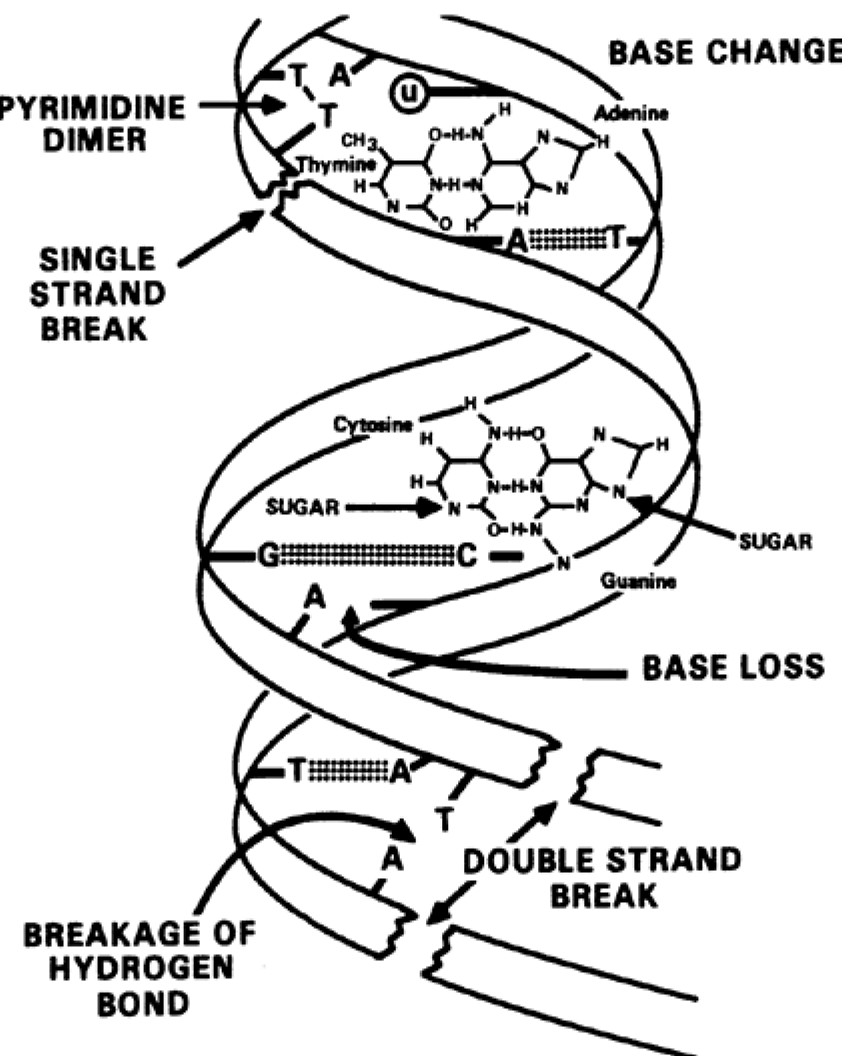

FIG. 15.3. Radiation damage to deoxyribonucleic acid. The basic categories of molecular damage, degradation, bond breakage, and cross-linking that occur in biomolecules following radiation exposure are illustrated for this double-stranded segment of DNA. The dotted lines represent hydrogen bonding between the bases, three between cytosine (C) and guanine (G), and two between adenine (A) and thymine (T). (From Reference 685. Used with permission.)

Page 716
deprotonated cation, H-addition radicals, H-abstraction radical, and opened sugar ring nature (295). DNA damage to the carbohydrate produces strand breakage, glycosylic bond breakage, and formation of precursors to malonaldehyde (263, 681, 692). DNA cross-linkages occur between DNA and DNA, DNA and proteins, or DNA and lipids. DNA to DNA cross-links may form between adjacent bases on the same strand or between different strands. The most common DNA-protein adducts would be between DNA and the associated histones and are more likely to involve tyrosine or lysine residues (508). DNA-protein cross-links formation is more common in expanded chromatin than in compressed chromatin (117). Intracellularly, DNA-protein crosslinks are enhanced by glutathione depletion but are reduced in the presence of oxygen. Important factors controlling injury are the medium composition, DNA conformation, and presence of repair enzymes (686, 692). For example, metal ions are thought to induce structural changes inhibiting free radical access to key sites and to stabilize the double-strand helix (615).

Thymine glycol is one of the oxidative DNA base damage products that can result from radiation exposure (380). Using a sensitive assay with 10–15 micromole detection limits, thymine glycol has been identified in the DNA of A549 human lung carcinoma cells irradiated in vitro with doses less than 5 cGy. The sensitivity at this low radiation dose was sufficient to detect 4.3 molecules of thymine glycol per one billion DNA bases. The responses to this assay, although linear, are dependent on the source of DNA, and irradiation of the DNA inside the cell (lower response rate, protective of DNA), as opposed to naked DNA in solution. The A549 cells were able to remove 50% of the thymidine glycol from their DNA within 2 hours and 80% by 4 hours (380).

Breakage of sugar phosphate bonds leads to single-strand breaks (SSB) and double-strand breaks (DSB). There are two hypotheses regarding DSB formation (692). In the first, hydroxyl radical attack on one strand produces a strand break through radical formation that attacks the opposite strand producing a DSB. According to the second hypothesis, DSB are produced by local multiply damaged sites to regional areas of both strands. Cell lethality is directly related to DSB. A 1-Gy dose of ionizing radiation results in 63 to 70 DSB per cell (49). The importance of DSB over SSB in relation to radiation-induced lethality is illustrated by the fact that a radiation dose that kills 63% of the exposed cells, produced 1000 SSB, but only 40 DSB (692). There would also be an estimated 440 locally multiply damaged sites. Exposure to hydrogen peroxide, by comparison, would require production of over 2.5 million SSB per cell to kill 63% of the cells. SSBs are chemical assay phenomena that do not lead to mutational events or expression of injury because the remaining strand is intact, holding the two ends together for repair by DNA ligase. With DSBs, there is no stable end point for repair, and the chromosomal material may be lost during the subsequent cell division or rejoined to a different chromosome, forming a chromosomal aberration.

Several types of chromosomal aberrations are observed following irradiation. These include rejoining to the original chromosome—normal, inversions, and translocations; terminal or interstitial deletions; and ring and dicentric formation. Irradiation of the chromosomes in G1 results in chromosomal aberrations, whereas exposure after DNA synthesis in G2 results in chromatid aberrations. Chromosomal exchanges occurring during G1 irradiation may either be reciprocal (two chromosomes) or nonreciprocal (three chromosomes). In human fibroblasts irradiated in vitro, 50% of the chromosomal exchanges were nonreciprocal (80). The rate of chromosomal aberrations is directly related to the radiation dose and is higher for higher LET irradiation and higher dose rates (49, 685, 686). Chromosomal aberrations were still evident in the lymphocyte chromosomes of the Japanese atomic bomb survivors 35 years after the bombing (544), and elevations have been identified in radiotherapy patients and in persons receiving occupational radiation exposures such as the uranium miners (49, 50, 685). Chromosomal aberrations have also been demonstrated to be elevated in the lymphocytes of astronauts who completed long-term space flights on the Russian MIR space station (502). They represent a reasonable means of biological dosimetry and can be detected by several methods including phytohemagglutinin-stimulated peripheral blood lymphocytes, premature chromosomal condensation, micronuclei technique, and fluorescent in situ hybridization (FISH; "chromosome painting"), and the comet assay (192, 339, 395, 685, 686). The results are influenced by the scoring criteria, type of irradiation, percent of body irradiated, degree of time following radiation exposure, culture time, and age of the individual, as well as exposure to other environmental toxins or agents that might also produce aberrations. Assays also exist for detection of somatic cell mutations including the hypoxenthine-guanine phosphoribosyl-transferase (HPRT) locus and the glycophorin A locus. The latter codes for a glycoprotein found on the surface of red blood cells (similar to and in conjunction with the ABO blood grouping) and expressed by alleles M and N (can also have "null," O). Increases in glycophorin A variants are dose dependent and have been elevated in the

atomic bomb survivors, and in patients from the radiation accidents in Goiana, Brazil, and Chernobyl (377). The assay required 0.1 ml of blood and can be completed in less than 1 day. An example of a variant of somatic mutation would be the detection of an MO allele expression in a person who was genetically MN (or MM).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_716.html[2010/10/28 18:47:07]

The final expression of DNA damage is modified by repair processes. Repair may occur at several levels: nonspecific suicide enzymatic repair, excision/ligation repair, SOS repair (mismatch repair), single base repair as with DNA glycosylases and methylation. Depending on the process, more than one enzyme may be required. Excision/ligation repair involves several enzymes, one to make a nick on the DNA strand containing the damaged site, presuming radiation has not already provided that nick, an excinuclease that excises damaged bases, synthesis of the new sequences based on the complimentary strand by the action of a DNA polymerase, and, finally, rejoining of the two loose ends by a DNA ligase (263, 381, 685, 686, 692). The main repair enzyme in bacteria is DNA polymerase I and, in mammals, DNA polymerase II. In addition, bacteria have a second category of repair enzymes called SOS-repair, or error-prone repair. As the name implies, they play a major role in repair of DSBs and are associated with a high error rate (263). Similar mismatch-repair genes have been identified in humans, and are designated hMSH1, hMSH2, hMLH1, and PMS2 (213). Cells with functional mismatch repair genes are more sensitive to ionizing radiation (cell survival) than mutants lacking active forms of these repair genes (213). The hardest break to repair without errors is the DSB; the repair depends on whether the two breaks are coincident, with possible loss of intervening information, or if the two breaks are separated with overlapping sequences to ensure proper rejoining and repair (49, 692). The closer the approximation of the two breaks, the greater the chance of loss.

Mechanisms

The biochemical response of a biological system to ionizing radiation is influenced by eight major groups of factors as outlined in Table 15.6. Repair, reoxygenation, redistribution, and regeneration have been called the "four Rs of radiotherapy" (708). It is appropriate to continue the "R" series. The first group of factors relates to the radiation itself (49, 686). Most biochemical responses are dose dependent or at least may have a damage threshold (12, 686). In addition, the rate at which the radiation dose is delivered and whether the dose is delivered in fractions or in a single exposure affect the biological response, and depend on the process and cell type in question. In general, increasing the dose rate over the range of 1 to 100 cGy/min results in an enhancement of the effectiveness of the radiation in producing injury secondary to overcoming compensating mechanisms of repair of sublethal damage and cellular proliferation (46, 269). Cells have specific repair processes for DNA and the ability to repair small amounts of damage to cell membranes. Therefore, damage that occurs

at rates below the cellular capacity will not be as cumulatively injurious. LET is another factor influencing damage. High LET radiation produces more ionizations per unit of matter and more localized damage, making repair difficult. Larger radiation doses given in single treatments tend to cause more injury than the same dose given in fractions or over a more prolonged period. Injury to early responding tissues (hematopoietic stem cells, intestinal crypt stem cells, and many tumors) is reduced by prolonging the duration of the exposure (or in the case of cancer therapy, by extending the treatment over days or weeks), whereas the total dose and fraction size are important to the degree of an effect on late

responding tissues (muscle, connective tissue, and nerve tissue) (269). Internal exposure is also a consequence for alpha and beta emitters; for example, 214Po, 218Po, 222Rn, or 236U cause alpha exposure to lung alveoli (49, 50). Transmutation produces both radiation exposure and chemical instability. The transmutation of carbon 14 in a key structural position to nitrogen causes mutations in *Drosophila* and in mice (48). Transmutation of tritium also causes mutations. However, the major effect of a transmutation is the radiation exposure (48, 50). The ability of beta-emitters to produce localized irradiation has been successfully applied to the use of 89Sr and samarium 153 to treat painful bone metastases in patients with breast cancer, prostate cancer, and multiple myeloma. These compounds are incorporated into bone similar

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_717.html[2010/10/28 18:47:08]

to calcium, and concentrated at sites of increased bone remodeling/growth activity, such as a fracture, or in a medical use, a cancerous lesion in bone. The localized radionuclide then releases radiation to the surrounding area and tumor as it radioactively decays. Similar therapies are under development to bring radioactive nuclides in contact with soft tissue tumors by attaching the radionuclide to a monoclonal antibody directed to the tumor. The incorporation of 90Sr and 131I through the food chain represents a concern for human exposure from nuclear weapon fallout and nuclear power plant accidents, like Chernobyl.

Biochemical responses may be modified by the presence of radioprotective or radiosensitizing agents (238, 686, 688). Substances may induce radioprotection by several mechanisms, including hypoxia, free-radical scavenging, immunomodulation, hematopoietic and intestinal stem cell recovery, and modulation of the cell cycle (239). Reversal of these same processes is radiosensitizing. Cells exposed to ultraviolet radiation or hyperthermia are more sensitive to ionizing radiation, whereas animals exposed to hypothermia are more resistant to ionizing radiation. Radiation may affect core body temperature through prostaglandin synthesis and histamine release (332). Many biological processes, enzymatic rates, and fidelity are temperature dependent. Even the normal spontaneous depurination of DNA can be accelerated by elevations in temperature and this could affect mutations. Irradiated tissues remain sensitive to extreme temperature variations. Cold temperatures can accelerate the degeneration of irradiated skin (624).

An interesting observation that may ultimately prove useful in the development of a radioprotective agent for the medical/civil defense/space environments is the paradoxical nature of many of the biological mediators, such as the cytokines, prostaglandins, leukotrienes, histamines, and serotonin (494, 685, 687, 688). Their release following radiation exposure plays a key role in the biological amplification of injury, yet when administered before radiation, they are the most potent of the naturally occurring biological substances. The degree of protection afforded by a radioprotective agent is described by its dose reduction factor (DRF) or dose modifying factor (DMF). Both values are ratios greater than 1 for protection, and represent the radiation exposure in the presence of a radioprotective agent to produce a given biological response divided by the radiation dose required without the agent. Radiosensitizing substances are described by the sensitizer enhancement ratio (SER). It is a positive value representing the dose of radiation required to produce a given biological endpoint without a protective agent divided by the radiation dose in the presence of the radioprotective agent. Many of the chemotherapeutic drugs (e.g., Adriamycin, bischloroethylnitrosourea (BCNU), bleomycin, cisplatin, fludarabine, gemcitabine, hydroxyurea, cyclophosphamide, cytosine arabinoside, doxorubicin, 5-fluorouracil, interferon, taxol, and topotecan) have additive or synergistic responses when given with radiation exposures (112, 267, 269). These may be beneficial for tumor therapy but may also adversely affect normal tissues such as heart (Adraimycin), lung (bleomycin), bone marrow, and mucosal tissue (such as the inner lining of the mouth and rectum). Significant advances in oncology have been made using combined modality therapy (chemotherapy and radiotherapy) to improve local control, disease-free survival, and even overall survival. Some patients with laryngeal, bladder, or rectal cancer are able to receive organ preservation therapies involving chemo- and radiation therapy without compromising survival. Patients with nasopharyngeal carcinomas who are treated by concomitant cisplatin/5-fluorouracil chemotherapy with radiation therapy have a greater overall survival than patients who receive an identical course of radio-therapy alone, 78% versus 47% 3-year overall survival, respectively (9). The chemotherapy is thought to reduce the tumor volume, radiosensitize the tumor, and to provide systemic treatment to prevent distant metastases.

For some drugs, because the mode of injury is similar, there may be a memory response equivalent to, or resembling a fractionated radiation exposure, rather than drug injury at one time and radiation injury at another. Caffeine and the cardiac glycosides, digoxin and ouabain, as well as metoclopramide, an antiemetic agent, are also radiosensitizers. Drugs that produce free-radical damage and/or alkylation of DNA, or produce biological responses similar to ionizing radiation, are described as *radiomimetic* (30, 269). Examples include azaserine, benzene, bleomycin, BCNU, cyclophosphamide, diethylthiocarbamate, furazolidone, hydrogen peroxide, mitomycin C, neocarzinostatin, nitrofurantoin, nitrosoureas, nitrosoguanidine, ozone, superoxide, streptonigrin, sulfur mustard, tetranodecanoylphorbor acetate, thiotepa, and the trichothecene mycotoxin T-2 (30, 269).

Alterations in cell populations influence biochemical responses by several mechanisms. Radiation may alter the population of the cell type responsible for producing a particular product, as in the reduction of estrogen which may occur following ovarian irradiation, or it may alter the population of a controlling or modifying cell. These processes may have dire consequences such as decrease in prostaglandin (PG)

production by the bone marrow stromal support cells responsible for maintaining a microenvironment suitable for hematopoietic stem cell development. Studies of bone marrow populations in culture demonstrate that radiation doses that do not kill the hematopoietic stem cells may still halt stem cell progression by injuring the stromal support cells. When stromal synthesis of prostaglandins was inhibited by ionizing radiation treatment, the hematopoietic stem cell

development stopped (239). It resumed when the marrow stromal cells were treated with a 100-Gy dose killing the stromal cells, but stimulating endogenous prostaglandin release. Repopulation kinetics and cell-cell influences play important roles in some forms of radiation-induced congenital anomalies where loss, reduction, or inhibition of one cell or tissue type influences the development of surrounding tissues and organs.

Hormonal control of homeostasis is affected by ionizing radiation and at the same time may affect biochemical responses and even survival to ionizing radiation. Physiological processes may be influenced by electrolyte imbalances, polydipsia, and polyuria following irradiation (686, 722). As mentioned later in the chapter, levels of the stress hormone adrenocorticotropin hormone (ACTH), glucagon, cortisol, insulin, and growth hormone are altered by ionizing radiation exposure. Radiation acts as a general stressing agent on the body (12, 685, 686). Estrogen and testosterone both induce radioprotection when administered to animals, and radiosensitivity has been shown to vary throughout the estrous cycle (685, 686). Correspondingly, testosterone acts as a growth stimulus for prostate cancer cells. The use of lutenizing hormone-releasing hormone agonists that reduce testosterone levels, in combination with radiation therapy can improve the success of therapy in some stages of prostate cancer (531). Circadian rhythm and season variations also modify responses. The spontaneous induction rate for congenital anomalies and the ability of radiation to induce anomalies are both enhanced during the winter months (685). The sensitivity of the individual to ionizing radiation is modified by the state of health, individual genetic and physiological variations, and the presence of combined injuries. Patients with medical histories of scleroderma and xeroderma pigmentosum have worse skin reactions to ionizing radiation. Although the lethal radiation dose for humans is approximately 4.5 Gy, a 5% lethality is estimated for a 2-Gy dose (722). In large radiation exposures, the presence of combined injuries such as infections or pathophysiological injuries, including burns, wounds, or other trauma, plays an important factor in survival (139, 197). Other factors are more difficult to describe. For example, a study on the ability of 210Po to induce lung cancers in hamsters found a 0% incidence of lung cancers when 40 nCi of 210Po was introduced by intratracheal administration, but a 5% incidence of lung tumors if the same administration was followed by an injection of saline (387).

Radiation induces a block in the G2 phase of the cell cycle and a prolongation of S phase (12, 269, 270, 566, 686). Cells are more sensitive when irradiated during the mitosis and G2 phases of the cell cycle and progressively less sensitive during early and late S phases, where preparation for and synthesis of DNA occurs. The G2 delay is probably related to repair processes. Studies with inhibitors of protein synthesis indicate that radiation inhibits the synthesis of a protein or key proteins necessary to proceed through the cell cycle (686). Decreased synthesis and phosphorylation of histones is observed after irradiation (511). When mitosis resumes, there is usually an increase in the percentage of cells undergoing mitosis compared to the unirradiated population due to a partial synchronization and abortive mitoses. There may also be an overcompensation from stimulation of cells normally in the G0 stage back into active cycling. Increasing the radiation dose proportionally increases the mitotic delay time up to a point at which the possibility of radiation-induced cell death becomes a more likely outcome. This delay in resumption of mitosis has significant consequences for repopulation kinetics and potential lethality. There are four major acute radiation lethality syndromes: instantaneous, hematopoietic, intestinal, and central nervous system death (722). Of these, the hematopoietic and intestinal cell deaths are governed by repopulation of the respective stem cell compartments. Hematopoietic death results in humans from doses between 2 and 7 Gy, with lethality occurring between 2 weeks to 2 months postirradiation. Death is directly attributable to the mitotic inhibition/ death of two stem cell populations, one responsible for hematopoiesis and one for marrow support. The formed components of blood, red and white blood cells, and platelets have finite lifetimes, 4.5 days for platelets to 120 days for red blood cells. They are continually replaced by the bone marrow; but, if marrow production is halted, maturation depletion occurs with hematopoietic progenitor cells in various stages of development. An acute aplastic anemia develops without the continued formation of new progenitors. The duration of mitotic delay is crucial in the recovery process because a point might be reached at which the pathological consequences of the loss of platelets and white blood cells cannot be reversed by the onset of new hematopoiesis in time to avert death. In theory, survival or transplantation of a single hematopoietic stem cell (with proper stromal support) can repopulate the entire hematopoietic system, resulting in survival. Bone marrow transplantation has been used to treat victims of radiation accidents. It is not necessary for the entire marrow to be mitotically inhibited for the acute hematopoietic syndrome to be initiated. Production can be suppressed below a threshold. With a loss of platelets and white blood cells, hemorrhaging and infectious processes lead to death. A similar inhibition

of the intestinal crypts of Lieberkuhn by radiation doses greater than 12 Gy progresses to acute intestinal syndrome death between 3 to 7 days post-irradiation. Intestinal villi cells continue to be sloughed off or die without replacement. This produces a decrease in villi height, with an associated decrease in absorptive

area, followed by eventual denuding of the villi surface, loss of electrolytes, and loss of the protective barrier permitting infection and hemorrhaging. Attempts to transplant intestinal crypt cells have not been successful. A person may survive a hematopoietically lethal dose of radiation only to die instead, and at an earlier period, from the acute intestinal syndrome. Agents that are radioprotective for the hematopoietic system may not necessarily affect the intestinal crypt cells in the same manner.
Radiation is unique among environmental mutagens in that it may affect any of the three stages of tumor development: initiation, promotion, and latency (48, 49, 269, 685, 686). There are several chromosomal breakage syndromes, such as xeroderma pigmentosum and ataxia telangiectasia, that are associated with deficiencies in DNA repair and are, therefore, more susceptible to radiation-induced mutational injury. Cancer induction has been related to the activation of proto-oncogenes to oncogenic status. Oncogenes may influence the development of cancer by direct stimulatory effects through altered or amplified gene products or by suppressive activity. In the latter case, the normal function of the gene acts to suppress cancer, and inactivation or loss leads to expression of transformation of cells and carcinogenesis. The most studied human suppressor oncogene, p53, is associated with the induction of retinoblastoma, colon cancer, and lung cancers in humans. Deletions and point mutations in the p53 gene have been observed in some radiation-induced cancers, including, in one study, 7 of 19 radon-associated lung cancers from uranium miners (666), and 16 of 52 in another study (639). Interestingly, 31% of the miners with lung cancer in the second study had a specific transversion of A<u>G</u>G to A<u>T</u>G (arginine to methionine) at codon 249 (639). This codon was not mutated in miners from the first study.
Radiation-induced genetic injury may arise from chromosomal loss of a gene or an entire chromosome, deletions resulting in codon loss, or frameshifts and point mutations involving base substitutions that produce amino acid substitutions or stop codons. Radiation-induced mutations have been observed in the p53, c-*myc,* c-***abl, β*** 2M, c-*fms,* K-*ras*, and H-*ras* oncogenes. Analyses of radiation induced gene inactivation in vitro suggest that induced mutations are more likely to be expressed through DNA deletions or rearrangements than as point mutations (643). Interestingly, the types of activated K-*ras* point mutations observed in neutron radiation-induced murine thymic lymphomas were lower in yield and differed from the spectrum of *ras* point mutations induced by gamma irradiation (612). They also lacked a characteristic point mutation of adenine for guanine in codon 12 that was present in 87% of the gamma-radiation induced *ras* mutations. Characteristic deletions have been observed for other radiation-induced cancers, such as the deletions on chromosome 2 in low LET radiation-induced murine myeloid leukemias (653).
Radiation exposure may alter both enzyme levels and the availability of substrates and cofactors. For example, the increase of PGs in mouse spleens following exposure to 2 Gy was shown to be related to a decrease in the activity of the enzyme associated with PG degradation, 15-hydroxy-PG dehydrogenase (689). This effect was not observed in irradiated human colon tissues (224). Prostaglandin synthesis has also been studied in the pig skin following X-irradiation (731). There was an increase in PGE2 levels within 12 hours after 10-Gy irradiation followed by decreases 24 to 48 hours postirradiation (731). Interestingly, during this same period PGF2α increased. Both changes were related to an increase in NADPH-dependent PGE2 9-keto reductase, an enzyme that converts PGE2 to PGF2α. In general, PGE2 antagonizes the actions of PGF2α, much like prostacyclin (PGI2) antagonizes the actions of platelet-clotting activity of thromboxane.
Exposure to ionizing radiation results in induction of a number of "immediate early genes" and early response genes (47, 60, 195, 207, 270, 490, 509, 535, 566, 571, 573). There are more than 100 stress-inducible genes, or "immediate early genes" induced by ionizing radiation (535). Several of these genes have been detected within 15 min postirradiation and have been elicited with doses as low as 10–50 cGy of ionizing radiation. Many of these can also be induced by oxidative stress and free-radical production (270, 619), and are associated with transcription (including *c-fos, c-jun,* and NF-*κ*B), translation, cell cycle regulation, carcinogenesis, and immunosuppression (270). Several are proto-oncogenes, including c-*fos,* c-Ha-*ras,* c-*jun* and c-*myc* (270, 535). In addition, radiation exposure produces biological mediators and second messengers, such as the cytokines (α-interferon, interleukin [IL]-1, interleukin-6, tumor necrosis factor [TNF]-α, and transforming growth factor-*β*) (18, 39, 270, 565), which in turn can induce specific gene transduction (270). Some genes are down-regulated producing postirradiation consequences. The decreased production of cyclin B following radiation exposure is an underlying factor in radiation-induced mitotic delay (173, 270, 305). Cyclin A and topoisomerase II-alpha also decrease following radiation exposure (173).
There are a number of important biological mediators that amplify and/or elicit inflammation, fibrosis, or biological end points. Among these mediators are hormones, histamine, serotonin, leukotrienes, PGs,

phospholipids, cyclic nucleotides, and cytokines. Each of these may have unique or cooperative interactions resulting in injury, death, or may even be necessary for recovery processes. Histamines and prostaglandins are mediators of radiation-induced skin erythema (85, 686). The cytokines

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_720.html[2010/10/28 18:47:10]

are a diverse class of proteins produced by lymphoid cells and other tissues that mediate cell-cell interactions in a hormonal manner. These proteins include IL-1 and IL-12, TNF, granulocyte/macrophage colony stimulating factor (GM-CSF), stem cell factor (SCF), transforming growth factor-*β*, and the interferons to name a few. These molecules act through specific receptors, and have important physiological and pathological functions/responses. Lung pneumonitis and fibrosis postirradiation are in part related to elevation of transforming growth factor-*β* and to interleukin-1α, both of which are capable of stimulating collagen gene expression and fibrosis. Prolonged plasma elevation of transforming growth factor-*β* in patients receiving radiotherapy has been associated with increased risk of developing pulmonary toxicity (18, 88, 494). Depending on the situation and the cytokine interactions, many of these compounds are able to elicit radioprotective properties or radiosensitization (494). TNF, SCF, and IL-1 and IL-12 are radioprotective in mice when administered individually 18–24 hours prior to irradiation, whereas IL-6 interferons α and *β* and transforming growth factor-*β* act as radiosensitizers (494). The end point of study is important, because administration of IL-12 to mice results in radioprotection of hematopoietic tissue, but gastrointestinal radiosensitization. Other cytokines including granulocyte colony-stimulating factor, keratinocyte growth factor, and transforming growth factor-*β*, are being examined in terms of their wound-healing effects and are undergoing clinical trial tests in patients receiving radio-therapy in order to minimize the injury to normal tissues, while not affecting the tumor tissues (657). Other agents that modify cytokine activity, such as lisofylline reduction of inflammatory cytokines, are also under evaluation to minimize radiation toxicity (657). Granulocyte colony-stimulating factor has been used to increase white blood cell production in patients who have become neutropenic to combinations of ionizing radiotherapy and chemotherapy. Thrombopoietin has been isolated, and is being investigated in clinical trials. It too should have advantages in those patients with radiation-induced bone marrow suppression (but not ablation), but its use will have to await appropriate clinical trials and FDA approval.

Biological processes may also be altered through changes in receptor expression (686). PG, leukotriene, *β*-adrenergic, histamine, serotonin, alpha IIb *β* 3 integrin, and 3H-corticosterone receptors have been studied in irradiated cells or animals. Radiation exposure had no effect on the specific binding of leukotriene C4 at doses up to 20 Gy (688). Adrenergic receptors play important roles in homeostasis by the autonomic nervous system. Radiation induces a decrease in adrenergic receptors in both the rat and rabbit during the first week postirradiation (378, 647). In rats, this is followed by an increase in *β*-adrenergic receptors apparently associated with a late developing radiation-induced congestive heart failure (378). Changes in receptor expression can be related to increased production or to increased use and destruction. An exposure of 2 Gy (a common daily fraction size in clinical radiation oncology) has been shown to increase the mRNA synthesis of the epidermal growth factor receptor in cells irradiated in vitro within the first 24 hours (584). The serotonin3, or 5HT3, receptor is active in radiation-induced emesis, and specific receptor antagonists (ondansetron or granisetron) have been successful in reducing emesis in radiotherapy patients. Administration of 5-HT3 antagonists to ferrets reportedly stopped radiation-induced emesis within 30 s of administration (58). Some radiation-induced receptor changes may have dire consequences because the increased expression of integrin receptors by B16 murine melanoma cells following irradiation is associated with increased lung colony forming ability, or metastasis (510). Expression of the integrin receptor was detected within 15 min postirradiation with downregulation occurring by 4 hours postirradiation.

There are several important signal transduction pathways and cascades that are variously activated by ionizing radiation with important resultant modifications of cellular physiology (329, 341, 583, 619). Among these are the stress-activated protein kinase pathway (SAPK), mitotic-activated protein kinase pathway (MAPK), protein kinase C, modifications of intracellular calcium with corresponding activation of calcium-dependent enzymes, bioactive lipids synthesized or released by phospholipases, and the nuclear transcription factor NF-*κ*B (341, 583). Activation of the MAPK pathway, with corresponding stimulation of mitogenic proliferation is thought to account for the accelerated repopulation of irradiated cells that affects the sensitivity and response of cells (including tumor cells) to chronic low doses as might occur environmentally or accidentally (e.g., Chernobyl), or fractionated doses of ionizing radiation (that are routinely used clinically) (583). The steps involved in the activation of this pathway by ionizing radiation are illustrated in Figure 15.4. This pathway can be activated by binding of the receptors on the membrane cell surface to their ligands (including TNF and other cytokines released or elevated by ionizing radiation) (341), or intracellularly through reactive oxygen intermediates (341, 619), changes in intracellular calcium, and phosphorylated activation of the epidermal growth factor receptor (583). Inhibition of epidermal growth factor receptor phosphorylation in vitro has been shown to block ionizing

radiation-induced cellular proliferation (583). In addition, use of specific inhibitors of MAPK in vitro, resulted in an enhancement of double-stranded DNA breaks and reproductive cell death (95). NF-κB, a nuclear transcription factor, is one of the

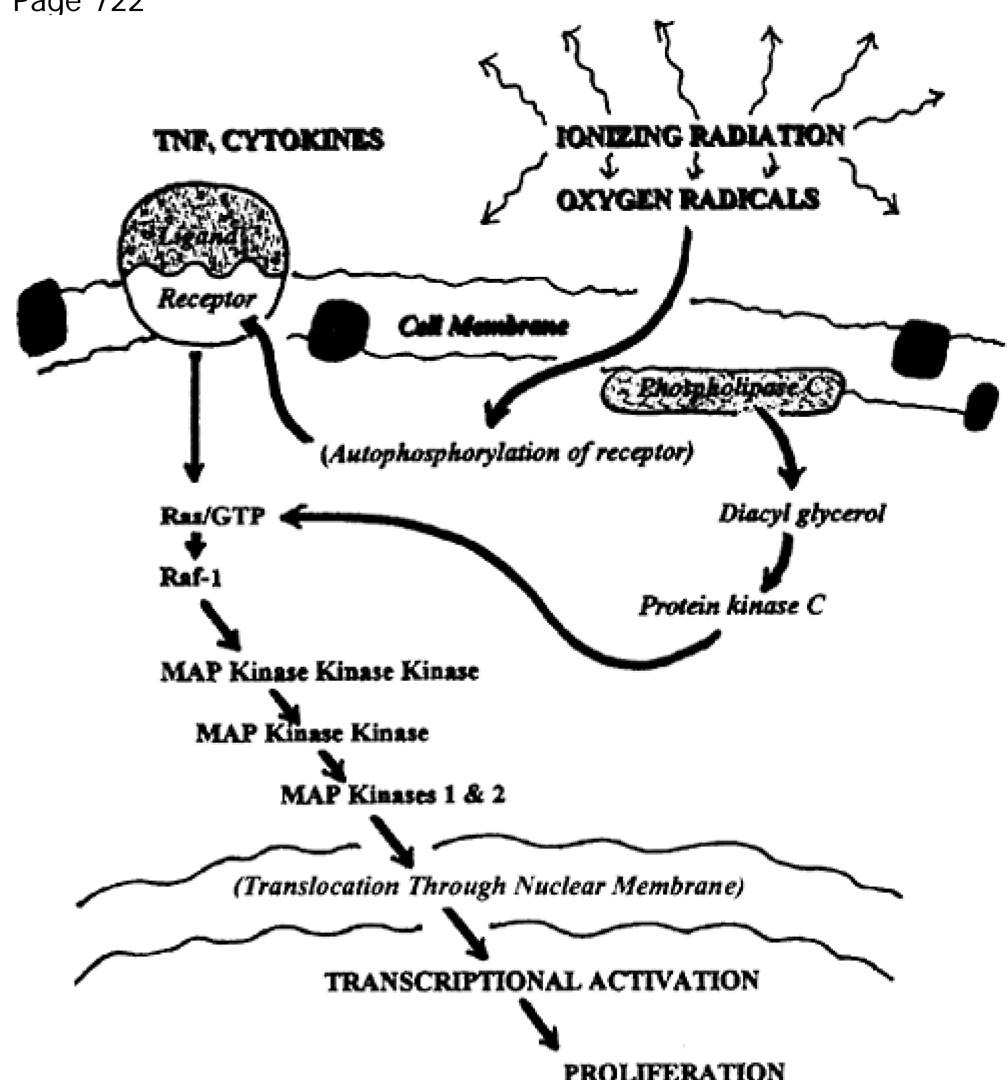

FIG. 15.4. Mitogen-activated protein (MAP) kinase signal transduction pathways can be stimulated in response to ionizing radiation. Radiation exposure results in signal transduction activation of the MAP kinase pathway. The MAP kinase pathway can normally be elicited by cytokines including tumor necrosis factor (TNF). The best characterized receptor-mediated initiation has been the radiation-induced activation through the epidermal growth factor (EGF) receptor by autophosphorylation. The exact mechanism is under investigation, and may involve reactive oxygen intermediates, intracellular calcium mobilization, or indirectly through other biological mediators (diacyl glycerol is released from the phospholipid membrane through the action of phospholipase C). The pathway involves activation of several kinases (phosphorylation activation), and can also be inhibited by phosphatase activities. The resultant pathway action is cell proliferation and differentiation. (Based on References 329, 583, 619.)

early response genes induced by ionizing radiation exposure (270, 341). Its regulation is dysfunctional in people with the genetic disease, ataxia telangiectasia, and is thought to account for their increased sensitivity to ionizing radiation (341). There is also an ataxia telangiectasia-mutated gene (ATM) that participates in DNA repair and recombination, suppression of apoptosis, and induction of p53 (566). The mutated gene is deficient in these functions.

MOLECULAR AND CELLULAR EFFECTS

Effects on Energy Systems

Radiation exposure affects biological energy processes by specific and nonspecific interactions. Nonspecifically, absorptive functions in the stomach and colon may be altered and lead to prolonged gastric emptying times (185), induction of nausea and vomiting, increased stool frequency, loose stools or diarrhea, fatigue, and/or loss of appetite. Radiation affects carbohydrate metabolism by the release of stress-related hormones and by reducing the levels of the thyroid hormones triiodothyronine and thyroxine (686). The reduced thyroid activity is also reflected by an increase in thyroid-stimulating

hormone (TSH). In humans receiving radiotherapy, a single dose of 7.5 Gy results in a 35% incidence of elevated TSH (610). Subclinical hypothyroidism is more common (normal thyroid hormone level, elevated TSH), and like clinical hypothyroidism, responds to thyroid hormone (levothyroxine) supplementation.

Specifically, radiation exposure causes an uncoupling of nuclear and oxidative phosphorylation with corresponding decreases in oxygen-dependent ATP synthesis

Page 723
(12, 686). It has been suggested as a mechanism for radiation-induced interphase death (354). This effect has been observed in the rat spleen with doses as low as 1 Gy (668) and as early as 15 min postirradiation (37). It is observed in the spleen, liver, and thymus but is not present in all tissues. The decrease in oxidative phosphorylation is preceded by a decrease in NAD+ levels, and the decreases in ATP are preceded by reductions in AMP and ADP. The losses are attributable to decreased synthesis, use of remaining stores, and increased leakage through the cell membrane. In nuclei, macrophages, and neutrophils, a specific membrane NADPH oxidase consumes molecular oxygen to produce superoxide but depletes NADPH in the process. The depletion of NADPH, coupled with radiation-induced inhibition of glucose-6-phosphate dehydrogenase, results in the uncoupling of oxidative phosphorylation.
NAD concentrations also decrease following irradiation. Decreases are observed within 15 min postirradiation and have been elicited with doses as low as 0.25 Gy, although doses of 9 Gy or higher are usually required to observe changes (686). This decrease is related to the activation of adenosine 5′-diphospho-5-β-D-ribosyl transferase (ADPRT) by double-stranded DNA breaks. ADPRT uses the ADP contained in NAD to form a poly (ADP-ribosyl) chain that attaches to histones and to several DNA-repair enzymes, including DNA ligase II, Ca2+- and Mg2+ -dependent endonucleases, and to protein elongation factor 2. Although its specific function is not known, poly (ADP-ribosyl) affects many biological processes, including DNA repair and cell growth and differentiation. It is also important in some infectious processes because cholera and diphtheria toxins have ADPRT activity. The Poly (ADP-ribosyl) binds to the histones initiating a relaxation of chromatin, facilitating DNA repair. As long as double-stranded DNA damage is present, ADPRT will remain activated and the poly (ADP-ribosyl) chain will remain attached to the histones, preventing condensation of DNA necessary for metaphase. A suicide model of cell death has been proposed in which extensive DNA damage leads to activation of ADPRT, with the subsequent use and depletion of NAD (56). The decrease in NAD for electron transport results in decrease in ATP synthesis, leading to a decrease in other biosynthetic and active transport processes, with a consequential interphase cell death. Most cells can maintain sufficient NAD concentrations to avoid this complication with radiation doses under 20 Gy. Because poly (ADP-ribosyl) participates in both DNA repair, where inhibition would be radiosensitive, and in this cell death model, where inhibition would be protective, the use of ADPRT inhibitors such as caffeine, nicotinamide, and 3-aminobenzamine have produced mixed results (686).
Human immunodeficiency virus (HIV) activation is not a major response to ionizing radiation exposure; however, both ultraviolet (UV) radiation (732) and X-irradiation can stimulate the in vitro replieation of the HIV responsible for the acquired immunodeficiency syndrome (AIDS) in humans (497). A 200% increase in viral replication was observed following a 1.5-Gy X-irradiation dose. The increase was thought to be mediated by a cAMP-dependent process. Much larger doses of either UV- or X-irradiation are required for inactivation (282). The LD37 dose was 4.5 kGy. In another study, transcription of the HIV promoter could be activated in cells in vivo by doses as low as 25 cGy (198). Radiotherapy remains an effective means of treating Kaposi's sarcomas, lymphomas, and other radiosensitive tumors in AIDS patients (140). Radiation can also cause activation of the herpes zoster virus responsible for chicken pox and shingles (zoster) in humans. Reactivation of the virus (shingles) has been reported in 16% (up to 50% in some studies) of patients receiving radiation therapy for Hodgkin's Disease (257). Most cases occurred within 18 months following completion of radiation therapy and was most common in patients receiving chemotherapy and radiotherapy, and in children.
The Target
The "target" for radiation-induced cellular injury depends on the end point examined. The membrane appears to be the target for some of the behavioral alterations following ionizing radiation, while the chromosome material is thought to be the target for cell lethality. This is supported by the results of microsurgical techniques on irradiated amoeba to transfer the nucleus to unirradiated amoeba and to transfer an unirradiated nucleus to the irradiated cytoplasm. Significantly greater lethality followed the irradiated nucleus. The unirradiated amoeba that contained the irradiated nucleus behaved as if the entire nucleus had been irradiated, whereas the amoeba with the irradiated cytoplasm containing the unirradiated nucleus required much higher doses to the cytoplasm for lethality (255).
In a classic set of experiments, Munro (486) irradiated either the cytoplasm or the nucleus of Chinese hamster fibroblast cells using a needle made of 210Po, an alpha emitter. When the needle remained in the cytoplasm, away from the nucleus, the alpha radiation doses of 250 Gy were dissipated in the cytoplasm with no effect. However, when the needle was placed close to the nucleus, cell lethality resulted from much smaller doses. Finally, cell lethality is directly proportional to the number of chromosomal aberrations observed after irradiation. They may be detected by several methods including

phytohemagglutinin (PHG)-stimulated peripheral blood

< previous page page_723 next page >

lymphocytes, premature chromosomal condensation, micronuclei technique, and FISH (686). The result is influenced by radiation factors, the degree of time following exposure to ionizing radiation, culture time, and age of the individual. The premature chromosomal condensation technique can be assayed in 2 h, whereas the other assays require 48–52 h to allow the stimulated lymphocytes to grow sufficiently for assay. The basic technique permits growth of the blood lymphocytes to permit sufficient numbers of cells to conduct the assay. The complete assay time including culturing the blood lymphocytes takes 3–5 days.

Other experiments that indicate that the DNA is the main target for radiation injury are those conducted with the halogenated pyrimidines, 5-iododeoxyuridine and 5-bromodeoxyuridine (269, 309). These compounds are incorporated into the DNA and increase cellular radio-sensitivity by increasing susceptibility to free-radical attack (including the hydrated electron) and damage and by modification of DNA repair (269, 309, 325). Cells in exponential growth are more sensitive than cells in plateau growth containing equivalent amounts of base substitution. Experiments incorporating 125I-iododeoxyuridine into cellular DNA, or iodinated proteins into cell membranes, further demonstrated that the nucleus, rather than the plasma membrane, is the target for radiation-induced chromosomal instability that occurs after several cell divisions as well as later after radiation exposure (333).

Cellular Responses

There are three basic categories of cellular damage and eight basic responses of cells to ionizing radiation. The basic categories of damage are sublethal damage, potentially lethal damage, and lethal damage. Potentially lethal damage is radiation-induced damage that would result in cell death if not repaired (63), and is affected by postradiation therapy or environment (269). The basic responses of cells to ionizing radiation include no visible response, mitotic delay, transformation, hyperplasia without accompanying cell division leading to giant cells, instant cell death, interphase cell death, reproductive cell death, and apoptosis.

The cell cycle describes the process of cells preparing for and undergoing cell division. Some cells are in a resting phase, termed G0, and are not actively dividing or preparing for division. Cells go through a G1 (Gap 1) phase incurring growth prior to initiating the S phase (synthesis), during which the chromosomes are replicated. This is followed by a second gap (G2), in between DNA synthesis and cell division (mitosis). Classical radiobiology studies of synchronized cells in culture have shown that cells tend to be most sensitive to ionizing radiation when irradiated in G2 and mitosis, and to be less sensitive when irradiated in S phase. Because cells in mitosis and G2 are more sensitive than the other stages of the cell cycle, cells that are rapidly cycling have more likelihood to be in a radiosensitive phase of the cell cycle than cells that are slowly dividing or cells that are removed from the cell cycle (G0, or resting phase). This can be particularly important in radiation therapy where differences in radiosensitivity are exploited to maximize tumor kill and patient cure. In fact, agents that affect cell cycle progression, or synchronize cells (for example hydroxyurea), can be used for radiosensitization. Molecular and cellular biology studies are providing insight both on cell cycle regulation and how radiation is able to affect the cell cycle (270, 487, 566). There are two key check points in the cell cycle which can be inhibited by ionizing radiation, the first is at G1/S, and the second is at G2/M. Several sets of key proteins are involved. The first set of proteins, called cyclins, are specific for particular phases of the cell cycle. They bind to and activate phosphorylating enzymes called cyclin-dependent kinases (566). There may be several cyclins within a particular class, and there are specific inhibitors for the activated cyclin/cyclin-dependent kinase complexes. Seven different cyclins, A-E, G, and H, have been identified (Table 15.7).

Radiation results in stimulation/accumulation of p53 (Figure 15.5), a tumor suppressor protein with DNA transcriptional and other regulatory roles, which in turn induces transcription of the protein, p21 (Cip1/waf1). Increased levels of p21 inhibits both cyclin E cyclin-dependent kinase 2 (cdk2) and cyclin A-cdk2 kinase with a resultant arrest in G1 (189, 270, 566). The cdk4/cyclin D kinase activity is also inhibited. In the presence of p21, the cyclin E-cdk2 complex remains in the unphosphorylated and inactivated form. Cells with normal expression of the p53 protein are called "wild type" (normal). Cells with p53 deficiencies or mutations are unable to elicit the inhibition of cyclin E-cdk2 activation, or cell cycle inhibition at G1 (269, 270, 566). Irradiated mice with deficiencies in p21 (p21 −/−) are still able to elicit G1 cell cycle inhibition, but to a lesser degree (169). This indicates that dual pathways can result

Table 15.7 Role of cyclins in radiation-induced cell cycle response

Cyclin	*Dependent kinase*	*Cell cycle phase*	*Radiation Effect*
Cyclin A	cdk2	S	G1/S Block
Cyclin B	cdk1	G2/M	*G2/M Block*

Cyclin C	cdk, cdk9	G1/2, G2/M	?

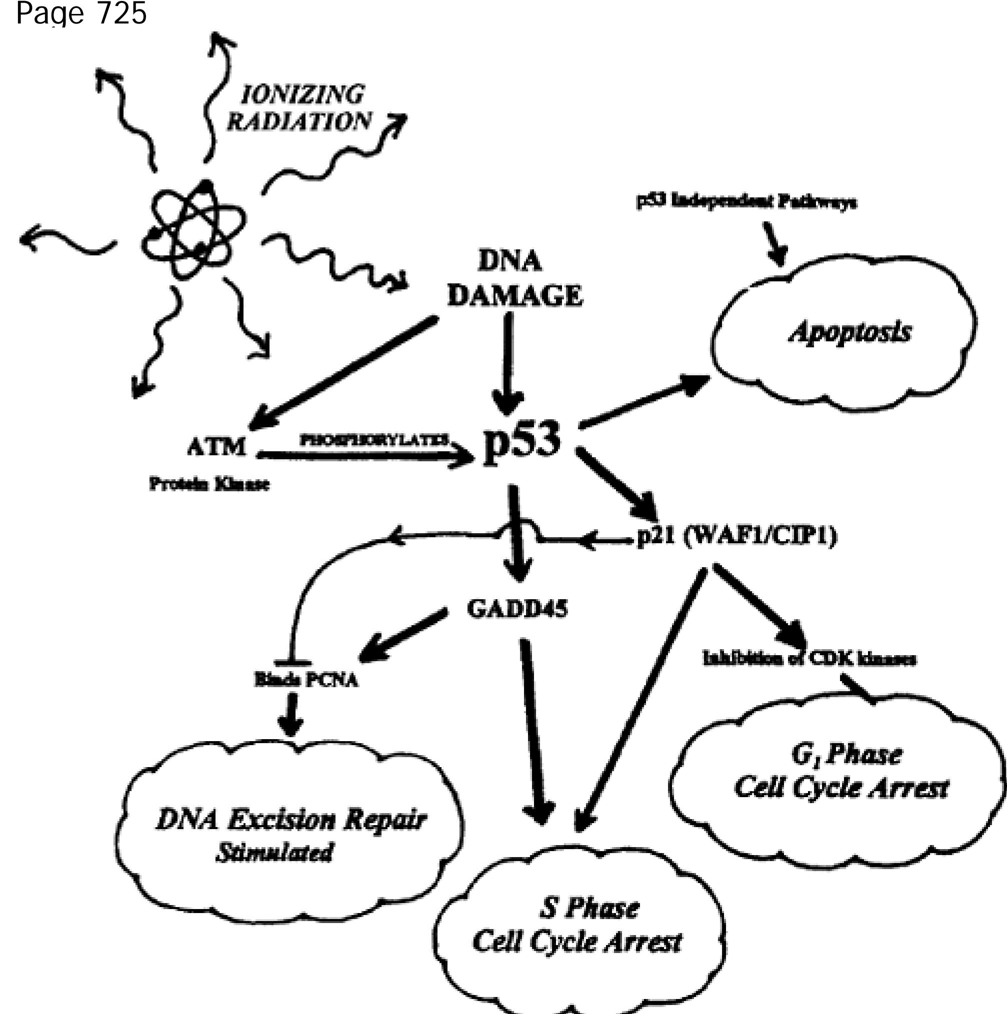

FIG. 15.5. Roles of p53 in response to ionizing radiation. Radiation or DNA damage results in activation of the ataxia telangectasia gene (ATM), a protein kinase that phosphorylates and activates the tumor suppressor/transcriptional activator protein, p53. The actions controlled by p53 are shown. p53 induces transcription of p21, a protein that subsequently inhibits kinases, regulating cell cycle control. p53 increases GADD45 protein levels, which can interact with PCNA (proliferating cell nuclear antigen) to stimulate DNA repair (as shown, p21 can inhibit PCNA binding and activity). p53, in turn, is important in mediating apoptosis, but there are also p53-independent pathways (ceramide signalling) that result in apoptosis.

in G1 inhibition, but that the major pathway is through p53 induction of p21. In general, cells with deficient p53 genes do not get blocked at the G1 check point after exposure to ionizing radiation. Radiation also produces a delay in the cell cycle by blocking the G2 check point. Combination of the cyclin B with cdk1 forms a phosphorylated complex called the *mitotic proliferating factor*. Ionizing radiation results in a decrease in the cdc25 protein that normally dephosphorylates the threonine 14 and tyrosine 15 position of the mitotic proliferating factor, resulting in its activation, and allowing the cell to proceed through mitosis (270, 305, 566). The radiation-induced decrease in cdc25 results in an unactivated/phosphorylated mitotic proliferating factor and, in turn, inhibition at the G2 check point. Reduction in cyclin B transcription, decreased stability of the cyclin B mRNA, and increases in elongation factor 1-delta following irradiation have also been implicated in cell cycle blockage at G2 (270, 305, 487, 566). This a simplified description of a more complicated interaction involving over- and under-expression of cyclin-dependent kinase inhibitors, upstream regulators, and other integrated pathways. Interestingly, overexpression of cyclins have been identified in several cancers (566).

If the reproductive potential of a cell has been eliminated but other functional components of a cell remain intact, the cell may continue to grow without dividing, forming a giant cell. In interphase, death occurs after an individual/organism receives a dose of radiation with so much resulting damage that the cell dies before it can undergo mitosis and potentially gets “stuck” in mitosis. The lymphocyte is considered a very radiosensitive cell in humans where doses of 0.05 Gy have been shown to kill

lymphocytes (722). Reproductive death refers to the cellular processes by which a cell dies by inhibition in metaphase within several cell divisions after radiation exposure. Apoptosis, characterized by nuclear pyknosis, cytoplasmic condensation, and cellular phagocytosis with appearance of apoptotic bodies,

requires the synthesis of specific proteins and has been observed in rat thymocytes following exposure to ionizing radiation (715).

Following radiation exposure, some cells die by apoptotic death, through activation of a genetically preprogrammed cascade. The apoptotic cascade is not specific to ionizing radiation, but has been reported in cells exposed to other cellular stresses, including oxidative stress, hyperthermia, viruses, microbiological toxins, cytotoxic chemotherapeutic agents, hormone deprivation, steroid therapy, cytokine-stimulated stress, antibody/immune-related stress, photodynamic therapy, and UV light (65, 264, 342, 489). It has been estimated that apoptotic death may be a factor in up to 25% of cells dying from radiation (174, 264), although radiation-induced apoptosis is not found in some cell types (264). Apoptosis functions normally in embryos to reduce cell numbers, and also functions in the adult organism. It differs from necrosis in the nuclear pyknosis, with organized degradation of the DNA into nucleosomal units, and condensation of the cytoplasm with packaging of apoptotic products into membrane bound apoptotic bodies (65, 340). This organized process can involve isolated cells, without inflammation (65).

There are at least two mechanistic routes by which ionizing radiation initiates apoptosis. The first is by initiation of DNA damage (65, 264, 342) and the second is mediated through the cell membrane action of sphingomyelinase, releasing the second messenger ceramide (118, 264). The pathway mediated through DNA damage requires nonmutated/functional (wild type) expression of the p53 protein, which controls production of bax, an apoptotic inducing protein. Cells that have a mutated p53 protein (as many cancer cells have) do not undergo apoptotic death in response to radiation-induced DNA damage and p53 activation, but may still be induced to undergo apoptosis through the membrane-induced (ceramide) pathway (118, 264). Bcl-2 and bcl-x1 are suppressor proteins of apoptosis that are thought to bind to each other and to bax (65, 264), forming either homodimers or heterodimers. The key events in apoptosis are speculated to occur either from homodimerization of bax, and/or from decreased availability of the bcl-2 and bcl-xL suppressors (65). Membrane receptor mediated events can inactivate bad, another apoptotic promoter that would otherwise bind to and inactivate bcl-xL. Bcl-2 and bcl-xL prevent the translocation of cytochrome c from the mitochondria (209). In the cytoplasm, cytochrome c acts as an apoptotic protease-activating factor, leading to the activation of cysteinyl-containing aspartate-specific proteases (caspaces, there are at least nine types) that mediate the apoptotic cascade, including a caspace activated DNase (209). Activation of caspaces 3, 8, and 9 are considered important in the apoptotic cascade, and further differences in activation pathways can be delineated based on whether the initiating processes are caspace 9 dependent, caspace 3 dependent, or caspaces 3 and 9 independent (caspace 8 dependent) (265). Among the ligands that can bind to receptors and activate the apoptosis pathway are the *fas* ligand and TNF. The membrane-mediated pathway for radiation-induced apoptosis is inhibited by protein kinase C activation (264). There is interest in tumor therapy to enhance the radiosensitivity of tumor cells through stimulation of apoptosis, either by restoring a normal (wild type) p53 protein, or by inhibiting protein kinase C.

The sensitivity of cells to ionizing radiation is influenced by several factors, but the general principles describing cellular radiosensitivity were described for cancer cells in 1906 (57), and are referred to as the Law of Bergonie and Triblondeau. The radiosensitivity of cells and tissues is related to the rate of cell division and the reproductive potential. Cells that are more rapidly dividing and have the potential for a number of successive generations will be more radiosensitive. There are some exceptions to these principles, such as the terminally differentiated lymphocytes, but it may be used to explain why rapidly dividing cells such as hematopoietic stem cells and intestinal crypt cells are more sensitive than nondividing tissues such as heart, skeletal muscle, and nerve cells. The law is usually presented as an explanation for the radiosensitivity of cancer tissues that are rapidly dividing and have unstable chromosome compositions. There may not be sufficient time to repair the chromosomal damage before the next cell division. The expression of injury in some biological systems may require long periods simply because the rate of cell division in a particular tissue is very slow. Even if radiation exposure produced so great a damage as to modify or prevent cell division, it would take years for the cell to reach the point where the division would occur and injury is expressed. The cell cycle time of some ocular cells is 3 years, explaining in part the long latency period for expression of radiation-induced cataract formation (48).

Prokaryotes and insects also represent contradictions to the Law of Bergonie and Triblondeau. Mammals are much more sensitive, with the LD50s for pigs, mice, and men being 2.5 Gy, 6–8 Gy and 4.5 Gy, respectively (23). The LD50 for *Escherichia coli* is between 20–50 Gy, compared to 100–1000 Gy for insects and 1000 Gy for amoeba (23). Plant sensitivities range from 4–400 Gy, with 75–90 Gy being

lethal for the common chrysanthemum (36). These differences are explained in part by application of the target theory, in that cells with large chromosome numbers and large nuclear to cytoplasmic ratios tend to be more radiosensitive in part because they have larger critical target sizes (36). The chrysanthemum has a polyploidy of 22. Some plant species such as pine

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_726.html[2010/10/28 18:47:14]

Table 15.8 Radiation dose ranges and associated pathophysiological events*a*

Dose range (cGy)	Pathophysiological events		
	Prodromal effects	Manifest-illness effects	Survival
75–150	Mild	Slight decrease in blood cell count	Virtually certain
150–300	Mild to moderate	Beginning symptoms of bone marrow damage	Probable (>90%)
300–530	Moderate	Moderate to severe bone marrow damage	Possible bottom third of range: LD5/60 Middle third: LD10/60 Top third: LD50/60
530–830	Severe	Severe bone marrow damage	Death within $3\frac{1}{2}$–6 weeks Bottom half: LD90/60 Top half: LD99/60
830–1100	Severe	Bone marrow pancytopenia and moderate intestinal damage	Death within 2–3 weeks
1100–1500	Severe	Combined gastrointestinal and bone marrow damage; hypotension	Death within 1–$2\frac{1}{2}$ weeks
1500–3000	Severe	Severe gastrointestinal damage with upper half of range: early transient incapacitation (ETI); gastrointestinal death	Death within 5–12 days
3000–4500		Gastrointestinal and cardiovascular damage	Death within 2–5 days

a From Reference 42.

trees have radiosensitivities similar to humans, making them ideal biological dosimeters surrounding nuclear facilities (255).

One last interesting aspect of radiobiology is that radiation exposure does not always result in harm. Hormesis describes the beneficial responses to biologically harmful agents such as poison and even radiation, Radiation has been used to improve the growth of seeds, separate from production of genetic mutations. It has even been reported to extend the life span of female mice, although it did so by sterilization, which eliminated the repeated stress of pregnancy.

SOMATIC EFFECTS OF RADIATION

In higher animals there is no simple, direct relationship between nuclear chromosome volume and sensitivity to ionizing radiation. Rather, the effects of irradiation on specific organ systems are more critical (504).

Acute Radiation Syndrome

There have been less than 25 documented fatalities worldwide, between 1946 and 1985, that may be attributed to radiation accidents (437). Although exposure of the whole body to lethal amounts of ionizing radiation is very rare, any discussion of the biological effects of ionizing radiation would be incomplete without mentioning acute radiation sickness and the acute radiation syndrome (ARS).

Acute radiation sickness is manifest in characteristic clinical sequelae known as the ARS, a combination of syndromes determined primarily by the total radiation dose received, the rate the radiation is delivered, and how the radiation is distributed in the body (722). Signs and symptoms of the ARS result from injury to bone marrow, gastrointestinal system, cardiovascular system, central nervous system, gonads, and skin. The variation in radiation sensitivity of these tissues causes the signs and symptoms of the ARS to occur in three successive phases: an initial prodromal phase, a later latent period, and the manifest illness phase. The length of each phase may vary directly with the radiation dose and the time between each phase may vary indirectly with the dose, so at an extremely high dose of radiation, the phases will blend, with the latent period disappearing completely (Table 15.8).

The prodromal phase may begin about 2–4 h after doses of 3–5 Gy or within minutes after exposure to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_727.html[2010/10/28 18:47:14]

Page 728
45 Gy or higher. The initial prodromal phase is characterized by a combination of gastrointestinal and neuromuscular symptoms such as anorexia, nausea, vomiting, diarrhea, apathy, tachycardia, fever, headaches, insomnia, dizziness, and vertigo. The pathogenesis of the prodromal phase is not known, but several causal factors have been suggested, including direct radiation effects on the central and autonomic nervous systems, disturbance of the endocrine balance, and the production and release of various chemical mediators (176, 687). The latent period, which follows the prodromal phase, is relatively asymptomatic and is believed to be the time between initial cell damage and the interference of radiation with cell renewal in the affected organs (722).
The manifest illness phase of the ARS is classically divided into three major syndromes, traditionally known as the hemopoietic, gastrointestinal, and central nervous system (CNS) syndromes (410). However, the current view replaces the CNS syndrome with the neurovascular syndrome (722).
The hemopoietic syndrome may be encountered after exposure to 2–7 Gy, and 1 Gy or more can significantly damage the blood-forming capability of the body. Radiation kills the mitotically active hemopoietic precursors of red cells, white cells, and platelets. Pathophysiological consequences include increased susceptibility to infection, bleeding, anemia, and lowered immunity. Death usually results from hemorrhage and infection (410, 437, 722).
Radiation exposure above 7 Gy contributes to the gastrointestinal syndrome by inhibiting the renewal of the cells lining the digestive tract. At doses of 3–8 Gy, tight junctions between the epithelial cells are disrupted, allowing increased fluid and electrolyte loss and permitting the movement of bacterial endotoxins into the blood. At higher doses (10–15 Gy), denudation of the mucosa occurs and death results from dehydration, electrolyte imbalance, and septicemia (437, 722).
The neurovascular syndrome is the least understood of the radiation-induced deaths. The syndrome is unique in that death occurs very quickly before damage to the gastrointestinal and hemopoietic systems becomes apparent. Readily obvious CNS signs and symptoms include disorientation, loss of muscular coordination, respiratory distress, apathy, prostration, convulsive seizures, and coma associated with death. Some researchers believe that 50 Gy is necessary for the neurovascular syndrome and doses above 100 Gy are required for direct damage of the nervous system. However, ionizing radiation exposure modified electroencephalographic activity (649) and in vivo exposure decreased hippocampal synaptic transmission and spike generation (297) at lower doses than anticipated. Details of nervous system effects are given later.
Radiation-Induced Developmental Effects
Preimplantation in utero is never succeeded directly by postimplantation, the two being separated by the time it takes the placenta to develop into a functioning organ (472). This interval of development takes 1–2 days in rodents and 10–14 days in humans. Therefore, the traditional categories of prenatal development known as preimplantation, postimplantation, and fetal are replaced by conceptus, embryo, and fetus. The term conceptus is used for the stage of development lasting from ovulation until the placenta becomes a functioning organ. Even though there is some controversy about the maturation of an embryo to a fetus, most classifications of human developmental stages agree that this metamorphosis occurs in the last portion of the first trimester of gestation (289).
The developing conceptus and early embryo have a variety of rapidly dividing progenitor cells. These proliferating cells are much more sensitive to irradiation than differentiated, nondividing cells, making an organism more radiosensitive during its early stages of development than at any other stage of its life. The conceptus exhibits the lowest LD50 of any stage of development and is easily killed by doses of ionizing radiation that would cause abnormalities at later stages of development (77, 555). Rather than a malformed organism developing to term, it dies in the conceptus stage due to irradiation-induced chromosomal damage (77). Thus, it is believed by some that the highest risk of irradiation during this stage is the death of the developing organism rather than teratogenesis (472).
In some animals, exposure to ionizing radiation in utero can result in anomalies in every organ system and the concept has been formulated that irradiation, however small, can inflict damage to the embryo or fetus (555, 558). Irradiation-induced anomalies occurring during the middle stages of development may result in death of the organism or abnormal development of one or more organ systems. However, instead of lethality, morphological abnormalities are associated with irradiation during this time. Exposure during this period may result in gross malformations, growth retardation at term or as an adult, and structural pathology (437, 726). In the human, most major organogenesis occurs during the first trimester of pregnancy with embryonic death and congenital abnormalities resulting from irradiation exposure during this period (555).
During late organogenesis and in the perinatal period, just before and just after birth, radiation damage

tends to be functional rather than structural. Perinatal irradiation with x-rays and gamma rays (140–180 cGy) induces changes in tissue enzyme activity (14), hormone production (190, 311), and hemopoiesis (247, 471). The major effects of perinatal in utero exposure in humans

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_728.html[2010/10/28 18:47:15]

Page 729
is seen in the developing CNS with neurological damage and behavioral changes not always obvious in histological examination (77, 133, 458, 470, 499, 555).
Susceptibility to radiation carcinogenesis is relatively high during prenatal development (440, 556, 684). During the last four decades, a major concern has been the risk of childhood leukemia and other neoplasms following irradiation in utero (50, 55, 77, 247, 437, 527, 685). Studies of the effects of ionizing radiation on the fetus are extremely important because there seems to be no biological reason to expect the fetus to be resistant (160). The embryo may be 50 times more vulnerable than the adult to irradiation-induced leukemia (77) and the risk of a child dying of cancer before the 10th birthday may be increased 40–60% by in utero irradiation (476).
The developing conceptus, embryo, and fetus show high susceptibility to ionizing radiation and the extent of injuries depends on the stage of development as well as the dose of radiation. Developmental anomalies are induced with doses much lower than previously used to demonstrate anomalies in adults (317, 440, 458, 471).
The risk of leukemia in children with Down syndrome (trisomy 21) is estimated to be about 20 times higher than in the normal population and there has been some evidence that preconceptional ionizing radiation is linked to the nondisjunction of chromosome 21 (638). Clusters of cases of Down syndrome have been observed in Germany following the passage of the radioactive cloud from Chernobyl and experimental results have demonstrated that ionizing radiation may induce nondisjunction in oogenesis and spermatogenesis (674).
Even though there is a long latency period of radiation-induced cancer, a dramatic increase of up to 100-fold in the number of childhood thyroid cancers have been observed in the heavy radiation contaminated areas of Belarus and Ukraine and the Bryansk regions of Russia following the Chernobyl accident (28, 569). A strong relationship is indicated between the thyroid cancer and radiation from the Chernobyl cloud.
The in utero developing nervous system is particularly vulnerable to ionizing radiation with defects of the eye and of spinal development among some of the more common malformations encountered following early gestational exposure (83, 84, 243). Later prenatal radiation exposure may result in dose related abnormalities of the hippocampus with disorganized and loosely scattered neurons in the CA-1 and CA-3 regions and agenesis of the corpus callosum (455). Perinatal irradiation, during neuronal migration and differentiation, resulted in delay of migration and severe reduction of neuronal tissue in the cerebral and cerebellar cortex and in the hippocampus (220, 221, 321). Postnatal cephalic irradiation of newborn rat pups produced an increase (122%) in noradrenaline activity and a marked decrease (38%) in monoamine oxidase activity in the cer ebellum (177). The irradiation-induced 60% reduction in cerebellar weight may account for some of the marked increase (223%) in noradrenaline concentration and increase (206%) in tyrosine hydroxylase activity.

Direct Effects of Radiation on Reproductive Organs

During a period of approximately 20 years in the early part of this century, radiation was used in an attempt to increase fertility. Exposure normally was to 1.5–2.5 Gy over a period of 3 weeks. These levels apparently had little effect on fertility or on any later conceived children (437). However, neonatal irradiation of rats (211, 212) and hamsters (637) demonstrated impaired fertility in mature male and female animals. In utero irradiation of male rat pups resulted in atrophy of the testes, ventral prostates, and seminal vesicles with a complete disappearance of germinal cells from the testes (629). Irradiation treatment of children 15 years of age and younger with Hodgkin's disease resulted in azoospermia in many of the mature males and ovarian injury in some of the mature females (512).
The safety of radiation levels is often questioned because the threshold for the effects of ionizing radiation on male reproduction is difficult to predict (588). Although fully developed sperm cells and primary spermatocytes are relatively radioresistant, the quiescent and proliferating spermatogonial cells of the testis are highly sensitive to ionizing radiation (437, 555, 670, 671). Germ cell dysfunction is common following testicular irradiation and a dose-dependent impairment of spermatogenesis with gradual recovery may be seen following doses of up to 6 Gy (274, 351, 611). The effects of ionizing radiation on spermatogenesis are normally reversible with the recovery of fertility predictable. Although an acute irradiation dose of 6 Gy to the testis is likely to produce permanent sterility, conception has occurred for males after years of either aspermic or hypospermic conditions following absorbed doses between 2.3 and 3.7 Gy (437, 555). However, following the Chernobyl nuclear reactor disaster there has been a widespread fear of damage to the reproductive system, with implications for fertility problems and adverse effects on offspring. A pilot study of 18 salvage workers (liquidators) revealed incomplete genesis of sperm characterized by certain ultramorphological parameters of the sperm head (205). The

frequency of amorphous sperm head shape in the study group was significantly higher than in the local Ukrainian control group of 18 men.

Although the human testis is considered relatively resistant to the carcinogenic effects of radiation (50), occupational radiation exposure of the testis produces

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_729.html[2010/10/28 18:47:15]

significant changes in serum gonadotropins and semen parameters. Testicular irradiation may be associated with elevated plasma levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), reduced levels of androgen-binding protein (ABP) and testosterone, and reduced prostate and seminal vesicle weights (246, 330, 351, 432, 529, 686). The decreased ABP levels and increased FSH levels are associated with Sertoli cell dysfunction, although the FSH increase may be a secondary result of germ cell depletion rather than a direct effect of irradiation. The changes in LH and testosterone levels and the decrease in prostate and seminal vesicle weights are indicative of Leydig cell function impairment.

As a direct effect of ionizing radiation, the human prostate epithelial cells may also display malignant transformation after multiple exposure (366). After a cumulative x-ray dose of 30 Gy, tumors characterized as poorly differentiated adenocarcinomas developed from prostate epithelial cells. This report may provide the first evidence of malignant transformation of human prostate epithelial cells resulting from direct exposure to ionizing radiation.

Although there are no proliferating stem cells in the mature female reproductive system, the oocytes are in follicles in various stages of development. Animal experiments indicate that radiosensitivity of the ova depends on the maturity of the follicle (555). Irradiation depletion of the radiosensitive mature and intermediate follicles will result in periods of temporary sterility followed by fertility due to maturation of surviving immature follicles. Sensitivity varies among species and temporary sterility can be produced in humans with doses as low as 1.5 Gy (686). Cases have been reported of irradiated women receiving as much as 6.4 Gy becoming pregnant as long as 2 years later and delivering normal children (437). However, the estimated dose required to produce permanent sterility in the female ranges between 6.25 and 30 Gy, depending on age of the subject (555), sensitivity increasing with the approach of menopause (686).

Ovarian failure is associated with whole body irradiation (149), abdominal irradiation (690, 691), or radiation therapy for cervical carcinoma (425). Pubertal failure or premature menopause was common in females irradiated in childhood (690, 691). Premenopausal women receiving radiation therapy may produce sign and symptoms associated with menopause, such as amenorrhea, dyspareunia, hot flashes, irritability, and loss of libido (199).

Breast cancer, the most frequent spontaneous malignancy diagnosed in women in the western world is increasing in incidence (568). Exposure of the breast to ionizing radiation is now known to increase the risk of breast cancer, especially for younger women (420, 421). The risk of developing breast cancer is very high in women exposed to ionizing radiation before or during puberty, when the differentiation of terminal mammary end buds and alveolar structures is occurring (605). In fact, the carcinogenic effects of ionizing radiation on the vestigial male breast may be quite similar to that seen in the prepubertal female breast (644). The male breast displays an increase in risk for breast cancer with three or more radiographic examinations.

The Lymphohematopoietic System and Immune Competency

One of the systems most sensitive to irradiation is the hematopoietic system. Because of the rapidly proliferating hematopoietic elements of the bone marrow, the hemopoietic syndrome may be encountered following irradiation of 100 cGy or more (475, 555). Approximately 50% of individuals exposed to 300 cGy (LD50/60) will die within 2 months. The signs and symptoms result from radiation damage to the bone marrow, lymphatic organs, and immune system. The hematopoietic syndrome is characterized by a depression in the peripheral blood levels of mature erythrocytes, granulocytes, lymphocytes, monocytes, and platelets. Except for lymphocytes, the mature blood cells are relatively radioresistant and function normally in the peripheral blood after irradiation levels that will produce bone marrow damage.

Mature cells in peripheral blood have limited life spans and the replacement of their functional cell types is dependent on the proliferation of the hematopoietic elements of the bone marrow. One type of stem cell, a pluripotent stem cell (PPSC), has the dual capability of self-perpetuation and differentiation, and can meet the demands of the lymphohematopoietic and reticuloendothelial systems.

The progeny of the PPSC have specific functions in the body. Granulocytes are involved in activities against invasive bacteria and are related to the nonspecific immune response, whereas the cell-mediated and humoral responses of the lymphocytes are related to the specific immune response. The monocyte migrates into specific tissues and differentiates into a macrophage of the reticuloendothelial system. The platelet is a critical element of hemostasis and thrombocytopenia may result in hemorrhage and purpura. Thus, radiation damage to the PPSC may seriously compromise all of these systems, resulting in hemorrhage, infection, and death.

Depression of the mature cells in circulating blood is dose dependent (437, 475). At radiation doses near the LD50 changes in the small lymphocytes can be seen in 1 h and lymphocytes may totally disappear from peripheral blood in 2–3 days (245, 409, 418, 437, 555). Although lymphocyte depletion may be measured in hours,

granulocytes and platelets are depleted over days, and depletion of erythrocytes may be measured in weeks.

The small lymphocytes in lymphoid tissue are some of the most radiosensitive cells in the body and the small lymphocyte is the earliest to decrease in the peripheral blood following irradiation of man or animals. The lymphocyte not only shows the most rapid reduction in number, but it is the slowest to return to normal (418). The reduction in lymphocytes leads to impaired specific immune responses and immunosuppression. Regeneration of both the T- and B-lymphocyte levels depends on the lymphoid stem cells, which in turn depend on the PPSC of the bone marrow. Radiation-induced alterations in the nuclear material of lymphocytes might also have a significant impact on the function of this cell type. Chromosomal aberrations have been found in individuals exposed to radiation from both the Chernobyl accident-related cleanup activities (618) and to the subsequent fallout afterward (582).

Radiation depresses nonspecific immune responses by reducing the levels of circulating monocytes and granulocytes (475). Granulocytes serve as the first line of bactericidal defense at wounds whereas the macrophage, a progeny of the monocyte, can phagocytize and catabolize foreign substances such as microorganisms and toxins. The macrophage is also involved in the humoral specific immune response by processing foreign substances and presenting them as antigens for recognition. Radiation-induced depression of both specific and nonspecific immune responses through the reduction of monocytes, granulocytes, and lymphocytes is potentially life-threatening because of the enhanced susceptibility to opportunistic infections (197, 521).

Ionizing radiation induces functional and quantitative abnormalities in the lymphoid cells of both man and experimental animals (6, 252). Although ionizing radiation was found to deplete both T and B murine cells in equal proportions in the spleen (252), studies of late effects of atomic-bomb radiation on the immune system showed alteration of the balance and interaction between T and B cells, with a decrease in the T-cell population and an increase in the B-cell population in the periphery (6). Autoimmune deviations, both humoral and cellular, were observed in residents of areas contaminated from the Chernobyl accident and subjects participating in the clean-up of the accident (27, 159, 473, 607). Structural and functional changes seen in the kidney, thyroid, and crystalline lens of the eye well may be associated with significant changes in the humoral immunity systems related to ionizing radiation exposure.

Irradiation usually does not depress the platelet (thrombocyte) count significantly in a healthy individual (437, 475). The platelet's life span is 9–12 days and depression in circulating levels reach an initial nadir 10 days after irradiation. The individual will face problems similar to those of a patient with aplastic anemia: thrombocytopenia, capillary fragility, abnormal bleeding, and purpura. When the platelets reach a critical level, hemorrhage is likely to occur and may result in death of the individual. Therefore, platelet transfusion becomes critical for the irradiated individual.

Because of the relative radioresistance and long life span of erythrocytes (120 days), circulating blood levels fall slowly without complicating hemorrhage or infection (475). In the presence of thrombocytopenia and hemorrhage, transfusions may be required. Erythrocyte recovery after irradiation normally follows granulocyte and platelet recovery.

Radiation at the LD50/30 dose level (350–400 cGy in humans) may kill more than 99% of the critical cells in the hematopoietic tissue (437, 475). At this dose level cytological restoration of the bone marrow begins about the 25th day postirradiation in man. The PPSC will self-replicate and differentiate to produce hematopoietic progenitor cells. The risk of death from hematopoietic radiation injury depends on the regeneration rate of bone marrow stem cells (306), and the level of medical treatment provided (593). With bone marrow transplantation and heroic supportive therapy, survival is possible following whole-body irradiation as high as 1200 cGy (105, 293, 437). Although bone marrow transplantation certainly may be indicated, other clinical support regimens will stimulate hematopoietic regeneration, accelerate recovery, increase the LD50/30, and enhance survival (405, 406, 518–520, 592).

The most common neoplastic disorder of the hematopoietic system are the leukemias and several different types of leukemia have been observed in a variety of experimental animals following exposure to ionizing radiation (550, 713). Leukemias account for about 32% of all cancer diagnosed in children, with about 85% of leukemias classified as acute (728). The acute leukemias in children may be related to parental occupational exposures to a number of carcinogenic substances or with prenatal and postnatal exposures to ionizing radiation.

Clinical evidence leads to the concept that ionizing radiation can cause leukemia by inducing DNA damage. Two hematopoietic cell lines were subjected to gamma irradiation to investigate the susceptibility of human cells to irradiation at the genetic recombination stage of leukemogenesis (168).

The irradiation induced the formation of fusion genes characteristic of leukemia in both cell lines. The cell lines studied showed differences in susceptibility and frequency at which the different fusion genes were formed. These differences in selectivity may help to explain the differences in risk development of some types of leukemia that have been observed following high doses of irradiation.

Digestive Tract Dysfunction

The digestive tract includes the esophagus, small and large intestine, and rectum. The mucosa of the digestive tract undergoes continuous stress and in order for its functions to remain unimpaired, it must renew itself rapidly to replace lost cells. This fast turnover supported by a marked mitotic activity makes the digestive tract mucosa extremely radiosensitive. The duodenum is the most radiosensitive region of the digestive tract, followed by jejunum, ileum, esophagus, stomach, colon, and rectum, in order of decreasing radiosensitivity (45).

Surprisingly little has been written about radiation damage to the esophagus (665). The mucosal cells are characterized by a rapid proliferation rate and a relatively high degree of radiosensitivity. Acute radiation injuries are quite symptomatic with submucosal congestion and leukocytic infiltration, followed by mucosal necrosis and sloughing. Healing occurs rapidly and in animals with esophageal irradiation, the mucosa appeared completely normal 1 year following 2.5 Gy exposure. Humans who received 7.3–7.6-Gy irradiation exhibited narrowing of the esophageal lumen, partial loss of the mucosa and muscularis, and widening of the submucosa for 2–8 months following exposure. In spite of the initial radiation injury, radiation therapy for esophageal carcinoma results in very low mortality.

At radiation doses of 7–50 Gy, injury to the gastrointestinal tract inhibits the renewal of the cell lining. The intestinal epithelial stem cell is the target of radiation damage, and the resulting decrease in mitotic activity leads to denudation of the intestinal mucosa, fluid and electrolyte imbalance, and bacteremia (258). The symptoms of the gastrointestinal syndrome include lethargy, emesis, diarrhea, dehydration, and sepsis. At doses of 3–8 Gy, temporary injury to the tight junctions between epithelial cells of the mucosal lining permit the escape of bacterial endotoxins into the bloodstream. As dose increases, the epithelial lining is more extensively depleted. With doses of 10–15 Gy, denudation of the mucosa exacerbates the loss of fluid and electrolytes. Beginning at about 12.5 Gy, early mortality occurs due to dehydration and electrolyte imbalance, with death occurring 4–5 days postexposure.

At doses of 1 Gy or more irradiation of many mammals produces nausea and vomiting, signifying the prodromal phase of the acute radiation syndrome (45, 186, 258, 349). Radiation-induced emesis, often accompanied by delayed gastric emptying, may be associated with areas of the brain known as the area postrema and the vomiting center, both located in the medulla (258). Ablation of the area postrema has been observed to abolish radiation-induced emesis in some mammals (258) and zacopride, an antiemetic, inhibited radiation-induced emesis and suppression of gastric emptying in the monkey (186) and abolished radiation-induced emesis in ferrets (350). Inhibition of radiation-induced emesis has been achieved also through the use of the selective 5-hydroxytryptamine (5-HT3) receptor antagonists granisetron (58, 305), ondansetron (284, 536), and Y-25130 (216).

Functional alteration of the stomach by radiation included a decrease in the production and secretion of HCl, pepsinogen, and mucus (45), and an increase is serum levels of pepsinogen and gastrin (696). Histopathological alterations included vasodilation and edema indicative of increased microvascular permeability (86), and marked degenerative features including atrophic mucosa and ulceration (45, 75).

Intestinal mucosa cells originate from a single stem cell type located at the base of the intestinal crypts. As the cells proliferate and differentiate they move to the tips of the villi, a journey of 3–5 days. The differentiated cells are shed continuously from the tips of the villi. Radiation damage to the cells of the crypt leads to the death of some cells and an arrest of mitotic activity of others (15, 45, 491). The severely damaged crypt stem cells do not divide and replace the cells lost from the tips of the villi. This results in decreased absorption and allows a ready entry for intestinal flora into the systemic circulation (103, 259, 515). Electrolyte transport is also altered in the jejunum and ilium following exposure to ionizing radiation and this functional change may be related to the decreased mast cells and histamine (402, 403).

Intestinal absorption may also be decreased due to vascular concrescence. In examinations of irradiated animals the villous capillaries showed initial marked vasodilation followed by constriction, with many capillaries becoming totally nonpatent while the endothelial cells showed changes consistent with vascular damage (2, 3, 402). These findings were consistent with functional changes seen in several studies reviewed by Cockerham and Hawkins (131).

The colon has a relatively high radiotolerance, possibly due to the long turnover of its cells, and the rectum may tolerate more than 50 Gy irradiation (45). Postirradiation pathological events are essentially the same as in the small intestine with inhibition of mitosis, changes in cell morphology, and edema and vascular changes in the submucosal and serosal layers. An inflammatory response occurs within 24 h and a progressive degeneration leading to ulcerations occurs after high doses (86). A late development of colorectal irradiation seen in murine studies was a dose-dependent decrease in compliance (417),

possibly due to altered ratios of collagen isotypes, especially in the circular muscle layer and villi (416). As with the other portions of the gastrointestinal tract, the loss of water and electrolyte imbalance due to diarrhea and the development of bacteremia are considered the most important

factors in the gastrointestinal syndrome (258). The rat colon also becomes unresponsive to neurally evoked electrolyte transport following exposure to ionizing radiation of 10 Gy (208). This response also correlates with decreased mast cells and histamine.

Cardiovascular Dysfunction

Cardiovascular dysfunction (CVD) has been defined as the inability of any element of the cardiovascular system to perform adequately upon demand. The maintenance of cardiovascular integrity is determined by the changes in (i) the pumping action of the heart, (ii) compliance of the vascular beds, (iii) resistance of the peripheral circulation, (iv) quantity of blood in the vascular system, and (v) viscosity of the blood. Failure of any of the mechanisms to respond properly may compromise the integrity of the entire cardiovascular system (131, 272, 280). Exposure to supralethal doses of radiation has been shown to induce alterations in cardiovascular function in many species, including human. The extent of the radiation-induced CVD and its etiology may vary with the species, level of exposure, and dose rate. Radiation-induced CVD is surprisingly common (26) and may be manifest as circulatory shock. Although postirradiation hypotension does not occur with equal frequency in all species, it has been reported in rats, monkeys, and dogs (124, 130, 242, 441). However, evidence indicates than even if sublethal doses of radiation induce a functional cardiovascular deficiency that manifests itself as early hypotension, the lesion may be masked during a period of circulatory deterioration because of cardiovascular reserve (230, 488). When the cardiovascular reserve is no longer capable of maintaining homeostasis the damage may then be recognized as radiation-induced shock (278).

Irradiated rats displayed compromised myocardial function with a decline in cardiac output and an increased left ventricular end-diastolic volume (591, 719), which correlated with a decline in capillary density and focal degeneration of the myocardium. Cardiac performance after irradiation using an isolated working rat heart preparation showed a dose-dependent decrease in cardiac function and Frank-Starling curves, suggesting a loss of contractile function of the myocardium (712). Ultrastructural findings in the irradiated rat heart included intercalated disc damage and mitochondrial damage of the myocytes and swelling of the capillary endothelial cells and collapse of the capillaries (120). Mediastinal irradiation of human patients damages endothelial cells with loss of capillaries and ischemia, leading to increase in collagen and fibrous tissue throughout the heart (26). Long-term side effects of mediastinal irradiation include pericarditis, accelerated coronary artery disease, myocardial fibrosis, and valvular injury (26, 93).

The response of the gastrointestinal microcirculation to radiation has received little attention, although this may be an important factor in the development of both the cardiovascular and gastrointestinal subsyndromes. Here, as in other parts of the vascular system, the endothelial cell is one of the most radiosensitive cells (545). The initial expression of radiation injury to the endothelial cells is an increased vascular permeability leading to changes in extracellular environment (24). Following a single irradiation of 10–20 Gy, acute damage to endothelial cells may be detected in 1–5 days. Although not identical, radiation-induced endothelial damage in the lungs, kidney, myocardium, and intestine are similar and characterized by the plasma membrane becoming irregular with projections into the vascular lumen, followed by focal or generalized cytoplasmic swelling that narrows the lumen and may obstruct it completely. Damaged endothelial cells may retract from the basement membrane, causing exposure of the membrane. This results in platelet adhesion, followed by aggregation and the development of thrombosis and vascular occlusion. Damaged capillaries may be manifest by telangiectasia or be replaced by a collagen scar formation (38, 545). When reviewing the response of any microcirculation to irradiation, the variables of total dose, dose rate, type of radiation, variability of the animal model, and postirradiation time of observation must be considered. Irradiation damage to the microcirculation may cause dilation or constriction and either an increase or decrease in blood flow, depending on the above factors (131).

A complication involving the endothelium of intracerebral vessels is the impaired integrity of the blood-brain barrier (BBB) following irradiation (279). Functional alterations of the BBB are manifest in the endothelium by the activation of pinocytotic vesicular transport (162, 655) and in astrocytes by glycogen deposition. The changes in BBB permeability seem to be the result of the intense vesicular response of the endothelium rather than opening of endothelial tight junctions or altered regional blood flow (162, 656). The opening of the BBB has been associated with cerebral vasogenic edema and ischemia (352, 630). However, Gobbel et al. (248) suggest that postirradiation edema-induced vascular compression was not responsible for changes in regional cerebral blood flow observed in dogs.

A reduction in systemic blood pressure can reduce the driving force required to maintain cerebral blood flow and result in cerebral ischemia. The acute irradiationinduced hypotension in the monkey has a

temporal, if not causal, relationship with observed postirradiation reduction in regional cerebral blood flow (134). However,

< previous page page_733 next page >

the reduced cerebral blood flow seen in hippocampi and cortices of rat brains and the hypothalamus of humans 10–24 weeks postirradiation was probably due to the telangiectatic vessels, spreading edema, focal regions of necrosis, and hemorrhage observed in the brains (31, 115, 358, 392).
Several biochemical mediators have been implicated in postirradiation CVD and reduced cerebral blood flow, including histamine, serotonin, opiate peptides, platelet-activating factor, eicosanoids, cyclic nucleotides, and catecholamines (176, 279, 686). Evidence that further implicates histamine includes the finding that plasma histamine increases precipitously in dogs and monkeys after exposure to radiation (126, 132). Infusing histamine into humans resulted in decreased blood pressure and altered cerebral blood flow (8, 602). Pretreatment with antihistamines diminished the cardiovascular effects of irradiation in dogs and monkeys (125, 132), further implicating histamine in postirradiation CVD. However, in another study infusing histamine into humans, Krabbe and Olesen (362) were unable to alter either blood pressure or cerebral blood flow. Likewise, the "histamine hypothesis" does not explain the postirradiation response of the rat (279). Considering that the etiology of postirradiation CVD may vary with the species, perhaps the radiation-induced production or release of other intermediates such as serotonin (129) or free radicals (123) may account for the CVD.

Radiation Effects on Bone, Cartilage, and Muscle

Mature bone is relatively radioresistant and radionecrosis of bone is very rare (437, 585). Many of the effects from irradiation seen in bone may be attributed to a reduction in the number of blood vessels supplying the bone and a decreased blood flow. Radiation damage to bone may be apparent only after months or years following irradiation because of impaired progenitor cell proliferation (161, 702). If the vascular support of the bone can recover, mitotic activity may reappear within 2 weeks after a dose of less than 17.5 Gy. However, osteoradionecrosis, the characteristic late bone injury, often accompanied by osteomyelitis, occurs at a minimum dose of 50 Gy (585).
Radiation-damaged adult bone characteristically displays a decreased ability to resist infection, increased susceptibility to fractures, and poor healing after damage (148, 437). The most common site for osteoradionecrosis and postirradiation complications is the mandible, probably due to its less than abundant blood supply. Clavicles and ribs have an increased incidence of fractures after radiation therapy for breast cancer and tumor-induced fractures of long bones do not heal following radio therapy of approximately 30 Gy (585). Following surgical trauma of rat femur, a dose-dependent radiationinduced delay is seen in new bone formation (25).
Radiation effects on bone are age dependent, with developing bone more sensitive to irradiation than adult bone, with the most pronounced effects seen during organogenesis (437, 585). However, a reduction in number of blood vessels and decreased blood flow are not thought to be the primary causes of reduction in growth. Impaired progenitor cell proliferation may be the reason, because a single dose of 6 Gy has been demonstrated to produce a decrease in mitotic activity.
Internal irradiation of bone by radionuclides may occur through occupational exposure or therapeutic administration (437). A famous case of iatrogenic poisoning was the use of Radithor, a patent medicine used as a metabolic stimulant and aphrodisiac (400). Unfortunately, the victim died of radium poisoning after his skeleton accumulated a dose that may have been greater than 350 Sv.
Probably a more famous case of radioisotope poisoning involved the manufacture of watch dials painted with luminous compounds containing radium (437, 564). The radioisotopes 226Ra and 228Ra were ingested by the women workers when they tipped the brushes with their lips. Isotopes of radium, strontium, and calcium are considered *volume seekers* and ultimately are included in the matrix of bone, whereas plutonium and thorium isotopes are considered *surface seekers* and accumulate on the periosteum and endosteal surfaces of the bone. The accumulation of radium in the bones of the female dial painters correlated with fractures of long bones, coarsening of the trabecular pattern, bone infarcts, and aseptic osteonecrosis. Bone sarcomas and head carcinomas have occurred at a higher than normal rate.
More than 3000 children of the 1495 women dial painters in the basic group were exposed continuously to an alpha and gamma-enhanced radiation environment during their entire period of gestation (564), but no evidence exists to suggest that any effects have occurred.
Growing cartilage is more radiosensitive than growing bone (585). Radiation doses exceeding 18 Gy cause permanent cessation of growth but chondrocytes recover from irradiation less than 10 Gy. Children aged 6 years and under and during puberty are the most vulnerable to irradiation-induced growth depression. Uneven irradiation of the spine results in scoliosis and doses up to 20 Gy result in major deformities. Pronounced growth retardation occurs above 35 Gy.
Mature cartilage, like adult bone, is fairly radioresistant (437, 585). Doses of 60–70 Gy may be tolerated

by mature cartilage if the irradiation is applied over 6–7 weeks. However, if the same dose is given in less than 6 weeks, radionecrosis of the cartilage is to be expected.

Although atrophy of muscle fibers may be seen following fractionated irradiation of 22–54 Gy, doses more than 500 Gy are required to produce acute radionecrosis of skeletal muscle (437). Recently, destructive alterations in muscle proteins were observed after 60Co gamma irradiation as low as 1.0 kGy, with a three-fold decrease in elasticity with doses of 15 kGy (356). Ischemia from a radiation-damaged vascular supply may result in fibrosis, but the extent of muscle damage depends, in part, on whether the entire muscle was exposed, or only a portion.

Radiation Dermatosis

The effects of ionizing radiation on the skin range from erythema to necrosis. The regular sequence of change progresses, as the dose is increased, over two periods, one occurring within 70–120 days and the other from 4 months to years later (22). The first period is characterized by erythema, pigmentation, epilation, dry desquamation, and moist desquamation, whereas the second period is characterized by atrophy, telangiectasia, fibrosis, and necrosis. Erythema, associated with an increased vascular permeability, appears after a single dose of 500 cGy or more and after multiple-dose fractions when the total dose is 1200 cGy or more (22). The first phase of erythema, presumably due to release of vasoactive amines, usually occurs within the first 1–2 days and lasts for a week. The second phase begins at about 10–12 days, reaches a maximum at about 20 days, and lasts for 30–40 days. This second phase is due to vascular damage and increased blood flow (437). The fading of erythema merges with increased pigmentation that may be permanent or fade for days or weeks as dry desquamation proceeds (22, 437). This pigmentation is associated with an increased melanin content of the basal layer.

Some epilation may be noted at 10 days following irradiation with a single dose of 300–600 cGy (22, 437). The evolution and time course of epilation are not dose dependent but epilation may be complete at 4 weeks with hair beginning to return in the second month and continuing for up to a year. However, a single dose of 700 cGy may cause permanent epilation (437). Radiation epilation sensitivity varies with body area; the scalp and beard are the most sensitive, followed by chest, axillary, abdominal, eyebrow, eyelash, and pubic hair.

Dry desquamation, preceded by decreasing erythema and an increasing pigmentation, is characterized by a loss of epidermal cells accompanied by replacement. The cells may scale off or peel off in a sheet, leaving an intact, erythematous epidermal surface. The regenerative capacity usually exceeds the destructive capacity as long as the single dose does not exceed 2000 cGy, or the mul tiple fraction total does not exceed 4500 cGy (22, 437). The reduced proliferative potential and regenerative capacity of irradiated skin cells may be manifest also in an interference with wound healing at doses of 400 cGy or greater (141).

If the dose exceeds the levels allowing regeneration to occur, 2400 cGy for single dose and 5000 cGy for multiple fraction total, the epidermal cell population becomes depleted and the loss of epidermis allows serum leakage and a moist desquamation (22). A bullous-type, moist desquamation may occur with the small blisters tending to coalesce and rupture (437). Blisters may even form beneath the basal layer and the lesion may appear, similar to a second- or third-degree thermal burn. The ruptured blisters may become infected and ulceration may occur. The ulceration is usually associated with a reduction in circulation due to obliterative arteriolar and small artery changes.

Late skin damage may follow the early reactions by week to years or not at all. Alternatively, late skin damage may be manifest without an earlier reaction. The late reaction is, in part, dose dependent and may progress or remain static (22).

In the weeks or months following irradiation at a single dose level of 1700–2400 cGy or a multiple fraction total of 4500–5000 cGy, telangiectasia manifest as superficial, elongated, and dilated blood vessels (22). Radiation-damaged endothelial cells are lost and the microvessels shorten, uncoil, and dilate. A loss of total microvasculature occurs as well as a decrease in functional vessels. The formation of telangiectatic vessels is dose dependent and if the epidermal response is severe, focal keratosis and dysplasia may be present.

Skin changes occurring months to years following irradiation may include increased induration, stiffening, and thickening of the dermis associated with increasing fibrosis (22, 437). Although the onset and formation of fibrosis are dose dependent, once started, fibrosis is progressive with a characteristic proliferation of the small arteries and arterioles. As the degree of fibrosis increases, so does the probability that necrosis will be the result.

Following a single dose of radiation that exceeds 2700 cGy or a multiple fraction total dose greater than 6000 cGy, the end stage of radiation dermatosis is a nonhealing necrosis (22). Radiation-induced necrosis is associated with the progressive loss of the dermal microvasculature and is the end stage to

progressive fibrosis.

Chronic exposure to low-dose (0.015 cGy/s) x-ray for 9–18 months (total doses equal 2.025 and 4.05 cGy) will produce a hyperkeratinization in the rat, along with a decrease in skin concentration of zinc and an increased concentration of iron (111). The chronic sequelae following cutaneous radiation may include telangiectases, radiation keratoses, radiation ulcers, hemangiomas,

splinter hemorrhages in the distal nail bed, lentiginous hyperpigmentation, and severe subcutaneous fibrosis (525). This predominant involvement of the skin is sometimes described as the cutaneous radiation syndrome and can become the characteristic feature of chronic cutaneous irradiation.

The Urinary System

The kidney is relatively radiosensitive compared to other abdominal organs and has a definite but low sensitivity to radiation carcinogenesis (48, 50, 437, 714). The time course for pathophysiological and histopathological changes are dose dependent with a fractionated tolerance dose (TD) of 20–23 Gy for the human kidney (437, 714). The kidneys are considered to be late-reacting organs with the effects of radiation nephropathy appearing months to years after exposure. However, pathological changes in the endothelial cells of the renal microvasculature seen soon after exposure may have long-lasting effects and later tubule and glomeruli degeneration may be secondary to renal ischemia (714). Functional changes seen in mice following fractionated irradiation with x-rays include decreased EDTA clearance, increased urine output, and reduced hematocrit (623).

Reports of patients dying of renal failure and hypertension following therapeutic radiation include subacute changes of intimal necrosis, subendothelial thickening, fibrinoid thrombosis, atrophy of tubules, and replacement with collagen (437). In some instances myointimal proliferation with "foamy cells" and sclerosis of the glomeruli may be seen as well.

There are no human data on acute radiation effects following exposure to single doses (437). However, acute pathological changes seen in animals are hyperemia, increased capillary permeability, interstitial edema, and microvascular endothelial degeneration. These changes are usually followed by occlusive changes in the interlobular arteries and afferent arterioles, reducing blood flow to the nephron. Although in many cases the changes are transient, they may progress to severe diffuse endarteritis and necrotizing vasculitis, which may result in malignant hypertension (714).

Irradiation of pigs with a single 60Co gamma ray dose of 7.8 Gy or higher resulted in a dose-dependent reduction in effective renal plasma flow (ERPF) and glomerular filtration rate (GFR) (553, 554). A normochromic normocytic anemia, with a significant reduction in erythrocyte count, hematocrit, and hemoglobin levels, developed within 6–8 weeks following irradiation. Studies in pigs (552) and mice (620) indicate that the kidney fails to exhibit complete recovery in function following irradiation and that irradiation of a pre viously irradiated kidney is likely to lead to severe renal damage.

Chronic renal dysfunction develops 1–5 years after irradiation and involves a slow evolution of anemia, hypertension, and impairment of renal function (437). The changes are progressive and irreversible, with the treatment usually symptomatic. The pathology is an extension of that seen in short term radiation-induced renal dysfunction. Chronic glomerulonephritis has been reported in subjects participating in the clean-up after the Chernobyl accident (159). The renal pathology was associated with significant changes in the humoral immunity system manifested by increased serum levels of immunoglobulin M, immunoglobulin G, and circulating immune complexes. However, chronic ingestion of drinking water containing uranium (0.004–9 μg/kg body weight) indicated that the proximal tubule, rather than the glomerulus, was the site of injury (727).

The urinary bladder is relatively more radioresistant than the kidney and can usually tolerate 55–60 Gy if the dose is fractionated (437). Bladder complications are seen most often in humans following radiotherapy for cancer of the cervix, prostrate, or bladder (626). The symptoms of acute radiation cystitis appear 4–6 weeks following treatment and include dysuria, nocturia, and increased frequency. Edema, hyperemia, and partial desquamation of the mucosa may be seen. Acute pathological changes in humans are less well documented than those in animals.

Acute changes in the bladders of dogs following irradiation are more pronounced than those seen in rodents (626). Acute and short term pathophysiological changes in the rodent bladder include an increase in urination frequency, reduced bladder volume, decreased compliance of the bladder wall, and diminished pressure during micturition (179, 396, 439, 620). Reirradiation tolerance for late bladder damage was inversely related to the first dose and independent of the interval between treatments (622).

Late-occurring or chronic pathological alterations seen in the urinary bladders of dogs following irradiation are similar to those observed in humans. These include a small, shrunken, and contracted bladder with thick and fibrotic walls (437, 626). There may be multiple areas of edema and telangiectasia and collagen may replace muscular tissue. Squamous metaplasia is common and extensive mucosal ulceration may extend into and beyond the muscle layers. In women treated for cervical carcinoma, this ulceration can lead to vesicovaginal fistulas.

The most radioresistant portion of the urinary system is said to be the ureter (437). However, others

classify the ureter as radiosensitive, with ureteral fibrosis, stenosis, and obstruction following doses of 12.5 Gy (292, 600).

Dogs have been shown to tolerate 17.5-Gy irradiation of the ureter with early injury due to ulceration of the epithelium seen at 25 Gy or above (241). However, histological evidence suggested that chronic injury of the canine ureter seen after 5 years was of vascular etiology.

Radiation-Induced Hepatic Dysfunction

Early literature describing hepatic irradiation contained many contradictory reports concerning the radiosensitivity of the liver (322, 437). The hepatic cells are relatively radioresistant and there is a marked capacity for regeneration following destruction of a large portion of the liver. The liver is able to tolerate fractionated doses of 30–35 Gy over 3–4 weeks, but 35 Gy should not be exceeded (322). Following liver damage the regenerating portion is more radiosensitive (437).

Radiation-induced hepatic injury represents a continuum of clinical, pathological, and radiographic findings, ranging from asymptomatic biochemical changes to fulminant, fatal hepatic failure (322). Radiolesions in the liver are dose dependent in animals (74, 260, 261) and are primarily due to damage to the fine vasculature and connective tissue (234, 235, 322). Characteristic changes following liver irradiation portray a nonspecific form of venous occlusive disease (VOD) resembling pathologically the Budd-Chiari syndrome (322, 437).

Pathological changes that occur following irradiation of the liver to doses greater than 35 Gy may be divided into two stages. The acute phase may begin 2–6 weeks postirradiation and continue for 3–6 months. Clinical signs include hepatomegaly, ascites, jaundice, and elevated serum alkaline phosphatase and serum transaminases (SGOT and SGPT) (74, 234, 322, 437). A distinct decrease in hepatic biotransformation and tolerance to a wide variety of drugs may be seen within a few days postirradiation (480, 711). These clinical manifestations are usually associated with pathological changes that include sinusoidal congestion, occlusion of the central vein, disrupted intrahepatic blood flow, and parenchymal cell damage, atrophy, and necrosis (235, 322, 437).

The late phase of pathological changes and hepatic dysfunction manifests itself more than 6 months postirradiation (322, 437). There is less hepatic congestion, but the signs and symptoms of portal hypertension and right-sided congestive heart failure are manifest. Pathological findings are those of a veno-occlusive process leading to obstruction of hepatic outflow. The centrilobular veins may be obliterated with dense collagen and periportal fibrosis is extensive. The liver appears shrunken and pale, and atrophy due to cell loss is evident. Serum phosphatase and transaminase levels may be slightly elevated or normal but the serum albumin levels are decreased (322, 480). The postirradiation VOD seen in the liver is unique but is similar to conditions caused by various drugs (437).

Radiation Pneumonitis and Pulmonary Fibrosis

The lung is relatively radiosensitive and lesions in the lung are common after any irradiation. Involvement of even a small portion of the thorax results in some degree of pulmonary damage (437, 654).

The lung's response to irradiation is biphasic (231). The first phase, *radiation pneumonitis,* may vary in postirradiation time of onset depending on species, type of radiation, and dose (231, 379, 526, 646). A clinical threshold of 6–7 Gy and a maximum of 8 Gy in a single dose has been suggested for the development of radiation pneumonitis (437).

During the pneumonitis phase functional changes are prominent, including respiratory distress, hypoxemia, increased bronchoalveolar lavage protein, impaired surfactant function, decrease in pulmonary blood flow, and pulmonary hypertension (231, 526, 646). Alveolar epithelium and endothelial damage (379, 526) may be associated with a radiation-induced production of free radicals, release of histamine, leukotriene, and prostaglandin, and the acceleration of lipid peroxidation (78, 253, 501). Pulmonary blood flow problems are indicative of loss of fine vasculature, pulmonary hypertension, right ventricular hypertrophy, and radiation-induced heart failure (54, 599).

The second phase of pulmonary injury, *pulmonary fibrosis,* is seen with or without the presence of pneumonitis (654). Although many patients are asymptomatic during the fibrosis phase, functional changes include arterial hypoxia, a decreased lung volume, decreased compliance, and a reduced maximum breathing capacity. Endothelial and epithelial cell damage may contribute to the development of postirradiation pulmonary fibrosis (526), but the final picture includes replacement of septa by collagen, decreased total alveolar volume, reduced functional microvasculature, and atelectasis (437, 654).

Radiation Effects on Endocrine Function

Many discussions of radiation effects of the endocrine system are limited to the pituitary, thyroid, parathyroid, and adrenal glands (437). Other endocrine glands less often considered are the pineal, pancreas, ovary, and testis. Although most endocrine glands are relatively radioresistant with direct

effects of radiation resulting from injury to the fine vasculature, endocrine abnor-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_737.html[2010/10/28 18:47:20]

malities are relatively common following irradiation of the head and neck (437).

Pineal Gland (Epiphysis)

Melatonin, a hormone that inhibits ovarian and testicular function, is synthesized and secreted by the pineal gland (148, 686). In several species, including human, melatonin synthesis and secretion increase during the dark period of the day and is at a lower level during the daylight hours (228). Pineal synthesis of melatonin in response to the light cycle is altered by radiation, with a decreased synthesis seen in rats following 3.5-Gy exposure (686). However, melatonin has been shown to be radioprotective, with cellular destruction occurring postirradiation in other glands without melatonin (369, 686). Even so, the function of melatonin and the pineal in the radiation response of human remains relatively obscure.

Pituitary Gland (Hypophysis)

Physiologically, the pituitary gland is divisible into two distinct portions: the *anterior pituitary* or the *adenohypophysis,* and the *posterior pituitary* or the *neurohypophysis*. Most control of secretion by the pituitary comes from the *hypothalamus* by either nervous or hormonal signals. Secretion by the anterior pituitary is controlled by hormones secreted within the hypothalamus and transported to the anterior pituitary through the *hypothalamic-hypophysial portal system* of blood vessels. Secretion from the posterior pituitary is controlled by nerve fibers originating in the hypothalamus and terminating in the posterior pituitary. The hypothalamus receives signals from sources throughout the nervous system and uses this information to control secretion of the pituitary hormones (228, 262).

Six important hormones are secreted by the anterior pituitary and play major roles in the control of metabolic functions throughout the body. These six hormones are (i) *growth hormone* (GH), (ii) *adrenocorticotropic hormone* (ACTH, corticotropin), (iii) *thyroid-stimulating hormone* (TSH, thyrotropin), (iv) *prolactin* (luteotropic hormone, LTH), (v) *follicle-stimulating hormone* (FSH), and (vi) *luteinizing hormone* (LH). The two hormones secreted in the posterior pituitary are, (i) *antidiuretic hormone* (vasopressin, ADH), which controls water excretion, and (ii) *oxytocin,* which helps deliver milk from the glands to the nipple and may help in delivery at the end of gestation. ADH and oxytocin are formed in the supraoptic and paraventricular nuclei of the hypothalamus and released from nerve endings in the posterior pituitary (228, 262).

Hypothalamic-pituitary failure is a common complication of cranial and neck irradiation and signs of endocrine deficiency may appear from 1–15 years postirradiation. Some researchers propose that radiation-induced alterations in pituitary function can be attributed to effects of radiation on the hypothalamus (574). There is good evidence that the earliest irradiation damage to the hypothalamic-pituitary axis is at the level of the hypothalamus and that any subject receiving a total irradiation dose of 20 Gy or more to the axis is at risk of hypopituitarism (302, 370, 388). In general, the direct effects of radiation on the hypothalamic-pituitary axis result in hypopituitarism manifested through alterations of the direct actions of the pituitary hormones or through their influence on other endocrine glands (389, 437). Radiation-induced pituitary dysfunction may result in loss of weight, loss of body hair, dry skin, slow pulse, low body temperature, dwarfism in children, genital atrophy, primary amenorrhea in females, failure of sexual development in males, and other dysfunctions associated with the endocrine system (437, 574).

Thyroid

Thyrotropin-releasing hormone (TRH) is secreted by the hypothalamus, and stimulates the release of TSH by pituitary thyrotrophs and the release of *calcitonin* from the C cells of the thyroid. TSH stimulates all thyroidal functions associated with the production and release of *triiodothyronine* (T3) and *tetraiodothyronine* (thyroxine, T4). Through a classic feedback loop, excessive amounts of T3 and T4 suppress the release of TSH by the pituitary (343). Calcitonin, from the C cells or parafollicular cells in the thyroid gland, serves to lower the serum calcium and phosphate levels (228).

Radiation-induced injury of the hypothalamic-pituitary axis may be manifest in the development of hypothyroidism (370, 388). However, direct irradiation of the thyroid gland results in decreased production of T3 and T4 (686). Estimates of irradiation doses required to produce hypothyroidism vary from 2–50 Gy, with thyroid ablation a possible result of the larger doses. Data confirm the high incidence of thyroid dysfunction when the gland is included in the radiation field (19, 202, 273, 505, 718).

Radiation hypothyroidism, through the feedback loop, will result in an increase in TSH secretion by the pituitary. This increase in TSH has been associated with increases in radiation-induced thyroid cancer (686). TSH has also been studied in relation to radiation exposure in children, particularly after the Chernobyl nuclear disaster (249, 538).

The latent period for radiation-induced thyroid cancer was in excess of 15 years following the exposure of the Japanese to the atomic bomb explosions at Hiroshima and Nagasaki. Increased numbers of thyroid cancer cases became evident within just 4 or 5 years following the Chernobyl nuclear accident, however, and continued to increase substantially over the next decade (66, 232). Another interesting aspect of the dynamics of thyroid

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_738.html[2010/10/28 18:47:21]

cancer incidence in that accident was that geographic correlation of thyroid cancers was more closely related to the transportation corridors than to the isopleths of 131I distribution or to population density (517).

Hypothyroidism following 10-Gy irradiation has been associated with a shift in the ratio of the alpha-myosin heavy chain to the beta-myosin heavy chain in the rat heart, a shift usually associated with overload of the heart or aging (686). This change may correspond with a low resting ejection fraction and decreased response to exercise seen in cardiac scans following therapy for Hodgkin's disease (431). Therapy for hyperthyroidism using 131I decreases basal calcitonin levels and may cause C cell deficiency (43). However, this may not be of extreme consequence because total thyroidectomy does not reduce the circulating level of the hormone to zero (228).

The thyroid gland of children is especially vulnerable to the carcinogenic action of ionizing radiation, with one of the highest risk coefficients of any organ and may be the only tissue with convincing evidence for risk at about 0.10 Gy (559). This vulnerability is dramatically illustrated in the 100-fold increase in the number of childhood thyroid cancers observed in heavily contaminated areas of Belarus, Ukraine, and the Bryansk regions of Russia following the accident at the Chernobyl nuclear power plant in 1986 (28, 569).

Parathyroid

In humans there are usually four parathyroid glands embedded in the poles of the thyroid gland. Chief cells in the parathyroid are sensitive to circulating levels of ionized calcium and act to secrete parathyroid hormone (PTH) in response to decreased Ca^{2+} levels. The PTH acts directly on bone to increase bone resorption and mobilize Ca^{2+}. PTH also acts to depress plasma phosphate by increasing phosphate excretion (228).

Although parathyroid cells are relatively resistant to radiation, data confirm an association between hyperparathyroidism and radiation exposure (44, 215, 437). The hyperparathyroidism may be secondary to a depletion of calcium that occurs in mammals following exposure to greater than 3 Gy radiation (686, 687). Other biological responses occurring as a result of irradiation-induced calcium loss include increased blood clotting, bone damage, and convulsions (686).

Adrenal Glands

The endocrine functions of the adrenal glands are associated with the adrenal cortex that produces over 30 different steroids. Only two of these corticosteroids are of exceptional importance to the endocrine function of the adrenal cortex: *aldosterone,* the principal mineralocorticoid and *cortisol,* the principal glucocorticoid. The mineralocorticoids affect the levels of the electrolytes of the extracellular fluids and the glucocorticoids serve to increase blood glucose concentration and affect protein and fat metabolism. Aldosterone secretion is regulated by: (i) potassium ion concentration in extracellular fluid, (ii) renin-angiotensin system, (iii) quantity of sodium in the body, and (iv) ACTH. Secretion of cortisol is controlled almost entirely by ACTH (262).

Radiation-induced changes in the endocrine functions of the adrenal glands are difficult to document because stress factors, including radiation, result in increased release of ACTH from the pituitary (437, 686). ACTH acts on the adrenal cortex stimulating the synthesis and release of aldosterone and cortisol. Even though irradiation of the hypothalamic-pituitary axis produces a defect in ACTH release, adrenal corticosterone levels may be normal or elevated following irradiation, indicating a possible hypersensitivity to the ACTH present or the presence of some other controlling factor (686).

The direct effects of radiation on the adrenal glands are manifest in three phases of activity, each associated with increases in plasma and adrenal corticosterone levels (686). The first phase occurs early postirradiation and the second peak of activity is associated with gastrointestinal damage. The third phase of activity is associated with hematopoietic injury. The increase in activity may be seen following absorbed doses of 15–35 Gy (437, 686). However, if the dose exceeds 35 Gy, normal steroidogenesis may occur under nonstress conditions, but the ability to respond to stress is impaired. Hypertrophy of the adrenal cortex has been demonstrated following irradiation with 15 Gy and higher (172, 686).

Pancreas

The pancreas has both endocrine and exocrine functions. The islets of Langerhans in the pancreas are associated with its endocrine function and act to secrete *insulin* and *glucagon*. Insulin is produced by the beta cells of the islets and glucagon by the alpha cells. The secretion of insulin and glucagon is controlled by the blood glucose concentration. An increase in blood glucose concentration stimulates insulin secretion and inhibits glucagon secretion. A decrease in blood glucose concentration has the opposite effect on both hormones. Insulin acts to increase glucose uptake by most tissues of the body and to stimulate glycogen synthesis. Glucagon stimulates breakdown of hepatic glycogen and adipose

tissue, and also stimulates gluconeogenesis from amino acids. All its actions increase blood glucose concentration (228).

The pancreas is relatively radioresistant compared to the surrounding structures such as the liver and small intestine (437). The islet cells show more postirradiation changes than do the acinous cells, with the beta cells of the islets being more radioresistant than the alpha cells (172, 477). Decreases in insulin and glucagon have been observed following radiotherapy and impaired insulin

secretion and hypoglycemia were seen in rats 4 days after 10-Gy irradiation (576, 686). One month postirradiation the insulin secretion impairment persisted and was accompanied by a reduced number of beta cells.

Ovaries

The two types of ovarian hormones are the *estrogens* and *progestins* and are secreted by the ovaries in response to FSH and LH from the anterior pituitary. FSH and LH, in turn, are secreted by the anterior pituitary in response to luteinizing hormone-releasing hormone (LHRH) from the hypothalamus. By far the most important of the estrogens is *estradiol,* secreted by the theca interna and granulosa cells of the ovarian follicles and by the corpus luteum. The most important progestin is *progesterone,* secreted by the corpus luteum (228, 262).

Ovarian radiation severely reduces the formation of ovarian steroid hormones, even to the point of gonadal failure (389, 691). Estrogen decreases have been seen in humans following radiation doses of 6–100 Gy (389, 686, 691), with large doses producing premature menopause (686). Persistently elevated gonadotrophin levels (FSH and LH) and amenorrhea were associated with the reduced ovarian hormones (389, 691). Abdominal radiation of females in childhood resulted in pubertal failure or premature menopause (690). Neonatal irradiation of rats with 15 cGy produced a decrease in progesterone levels, but not estradiol levels, in adult animals (211).

Testes

The testes secrete several hormones that are called *androgens* because of their masculinizing effects. *Testosterone,* considered to be the most significant testicular androgen, is formed by the interstitial cells of Leydig. As in the female, LHRH from the hypothalamus stimulates secretion of LH by the anterior pituitary. LH in turn stimulates hyperplasia of the Leydig cells and the production of testosterone by these cells (228, 262).

The most dramatic endocrine effect of irradiation of the testis is the increase in FSH and LH secretion from the anterior pituitary (432). FSH levels have been used as an indication of damage to the germinal epithelium. Elevated LH levels associated with normal testosterone levels are indicative of Leydig cell damage (97, 351, 390, 432, 530). This condition may occur at irradiation doses of 2–12 Gy, because damage to the Leydig cells may be compensated by an increase in the number of cells (hyperplasia) in response to the elevated LH (686). Higher doses of irradiation (20–30 Gy) have been shown to produce Leydig cell damage, decrease testosterone production, and increase secretion of LH (246, 432, 597). Of course, sperm cells and the less differentiated cells giving rise to sperm cells are also known to be affected by radiation exposure. For example, ultramorphological sperm characteristics have been altered in workers cleaning up materials containing relatively high levels of radioactivity following the Chernobyl nuclear accident (205).

Nervous System

Radiogenic Effects on Sensory Functioning

Ionizing radiation can be sensed at extremely low levels (698). For instance, the olfactory response threshold to radiation is less than 1.0×10^{-4} Gy and the visual system is sensitive to levels below 5.0×10^{-6} Gy. Ionizing radiation has been shown to be as efficient as light in producing retinal activity (as assessed by the electroretinogram), and the visibility of ionizing radiation is now firmly established (344).

Whereas visual system pathomorphology occurs only at high doses (219), this is not true of visual function disruption. Rats trained to a brightness discrimination task were unable to differentiate shades of gray after 3.6 Gy or to make sensitivity changes after 6 Gy of whole-body x-rays (for review, see 344). Chimpanzees showed impaired accuracy and visual acuity on visual discrimination tests after about 4 Gy of gamma irradiation (551). Kekcheyev (337) reported that 1 day after exposure to 0.3–1.0 Gy of x-rays, temporary decrements in scotopic visual sensitivity were observed in humans. Further, Lenoir (383) found long-term delays (20–36 days) in dark adaptation in patients exposed to 4–62 Gy of x-rays.

Most of the literature suggests that significant hearing changes, unlike vision changes, require massive doses (e.g., 10–70 Gy) of radiation (for review, see 217). Heinz (285), using fractionated head-only exposures of baboons to x-rays, found that 10, 12, and 15 Gy caused a long-term hearing deficit. The highest exposure produced a hearing loss of >90 dB that was not frequency specific. Lower doses of x-rays caused slowly developing, transient elevations in auditory reaction times. Vestibular function may be more radiosensitive than audition. Depression in vestibular function may exist at doses close to the LD_{50}, with higher doses producing longer lasting disruptions than low doses (21).

Although not much literature is available, several reports exist of olfactory, gustatory, and cutaneous sensory changes in patients exposed to therapeutic irradiation (217). Altered taste perception was found

in patients exposed to 36 Gy of x-rays, with a metallic taste being the most common report. Transient changes in taste and olfactory sensitivity were also reported in radiotherapy patients and rats (see review in 344). There is empirical evidence of radiogenic changes in pain perception. While gamma photons produce a dosedependent analgesia in mice (642), data also suggest that X- or gamma rays do not alter the analgesic effects of

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_740.html[2010/10/28 18:47:22]

morphine or the anesthetic effects of halothane in rats, except under a narrow set of experimental conditions (89, 181). Miyachi and colleagues reported that the olfactory system of mice is important in detecting radiation (467) as well as modulating radiation-induced analgesia (465).

Radiogenic Pathology of the Adult Nervous System

A review of standard radiobiology textbooks revealed the common belief that the adult CNS is relatively resistant to damage from ionizing radiation exposure (96). This conclusion was derived, in part, from early clinical reports suggesting that radiation exposures, given to produce some degree of tumor control, produced no immediate morphological effects on the CNS (299). However, this view was changed when it was later shown that the latency period for the appearance of radiation damage in the CNS is simply longer than it is in other organ systems (399). Later interest in the pathogenesis of delayed radiation necrosis in clinical medicine has produced a significant body of literature. Studies of radiation-induced brain damage in patients used computed axial tomography (CAT) technology to confirm CNS abnormalities that are not associated with tumor treatment but that occur because of the radiotherapy (294).

General, although not universal, agreement exists that there is a threshold dose below which no late radiation-induced morphological sequelae in the CNS occur. In laboratory animals, single doses of radiation up to 10 Gy produced no late morphological changes in the brain or spinal cord (281, 385). Necrotic lesions were observed in the forebrain white matter from doses of 15 Gy (92, 100, 338). In human, the "safe" dose has been a topic of considerable debate. Depending on the radiation field size, the threshold for CNS damage was estimated to be 30–40 Gy if the radiation was given in fractions (516); spinal cord damage occurred with fractionated doses as low as 25 Gy (191). The difference between a safe and a pathogenic radiation dose to the brain may be as small as 4.3 Gy (414).

Different topographical regions of the brain may vary in susceptibility to ionizing radiation (667). The most sensitive area is the brain stem (24). The cerebral cortex may be less sensitive than the subcortical structures (385), such as the hypothalamus (720), the optic chiasm, and the dorsal medulla (562). Although radiation lesions occur more frequently in brain white matter (307, 557, 669), the radiosensitivity of white matter also appears to vary from region to region (385). It may be that selective necrosis of white matter is due to the slow reproductive loss of glia or their precursors. The radiosensitivity of certain types of glial cells (beta astrocyte) is well recognized (547, 548). The earliest sign of their damage is widening of the nodes of Ranvier and segmental demyelination as early as 2 weeks after a dose of 5–60 Gy (419).

The technique and end points selected to assess neuropathology can profoundly influence its detection. In proton-irradiated brain tissue stained with silver to detect degenerating neural elements, punctate brain lesions were found within 3 days after as little as 2 Gy (631). The lesions were not detectable with standard hematoxylin and eosin stain. These effects are similar to a multi-infarction syndrome in which the effects of small infarctions accumulate and may become symptomatic. Similarly, Philpott and his associates (528) found that both the synaptic density and the spine length in area CA1 of the hippocampus were lower in mice irradiated with 0.005 or 0.5 Gy of 40Ar. Because this pathology was observed at doses of radiation previously believed to be completely safe, confirmation of these data may profoundly influence our view of the radiosensitivity of brain tissue.

The phenomenon of latent CNS radiation damage with doses above threshold has been well documented (55, 96, 567). The long latent period has led to considerable speculation on the likely pathogenesis of late radiation lesions: (a) radiation may act primarily on the vascular system, with necrosis secondary to edema and ischemia; and (b) radiation may have a primary effect on cells of the neural parenchyma, with vascular lesions exerting a minor influence (299).

The first evidence in support of a vascular hypothesis was obtained when canine brains that had been exposed to x-rays were examined (399). It was suggested that delayed damage of capillary endothelial cells may occur, leading to a breakdown of the blood-brain barrier. This would result in vasogenic edema (163), the elevated pressure-impaired circulation of cerebral spinal fluid, and eventually neuronal and myelin degeneration (100, 101). The finding that hypertension accelerated the appearance of vascular lesions in the brain after irradiation with 10–30 Gy also supports a hypothesis of vascular pathogenesis (300). The occlusive effects of radiation on arterial walls may cause a transient cerebral ischemia (288). Sequential monkey-brain CAT scans revealed brain edema and hydrocephalus that accompanied hypoactivity and the animal's loss of alertness following 20 Gy of radiation (271). Head-only exposure of rabbits to 4, 6, or 8 Gy of x-rays disturbed the blood-brain barrier permeability, which returned to normal after only 6 days (704). The transient nature of the vascular phenomena may partially explain some of the behavioral deficits observed after exposure to intermediate or large doses

of ionizing radiation (426, 601).

Evidence of the direct action of radiation on the parenchymal cells of the nervous system, rather than the indirect effect through the vascular bed, was first provided when brain tissue in irradiated human patients was examined (503). None of the brain lesions could be attributed to vascular damage because they were (a) predominantly

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_741.html[2010/10/28 18:47:23]

Page 742
in white matter and not codistributed with blood vessels, (b) not morphologically typical of ischemic necrosis, and (c) often found without any vascular effects (146, 301, 312, 533, 729). Thus, it appears that direct neuronal or glial mechanisms caused at least some of the observed radiogenic brain lesions.

Alterations in Nervous System Physiology and Functioning

In addition to radiogenic changes in CNS morphology, a variety of changes in parameters of brain function were reported. For example, changes in brain metabolism were reported after very low (0.11–0.24 Gy) doses of ionizing radiation (194). In a more detailed analysis with the 14C-2-deoxyglucose method of measuring local cerebral glucose utilization, a dose of 15 Gy of x-rays was administered to the rat brain (313). Significantly lower rates of glucose use were found in 16 different rat brain structures at 4 days after irradiation and in 25 structures at 4 weeks. Although large radiogenic changes existed in the metabolism of particular brain nuclei, a weighted average rate for the irradiated brains was approximately 15% below that for the controls.

Researchers measured the functional sensitivity of some brain areas and the insensitivity of others (4, 444). The activation of behaviors through electrical stimulation of the lateral hypothalamus (but not of the sepal nucleus or substantia nigra) is still possible after 100 Gy (119, 452). However, years after clinical irradiations, dysfunctions of the hypothalamus are prominent even without evidence of hypothalamic necrosis (427). Local subcortical changes may exist in the reticular formation and account for radiation-induced convulsability of the brain (560, 561). Similarly, postirradiation spike discharges are more likely to be observed in the hippocampal electroencephalograph (EEG) than in the cortical EEG (226). This idea of selective neurosensitivity is further supported by experiments in which electrical recordings were made from individual nerve fibers after irradiation (237). These data reveal a hierarchy of radiosensitivity in which gamma nerve fibers are more sensitive than beta fibers, and alpha nerve fibers are the least sensitive.

Electrophysiology

Measures of electrophysiology illustrate changes in brain function after exposure to ionizing radiation. Several studies were reported in which cortical EEG changes were observed in humans and in animals following doses as low as 0.05 Gy (382). Typically, an initial temporary increase in bioelectric amplitude was followed, within minutes, by a depression. Other investigations frequently needed higher doses of radiation to observe changes in EEG. For example, changes were not seen in EEGs after 0.03–0.04 Gy x-rays, but significant alterations were observed after 2 Gy (266). At a higher dose (15 Gy), monkey cortical EEG abnormalities consisted of the slowing of activity, with an increase in amplitude (562). Spiking and patterns of *grand mal* seizure also occurred. A rapid onset of high-amplitude slow waves (delta waves) seemed to relate to periods of behavioral incapacitation (424). Exposures to 4–6 Gy 60Co gamma radiation appeared to stimulate spontaneous activity in the neocortex, whereas exposures of higher than 9 Gy inhibited all brain activities (474). Many of the liquidators involved in the cleanup of the Chernobyl nuclear accident were reported to have abnormal EEGs (682, 730).

The hippocampus shows significant changes in physiological activities after gamma irradiation with even less than half of the 18-Gy threshold dose needed to produce changes in cortical activities (24, 227). Hippocampal spike discharges were first identified in cats (226) and later confirmed in rabbits (227). This spiking developed soon after irradiation (2–4 Gy x-rays) when no other clinical signs of neurological damage or radiation sickness were present.

The apparent radiosensitivity of the hippocampus and its importance in critical functions, such as learning, memory, and motor performance, have led others to investigate the electrophysiology of this brain area. The firing of hippocampal neurons was found to be altered by exposure to 4 Gy of 60Co gamma radiation in rabbits (40). In guinea pigs exposed to 5 or 10 Gy x-rays, significant changes in hippocampal neuronal function were observed to be time, dose, and dose-rate dependent (523). Higher doses (40–65 Gy x-rays) decreased the ability of hippocampal neurons to generate an action potential (524). In addition, in vitro experiments suggested that spontaneous discharges of hippocampal pacemaker-like neurons were induced by X- and gamma rays at a dose of only 0.08 Gy (522). If confirmed, these data suggest that hippocampal electrophysiology may be the most sensitive measure of functional brain changes after irradiation.

Alterations in the thresholds and patterns for audiogenic and electroconvulsive seizures have been produced by exposing animals to ionizing radiations. Such effects are interpreted as reflecting gross changes in CNS reactivity. Early work with dogs showed that spontaneous seizures sometimes occurred following very large doses of radiation (399). Later experiments confirmed that seizures can be induced by whole-body or head-only exposures to 30–250 Gy in a variety of species. For example, rats were exposed to 5 Gy of X-radiation and the electroconvulsive shock (ECS) threshold was determined for 180

days after irradiation (560). ECS thresholds were reduced in irradiated rats over the entire test period. Later studies (561) reported that considerably lower doses (perhaps as little as 0.01 Gy) also reduced the thresholds for ECS seizures and audiogenic seizures (457, 532).

Page 743
Unlike the CNS, peripheral nerves are quite resistant to the functional alterations produced by ionizing radiation. Most data indicate that peripheral nerves do not show any changes in electrophysiology with x-ray exposures below 100 Gy (577). After higher doses, the action-potential amplitude and the conduction velocity temporarily increase but then gradually decrease (32–35, 577). Also, alpha and beta particles are more destructive to peripheral nerves than gamma or x-rays, and usually cause a monophasic depression of function without the initial enhancement of activity (222, 229, 717). Perhaps the lowest dose of ionizing radiation ever found to produce an alteration in the function of peripheral nerves was reported in a study in which T-shaped preparations of isolated frog sciatic nerves were produced when the nerves were partially divided longitudinally (364). Electrical stimulation was applied to the intact stem of the T, and electrical recordings were made from the ends of the two branches. A small segment of one of the branches was irradiated with 0.04–0.06 Gy of alpha particles, producing a definite decrease in action-potential amplitude and an increase in chronaxy. These results were remarkable because of the much higher doses required to affect these peripheral nerve functions in most other studies.

Paralysis of the hind limbs of animals can result from localized irradiation of the spinal cord. Rabbits developed this paralysis at 4–33 weeks after exposure of the upper thoracic region to 30–110 Gy of X-radiation at 2.5 Gy/day (586). The minimum single exposure found to produce paralysis at 5 months was 20 Gy (587). As in other model systems, the interval between irradiation and the appearance of neurological symptoms decreased as dose increased. For example, 50 Gy of x-rays to the monkey midthoracic spinal cord produced immediate paraplegia, whereas 40 Gy was effective only after a latent period of about 5.5 months (164).

Radiation effects on the electrophysiology of the synapse were first studied using the cat spinal reflex (394, 578–581). These studies showed that excitatory synaptic transmission was significantly increased by x-ray exposures of 4–6 Gy. Synaptic transmission at the upper cervical ganglion of the cat was also facilitated 15–20 min after exposure to 8 Gy of x-rays (481). Both monosynaptic and polysynaptic spinal reflexes were significantly augmented immediately after exposure to 5 Gy of X-radiation. Interestingly, significant augmentation of monosynaptic excitatory postsynaptic potentials (EPSPs) was found immediately after exposure to 6–12 Gy of x-rays, whereas inhibitory postsynaptic potentials (IPSPs) recorded from the same cell were not significantly affected by a 12-Gy exposure (578, 581). Similarly, polysynaptic EPSPs were significantly augmented as the dose increased, whereas the polysynaptic IPSPs were little influenced even by an exposure of 158 Gy. At higher doses (50–200 Gy), ionizing radiation may damage both synaptic and postsynaptic functioning, probably through different molecular mechanisms (649). These radiogenic changes in synaptic transmission may be important factors underlying the complicated functional changes that occur in the CNS following radiation exposures.

Neurochemistry

Ion flow across the neuronal semipermeable membrane is one of the most important mechanisms of postirradiation nervous transmission to be studied. In particular, the flow of sodium ions is believed to be involved in the control of neuronal excitability (99) and apparently can be disrupted after either a very high or very low dose of radiation. A study using the radioactive isotope 24Na compared the sodium intake across the membrane of the squid giant axon before and after exposure to x-rays (563). A significant increase in sodium intake was found to occur during the initial hyperactive period induced by a dose of 500 Gy. These observations were confirmed, although a simultaneous decrease in the rate of sodium extrusion also occurred in a study of frog sciatic nerves that had been irradiated with 1500–2000 Gy of alpha particles (222). As was described earlier, peripheral nerves may be less radiosensitive than CNS neurons and perhaps differ in their radiation response. In a study that used a different technique, the artificially stimulated uptake of sodium into brain synaptosomes was significantly reduced by an ionizing radiation exposure (high-energy electrons or gamma radiation) of 0.1–1000.0 Gy (485, 709).

The brain has been described as a radiosensitive biochemical system (194); in fact, many significant changes in brain neurochemistry have been observed after irradiation. An early study revealed that 1–2 days after an exposure to 3 Gy of X-radiation, neurosecretory granules in the hypophysial-hypothalamic system showed a transient increase in number over the controls (634). A leaking of brain monoamines from the neuronal terminals of rats irradiated with 40 Gy of x-rays was also observed (153). These changes in neuronal structure may correlate with radiogenic alterations of neurotransmitter systems. Normal catecholamine functioning appears to be damaged following exposure to intermediate or high doses of ionizing radiation. After 100 Gy 60Co gamma radiation, a transient disruption in dopamine functioning (similar in some ways to dopamine-receptor blockade) was demonstrated (303). This

radiogenic change in dopaminergic systems is further supported by the finding that a 30-Gy 60Co radiation exposure increased the ability of haloperidol (a dopamine-receptor-blocking drug) to produce cataleptic behavior (328). Relatively low doses of 56Fe (0.1–1.0 Gy) also caused a profound reduction

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_743.html[2010/10/28 18:47:24]

in K+-stimulated dopamine release from perfused striatal slices of rat brain (326, 327). This decrement lasted as long as 180 days postexposure. Radiation-induced effects on dopamine have been correlated in time with behavioral deficits. However, other neuromodulators (such as prostaglandins) also seemed to influence dopaminergic systems to help produce some radiation-induced behavioral changes (328). A transient reduction in the norepinephrine content of a monkey hypothalamus was observed on the day of exposure to 6.6 Gy of gamma radiation. Levels of this neurotransmitter returned to normal 3 days later (367). Similar effects were reported elsewhere (673), but another study found no change in noradrenaline after 8.5 Gy of x-rays (323). An increase in the catecholamine enzyme monoamine oxidase (MAO) was reported within 4 min of exposure and lasted for at least 3 h (98).

A variety of functions involving the neurotransmitter acetylcholine (ACH) are significantly altered by exposure to ionizing radiation. ACH synthesis rapidly increased in the hypothalamus of the rat after as little as 0.02 Gy of beta radiation, but it was inhibited at only slightly higher radiation doses (194). A dose of 4 Gy of 60Co gamma radiation produced a long-term increase in the rate of ACH synthesis in dogs (165). Also, high-affinity choline uptake (a correlate of ACH turnover and release) slowly increased to 24% above control levels 15 min after irradiation with 100 Gy (303). Choline uptake returned to normal by 30 min after exposure. Massive doses of gamma or x-rays (up to 600 Gy) were required to alter brain acetylcholinesterase activity (570), whereas much smaller doses depressed plasma acetylcholinesterase by 30% (397).

Exposure to large doses of ionizing radiation resulted in postirradiation hypotension in monkeys (82, 133, 279), with arterial blood pressure decreasing to less than 50% of normal (184). Postirradiation hypotension also produced a decrease in cerebral blood flow immediately after a single dose of either 25 or 100 Gy of 60Co gamma radiation (106, 107, 128, 130). This hypotension may be responsible for the early transient incapacitation (ETI; see later description) observed after a supralethal dose of ionizing radiation (82, 108, 658). A study with untrained monkeys, whose postirradiation blood pressures were maintained by norepinephrine or other pressor drugs, showed that as long as arterial pressure was above a critical level, the monkeys remained attentive and alert (456). However, in a follow-up study on monkeys trained to perform a task, norepinephrine maintained blood pressure but did not consistently improve performance during the first 30 min after irradiation (660). Other authors observed no close association between blood pressure and behavioral changes (424). Further contrary evidence was obtained from experiments with the spontaneously hypertensive rat (SHR), in which exposure to ionizing radiation reduced the blood pressure of most rats to near-normal levels. However, the irradiated SHRs still showed a significant behavioral deficit after exposure to 100 Gy of high-energy electrons (453). Finally, a significant association was found between the degree of hypotension and the frequency of early performance deficits (EPDs) (82). Still, half the monkeys with a 50% drop in blood pressure did not show behavioral decrements. Thus, even though the relationship between decreased blood pressure and impaired performance is intriguing, simple changes in blood pressure may not be sufficient to explain transient behavioral changes.

The massive release of histamine observed after exposure to a large dose of ionizing radiation was proposed as a mediator of radiogenic hypotension and EPDs (183). Histamine was found to be a very active biogenic amine and putative neurotransmitter located in neurons and mast cells throughout the body, especially around blood vessels (180). Attempts to alter the development of behavioral deficits by treating animals with antihistamines before exposure have been encouraging (73, 182, 184). Monkeys pretreated with chlorpheniramine (H1-receptor blocker) performed better and survived longer after irradiation than did controls (184). Similar benefits were observed in irradiated rats (442). Further, the use of diphenhydramine (a histamine H1-receptor antagonist) inhibited radiation-induced cardiovascular dysfunction (11). Because these antagonists produced only partial relief from radiation effects, it appeared that the histamine hypothesis explained just a portion of the behavioral and physiological deficits observed after radiation exposure (94).

When most animal species were exposed to a sufficiently large dose of ionizing radiation, they exhibited lethargy, hypokinesia, and deficits in performance (109, 344, 452). Because these behaviors seemed similar to those observed after a large dose of morphine, a role was proposed for endogenous opioids (endorphins) in the production of radiation-induced behavioral changes (171, 314). Endogenous morphine-like substances were thought to be released as a reaction to some (5, 254, 283), but not all (413), stressful situations. Like a sufficiently large injection of morphine, endogenous opioids produced lethargy, somnolence, and reduction in behavioral responsiveness (335, 413). Cross-tolerance between endorphins and morphine was demonstrated for a variety of behavioral and physiological measures (81, 632). Because of the similarity of radiation- and opiate-induced symptoms, it is not surprising that

endorphins are involved in some aspects of radiogenic behavioral change. Ionizing radiation produced dose-dependent analgesia in mice, and this radiogenic analgesia was reversed by the opiate antagonist naloxone (642). In another experiment, morphine-induced analgesia of the rat was significantly enhanced 24 h after neutron (but not

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_744.html[2010/10/28 18:47:25]

gamma) irradiation, suggesting some combined delayed effects of endogenous and exogenous analgesics that may be radiation specific (89). Ionizing radiation exposure also attenuated the naloxone-precipitated abstinence syndrome in morphine-dependent rats (152).

Further supporting the hypothesis that endorphins are involved in radiation-induced behavioral change, C57Bl/6J mice exhibited a stereotypic locomotor hyperactivity similar to that observed after morphine injection, after receiving 10–15 Gy of 60Co gamma radiation (451). This radiogenic behavior was reversed by administering naloxone or by pre-exposing the mice to chronically stressful situations, a procedure that produces endorphin tolerance (447). In addition, opiate-experienced mice reduced the self-administration of morphine after irradiation, suggesting that the internal production of an endorphin reduced the requirement for an exogenous opioid compound (450). Biochemical assays also revealed changes in mouse brain beta-endorphin after exposure to ionizing radiation (449). Rats and monkeys had enhanced blood levels of beta-endorphin after irradiation (10, 158), and morphinetolerant rats showed less performance decrement after irradiation than nontolerant subjects (448). Further, naloxone (1 mg/kg) given immediately before exposure to 100 Gy of high-energy electrons significantly attenuated the early behavioral deficits observed in rats (10). Conversely, rats either underwent no change or were made more sensitive to radiation effects after chronic treatment with naloxone on a schedule that increased the number of endorphin receptors (479). However, the manipulation of opioid systems did not produce total control over postirradiation performance deficits. Thus, these data do not suggest an exclusive role for endorphins in radiogenic behavioral change.

BEHAVIORAL EFFECTS OF IONIZING RADIATION

Behavioral and Neurophysiological Eff effects of Prenatal or Neonatal Radiation Exposure

The developing nervous system is significantly more radiosensitive than the adult nervous system, because ionizing radiation, like other teratogenic agents, is apt to affect embryonic cells with high proliferative and metabolic activity (for reviews, see refs. 347, 645). Thus, prenatal exposure to ionizing radiation can cause either organogenic malformations (abnormal closure of the neural tube) or histogenic abnormalities (abnormal proliferation or migration of neurons) (331, 542). Because postnatal neurogenesis may be protracted (256), radiosensitivity of selected brain areas (e.g., the dentate gyrus) may well extend into the neonatal period and even young adulthood in some species. For example, 4 Gy of 60Co gamma radiation caused a significant reduction in synaptic contacts made by hippocampal neurons from 7-day-old rats (272). Early postnatal exposure to 137Cs (5–25 Gy) produced a dose-dependent reduction in myelin synthesis (316).

Other cells important to the functioning of the CNS (e.g., glia) develop early in gestation and continue to divide in the mature organism. Glia guide neuronal migration in the fetal brain and subserve neuronal activity in the adult. The present limit for detection of morphological changes in glia was determined to be as low as 0.2 Gy x-rays (549).

Corresponding behavioral alteration may also be observed after relatively low doses of ionizing radiation if exposure occurs prenatally or soon after birth when many cells are actively dividing or migrating (104). In fact, behavioral indicators were shown to be more sensitive indicators of radiogenic damage than were morphological assessments of brain development (331, 513). Schull and Otake (590) estimated that survivors exposed in utero to the atomic bombings in Hiroshima and Nagasaki exhibited a diminution in intelligence score of 21–27 points/Gy. The highest risk of severe mental retardation occurred during the 8th-15th week of gestation when radiation exposure coincided with the most rapid period of proliferation of neuronal elements and the migration of immature neurons to the cerebral cortex (514, 589).

The behavioral results of prenatal irradiation are discussed in several in-depth reviews (76, 344, 347). Most of the work focuses on motor performance. Prenatal irradiation can cause significant alterations in gait. For example, D'Amato and Hicks (157) observed a hopping locomotion in rats exposed to 1.5 Gy on gestation days 14 and 15. After some initial difficulty, these animals learned to traverse horizontal ladders by adapting their hopping gait to navigate the rungs. Norton and Kimler (498) also found that rats exposed to 1 Gy from 137Cs source on gestation day 15 showed deficits in muscular endurance as measured by their ability to sustain their own weight by hanging from a rod. This behavioral deficit (and others) were correlated with reduced thickness of the cerebral cortex. Fractionation of the radiation dose resulted in less damage to the developing rat cerebral cortex, as measured by postnatal growth, behavioral tests, and morphological assessment (348, 675). Motor deficits were also observed in rats exposed to a low dose (0.6 Gy) on gestation day 16 (73). These animals had difficulty obtaining a reward if they were required to make motor responses in rapid succession (pressing a lever four times in 2 s).

Locomotor hyperactivity was reported after prenatal or perinatal radiation exposure (445). In particular, locomotor activity was enhanced in mice irradiated with 1 Gy 137Cs on gestation day 14 (461), and in rats exposed

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_745.html[2010/10/28 18:47:25]

to 1.25 Gy x-rays on gestation days 14 or 15 (500) as well as 2 Gy x-rays on gestation day 17 (321). Mice exposed to 1.0 Gy 137Cs on day 14 of gestation exhibited higher levels of open-field activity at 19–20 months, but not at 6–7 or 12–13 months of age. Thus, it was concluded that later behavioral changes of prenatally irradiated animals may depend on the age of testing (460).

Other behaviors were also affected by prenatal irradiation. Male mice irradiated with 2 Gy 137Cs on gestation day 14 and tested at 100–135 days of age exhibited increased aggressiveness compared to controls (459). When rats were exposed to 2 Gy X-irradiation on gestation day 17 and tested as adults, they showed enhanced performance on an active avoidance task (requiring movement in a shuttle box) (321, 633), whereas passive avoidance (requiring a freezing response) was impaired (633). Rats exposed to 1.5 Gy 60Co gamma radiation on gestation day 15 exhibited a hyperresponse and delayed habituation on an acoustic startle test (462). Mice receiving 0.1–0.5 Gy x-rays (609) or 0.5 Gy mixed neutron/gamma radiation (175) on gestation day 18 and tested in adulthood showed impairment on a spatial memory task (609). Administration of *d*-amphetamine 10 min before testing as adults, however, alleviated neonatally induced X-irradiation-related deficits in short-term memory of rats (286).

Radiogenic deficits were also observed when animals (previously irradiated in utero) performed tasks with substantial cognitive components (79). In 90-day-old squirrel monkeys exposed to gamma radiation (0.5 or 1 Gy) on gestation days 89–90, the correct responses in visual orientation, discrimination, and reversal learning tasks were significantly lower than that of controls. Decrements in reversal learning persisted undiminished in the irradiated subjects at 2 years of age.

Cognitive dysfunction is a common sequela of cranial radiation therapy (16), particularly in young children treated for acute lymphoblastic leukemia (1, 13, 287, 672). A dose of 24 Gy or more of radiation to the CNS of children under 5 years of age resulted in neurocognitive deficits that, it was reported, may not become apparent until 2–5 years after treatment (478). Young children are most vulnerable due to toxicity to the developing brain. Mullenix and her colleagues, at this writing, are using a neonatal rat model to investigate the use of drugs to mitigate the effects of cranial radiation-induced behavioral deficits (483, 484).

Significant changes in neurotransmitter levels can be measured in brains of rats exposed prenatally (e.g., 0.95 Gy on day 10, 12, or 15 of pregnancy). Marked changes in serotonin and serotonin receptors were found in several brain structures (e.g., hippocampus) and dopamine increased significantly in striatum. There were also significant increases in glutamate, glutamine, and γ-aminobutyric acid (GABA) in cortex, hippocampus, striatum, and thalamus (170). Interestingly, these radiogenic changes in concentrations of neurotransmitters did not correspond with changes in receptor binding (648).

Administration of the N-methyl-D-aspartate (NMDA) receptor antagonist, dizocilpine (MK-801), a glutamate blocker, before neonatal X-irradiation produced a dose-dependent behavioral protection in adult rats with radiation-induced hippocampal damage (446). In a related study, dizocilpine administered 20 min after neonatal 60Co irradiation significantly reduced neuronal damage in rats 6 h after exposure (7).

Behavioral Effects of Adult Radiation Exposure

Naturalistic Behaviors

Naturalistic behaviors (normal parts of an animal's response repertoire) may be altered by radiation exposure. In particular, spontaneous locomotor activity is of interest because this behavior is an important component of many other responses. Jones et al. (324) reported an immediate depression in rat volitional activity-wheel performance following an acute, whole-body dose of 2–7 Gy x-rays. Exposure of rats to 10 Gy high-energy electrons (200) or mice to 10 Gy 60Co gamma radiation (408) resulted in reductions in both horizontal and vertical activity within 1 h of exposure. Radiation-induced hypoactivity has also been reported for a variety of species (for review, see ref. 444). A biphasic locomotor response to radiation exposure (initial decrease, followed by partial recovery and then secondary hypoactivity) was reported for mice (371), and is consistent with the phasic postirradiation clinical symptomatology observed in humans (219).

Exposure to ionizing radiation also produces a dose-dependant reduction in food and water consumption, as well as nausea and vomiting (emesis) in a variety of species (217, 218, 344, 350, 422, 650). Taste-aversion learning (an association between a distinctive taste and radiation-induced malaise) appears to be an especially sensitive indicator of radiation's effects on consummatory behaviors (539, 541). The ED50 for the formation of a taste aversion following 56Fe exposure was only 0.21 Gy (540). Diltiazem, a calcium channel blocker, prevented the onset of radiation-induced taste aversions in rats (482).

Another indicator of gastrointestinal malaise, vomiting, is more likely observed after irradiation with

neutrons than gamma rays (185). Increasing doses of radiation up to 10 Gy (neutron: gamma=0.4), corresponded with the enhanced likelihood of vomiting in the monkey (454). Above 10 Gy, however, the number of monkeys that vomited decreased with increasing dose. The ED50 was approximately 4.5 Gy. Eighty percent

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_746.html[2010/10/28 18:47:26]

of monkeys exposed to mixed neutron/gamma radiation (6 Gy), with a high neutron: gamma ratio of 0.85, vomited in about 45 min (415).

The relationship between vomiting and performance decrement was shown to be complex (721), with irradiated animals rarely vomiting during early behavioral incapacitations (see later discussions). For example, Franz (210), found no relationship between vomiting and early performance deficits in monkeys performing in a physical activity wheel and exposed to less than 50 Gy of mixed neutron/gamma radiation. Animals that were not incapacitated but received the same dose as the incapacitated animals vomited as expected (721, 723). Although these data are revealing, the relationship between radiation-induced vomiting and behavioral deficits remains to be fully elucidated. Serotonin receptor blocking agents were shown to be effective against radiation-induced vomiting (51, 186, 211, 415), and to have relatively few behavioral side effects (53, 54, 68).

Social behaviors have not received much attention from radiobiologists. Miyachi and colleagues reported a paradoxical effect when both sexual (468) and aggressive (466, 469) behavior of mice were reduced following exposure to doses of 0.05–0.15 Gy x-rays but not after higher doses of 0.25–0.35 Gy. Maier and Landauer (407, 408) found that aggressive behaviors were surprisingly robust after 10 Gy (electron or 60Co gamma radiation) and persisted until radiogenic moribund behavior was evident.

Motor Performance

Several studies revealed chronic deterioration of motor performance after doses of radiation at or below the LD50. For example, Stapleton and Curtis (616) reported a long-term (42-week) progressive deterioration of forced wheel running behavior in mice exposed to a LD50 dose of neutron radiation. Kimeldorf et al. (346) also found significant reductions in motor capacity of rats swimming daily to exhaustion before and after exposure to 3–10 Gy of x-rays. Rats performing a task where they had to press a bar 20 times rapidly to avoid footshock showed significant performance decrements following 7.5 Gy 60Co gamma radiation. This decrement persisted for the first 4 weeks after exposure (434). Performance of a physically demanding motor task can alter survival after irradiation. Kimeldorf and Jones (345) reported that swimming to exhaustion before and after X-irradiation significantly reduced rat performance and lowered the LD50 by about 2 Gy. Bogo and colleagues (67, 71) observed a similar phenomenon in rats performing a strenuous, shock-motivated motor task after irradiation.

Learning, Memory, and Cognition

A number of studies suggest learning can be altered by ionizing radiation exposure. Meyerson (438) conditioned rabbits to associate a light and tone stimulus with the respiratory reflex of apnea (cessation of breathing) produced by inhalation of ammonia vapor. A 15-Gy exposure to 60Co gamma radiation produced an absent, or considerably reduced, conditioned apnea response to the light/tone. In contrast, the unconditioned apnea (normal response to ammonia inhalation) was enhanced after irradiation, suggesting the performance capacity of the animal was intact. Another investigator (204) found reduced maze-learning behavior after up to 10 Gy of x-rays. Urmer and Brown (662) also reported a temporary reduction in the ability of rats to reorganize previously learned material after 4 Gy 60Co gamma radiation.

These data support the notion of radiation's effects on some components of learning, and they are consistent with other results (90) suggesting that radiogenic disruptions in behavior may not merely reflect defects in nonassociative factors. Although the predominant work in this field concludes there are postirradiation learning deficits, improved or unaltered learning capacity after irradiation was observed under certain circumstances (for review see ref. 444).

Radiation exposure also may disrupt memory. For example, Wheeler and Hardy (697) reported a significant retrograde amnesia in rats after low doses of electron irradiation. Human memory may be impaired by radiation exposure as well. A few cases of acute retrograde amnesia were reported by people who survived the bombing of Hiroshima (320). Five years after the attack, deficits in memory and intellectual capacity were noted in individuals experiencing radiation sickness (138). Although there may be alternative explanations for these amnesias (e.g., psychological trauma), the data seem consistent with Soviet literature, which reported memory deficits in patients undergoing therapeutic irradiations (319).

Exposure to ionizing radiation is known to alter performance on behavioral tasks requiring nondemanding physical movements and the involvement of functional cognitive processes, such as timing, decision making, or concept formation. For example, Cynomolgus monkeys tested 2–3.5 months after a 20-Gy head-only exposure to X- or gamma rays showed a deficit on a series of discrimination problems (551). Cranial irradiation of rats with single doses of 20 or 25 Gy of x-rays produced delayed impairment of spatial learning and working memory (291). Chimpanzees exhibited a chronic inability to

perform an oddity discrimination task after a whole-body 60Co radiation of 4 Gy (551). Highly-trained complex behavior in laboratory rats can be disrupted with

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_747.html[2010/10/28 18:47:26]

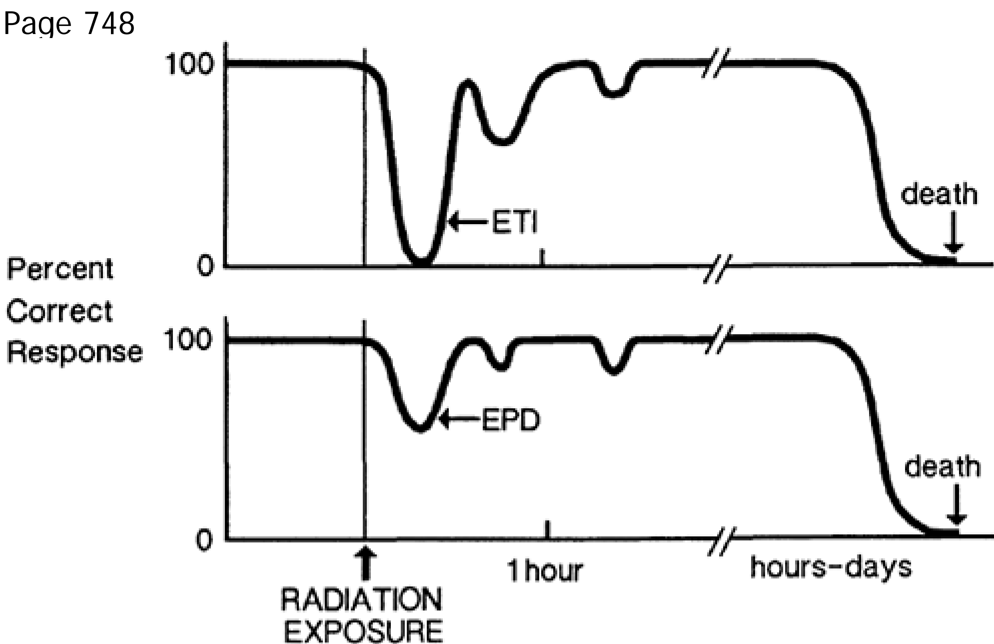

FIG. 15.6. Idealized performance time-courses for acute radiation-induced behavioral decrement. As shown, soon after a sufficiently large dose of radiation, several animal species exhibit an early transient incapacitation (ETI; *upper panel*) or an early performance decrement (EPD; *lower panel*). Subsequent smaller transient deficits may occur approximately 45 min and 4 h later. From References 210, 595, 723.

sublethal levels (4.5–6.75 Gy) of 60Co gamma radiation (433–435, 705, 706). Typically, radiation-induced disruptions in rates and patterns of responding became evident within 1 day of exposure, with a duration of 24–96 h, before returning to pre-exposure levels (435).

Early, Transient Performance Deficits

Transient performance deficits were observed in animals and humans after a large, rapidly delivered dose of ionizing radiation. This response was termed early transient incapacitation (ETI) (590). An idealized, individual ETI profile is shown in the upper part of Figure 15.6. As shown, 5–10 min after radiation exposure, performance rapidly fell to near zero, followed by partial or total recovery 10–15 min later. Delayed ETIs also occurred about 45 min and 4 h after irradiation.

A less severe variant of ETI is early performance decrement (EPD), in which performance is significantly degraded rather than totally suppressed. ETI and EPD were presumed to occur only after supralethal radiation doses in which, following behavioral recovery, death occurred in hours or days. However, some data suggest lower doses may also produce these effects (70).

Early transient performance decrements are modulated by several factors. For instance, the radiation dose required to disrupt behavior is directly related to the requirements of the task being performed. Demanding/complex tasks and tasks that require rapid responding are most disrupted after radiation exposure (for review, see ref. 444). Radiation dose and dose rate can also influence behavioral deficits. When 10 Gy 60Co gamma radiation was given at dose rates from 0.3–1.8/min, it produced 7–81% ETI, respectively (82).

The type of radiation can also differentially influence early transient behavioral deficits. The median effective doses required to disrupt rat performance on an accelerating rotating rod were 61 Gy for 18.6 MeV electrons, 81 Gy for 18.1 MVp Bremsstrahlung, 89 Gy for 1.25 MeV gamma photons, and 98 Gy for 1.67 MeV neutrons. Thus, in contrast to typical lethality data, electrons are significantly more effective than neutrons in producing motor deficits (69).

Several human accidents have involved very large doses of ionizing radiations sufficient to produce behavioral incapacitation. One of these exposures occurred in the early days of fissionable material production at Los Alamos Scientific Laboratory (United States) and resulted in the fatal radiation injury of a worker known as Mr. K. The accident victim received a rapid total body dose of 45 Gy and an estimated upper abdominal dose of 120 Gy of mixed neutrons and gamma radiations (606). During the event, Mr. K either fell or was knocked to the floor. For a short period, he was apparently dazed as he turned his plutonium-mixing apparatus off and then back on again. He was able to run to another room but soon became ataxic and disoriented. He could not stand unaided, was incapacitated, and drifted in and out of consciousness for more than a half hour before he was rushed to a local hospital. Later, Mr.

K regained consciousness and coherence. From 2–30 h after the accident he showed significant behavioral recovery, at some points experiencing euphoria, although his clinical signs were grave. The few hours before his death (35 h postirradiation) were

characterized by irritability, uncooperativeness, mania, and eventually coma. This case is consistent with the animal literature suggesting that a supralethal dose of radiation can produce early transient performance deficits. The physiological and behavioral symptoms associated with acute radiation effects in humans following exposure to doses of 0.5–30 Gy were summarized by Anno and his colleagues (17). The Chernobyl (Ukraine) nuclear reactor accident in 1986 also produced behavioral deficits in personnel attempting to perform duties in high-radiation environments. A firefighter who fought the blaze of the burning reactor core suffered performance deficits and eventually had to withdraw because of radiation exposure (L.Telyatnikov, personal communication, 1987). Another individual exposed to an estimated 2.0–3.5 Gy radiation during the accident was reported to have permanent headaches and vision impairment (64). These human accidents add to the animal literature suggesting sublethal doses of radiation can also induce performance decrements.

Protection Against Radiogenic Behavioral Disruption

Few studies have attempted to normalize behavioral changes observed immediately (up to 24 h) after irradiation. However, as described earlier, antihistamines (i.e., chlorpheniramine) (183, 442) and opiate antagonists (e.g., naloxone) may offer behavioral radioprotection under certain circumstances (446). Other data suggest that estrogens, already known for their ability to reduce the lethal effects of ionizing radiation (642), can reduce the intensity and duration of radiation-induced early transient behavioral deficits in castrated rats trained to perform an avoidance task (441). Currently, no definitive data identify agents capable of completely restoring normal behavior after irradiation-induced changes.

Separate experiments evaluated behavioral toxicity of radioprotectants used for their ability to reduce the lethal effects of irradiation (for reviews, see ref. 87, 411, 695). Most of these radioprotectants act as free-radical scavengers. Early studies administered *n*-decylaminoethanethiosulfuric acid, WR-1607 (10 mg/kg, IV) to monkeys and reported some protection against ETI (598, 659). WR-1607 also extended the life of the subjects beyond that of controls. Today, the leading radioprotective drug is amifostine, formerly known as WR-2721 (635). Although amifostine is available for clinical use in conjunction with radiotherapy (72, 636, 683), the drug's side effects (emesis, hypotension) limit its use (694). Unfortunately, in all species and tasks studied, WR-2721 alone at the best radioprotective doses was behaviorally toxic (that is, it disrupted trained behavior or it reduced locomotor activity), and it potentiated rather than attenuated radiation-induced performance decrements (372, 373, 376, 423). In general, the behavioral toxicity of each of a variety of radioprotective compounds increases in parallel with the radioprotective properties (374, 375).

Psychological Factors of Radiation Exposure

Compared to what we know about the physiological changes brought about by ionizing radiation exposure, we know little about the psychological changes that may also be exhibited. The information we do have is derived from the Japanese atomic bomb experience, human radiation accidents, clinical radiation exposures, and selected animal studies. The data from animal studies reflects behavioral changes resulting from direct effects of radiation on nervous system functioning. The human data reflect additional social, cognitive, and cultural factors that modulate human emotional and psychological phenomena (443).

The animal data have shown, for example, that we can expect motivational changes after sufficiently large doses of ionizing radiation. Rats that initially exerted similar amounts of work to receive rewarding brain stimulation of several different brain nuclei, following exposure to 100 Gy high-energy electrons, stopped working for stimulation of some nuclei (e.g., septum) but continued working for stimulation of the lateral hypothalamus (452). Although these irradiated subjects maintained the capacity to perform barpressing, there was selective modification of their motives such that they chose to exert work to obtain a selected subset of the incentives that were previously all rewarding.

In addition to the physiologically mediated changes in psychological variables that might be revealed by animal studies, human perceptions, interactions, and expectations can combine to produce distinct changes in emotional responses after radiation exposure (136). For example, the nuclear reactor accident in 1979 at Three Mile Island (United States) produced virtually no radiation exposure above background levels. Still, the perceived radiation hazard and the public's "nuclear phobia" evoked long-term emotional, behavioral, and physiological signs of stress (41, 135). The particular fear associated with potential radiation exposure from nuclear power plants seems to be heightened by the fact that ionizing radiation presents an invisible, unfamiliar, man-made (and therefore "unnatural") hazard (572). Interestingly, fear and dread of radiation is lessened when the radiation source is natural and the individual may encounter it in a familiar setting (e.g., his/her own basement), as is the case with radon (693).

Psychological symptoms that have been reported following radiation accidents have been quite dramatic. Fear, anxiety, stress, depression, neurasthenia, and hypochondria were reported as part of the clinical course of persons exposed to radiation during the Chernobyl nuclear power plant accident (150, 151, 244, 336, 651, 676). Deficits in memory, attention, and sensorimotor activities were also observed in these patients (116). Many individuals, and children in particular, reported symptoms of fatigue, pallor, inattention, abdominal pain, and headache as a result of the Chernobyl accident. Ukrainian doctors have labeled this syndrome "vegetative dystonia" (412, 625).

In one of the most highly contaminated areas of Belarus, the results of a large health survey found that the Chernobyl accident caused long-standing loss of health-related quality of life, psychological well-being, and changes in illness behavior (276). Even immigrants from the former Soviet Union were found to have various stress-related disorders many years after leaving the Chernobyl-contaminated areas (151). As might be expected, one of the highest risk groups for these effects were the Chernobyl liquidators, the large number of people who were involved in cleaning up after the accident (676). The clinical significance of this well-documented psychological stress due to the Chernobyl accident, however, is still unknown (240, 277, 677).

The reaction of the public, and even the medical establishment, to radiation accident victims is often characterized as fearful (167). Following the radiation accident in Goiânia, Brazil, in 1987, the radiation exposure victims were subjected to chronic stress (137) and intense ostracism (167). Everyone fled from them, including doctors and nurses who were afraid they would become contaminated themselves (167). These fears are not totally unrealistic. Although the intrinsic radiation produced by a single patient may not be life threatening under these circumstances (139), care of many of these individuals may produce some risk to medical staff.

Summary

Radiation doses below the LD50 (whole body) do not produce permanent sensory changes; however, transient alterations were reported in several modalities at doses from 1–5 Gy. High radiation doses can cause more permanent sensory and perceptual impairments. Radiogenic damage to mature brain morphology may occur after an exposure of less than 15 Gy and is an accepted finding at higher doses. The developing CNS is significantly more sensitive than the mature nervous system to radiation-induced changes in a variety of histological, morphological, and behavioral parameters. Likewise, indicators of brain functioning (e.g., electrophysiology, neurochemistry) are more radiosensitive than are neuroanatomical end points.

Under many circumstances, exposure to ionizing radiations can significantly impede performance. This conclusion is supported by extensive research on experimental animals and limited human experiences. At low to intermediate doses of radiation (up to 10 Gy), performance deficits may be slow in developing and relatively long-lasting. After high doses, the behavioral effects are often rapid (within minutes) and usually abate before the debilitation of chronic radiation sickness begins. These rapid effects can also occur at intermediate doses under certain circumstances.

Not all task performance is equally radiosensitive. Tasks with complex, demanding requirements are more easily disrupted than simple ones. The exception may be found in certain naturalistic behaviors (e.g., eating and drinking behavior) that are also quite radiosensitive. Postirradiation deficits in memory, cognitive ability, and motor performance have been reported. Radiation parameters such as dose, dose rate, and radiation quality can all influence the degree of performance decrement observed.

Many of the pharmacological compounds that protect animals from the lethal effects of ionizing radiation also have severe behavioral effects. In addition to the well-studied physiological and behavioral effects of ionizing radiations, psychological changes (e.g., motivational deficits, anxiety, depression) may also accompany radiation exposure.

CONCLUSION

To assess the average exposure of residents of the United States to ionizing radiation, the National Council on Radiation Protection and Measurements obtained the collective effective dose equivalent from each of six main radiation source categories (492). The collective effective dose equivalent is calculated by multiplying the average per capita effective dose equivalent by the estimated number of people exposed (34). The average effective dose equivalent was then calculated by dividing the collective effective dose equivalent by the total U.S. population. The dose equivalent accounts for differences in relative biological effectiveness by multiplying the absorbed dose by the quality factor while the effective dose equivalent relates the dose equivalent to risk.

As seen in Table 15.2, natural radiation sources contribute 82% of the total average annual effective dose equivalent of 3.6 mSv. By far the largest contribution (55%) is made by radon and its decay

products. Radon in domestic water supplies is also the chief contributor to radiation exposure from consumer products (34).

Although much is written about radiation exposure from nuclear power production and nuclear weapons testing fallout, their contributions are negligible compared to the importance of environmental radon, the largest source of human exposure to ionizing radiation.

Unfortunately, the exception to the rule occurred on April 26, 1986, when the graphite-moderated reactor of Unit No. 4 of the Chernobyl nuclear power station of the former Soviet Union exploded, distributing a large amount of a variety of radionuclids throughout the northern hemisphere in what has been estimated to be the single most costly industrial accident in history (20, 122, 196, 214, 310, 355, 596, 661). One result of the accident is that the contaminated areas of Belarus, Ukraine, and Russia have become a living laboratory of the consequences of radioactive contamination. The ecotoxicological effects of the Chernobyl accident have provided unprecedented observations of radionuclides in the environment and the human health effects are only now becoming evident with additional reports appearing each year. Many of these late reports have been included in this chapter because they are changing what is known about the toxicity of ionizing radiation.

QUESTIONS

1. What processes are involved in the amplification of a single exposure of ionizing radiation to a final end point of biological expression (injury, cancer, or death)?
2. The most important sensitizer of biological tissues to ionizing radiation is________________.
3. Describe how radiation is thought to affect the cell cycle. In which phase of the cell cycle are cells more sensitive to ionizing radiation? In which phase are they more sensitive?
4. Why is a 20 cGy dose of neutron radiation able to result in cataract formation, but not a 20 cGy dose X-radiation? What is the difference between a high LET radiation and a low LET radiation? How are RBE and LET related?
5. The "Law of Bergonie and Tribondeau" put forth in 1906 describes basically why some cells are more sensitive to ionizing radiation than other cells. Why are bone marrow cells and cancer cells sensitive to ionizing radiation?
6. What is the difference between *ionization* and *excitation*? What is a thiol, and how does it interact with a free radical?
7. What is the estimated lethal dose of ionizing radiation for humans? What are the lethality syndromes induced by ionizing radiation? Why can an organism tolerate a larger dose if it is protracted or fractionated, whereas a smaller, acute exposure dose can be lethal?
8. What is the role of apoptosis in response to radiation injury?
9. What have we learned about the effects of human populations living in the relatively highly contaminated areas around the Chernobyl reactor?
10. What is the reality of the actual incidence of birth defects from human exposure to environmental (not medical) radiation?
11. Discuss the behavioral alterations that can occur as a result of prenatal irradiation.
12. What is radiation-induced "early transient incapacitation"?
13. Explain the relatively high incidence of thyroid cancer in Belarus, Ukraine, and Russia in the 1990s.
14. How would a diet high in Brazil nuts contribute to a high body-burden of radionuclides and where in the body would they be concentrated?
15. Explain the difference in the risk of consuming clams, oysters, or scallops from an area contaminated with 60Co and from one contaminated with 90Sr.
16. Explain why denudation of the gastrointestinal mucosa may not be seen with death occurring from the neurovascular syndrome associated with the acute radiation syndrome.
17. Why does the conceptus exhibit the lowest irradiation LD50 of any stage of an organism's life?
18. How does irradiation depress both the specific and nonspecific immune responses?

This chapter provides an overview of laboratory animal science and medicine as it pertains to the use of laboratory animals in toxicologic research. The purpose of this chapter is to familiarize the toxicologist with a number of important issues involving the use of laboratory animals. It is not possible to explore all subjects that pertain to this topic nor to comprehensively review the subjects in this chapter. The reader is urged to seek more detail in the references provided and to consult specialists in the field for more information.

Veterinarians with specialized training in laboratory animal medicine have played important supporting roles in institutions conducting toxicologic research. Much of the information used by them, as well as by other laboratory animal professionals and toxicologists, has been developed as a direct result of studies initiated in the basic sciences and in toxicology. By their very nature, toxicologic studies have required

an understanding of the biological characteristics and needs of laboratory animals as well as an understanding of those variables that impact the performance of laboratory animals in research studies. Our understanding of laboratory animals is far from complete and is further complicated by the fact that there is a wide variety of species from which the toxicologist may choose. Species such as mice and rats are extensively used with vast amounts of background data available and whose biological characteristics have been well explored. Less commonly used species, such as guinea pigs, hamsters, and gerbils, have proportionally less known about them and much less published background data available. Recent efforts by a number of organizations to collect, analyze, and publish background

data on a continuing basis in a variety of disciplines is helping to extend the knowledge of certain laboratory animal species (48, 191).

Like any field, the quality of published information can vary widely. Moreover, a lot of dogma and unsubstantiated opinion still remain in the literature. A number of recommended practices still cannot be well substantiated in the peer-reviewed literature. In designing experimental protocols, the toxicologist should familiarize himself with the important variables associated with the animals that will be used in the study and put in place measures to control or to account for these variables.

In today's society the use of animals for research purposes has become a subject of much public discussion. Over the last century, economically developed countries in which most biomedical research takes place have moved further and further away from extensive public involvement with agricultural use of animals and replaced that exposure with zoos, family pets, and stylized animal characters in the media. This has caused society to reexamine their relationship with animals both in agriculture and in research. This has resulted in the development of laws, regulations, and guidelines that address responsible animal use. As with any controversial subject, there are those who find the measures taken to be insufficient and who advocate even further change through dialogue, protest, or terrorism. In many cases, radical views and actions are based on misinformation and a basic distrust of large organizations and governments. There are, however, a large number of individuals concerned with animal welfare who are open-minded and seek to strike an appropriate balance in their use in biomedical research. They, like the members of the research community, are focused on responsible animal usage, including, where appropriate, refinement, reduction, and replacement (the three Rs) of laboratory animals (278).

Responsible animal usage has stimulated interest in in vitro alternatives, computer-simulated models, and computer structure-activity analyses to screen for appropriate drug candidates. These efforts have had some limited success in the initial stages of the drug discovery process. They have not yet led to suitable in vitro replacements for most animal usage in toxicologic studies, especially product registration studies, nor do they appear likely to in the near future. This failure to develop complete substitutes for intact living organisms used in research is likely due to the complex interactions that exist on organ, cellular, and subcellular levels. A suitable replacement for animals will need to reliably predict biological phenomena, including being at least as good and consistent a model for risk assessment in humans as animals. Such systems will need to be extensively validated and accepted by regulatory bodies as suitable substitutes.

The use of animals in toxicologic research cannot be taken for granted. With their use comes responsibilities not only to adherence to institutional, governmental, and scientific principles, policies, laws, regulations, and guidelines, but also an ethical and moral responsibility for the lives of the animals used in research or product manufacture. Each researcher is also responsible for the quality of the care that they receive, the appropriateness of their use, and the minimization or relief of pain.

REGULATIONS, LAWS, POLICIES, AND GUIDELINES

The use of animals in research, as well as the assurance that provisions for appropriate animal welfare and care have been made, is controlled by a number of mechanisms. These can be subdivided into two general categories: (1) guidelines and recommendations and (2) laws and regulations. In addition, policies can be developed for either of these two categories. For example, guidelines or recommendations that are not regulated by law can be included in an overall policy that governs institutional activities or eligibility for receiving funding. Moreover, policies may also be created and used as accepted interpretations of regulations developed in response to laws.

Laws and regulations require mandatory compliance. Failure to meet the requirements imposed by laws or regulations usually is attended by legal actions that may culminate in fines, revocation of the ability to conduct animal-related activities, or imprisonment. In the case of laboratory animals in the United States, laws and regulations are administered by the U.S. Department of Agriculture (USDA). The regulatory body is charged with conducting regular inspections and registering all facilities using laboratory animals. Within the USDA, the Animal Plant and Health Inspection Service (APHIS) is charged with making such inspections. Within APHIS, the Regulatory Enforcement and Animal Care (REAC) unit is responsible for enforcing regulations developed in response to legislation governing the use of laboratory animals in research.

Guidelines and recommendations usually are developed by independent groups with expertise in one or more aspects of laboratory animal science and medicine. Compliance with guidelines or recommendations is voluntary; however, failure to do so may be accompanied by undesirable consequences, such as denial of funding by government institutions, inability to have data accepted for

publication, or inability to use data in submissions filed in response to mandated regulatory processes (81, 95). Compliance with such guidelines or recommendations may need to be assured through filing of legally binding statements, submission of regular reports to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_774.html[2010/10/28 18:47:44]

agencies tracking such activities, or by participation in a voluntary accreditation program, such as the one conducted by the Association for Assessment and Accreditation of Laboratory Animal Care-International (AAALAC), who uses a combination of regular reports and periodic site visits to evaluate programs, facilities, and animal care.

INTERNATIONAL ASSURANCE AND REGULATION OF LABORATORY ANIMAL CARE AND USE

The existence and complexity of laws, regulations, guidelines, and recommendations governing the care and use of laboratory animals varies significantly between countries. In general, nonindustrial countries commonly do not have laws governing the use of animals in research, teaching, or product production. Some international guidelines or recommendations may be followed, but only to the extent that they impact the suitability of work or products for registration in other countries.

Countries within the European Economic Union use certain minimal standards developed through the council of Europe and subsequently ratified by member states. These standards are used as the basis for individual country laws and regulations that meet or exceed these standards. Variation between countries can exist. Within an individual country, standards may be different for different aspects of animal production and use. These laws and standards may apply not only to research use of animals, but also to transportation of animals, as well as their exhibition and sale for other purposes. A comprehensive review of all of these items, including regulatory oversight and reporting requirements, are beyond the scope of this text. There are, however, a few important considerations that should be mentioned.

Protocol review at either a regional or national level is a common component of the regulations governing animal care and use in European countries. Protocols must fulfill certain guidelines and provide a detailed description of the proposed study as well as supporting rationale. There can be a significant time lag from the submission of a protocol until a decision is made by reviewers.

Licensing of researchers to perform specific procedures is often a component of the regulatory process. Guidelines for credentials and training are specified and licensing is often done on an individual procedure basis.

Evaluation of programs and unannounced inspection of facilities is often done through a government agency. Activities can be suspended based on findings of inspections, and licensure can be revoked. Other penalties can be imposed, depending on the country.

Unlike the United States, all species used in research conducted in Europe are covered by guidelines and regulations. Differences can exist between countries in terms of acceptable care and use practices, and there should be no assumption that all of these standards are similar to ones in the United States or elsewhere. The level of detail and the emphasis on various topics can differ substantially from United States standards.

The Federated European Laboratory Animal Science Associations (FELASA) is a European consortium of laboratory animal science associations. FELASA has developed a number of recommendations for health monitoring, accreditation of animal diagnostic laboratories, and other topics that can impact the quality of laboratory animals used in toxicologic research. Adherence to these recommendations is voluntary, and in some cases the recommendations may differ from accepted practices in other parts of the world.

In Canada, the Canadian Council on Laboratory Animal Care has produced guidelines for the care and use of laboratory animals. Inspection of research facilities is conducted on a voluntary basis by this organization (46, 47). In Japan, efforts are underway to develop voluntary guidelines similar to those in the United States, Canada, and Europe. Laws governing the use of laboratory animals in research are not present.

UNITED STATES LAWS, REGULATIONS, GUIDELINES, RECOMMENDATIONS, AND POLICIES

The Animal Welfare Act

Regulation of laboratory animals used in research is governed by the Laboratory Animal Welfare Act of 1966, Public Law (P.L. 89–544) (308). The USDA administers the Animal Welfare Act. The act establishes legal requirements for research facilities to provide certain minimum standards for the care of animals in research. In 1970, the Laboratory Animal Welfare Act was amended (P.L. 91–579), at which time its name was changed to the Animal Welfare Act because the term *animal* was changed to include all warm-blooded animals except those used for food or fiber (308). The 1970 Act required registration of research facilities as well as annual reporting requirements. Animals used for other purposes, such as exhibition or as pets, were also extended coverage.

The Act was again amended in 1976 (P.L. 94–279) in order to include more rigorous standards for transportation of animals (308). The Act was last amended in 1985 (P.L. 99–198) to include requirements for exercising dogs, the psychological well being of nonhuman primates, the consideration

of alternative procedures to ones causing pain or distress, training of personnel, and the establishment of an institutional animal care and use committee of specified composition (308).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_775.html[2010/10/28 18:47:44]

Page 776

In response to the Act and its amendments, a series of regulations and policies were developed. Significant additions to the regulations were added in, August of 1989, April of 1990, and February of 1991 that refined definitions and terms: set standards for humane handling, care, treatment, and transportation; set space requirements for primary enclosures for guinea pigs, rabbits, and hamsters; set standards for humane handling, care, treatment, and transportation of dogs, cats, and nonhuman primates (188, 280). The regulations promulgated by the USDA in response to the Animal Welfare Act are published in the Code of Federal Regulations (CFR, Title 9, Chapter A, Parts I, II, and III) (71). Currently, the Animal Welfare Act covers dogs, cats, nonhuman primates, hamsters, guinea pigs, rabbits, marine mammals, and any other domestic animal, as well as those animals normally found in the wild, used in research, testing, exhibition, experimentation, or kept as pets. The term *animal,* as defined in the Animal Welfare Act, has excluded rats, mice, and birds, as well as horses and other farm animals used or intended for use as food or fiber or for the use in improving animal nutrition, breeding, or production. Farm animals, including horses, are covered under the Animal Welfare Act if they are used for nonagricultural research or exhibition, which includes biomedical research (167).

Extension of the USDA's regulation of laboratory animals to include rats, mice, and birds is viewed by some as being inevitable. This exclusion was still in place as of 2000 and reflects a balancing of public and private resources with the perceived benefits to regulating these excluded species. The effects on toxicologic research in the United States of extension of regulation to these species is hard to predict, as these species represent the bulk of all animals used in such research, and hence the limited degree of experience with the present regulatory process may not be predictive of the consequences of extended coverage. Given the USDA's broad mandate for regulation, which includes transportation, the cost to the government and feasibility of providing the appropriate level of regulation of this activity may be difficult to accurately estimate.

The Guide for the Care and Use of Laboratory Animals

In the United States, the primary set of guidelines for the care and use of laboratory animals is *The Guide for the Care and Use of Laboratory Animals (The Guide)* which was developed by the National Academy of Sciences (243). *The Guide* is used as the primary reference for voluntary assurance and accrediting bodies, such as National Institutes of Health's Office for Laboratory Animal Welfare (OLAW) and AAALAC. This document was first prepared and published in 1963 and has been revised many times since. The last revision (1996) made substantial changes in the overall approach to laboratory animal care and use.

The Guide cannot be appropriately used without an institutional animal care and use committee (222, 243). The institutional animal care and use committee (IACUC) is appointed by the chief executive officer of the institution and is advisory to him. The committee, in order to comply with both the requirements of *The Guide* and USDA regulations, should include a doctor of veterinary medicine who is certified or has training or experience in laboratory animal science and medicine or in the use of the species used in research at the institution. The committee should also have at least one practicing scientist experienced in research involving animals as well as one non-scientist who may or may not be employed by the institution. The committee should also include at least one public member to represent community interest with respect to care and use of laboratory animals. The public member should not be affiliated with the institution, should not be an immediate family member of anyone affiliated with the institution, and should not be involved in the use of laboratory animals.

The IACUC is responsible for the evaluation and oversight of the institution's animal care and use program and all related issues set forth in *The Guide*. The IACUC must inspect all animal facilities used by the institution's research program as well as carry out a programmatic review of the research program every 6 months. The committee subsequently analyzes the findings of their inspection and review and prepares a written report for the responsible institutional official that details their findings and any recommendations for action. The institutional official, in turn, must address any major deficiencies detailed in the report by providing a reasonable plan for corrective action and a timetable. The committee must maintain written records of their meetings and all decisions taken. Meetings should be held as frequently as necessary to accomplish their designated tasks, but it should meet at a minimum of twice a year. A mechanism for documenting minority views must also be provided.

An essential component of the IACUC's activity is the review and approval of animal use protocols prior to the initiation of research or other animal-related activities. Protocols submitted for committee review should be complete with respect to their description of the animal care and use components. To prepare a protocol that covers all of the areas and issues posed both by the USDA regulations and *The Guide* recommendations, the IACUC often requires the researcher to place the protocol in a standard format

that may take the form of a questionnaire. Topics such as surgery, anesthesia, provision of analgesics during painful procedures, determination of acceptable alternatives to painful procedures, methods of euthanasia, criteria for

ending an animal's participation in a study or procedure, and assurance of appropriate housing and care practices are some of the many issues that are considered in the review of any protocol.

The Guide charges the users of research animals with the responsibility of achieving specific outcomes with respect to the care and use of animals, but by using a performance-based approach, provides latitude as to how these outcomes are achieved (222). Performance standards define an outcome in detail and provide criteria for assessing that outcome. They do not restrict the method by which this outcome is achieved. This is in contrast to engineering standards that do not provide for interpretation and modification of prescribed methods or procedures in the event that acceptable alternative methods are available or usual circumstances occur. The IACUC is charged with developing additional performance standards to evaluate alternative methods to achieve specified outcomes and is given the latitude to modify recommendations set forth in *The Guide* based on performance data generated by researchers to establish the adequacy of alternative methods.

Public Health Service Policy

The administration and coordination of the Public Health Services' (PHS) policy on Humane Care and Use of Laboratory Animals (The Policy) is administered by the OLAW (264). This policy requires institutions to establish and maintain proper measures to assure the appropriate care and use of all animals involved in research, research training, and biological testing activities conducted or supported by the PHS. The policy also endorses a set of principles developed by the Interagency Research Animal Committee (IRAC) that covers the use and care of vertebrate animals used in testing, research, and training (140).

The Policy applies to all research supported by PHS and places a heavy emphasis on training of all personnel involved in the care and use of animals in a research setting. The Policy requires the biannual preparation and evaluation of reports by the IACUC on the institution's programs and facilities that involve animal activities. The Policy requires the filing of an assurance statement with OLAW binding the institution to The Policy as well as to the use of *The Guide* as a basis for developing and implementing institutional programs for activities involving animals. OLAW also requires the filing of annual reports by the institution. Achieving and maintaining such assurance is a prerequisite for consideration for funding of activities supported by the PHS, and, by extension, may be adopted by agencies as an essential criteria for consideration for funding.

THE ASSOCIATION FOR ASSESSMENT AND ACCREDITATION OF LABORATORY ANIMAL CARE-INTERNATIONAL

The Association for Assessment and Accreditation of Laboratory Animal Care-International is a voluntary organization that was founded in 1965. AAALAC is a United States-based nonprofit corporation with national and international representation from scientific and educational organizations and whose goal is to promote responsible and high-quality animal care and use by research institutions through the use of a peer-review process. The organization assists institutions in developing and improving programs and facilities for animal care and use.

The accreditation process is designed to assess the institution's conformance with appropriate locally applicable guidelines, recommendations, laws, regulations, and policies, as well as evaluate the program's ability to ensure that animals' health and well-being is safeguarded by institutional processes and operational procedures. In the United States, AAALAC uses *The Guide* as its primary standard, outside of the United States, applicable regulations, laws, and other standards are used that are relevant to that country and the institution's activities.

The accreditation process is confidential. It is initiated by the submission of a comprehensive application that is designed to provide a detailed description of the institution's animal programs and facilities. An initial site visit is made by two or more individuals representing AAALAC, one of whom may be an ad hoc consultant with special expertise in programmatic areas that are relevant to the institution applying for accreditation. Following the initial site visit, a written report is filed along with recommendations. This is then considered by AAALAC's Council on Accreditation to determine if the facility should be granted accreditation. Facilities that have obtained accreditation are revisited every 3 years to determine eligibility to maintain continued accreditation. Annual reports of activities that include programmatic changes and animal usage must be filed.

The achievement of AAALAC accreditation may reduce the level of some reporting requirements for organizations such as OLAW but does not substitute for assurances filed with OLAW or with other requirements set forth in laws, or regulations. AAALAC does not publish separate guidelines or recommendations nor set other standards that are at variance with existing guidelines, laws, or regulations. Lists of institutions that have obtained full accreditation status are regularly published by

AAALAC; however, details of an institution's accreditation history are not made available.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_777.html[2010/10/28 18:47:45]

DESIGN AND CONSTRUCTION OF ANIMAL HOUSING FACILITIES

The design of animal facilities for biomedical research has evolved over time, as have housing methods for research animals. Key design concepts that have survived the test of time relate to practical matters, such as waste handling, sanitation, investigator access, disease control, and the size of the animal species being used. There is no universally accepted design for animal facilities, nor is it likely that any one given design for animal holding rooms will be appropriate for all species of animals that could be used in toxicologic research. Some reviews on the subject of animal facilities design have been prepared, as have design process considerations for specialized support facilities for research animals (9, 17, 45, 61, 64, 79, 113, 128, 130, 139, 174, 189, 222, 223, 258, 281, 297, 345).

The process of animal facility design requires, first and foremost, a clear documentation of the intended type and extent of use of the facility based on past and present toxicologic research programs, as well as a reasonable expectation of the growth of these programs over a period of 5–10 years (345). In considering the intended facility use, the numbers and types of animals by species must be determined. While studies involving small rodent species often consume the bulk of toxicologic research that use animals, other larger species are frequently used and may have to be provided for within a facility. As an alternative, facilities may be designed to accommodate only a limited range of species, with housing and usage of other species being outsourced to other facilities that are more well suited to their maintenance.

Once the level of usage has been determined, specialized requirements—such as the use of biohazardous material requiring biocontainment facilities, a surgical program requiring facilities for aseptic procedures, specialized radiographic or imaging facilities, diet preparation facilities, specialized equipment or procedures facilities, diagnostic laboratory or necropsy facilities, or other specialized spaces requiring specific types of equipment or housing for animals used in toxicologic research—need to be identified, as well as the level of activity that will occur in such facilities. Because these types of facilities often represent a significant cost to construct and operate, as well as consume considerable amounts of floor space, it is important to carefully assess the realistic level of activity projected for such facilities.

The animal care program itself must also be carefully described, and details of the program should be well worked out before the design process is started. The reason for this is that the location of various components of the animal facility will depend greatly on the methodology and equipment to be used in the animal care program. For example, caging and racking within an ani mal facility must move to and from cage washing facilities. The amount of labor involved in performing these tasks is directly related to the distance of various components of the animal housing facility from the cage washing facilities, as is the opportunity for transmission of adventitious microorganisms potentially infecting one group of animals spreading to others through the cage sanitation process. The frequency of cage changing, as well as the location in which cages are changed and the equipment required for such cage changing, will also influence the amount of storage space and operational space within individual animals rooms and storage space within the cage washing facility.

The type of caging and the level of bioexclusion of microorganisms to be achieved for certain groups of animals maintained within the animal research facility will also dictate many aspects of the design (344). Facilities housing large numbers of rodents in microisolation cages or in flexible or semirigid isolators will require different designs and operational practices, as compared to facilities that use conventional opencage housing.

Animal holding rooms can be classified into two general types. The first *rodent housing,* is characterized by smaller rooms with few fixtures whose design is orientated toward removal of caging from the room for sanitation and perhaps sterilization (204, 222, 223, 344). Such rooms usually have a small sink for hand washing and, if microisolation caging is used, will often be outfitted with a laminar flow hood designed for cage changing using aseptic technique. When microisolation caging is used, such rooms commonly have only a single access door to minimize traffic through the room. Such rooms generally do not contain floor drains or specialized equipment for spraying water under pressure during cleaning of the room or equipment.

The second type of animal holding room is designed to handle larger caging or runs/pens to house animals the size of rabbits or larger (222). Such rooms are equipped with floor drains or some form of trough-drain system to allow in-the-room cleaning of cage components or, in the case of rabbits, the frequent spillage of liquids onto the floor (222). While some caging may be removed from the room and taken to the cage washing area for more complete sanitation, certain components of daily cleaning are carried out within the room itself.

With the exception of some aspects of cage washing, most routine animal care activities are conducted manually, making the animal facility labor intensive. Moreover, the use of the animal facility by researchers also involves regular and often complex manual manipulations of the animals for study purposes. For this reason, distances between support facilities and the animal holding areas need to be minimized and provisions often need to be made within the design for strategic location of procedural rooms and, where appropriate,

critical laboratory facilities necessary to conduct determinations that cannot be adequately conducted at great distances from the animal facility. The final design of an animal facility needs to be analyzed for efficient traffic flow of both personnel and equipment. It is important that both users of the animal facility, as well as the animal care staff, analyze the design with respect to day-to-day tasks that need to be accomplished and the distances that need to be traversed by both people and equipment to accomplish these tasks.

Over time, two common arrangements of rooms within animal facilities have been developed (129). These have evolved from considerations of material and personnel flow patterns and from the use of specialized equipment and practices to control the spread of adventitious organisms and contaminants within animal facilities (288). The most common facility is one with a single corridor design. Often, these are a result of renovation of existing space originally designed for laboratory use in which a single corridor that provides both entrance and exit from individual animal rooms was necessitated by the available space and location or, in some cases, by the need to isolate specialized animal facilities, such as microbiological barriers, in which shower and clothing change for people and decontamination of supplies are required. Such barriered animal facilities have become popular in support of some forms of toxicologic research, especially those programs using transgenic or immunologically deficient animals (344).

The other common animal facility arrangement is the dual-corridor system orientated toward cage-washing facilities. In such a system, one or more corridors (i.e., supply or clean) that exit the clean side of the cage wash connect with one of two entrance doors to each animal room. The second door in each room is used to remove caging and other material for return through a second corridor (i.e., return or dirty) to the cage wash by a separate entrance in which soiled caging is collected for subsequent sanitation. This design addresses logical flow of personnel and equipment through animal rooms so as not to have crossing of equipment within common corridors. It is unlikely that such a design provides any realistic measure of disease control by preventing cross contamination, given the many other opportunities for movement of microorganisms through a facility (344). Commonly, there is an air pressure gradient maintained across the two-corridor system such that the supply corridor (clean) is at the highest pressure, with the next highest air pressure being maintained in the animal room and the lowest pressure in the return (dirty) corridor (222, 223).

Because toxicologic research programs are dynamic and requirements can change dramatically over time, most animal facility designs try to maintain some degree of flexibility (113). Animal rooms designed for large or small animals usually are designed with a minimum of fixed equipment or specialized mechanical systems. This allows easy conversion from use of one species to another within the categories of large or small animal holding areas. Because most caging and racking is more efficiently located along the perimeter of the room, rectangular designs for animal holding rooms are common, as they maximize wall space while minimizing the relatively unused center of the room space. It is the usual practice to keep the center of the room clear in order to allow the orderly movement of equipment, supplies, and personnel through the room and for the conduct of animal care and research functions. For this reason, common designs, whether on a one- or two-corridor system, usually have rooms with widths ranging from 12–14 feet and lengths of 18–20 feet.

Room sizes are also often dictated by building support structures which, in the case of multiple story buildings, result in support columns that must be maintained throughout the structure. The spacing of these columns is done at fixed intervals, and hence room dimensions must conform to these constraints in order to prevent columns being placed within the room itself rather than in the walls.

Animal rooms, as well as support areas, are often grouped by function in order to minimize the distance traveled between related functions and to minimize the runs of piping and other mechanical services between areas that have higher use of mechanical services (e.g., cage washing, operating rooms, and holding rooms containing dogs rooms, etc.).

In considering the design of animal research facilities, provisions must be made for future expansion (113). Certain items, such as cage washing facilities, specialized laboratories, and surgical facilities, are expensive components of new construction, and during the initial construction of animal facilities may be able to be designed with sufficient capacity to support larger animal populations through logical expansion of the existing building. In developing a design for an animal facility, planners often include provisions for future expansion that must be considered in the animal facility design so that architectural and mechanical barriers are not put in place.

An overriding concern in the construction of animal facilities is the need to frequently clean and disinfect surfaces within the facility. In some cases, specialized components of the animal facility, such as

biocontainment facilities or bioexclusion facilities, must also have the capability of being totally disinfected or sterilized using aggressive agents that would be unsuitable for use in the rest of the animal facility. Many of the construction guidelines presented below are directed at making such tasks and routine cleaning/sanitization easier to accomplish on a regular basis, as well as preventing

the deterioration of the physical facilities by conducting such practices. By their very nature, these guidelines are quite general and are based on common practices and equipment.

Floors

Opinion varies greatly on the best type of flooring to use for animal facilities. Each type of flooring has its advantages and disadvantages, and it is likely that no perfect flooring exists for animal facilities. Those materials showing the greatest chemical resistance often have difficulties withstanding impact with sharp or heavy objects, whereas those showing the greatest resistance to mechanical damage may have difficulty in resisting the action of chemicals and urine. To withstand repeated sanitation and spillage of urine and water, floors must be moisture resistant and nonabsorbent (222). They should be resistant to the action of hot water, cleaning, agents, disinfectants, urine, and other biological materials. They should be relatively smooth for ease of cleaning, although they may need to have textured surfaces, especially in high moisture areas, where injury to personnel could occur from slipping or to animals, such as hoof stock kept in pens that are regularly cleaned with water.

Floors need to be impact resistant and capable of supporting equipment, cage racks, and other stored items without becoming cracked, pitted, or gouged. To facilitate cleaning, there should be a minimum number of joints in which debris can become entrapped. Materials that have proved particularly satisfactory in many applications are epoxy aggregates, sealed concrete, and other hardened synthetic-based aggregates. Correct surface preparation of subflooring and experienced installation of the flooring itself is essential to its satisfactory performance.

Drains

Drains in animal facilities are a source of contention, but in some areas they are a necessity. Facilities housing large animals require drains. Floors in such areas should be gently sloped toward the drain, and in the case of pens and runs, a dedicated trough for draining should be considered. In such applications, drainage should be designed to allow rapid removal of water and the drying of surfaces to minimize elevation of humidity. Where waste is to be flushed down drains along with water, larger-diameter drains (4 inches or greater) should be considered (222). To facilitate this process, rim-flush drains that sweep waste collected from trough drainage systems down into drain pipes through coarse basket strainers fitted in the drains minimize maintenance considerations. It is critical in the sanitation program for animal facilities that drain traps be kept filled with liquid and that drains that are not in use for long periods of time be capped and sealed to prevent backflow of sewage, gases, and other contaminants into the animal holding areas.

Floor drains are not essential in all animals rooms. Rooms containing rodents can be sanitized better by using alternative cleaning methods, such as wet vacuuming or mopping with cleaning compounds and disinfectants.

Walls and Ceilings

Walls within animal facilities need to be frequently sanitized and therefore should be moisture resistant and nonabsorbent. They also should be free of cracks or holes, such as those created by unsealed utility penetrations. Junctions of the walls with the ceiling and floors, as well as to themselves, should be adequately caulked or otherwise sealed to prevent build-up of debris and harborage for insects. The construction of the walls can take a variety of forms, with masonry being the most durable; however, other wall construction materials may be more appropriate in certain situations. The surface coating of walls should be resistant to the chemical actions of disinfectants and cleaning agents and should have significant resistance to abrasion and impact. Common wall materials acceptable in other applications, such as painted gypsum board, may not prove satisfactory in some animal facility applications given their low impact resistance and significant damage when exposed to moisture. Some of the difficulties associated with certain wall construction materials can be overcome by protecting the wall surfaces through the use of strategically placed guard rails or bull-nosed curbing on the wall to floor junction in order to minimize the impact of equipment on the walls (222).

Like walls, ceilings should be smooth and moisture resistant. Their surfaces should be capable of withstanding detergents and disinfectants and be free of imperfect junctions that would allow the build-up of debris and harborage of insects. Generally, suspended ceilings are undesirable in animal facilities unless they are constructed in such a way as to be readily sanitizable and free of imperfect junctions or penetrations. Gypsum board that has been appropriately sealed and finished with a durable coating or concrete that has been smoothed and sealed or painted are the most appropriate and long-lasting choices for ceilings.

Doors to Animal Rooms

Doors to animal rooms should be constructed of and/or coated with materials that resist corrosion and

are amenable to disinfection. They should be appropri

ately sealed/gasketted and fitted with door sweeps to ensure adequate sealing with the floor and the door frames. This is critical in preventing the incursion of pests and the uncontrolled movement of air and particulates beneath and around the door. Doors should be self-closing and should open into animal rooms to prevent injury to personnel or damage to equipment moving in hallways. For safety reasons, viewing windows often are appropriate, but the ability to cover the viewing windows in certain instances where close control of lighting is required must be considered.

Doors should be equipped with recessed or shielded handles (to prevent damage from equipment) and equipped with metal or plastic strike plates to prevent equipment damage to the surfaces. Generally, doors that are 42 in ×84 in accommodate most animal equipment; however, larger doors may be required in certain portions of the animal facilities. Consideration of room level security is important in order to limit access to animals on study or in areas in which bioexclusion or biocontainment is required. This is best accomplished with mechanical or electrical locks; however, it is important that doors be designed to be opened from the inside without a key for emergency egress purposes.

Corridors

Corridors within the animal facility are the principal means of access to animal rooms and support areas. For this reason, they should be wide enough to accommodate the movement of equipment and personnel and be amenable to cleaning and disinfection. Generally, a width of 6–8 feet is sufficient for most purposes (45, 130, 222). All of the considerations reviewed for floors, walls, and ceilings generally apply to corridors; however, suspended ceilings are more commonly used in corridors due to the need to access mechanical fixtures, such as electrical conduits and plumbing. It is good practice to ensure that access to water lines, drain pipes, and other utilities supporting animal rooms is available through panels or chases in the corridor outside of the animal rooms. Wall-mounted equipment in the corridors, such as, telephones, fire extinguishers, fire alarms, and record-keeping stations, should be recessed or installed high enough to prevent damage from movement of equipment and personnel through the corridors.

Support Areas

In addition to the basic animal rooms, animal facilities must incorporate certain facilities and equipment to support the basic day-to-day investigational and animal care needs, including locker rooms often coupled with shower facilities and restrooms, break areas, cage washing facilities, feed and bedding storage, waste handling and storage areas, supply rooms, general storage areas, administrative offices, and procedural rooms for use by researchers. Although a comprehensive treatment of these areas will not be addressed in this chapter, information regarding their essential features and construction can be found elsewhere (222). A few essential points, however, bear emphasizing.

In designing animal facilities, it is a common error to undersize these facilities in comparison to the intended animal populations or types of research to be conducted. This is especially true of support areas that experience cyclic levels of activity during their normal function. For example, locker rooms where clothing change occurs are intensively used at the beginning and end of work days and, depending on the type of facility, may also experience significant activity at lunch time or during designated break periods. Commonly, the size of these areas are designed to only allow a few individuals to use them at a single time, requiring adaptation of schedules and difficulty in access to the facility during certain times throughout the day.

Such areas must be large enough to accommodate reasonable numbers of employees and to provide sufficient locker space for clothing and storage of uniforms and other supplies. If mandatory showering is required, as is the case in some barriered facilities, sufficient capacity for showers or other clothing change functions must be provided. From a programmatic standpoint, the necessity of certain types of clothing change or the use of certain items of disposable clothing, such as face masks or shoe covers, must be carefully considered. The more complex the clothing change, the more complex the support area for it needs to be. Similarly, if reusable garments are used, adequate storage space and provisions for laundering/disinfection must be made. If clothing changes are to be made at the level of the animal holding room, such changing must be provided for in the design of the facility and must be logical if it is to be routinely followed. Human use support areas, such as lockers rooms and break areas or administrative offices, should be separated from animal areas. They are often located at the periphery of the animal facility and are used as control points for entrance into the animal facility.

The location of support areas is dictated by the location of utilities and certain architectural features in the animal facility. For example, cage-washing facilities are usually located at the end of corridors servicing groups of animal rooms. These facilities usually are located near storage areas for bedding, feed, and building utility runs in order to minimize distances traveled and construction costs. Waste-

handling facilities are commonly located near cage-washing facilities, and such facilities usually are located within a convenient distance of loading docks or other exterior entrances.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_781.html[2010/10/28 18:47:48]

Cage-washing facilities are designed to allow the use of chemical detergents, and disinfectants, and large amounts of hot water. Regular cleaning of room surfaces is an essential part of their operation, and the facility must be designed to allow this to be easily done. Large amounts of equipment are moved in and out of these facilities and they must be big enough to accommodate such equipment both in process and for short periods of storage. Substantial quantities of heat and moist air are generated within the cage-washing facility, and Heating, Ventillation, and Air Conditioning (HVAC) systems must be designed to accommodate these loads.
Often the locations of support areas are selected to decrease the amount of unwanted noise and traffic passing by animal rooms (222). Noise-producing areas, such as, mechanical rooms, waste processing areas, and cage washers, are often grouped together and separated from animal holding areas by noise traps, such as air locks or sound-proofing surfaces. Commonly, species of animals such as dogs, nonhuman primates, and swine that produce loud vocalizations as part of their normal behavior are also separated from other holding areas that contain more noise-sensitive animals, such as rodents, by using similar building concepts. Housing for these noise-producing species is commonly located near support areas that produce noise, although the two functions usually are separated by air locks, doors, or other means.
Areas used for storage of feed are kept at lower environmental temperatures than other areas to inhibit decomposition of liable ingredients and the development of immature forms of insect pests that may contaminate the packaging or the feed.

Specialized Components of Animal Facilities

Within animal facilities there is often a need for specialized structures and equipment to support toxicologic research. Such facilities include, but are not limited to, barrier facilities for maintenance of animals in defined microbiological states, bio-containment facilities for housing and manipulation of animals exposed to biohazardous materials, surgical facilities, imaging facilities, necropsy facilities, and facilities for conducting diagnostic tests on animals.

Barrier Facilities/Barrier Rooms

Barrier facilities or individual barrier rooms may be used in toxicologic research for either bioexclusion or biocontainment purposes (344). Most commonly, they are used for bioexclusion. In this role, the room or series of rooms (facility) is separated from other components of the animal facility using a variety of construction methodologies in a manner to prevent undesirable microorganisms from entering the room whether carried on personnel, equipment, or materials. Barrier rooms are composed of durable materials that are impervious to liquids and free of unsealed penetrations. Personnel entry is usually through a lock system requiring progressive decontamination of personnel by shower and/or clothing change. Air to the room is independently supplied and HEPA (high efficiency particulate air) filtered. Water supplied to the area is independently decontaminated or sterilized, and provisions are available to provide sterilized feed, bedding, and other supplies for use in the room. Waste is removed using processes designed to prevent the incursion of unwanted microorganisms during the removal process.
Most commonly, multiple methods of introducing supplies and equipment are built into the barrier room. Generally, a through-the-wall autoclave is provided with sufficient capacity to handle reasonably large loads of materials. For maintenance purposes, the autoclave should be able to be serviced from the outside of the barrier. It is essential that the autoclave be calibrated and validated based on material types and load configurations. This calibration and validation should be done on a regular basis, usually yearly. The use of cumulative heat-sensitive or biological indicators placed at one or two points in a load to be autoclaved is not sufficient to confirm adequate disinfection or sterilization.
In addition to autoclaves for processing large volumes of materials that are unaffected or marginally affected by heat, alternative means of disinfection need to be provided for introduction of heat-sensitive materials into the barrier room. This is accomplished by using a double-door chamber into which materials that have been immersed in disinfectants can be placed and additional disinfectants sprayed into the port before it is closed and the materials held for an appropriate contact time. Once this chemical disinfectant process has taken place, materials can be removed from the chamber using the inside door for subsequent use in the barrier. As with autoclaving procedures, the use of chemical disinfectants must be calibrated so that adequate application procedures, concentrations and contact times are maintained. Materials processed by this method must be wrapped in coverings that can withstand the application of the disinfectants, and the materials inside of the packaging must be already disinfected by alternative means. For example, vacuum-packed containers of paper products that have been previously gamma irradiated could be introduced using this spray-port method.
Introduction of personnel into barrier rooms poses the greatest risk to the microbiological integrity of the

barrier room. Because it is impossible to adequately disinfect the external surfaces of people, it is necessary to place a barrier between them and the animals maintained within the room. This is accomplished in an entry lock system by an orderly removal of clothing and a re-gowning in

attire that covers the body surfaces using materials that are known to be free of organisms of concern (344).

The entry lock system usually is composed of four compartments. The first compartment, often referred to as an insect lock or air pressure lock, is used for static pressure control between other areas of the animal facility and the lock system. This first lock also serves to inhibit the passage of insects into the other more critical areas of the lock system. It is also used in some instances for storage of external clothing, such as jackets or for depositing of shoes worn elsewhere in the animal facility. The next component of the lock system is an undress lock, where all clothing is removed and placed in lockers or other suitable receptacles. Presumably, most, if not all, of the contamination that might be associated with personnel resides on such clothing.

At this point in the lock system there are two possible configurations. The first is termed the *wet entry system* and involves personnel taking a water shower. Depending on the rigors of the barrier facility, an electromechanical system may be placed in this portion of the lock system to assure that a wet shower is actually taken. This consists of interlocking doors with timers requiring a wait period within the shower area and an electrical interface with the water supply to the showers such that the release timers are only activated if water has run for a certain period of time. In the end, even such rigorous measures do not necessarily guarantee that the shower taken is adequate or consistent (344).

Although some decontamination of external surfaces of a person's body may occur to varying degrees with a shower, the principal rationale for the use of the water shower is to ensure that street clothing has been removed. There are a number of disadvantages associated with a shower in a lock entry system, including the time constraints associated with the entry procedure and the considerable requirements for expendable supplies used in the showering procedure. Following the shower, a separate room is provided for drying off and putting on a sterile/disinfected uniform, including components such as a cap, mask, gloves, and dedicated footwear. Once these procedures have been conducted, entrance into the barrier room can be made. Leaving the barrier room, the employee reverses the process; however, often the showering step is omitted.

Because the wet entry system is quite cumbersome and limits the number of employees that can enter the barrier facility at any given time, a new methodology, the *dry entry system,* has gained increasing favor in many research settings. This latter method involves the elimination of the wet shower and a direct change in a separate room from the de-gowning portion of the lock into clean, disinfected clothing as occurs in the last step of the wet entry system. Once clothed in appropriate attire, the employee enters an air shower that blows high-velocity HEPA-filtered air across all surfaces, removing particulates that may contain any contaminants imparted to the external surfaces of the gown during the changing process. Doors to the air shower are electrically interlocked, requiring that a full cycle be completed before the employee can enter the barrier room. Upon exiting the barrier room, all aspects of the process, including the air shower, are again used by the employee in reverse order.

In addition to time savings, the air shower also provides a very positive interlock between the barrier room and the lock system, preventing escape of any animals that have left their cages and any potential incursion of insects or other pests into the barrier room through the lock system. The air shower also greatly decreases the amount of particulates that are brought out of the barrier room serving as a safeguard for the general animal facility should a contamination occur within the barrier (344).

As a general rule, cage washing and other sanitation procedures are done within the barrier facilities rather than bringing caging materials out of the barrier. This is because each transport of materials across the barrier entails some degree of risk of introduction of unwanted microorganisms. Movement of caging from the barrier through common animal facility hallways and cage-washing facilities also poses a risk of contamination that may or may not be eliminated by the disinfection processes used to re-enter such materials into the barrier. Similarly, rigidly operated barrier rooms generally do not provide for personnel break areas or other administrative support facilities within the barrier. Such areas tend to encourage removal of protective clothing and inappropriate activities given the microbiological status of the barrier.

Barrier rooms are expensive to operate and are best used to house large numbers of animals or to house large animals under defined microbiological conditions. Due to their large size and the large amount of materials that must be passed across the barrier to maintain it, failure of the barrier, as measured by changes in the microbiological status of the animals maintained within the barrier, are common. Once an unwanted microorganism gains entrance, all animals within the barrier room are at risk of becoming contaminated unless some form of secondary containment/bioexclusion system (e.g., microisolation cages) is also used within the barrier (344). This practice is seldom done, given the high

cost of such secondary bioexclusion practices.

Biohazard Containment Facilities

Toxicologic research often requires the use of biohazardous materials in conjunction with animals. Such materials, whether they be toxic, carcinogenic, radioactive, or infectious, must be contained within a very

Table 16.1 Comparison of conventional animal care strategies with strategies for containing biohazards

	Recommended Animal Care Practices Strategies *a*	Biocontainment Strategies *b*	Rationale
Air flow	High	Low	A
Cage cleaning	Frequent	Infrequent	A
Bedding change	Frequent	Infrequent	A
Equipment/supplies	Reusable	Disposable	B
Animal handling	Frequent	Infrequent	C

a Practices or approaches commonly used to provide a clean, healthful environment for animals.
b Practices or approaches designed to minimize the release of hazardous materials from animals or their environment.
A—The more potentially contaminated material generated, the more that has to be decontaminated and the greater chance for error; B—processing materials for reuse while assuming proper decontamination is costly, logistically difficult, and has the potential for error; C—the more handling, the greater risk for personnel injury and contamination.

defined space and handled appropriately so as not to contaminate other animals or personnel (287, 288). It is a popular misconception that barrier facilities or certain other bioexclusion systems, such as microisolation cages, provide, in normal operation, the necessary level of biocontainment to meet most research needs. In general, good biocontainment practices are at odds with recommended animal husbandry and bioexclusion techniques (Table 16.1).

The type of biocontainment facilities required when using biohazardous materials in animals depends on the nature of the hazard and the level of risk posed by it. In the case of infectious materials, the Centers for Disease Control and Prevention (CDC) has published classification systems for microorganisms and have described biological containment facilities of four increasingly secure types designated BL I through BL IV (49, 50). These safety practices and equipment used in conjunction with these increasing levels of hazards are designed to prevent inadvertent transmission or release of contaminants from the work area. These guidelines set standards for reducing aerosol generation, hazards associated with sharp objects, the use of protective clothing, and the operational standards for hoods and other devices used to manipulate infected materials, including animals.

Biocontainment facilities are resource intensive, and their complexity increases with the size of the animals that must be contained at the various biosafety levels. Laboratory animals the size of rabbits or larger require considerable housing space and generate large amounts of waste material that is potentially contaminated. Normal operations of cleaning and disinfection, as well as removal of biological materials, including animal carcasses, may require complex systems, making such facilities expensive to construct and to operate. For this reason, those institutions conducting limited work in larger species involving biohazardous materials may choose to subcontract these tasks to more specialized institutions in which the volume of such work is sufficient to justify the cost of constructing and maintaining these facilities.

Most institutions, however, use cage-level biocontainment practices for studies involving rodents and other small mammals. Studies up through biosafety level III can be conducted in small, dedicated facilities using these systems, along with appropriate safety practices.

Surgical Facilities

The use of surgically altered animals is common in toxicologic research. Traditionally, the complexity of surgical procedures performed and the nature of the surgical facilities required was directly proportional to the body size of the animals being used. Small laboratory animals, such as rats and mice, were often used in studies in which relatively simple procedures involving organ removal was required. The facilities to support these operative procedures were not complex in nature, and often a portion of a multipurpose area could be used on a temporary basis for conducting them. Larger, more complex procedures were usually reserved for animals the size of dogs or domestic farm animals in which the operative field was much larger, and techniques used in human surgery, as well as the necessary support equipment, such as specialized gas anesthesia machines, bypass equipment, and specialized imaging equipment used in human or traditional veterinary practice, could be employed. Such procedures require a much larger, dedicated surgical facility.

A few guidelines for the design and construction of surgical facilities for use in biomedical research have been published (222, 345). In general, such facilities should have certain basic components, including the following:

an operating room in which the surgical procedure is conducted, a postoperative care area separated from the rest of the surgical facility in which animals can recover from the surgical procedure, an animal preparation area in which the animal can be anesthetized and other preoperative procedures conducted, an instrument and supply preparation area in which materials can be assembled, cleaned, and sterilized, and a surgeon preparation area in which personnel can decontaminate their hands and then become suitably attired for the surgical procedure. A number of support facilities may also be associated with the surgical facility, including a diagnostic laboratory, imaging facilities, and specialized procedure rooms to study instrumented animals.

Existing guidelines for surgical facilities endeavor to separate the various functions to be performed by physical barriers, distance, or by separating the functions in time (222). Surfaces and construction materials used in surgical suites are designed to be easily cleaned and disinfected (222). Air provided to surgical facilities should be highly filtered to remove microorganisms and should be appropriately conditioned in order to minimize temperature loss or gain during the surgical procedure. Such facilities are utility intensive and often require access to medical gases and emergency power.

Over the last decade there has been a trend toward miniaturization, and complex surgical procedures in support of toxicologic research can now be performed on small laboratory rodents. The increasing commercial availability of vascular catheterized rodents, coupled with numerous types of telemetry devices for continuous recording of a variety of parameters from nonrestrained animals, has provided new possibilities in drug discovery research. If sufficient numbers of such procedures are to be done, a dedicated surgical facility for rodents may be appropriate. In general, many of the same components used in traditional large-animal surgical facilities are present in such a dedicated rodent surgical facility but may not be separated by physical barriers, such as walls.

Due to the small size of the operative field in small laboratory animals, the use of sterile instrument tip procedures can be coupled with chemical disinfectants and table-top dry heat sterilizers to allow large numbers of rodents to be instrumented aseptically during a single surgical session (38, 68, 69). To facilitate these procedures, horizontal laminar-flow hoods may be used to minimize the chance of cross-contamination between animals during surgery and to reduce bacteriologic contamination of the operative site.

Unlike traditional operative procedures on larger animals, most rodent surgery is done in a sitting position and may require the use of magnification and focused, point-source illumination. For this reason, provision needs to be made for adequate counter space and electrical power. Because multiple groups of animals may be used in the surgical facility over a short period of time, preoperative and postoperative housing is often done in cage-level bioexclusion systems to prevent the chance of cross-contamination between projects when animals are used from either different sources of supply or from different locations employing different housing methods.

It is important to remember that the size of the animal or the species of the animal does not diminish the need to maintain appropriate aseptic procedures during the course of the surgical manipulation (20, 32), however, due to the small size of rodents and the relatively small operative field, the risk of postoperative infection and the need for maintaining large areas of a facility in an aseptic fashion is greatly reduced (68, 69).

CAGING AND HOUSING SYSTEMS

The environment of the laboratory animals used in toxicologic research is classified by levels of enclosure. A cage, pen, or stall is the immediate limit of an animal's environment in a research facility and is designated as its *primary* enclosure. The room or space in which the primary enclosure is located is termed the *secondary enclosure* (222).

The environmental conditions in the secondary enclosure influence, but do not control, the environment in the primary enclosure (26, 354, 355). The animal's primary enclosure needs to allow the animal to remain clean and dry, securely contain the animal so that it cannot escape and cannot injure itself while residing in the enclosure, and provide adequate ventilation in order to allow the animal a sufficient supply of fresh air that is appropriately conditioned to meet its needs. The primary enclosure should also provide for normal physiologic and behavioral requirements of the animals, including reproduction, movement, urination, and defecation. It should allow for investigator access and observation of the animal with minimal disturbance. In addition to these criteria, primary enclosures may also be used to maintain the animal and its environment in a specified microbiological status. This bioexclusion function requires a heavy reliance on aseptic techniques and personnel training, as well as significant support facilities, including autoclaves and laminar flow work stations (222, 344).

Primary Enclosures

Microisolation Cages

A microisolation cage consists of a plastic cage bottom with stainless steel wire top that is covered by a fitted plastic lid containing a filter. The filter usually is comprised of a polyester material that can be fabricated to

different thickness and average pore sizes. In principle, by the lid remaining on the cage, all ventilation occurs through the filter, which excludes particulates that may contain infectious organisms. As long as all manipulations are done in a laminar flow work station and all materials are adequately disinfected/sterilized, unwanted organisms should be excluded from the cage environment (72). For this to occur, all manipulations must be done using aseptic technique. Such systems can be effective in maintaining a particular microbiological status of animals, but manipulation of the animals may be cumbersome for researchers and requires that all research equipment and materials undergo rigorous and frequent decontamination/sterilization to ensure the microbiological status of the animals.

Microisolation caging does provide some disadvantages in terms of the environmental conditions surrounding the animals. Because static microisolation caging does not allow for significant air exchange through the filter, the concentration of water vapor, gases, and heat may build up to levels well above that in the secondary enclosure (161, 298). Another difficulty may be related to the adequacy of the fit of the filtered top to the cage itself. Studies have shown that in some designs of microisolator caging, ventilation occurs under the lip of the cage, allowing unfiltered air to migrate across cage surfaces and other areas into the sterilized environment of the microisolation cage (202, 203). This makes practices such as the exterior disinfection of the cage before manipulation in the change station an important consideration. In addition, when manipulating such caging in a laminar flow change station, it is important to minimize the amount of materials in the change station, as laminar flow air upon striking objects will eddy for a distance of at least three times the diameter of the object struck, causing unwanted movement of air between materials in the station, resulting in airborne cross-contamination (349).

Ventilated Microisolation Caging

To address some of the difficulties associated with poor ventilation of static microisolation caging, specialized racks designed to hold the microisolation caging have been developed. These racks contain a source of HEPA-filtered air that is discharged either through a nozzle directly into the cage or through small openings above the filter cage top such that the air moves directly into the cage. Ventilated racks usually have a mechanism for removing air from the cage, often through a port located directly above the filter top in another area of microisolation cage. This exhaust air is either HEPA filtered and discharged into the room or directly dis charged into the room exhaust system. These racks usually are equipped with individual blowers to pass air through the HEPA filters and generate the necessary static pressure. Like static microisolation caging, ventilated microisolators must be handled and managed in the same manner as static microisolation caging using aseptic technique, sterilized materials, and laminar flow change stations (344).

By supplying relatively large volumes of conditioned fresh air to each cage, heat, moisture, and gas contaminant build-up is minimized. Bedding materials often stay drier than in unventilated cages, improving the animal's environment and allowing longer intervals between bedding changes (222). In the case of the ventilated microisolation cage, it is important to remember that the cage itself is maintained under positive pressure with respect to the secondary enclosure. As such, if hazardous or unwanted microorganisms are present within any given cage, the possibility exists of leakage of contaminants to surfaces outside of the cage through leakage in individual filter tops. For this reason, ventilated microisolation cages must be used with caution in research involving the use of hazardous materials (344).

Conventional Caging

By far the most commonly used type of caging in toxicologic research is conventional open caging. In the case of rodents, this is of two types. The first is solid bottom plastic or metal caging with contact bedding. The cage body is covered with a lid that often contains an integrated feeder for holding feed pellets and a space for a water bottle. As an alternative, water may be provided by automatic watering systems, in which case a small hole is found in one end of the cage, through which a small water valve is introduced.

The most common type of cage is constructed of plastic with a solid bottom. These can be opaque or transparent. Transparent materials have the advantage of allowing easy visualization of the animals, whereas opaque materials provide a more sheltered environment for the animals by decreasing the amount of light striking them. The type of plastic materials used in the construction of the caging is important, as procedures such as frequent autoclaving and washing with high-temperature water and chemical compounds that are designed to disinfect can rapidly deteriorate some forms of plastic (58, 177). In addition, animal urine, which contains significant quantities of minerals and proteinaceous material, can cling tenaciously to plastic, requiring the use of mineral acids or other compounds to

remove them (222). Over time, all plastic caging will deteriorate and need to be replaced. Cracks or other deficits in the plastic make

sanitation difficult and may affect the structural integrity of the caging, requiring replacement.
A second type of caging is referred to under the general classification of *suspended caging*. Such caging usually is constructed of metal, most commonly stainless steel. The floors usually are of wire mesh, containing either two or four wires per inch. Some types of suspended caging have punched metal floors that have been electropolished or otherwise smoothed to prevent injury to feet. Punched metal flooring is commonly used for housing rabbits, as it provides greater support for their feet. As an alternative, some suspended caging is constructed of heavy duty plastics. Floors may also be constructed of the same plastic using the same principle as the punched metal flooring. Suspended cages for larger animals, such as dogs, cats, or swine, commonly use coated wire or coated, metal punched flooring to minimize the chance of damage to the animal's feet.
The mesh size of any suspended cage flooring is important. It must be sufficiently wide to allow the passage of feces while still providing sufficient support to the feet to prevent pressure injuries. In theory, suspended caging should allow feces and urine to pass onto catch pans containing sheet or loose bedding or, in some cases, onto catch pans that can be flushed into trough drain systems. Because most animals, including rodents, are coprophagic, if feces pass through the flooring, the animals will have limited access to it. Many species may consume feces as it is being defecated and before it can drop through the cage floor. Coprophagy is critical for normal health of some species, such as rabbits.
Larger suspended caging usually is cleaned in place, whereas caging for rodents and other small mammals usually is taken to a wash area for cleaning. Watering can be provided to suspended caging by means of automatic watering devices, water bottles, or, in the case of some large animals, water bowls. Feed usually is dispensed either in feeders that hang on the cages or within it or, for some larger animals, by use of feed bowls. Caging for some larger animals, such as nonhuman primates, cats, and dogs, often contain a resting board or perch that is suspended off of the floor. This allows the animals to express normal behaviors and provides them an elevated place on which to rest.
Neither solid-bottom nor suspended conventional caging is designed to prevent the airborne or fomite transmission of adventitious microorganisms. Control of such organisms when these cages are used is at the secondary enclosure level.
Pens and Runs
Domestic farm animals and dogs often are maintained in either runs or pens. A pen is a large indoor enclosure whose floor usually is the floor of the secondary enclosure. In the case of those animals that do not exhibit climbing behavior, indoor pens may be constructed such that the top of the pen is open. Most commonly, however, pens form a complete enclosure. Pens usually have an incorporated drainage system either by the use of a slanted floor underneath a raised pen floor that allows liquids to drain toward the back of the pen into a trough drain system or through the incorporation of a trough drain system in the floor of the pen itself. Pens are cleaned using water under pressure and detergent/disinfectants. Pens may also be bedded with loose bedding, which is removed and replaced on a regular basis. Whenever in-place cleaning of pens is done, it is important that the design of the pens be such that floor drains are large enough to accommodate fecal material and other items, such as bedding that may be flushed down the drainage system.
In theory, pens provide large animals the ability to move about normally and to acquire some exercise (131). Studies have shown, however, that such exercise is rarely spontaneous and usually is associated with the presence of humans (42, 43, 134). For this reason, components of some legislation, as well as certain guidelines, require regular periods of exercise for certain penned animals (308). Special provisions must be made to allow such exercise to occur.
The term *run* is often reserved for pens that have both an indoor and outdoor component. In such cases, the indoor component of the run often has a smaller floor area than the outdoor component. The indoor component usually is in a conditioned space or has other provisions for the thermal comfort of the animal, such as heated flooring. Access to the outdoor portion of the run may be limited through the use of animal-operated doors or doors that must be opened by animal facility personnel. Feeding and provision of water to animals housed in runs usually are done in the indoor portion of the run. Cleaning is done using water under pressure accompanied by detergents or disinfectants. Care must be taken during the process of cleaning such enclosures so as not to unduly stress or cause the animals to become wet during the process (222).
Housing of animals in pens or runs requires that consideration be given to handling and training of animals housed in such enclosures (256). Toxicologic research often requires repeated sampling or other manipulations. Removing animals from such enclosures, as well as protection of implanted sampling

ports or catheters while animals are in the enclosures, must be given adequate attention. Many problems can be overcome by conditioning periods during which the animals are handled and trained to respond in certain ways.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_787.html[2010/10/28 18:47:51]

SECONDARY ENCLOSURES

The construction of typical animal holding rooms has been previously discussed. A number of specialized secondary enclosures other than the conventional animal holding rooms have been developed for the purpose of minimizing transmission of adventitious microorganisms between groups of animals. In contrast to individual primary enclosure bioexclusion systems, these secondary enclosure systems provide some increased flexibility in animal handling and some decreased reliance on maintaining strict technical practices. They also pose an additional advantage of allowing the use of existing caging systems.

Cubicles

A cubicle is a small room partitioned off within another larger room and is used to decrease the chance of airborne cross-contamination between groups of animals housed in adjacent cubicles. The air supplied to the cubicle may come from a separate air supply within the cubicle or from the room in which the cubicle is located. In the latter instance, a negative pressure is created within the cubicle by an exhaust system, usually located in the ceiling of the cubicle, which pulls air into the cubicle through a space under the doors to the cubicle in a fashion similar to a fume hood. The cubicle is entered by opening the doors, at which point all directional control of air movement is lost (347). Unlike cage-level containment systems, cubicles only address airborne cross-contamination between cubicles, not fomite transmission, as might occur on dust particles or by manipulation by investigators or by animal care personnel. Due to the low face velocity associated with the air movement underneath the door to the cubicle, absolute prevention of airborne cross-contamination cannot be assured (344, 347).

Cubicles have been shown to be useful in some applications where separation of species is required in limited space, and they apparently can limit the spread of certain microorganisms under the right conditions (171). They are probably best used in conjunction with cage-level bioexclusion systems if reliable prevention of microbiological contamination is required.

Ventilated Cabinets

Ventilated cabinets consist of a cabinet with one or more doors. The cabinet has a small fan and HEPA-filter that extracts air from the room and releases it into the cabinet. Air is exhausted either between the doors to the cabinet or through an exhaust duct into the room. The exhaust air may or may not be filtered (185). Like cubicles, when the cabinet door is opened, caging within the cabinets no longer receives the benefit of the HEPA-filtered air supply. Airborne cross-contamination between cages within the system is not controlled unless a cage-level bioexclusion system is also used. Fomite transmission is not prevented by ventilated cabinets. Their use in toxicologic studies is limited.

Mass Air Displacement and Laminar Air Flow Rooms

These secondary enclosure bioexclusion systems are designed to decrease the airborne transfer of microorganisms between groups of animals. Both systems use a HEPA filter and blower to supply air to either diffusers or a plenum located in the ceiling of an animal room. In the case of mass air displacement rooms, large volumes of appropriately filtered air is released through a series of diffusers located in the ceiling in an attempt to wash any airborne contaminants to the floor and out through exhaust ducts located at floor level at several locations in the room (186, 194). By contrast, laminar air flow rooms pressurize a space above the ceiling (plenum) and discharge air out through the thousands of tiny holes in the ceiling, creating laminar movement of air (19). In theory, particles released from individual cages will be caught up in the laminar air stream and drop to the floor (65). In practice, once the laminar air flow strikes caging or other objects within the room, it eddies for distances of three or more times the diameter of any object that it strikes, causing mixing and producing an effect similar to mass air displacement (349).

Both of these room types do not effectively address airborne cross-contamination between adjacent cages and do not address fomite or other means of transmission of microorganisms. By themselves they are not a complete bioexclusion system (344). Depending on the design of the ventilation equipment, these rooms can be quite noisy and may be prone to excessive heat build up. Prior to the advent of cage-level bioexclusion systems, mass air displacement and laminar flow rooms were a common feature in toxicological research facilities using animals. They are less commonly used today.

ILLUMINATION

Light is an important environmental factor that can affect biological and behavioral processes in animals and the conduct of routine animal care duties. Numerous studies have documented effects of light on the morphology, physiology, and behavior of various animals (33, 82, 233, 316, 338). Not all of these effects have been adequately explored in all species or in sufficient detail

to predict the magnitude and the extent of impact on various toxicologic studies.

There are three factors that characterize lighting: (1) lighting spectrum (wavelength), (2) light intensity as measured in foot candles (English) or lux (metric), and (3) photoperiodicity (light/dark cycle) (22, 300). In addition, factors such as the light history of the animal, animal pigmentation, time of light exposure during the circadian cycle, species, sex, age, body temperature, hormonal status, and stock or strain of the animal can alter the influence of specific characteristics of the light on an animal (33, 76, 240, 285, 294, 331).

The one characteristic of light that has the most profound effect on animals is photoperiodicity. It regulates circadian (one day in length) and ultradian (greater than one day) biological rhythms in animals. These, in turn, can alter a variety of basic processes. Photoperiodicity is a critical regulator of reproduction and behavior (118, 196, 268, 339), including a behavioral influence on processes such as feed consumption and resulting body weight gain, nutrient intake, and hormone secretion (34, 54, 316). It appears that in most species, a period of 10–14 hours of light is required to maintain normal biological rhythms (200). Some species such as rats and mice are more tolerant of light cycle length than are species such as hamsters, which require at least 14 hours of daylight for normal reproductive function (54, 99). Continuous daylight, which can occur with malfunctioning light timers or inadvertent overriding of light timing devices, can have serious consequences for some toxicologic studies (28). For this reason, it is important to regularly assess the function of light timing devices and to build in safeguards to any light timer overriding mechanism to ensure that a consistent photoperiodicity is maintained (222).

A consistent photoperiodicity with adequate dark cycles is also essential to allow for the regular daily renewal of rods and cones in the eye, especially in nocturnal and crepuscular species (60). Without adequate dark periods, retinal degeneration cannot occur and can magnify the effects of retinal degeneration associated with high light intensity (236). Every effort should be made to minimize disruption of the dark cycle of the photoperiod. When procedures need to be conducted during the dark cycle, infrared illumination, low-intensity red lighting, and the use of point source low-intensity lighting, such as hand-held flashlights, may allow the necessary procedures to be performed without significant disruption. Alternatively, light cycles can be adjusted to fit work required (reverse light cycles), or the necessary procedures may need to be rescheduled into the light cycle.

Consistency in the photoperiod is important, and for this reason the use of windows in animal rooms needs to be carefully considered. Exterior windows allow seasonal ambient lighting conditions to alter photoperiodicity. This may not be important in certain species, such as nonhuman primates, dogs, and some agricultural or other large mammals, and may be considered a form of enrichment. In small rodents in which reproduction may be a study parameter, this lack of control may be an important variable (222).

Other significant concerns posed by exterior windows may be difficulties in temperature regulation within the animal holding room because of heat loss or gain through the windows and difficulties in providing adequate security for exterior windows (222).

Light intensity is another important characteristic of light that can dramatically affect certain laboratory animals. Many commonly used laboratory animals, including rats and mice, are nocturnal. Moreover, many of these species have been developed on albino backgrounds, thereby lacking pigment in their eyes, skin, and other tissues that provide some protection from the effects of light intensity. The most damaging effect appears to be phototoxic retinal atrophy, which occurs in albino rats and mice (175, 172, 271).

Because light intensity is affected by the type, location, and number of lighting fixtures in a room, considerable variation can occur between toxicologic research facilities. The age of the light-producing fixture (i.e., bulbs/tubes) is also important, as the output intensity will vary with length of use. It is unclear whether the effects reported for light intensity are related to a single wavelength/group of wavelengths or occurs equally over the whole spectrum. Light intensity is also affected by caging type and location as well as the reflective ability of other room surfaces (234, 339). Studies have shown that the position of mice in cages at various levels on the caging rack can influence the incidence of retinal atrophy, with an incidence of affected animals as high as 30.2% being recorded for animals housed in upper cages, as compared to 0.7% incidence for animals housed in lower cages (28, 115). For this reason, randomization of caging, as well as rotation of cages, is an important consideration if such effects are to be equally distributed between test and control groups (116).

When specifying light intensity, it is important that a uniform point of measure be used. In recent studies, as well as recommendations by various organizations, a measuring point of 1 m off of a floor in

the center of the animal holding room has been used and is considered to be the standard point of measure for intensity (22, 59, 222). This is used only to set an overall room intensity level for the purposes of comparing animal rooms and does not reflect the actual intensity experienced by the animals.

The light exposure history of individual animals can alter their sensitivity to phototoxicity. At least one study suggests that light intensities that are 130 to 270 lux

above the intensity under which the animal was raised may be the point at which retinal damage may begin to occur (294). Young albino and pigmented mice appear to have the ability to reverse some of the retinal damage associated with elevated light intensities (331, 341). Current recommendations suggest that a light level of 325 lux (30-foot candles) at 1.0 m (3.4 feet) above the floor is sufficient for routine sanitation while still avoiding significant retinal degeneration in albino animals (22). Other recommendations exist and are based on cage-level lighting intensities but are difficult to assess and administer (201).

The spectral distribution of light as it relates to adverse effects on laboratory animals has not been extensively studied. No artificial light has exactly the same spectrum as sunlight. Some fluorescent bulbs have a much wider spectrum with more output in the ultraviolet and infrared ranges than others. This can be partially compensated for by mixing standard fluorescent fixtures produced by different manufacturers in the same lighting fixture. Because different fluorescent compounds may be used by different manufacturers, this procedure can produce greater spectral diversity than bulbs from a single manufacturer. Overall, there is no definitive evidence to suggest that a wide spectral diversity in artificial lighting provides any direct enhancement of animal health or well being.

Some species of new-world primates are capable of synthesizing certain forms of vitamin D from dietary constituents and sunlight. Because it is common practice to provide enriched diets for these species that contain the appropriate forms of already converted vitamin D, access to full-spectrum artificial sunlight would not appear to be necessary.

A number of practical issues should be considered with respect to lighting in animal facilities. Many of these are covered in recommendations produced by the Illuminating Engineering Society of North American (IESNA) Handbook, which provides practical information on selection and installation of lighting (153, 154). It is generally recommended that light bulbs or fixtures have protective covers to ensure the safety of both the animals and animal care staff. Cleaning operations and the use of water in animal husbandry procedures can pose hazards from breakage and electrical shock.

NOISE

There is little doubt that extreme levels of acoustic energy (80–120 decibels of sound pressure) can, under the right circumstances, produce auditory and extra-auditory changes in laboratory animals (18, 92, 107, 108, 224, 249, 250, 251, 358). The assessment of sound-related interaction and injury in laboratory animals is complex, as the potential effects of noise on ani mals not only must take into consideration the intensity of the sound but also the frequency pattern of sound presentation, including rate of onset, duration, and vibration effects (12, 59, 241, 252, 255). The hearing range, noise-exposure history, and susceptibility to adverse effects of sound based on species, age, and strain further complicate any analyses (37, 145, 197, 199, 266, 284, 328). Many diverse effects have been reported in the literature and could pose unwanted variation in any toxicologic study. There are no comparative damage risk criteria for each of the common laboratory animal species, making it difficult to know what sound presentation is harmful (22).

In general, noise-producing animals and animal care activities should be separated from species and activities that do not generate noise (103, 222, 252, 283). This can be done by careful consideration of facility design and operational practices (11, 245). Physical barriers such as doors, air locks, and sound-absorbing materials can be useful in minimizing the effect of sound (245). Excessive and unpredictable noise patterns can be minimized through personnel training and the use of alternative practices and equipment in routine animal care duties.

VENTILATION

The purpose of ventilating an animal holding room is to dilute gaseous and particulate contaminants, supply adequate oxygen, remove thermal loads caused by animal respiration, lights, and equipment, adjust the moisture content of room air, and, where appropriate, create static-pressure differentials between adjoining areas (58, 222). It is, unfortunately, a common mistake to place heavy reliance on a ventilation system as the primary mechanism to prevent the movement of undesirable microbiological organisms from one location within a room or a facility to another. Other factors, including, movement of personnel between areas, movement of equipment, and transfer of animals within a facility, can quickly overcome any benefits associated with well-controlled ventilation. In theory, high ventilation rates should dilute out particulate and gaseous contaminants including undesirable microorganisms and allergens (104, 301, 307). Because, it is difficult to control the movement of air within secondary enclosures, viable particulates can easily escape any containment, provided strictly on the basis of ventilation.

As a general rule, air supplied to any secondary or primary enclosure should be free of contaminants

and be properly conditioned. HEPA filtration is recommended to provide some assurance that supplied air is free of particulates that could potentially harbor infectious organisms (189). HEPA filters are given efficiency ratings that can exceed 99% for particulate

< previous page page_790 next page >

exclusion within certain particle size ranges (5). Average pore diameters of HEPA filters are designed to exclude particulates the size of bacteria or larger but may not be small enough to exclude individual viral particles. Because viruses and other organisms tend to travel on particulates due to their high electrostatic charge, HEPA filters are effective in excluding them. Unfortunately, large volumes of air are processed by HEPA filters, and becasue their efficiency rating is not 100%, a certain amount of infectious particles will pass HEPA filters over time. Given the dilution in the air stream, this small amount of passage may not pose a significant threat in most situations. Moreover, because incoming air is seldom challenged with high concentrations of infectious particles, this deficiency usually is not a problem.

If HEPA filters become wet or excessively laden with particulates, bacteria associated with such particles may grow through the HEPA filters and be discharged on the clean side (77). Clogging of HEPA filters usually is monitored by measuring the static pressure across the HEPA filter. Increases in static pressure indicate that the HEPA filter is becoming laden with particulates and at some predetermined static pressure reading, should be changed.

Correct installation of HEPA filters is critical. If they are incorrectly mounted, untreated air can pass by the HEPA filters, producing the same effect as if they contained a large hole. For this reason, HEPA filters should be tested in place using particulate generation equipment (e.g., DOP testing) (77). It is important that such testing be done on a regular basis and should be thoroughly done when the HEPA filter is first mounted. It is critical that such testing be done by individuals experienced in the intricacies of the testing procedure, as inappropriate testing can fail to reveal difficulties in the mounting or construction of the HEPA filter. HEPA filters should be protected by pre-filters designed to catch the majority of particulates of large to intermediate size. This usually is accomplished by a series of pre-filters of different efficiencies. Such pre-filters should be changed regularly.

Air exhausted from animal holding rooms may or may not be filtered prior to discharge to the environment. In the case of toxicologic research involving hazardous agents, exhaust air usually is filtered using filters that are capable of excluding the material in question from the air stream. If the nature and level of hazard is low enough, dilution with large volumes of air by discharge into combined exhaust or into the environment directly may be sufficient.

Facility design guidelines emphasize the need for regulating air-pressure differentials either within animal holding facilities as a whole or within specialized support facilities, such as surgical, procedural, service, housing, or quarantine areas. In general, areas maintained under negative pressure with respect to adjacent areas are designed to prevent the escape in the air stream of unwanted materials from the area maintained under negative pressure (99, 287, 288). This would be most appropriate, for example, in an animal holding area being used for quarantining of animals. Conversely, maintenance of an animal holding area under positive pressure with respect to the surrounding areas would be undertaken under those circumstances where animals within the positive pressure area are free of certain microorganisms and whose exposure to particulates from other adjacent areas might increase their risk of contamination. Such positive pressure housing might be used in areas maintaining specific pathogen-free animals or used for surgery. While maintenance of static pressure differentials may pose some advantage with respect to contamination control, it should not be relied on for containment of chemical or infectious agents that could be transferred between areas. Most air handling systems have neither the capacity nor the necessary control mechanisms to maintain pressure differentials when doors, passthroughs, or other structures are opened even for brief periods (222).

For years the ventilation rate for animal holding rooms and primary enclosures has been an important focus of many recommendations for research animal facilities. The ventilation rate or air exchange rate in the context of animal facilities refers to the number of times the total volume of air in the room is exhausted and resupplied with appropriately conditioned air per unit of time. This often is expressed in air exchanges per hour. Rules of thumb have been developed based on experience and limited data. These guidelines have suggested the air exchange rates of 10–15 changes per hour are generally satisfactory for animal facilities (45, 222). Unfortunately, they do not take into account the range of possible heat loads, the type of bedding or frequency of cage cleaning; the species and number and size of animals housed; differences in room dimensions; or the efficiency of air distribution linking the secondary and primary enclosures (192, 193, 198, 222, 355). Given these variables, either under- or overventilation can occur, with resulting problems in heat and odor accumulation (58).

Instead of using general guidelines, such as 10–15 air changes per hour, more recent recommendations suggest that the heat generated by animals be calculated using an average total heat gain formula as developed by the American Society of Heating, Refrigerating and Air Conditioning Engineering (6). Using

this, the minimum ventilation required can be calculated from the total cooling load necessary to control heat generated by the animals and other heat sources. This, in turn, will allow determination of ventilation rates.

Additional ventilation capacity may be added as a margin of safety and to address any unusual odor generation (222).

The adequacy with which air is distributed within a room is an important consideration (193). If it is inadequately distributed, heat and water vapor build-up may occur unevenly. The coupling of secondary enclosure to the primary enclosure environments may also vary within the room (354). The use of computational fluid dynamic modeling has revealed that supply and exhaust diffuser placement, as well as type, can have a profound effect on air distribution (136, 137, 269). This has important implications not only for the environment of the animals with the resulting effect on studies, but also for researchers and technicians working in the animal room.

The concept of drafts as they relate to human comfort has been explored (192, 193). Unfortunately, little work has been done with animals to demonstrate whether or not there are biological consequences or if there is discomfort associated with the detection of movement of air. In the case of small laboratory rodents and rabbits, caging designs, and cage placements are unlikely to allow significant air movement within these enclosures to affect the animals contained therein. The one exception may be individually ventilated cages where high air exchange rates can be produced. Even so, there is no evidence to suggest that harmful effects occur. Similarly, larger species kept in pens, runs, or open cages have not been reported to have any ill effects associated with the detection of air movement.

Current guidelines allow the use of recycled air under certain conditions (222). In general, no less than 50% fresh air should be mixed with recycled air for reuse in animal holding areas. Recycled air must be appropriately conditioned and mixed with sufficient fresh air to control temperature, and humidity and other appropriate conditioning should be applied to remove particulates. Mixing recycled air from different animal holding areas is discouraged (222). Recycling of animal room air or the use of appropriately conditioned air from human use areas for animal rooms can provide energy cost savings and be an adjunct to other energy recovery efforts.

Ventilation should not be used as a substitute for good husbandry practices. Adjusting cage densities and bedding, or cage cleaning frequencies may prove a better solution to odor generation problems than trying to increase the capacity of air handling systems. The conditions within animal holding rooms should be regularly monitored to ensure that the ventilation system is working correctly. Plans should be made for action in the event of conditions that may affect the operation of the air handling system such as power failures, failure of mechanical parts, or failure of air filters.

TEMPERATURE AND HUMIDITY

The maintenance of body temperature within certain critical ranges is essential for animals if they are to maintain normal metabolic and physiologic processes (162, 263, 337). Thermal regulation has been extensively studied in some species (110, 111). Clinically observable effects can occur in unadapted animals that have been exposed to temperatures above 85°F (29.4°C) or below 40°F (4.4°C) that are denied access to shelter or other protective mechanisms (110, 162, 265, 343). Depending on the extent and length of time that the animals are exposed to temperatures outside of these ranges, the effects produced can vary from changes in reproductive ability to loss of life. In general, animals are quite adaptable to temperature changes and use behavioral, morphologic, and physiologic mechanisms to maintain body temperature (106, 110, 111, 121, 246, 343). Unfortunately, such adaptation takes time and can affect the animal's performance in toxicologic studies.

For the most common laboratory animals, a dry bulb temperature range from 61°F (16°C) to 84°F (29°C) has been suggested as acceptable (222). Within this range, depending on species, clinical effects are unlikely to occur, and experience has shown that there is little likelihood of toxicologic interaction. Of the common laboratory animals, rabbits are generally kept in a somewhat cooler environment because of their dense hair coat. The recommended temperature range for rabbits is 61°F (16°C) to 72°F (22°C) (222). Close control of temperatures within this recommended range may reduce some variation in certain studies. Unfortunately, very close control of temperature is not always possible within animal facilities, and some fluctuation during the course of any 24-hour period is to be expected. It has also been demonstrated that temperature will stratify within an animal room, especially one containing many cages. Temperature fluctuations of 2°F to 6°F within any given animal room as measured from the floor to the ceiling are not uncommon (26, 27). This is another reason that rotation of cages within any given animal room may be valuable. Variables such as cage construction, population density, the use of filter tops, and animal activity can also cause variations in temperature and humidity between the cage, the room, and between cages (4, 27, 234, 295, 298, 354).

Some means of regularly assessing the temperature within individual animal holding rooms should be used. Most commonly, temperature sensors placed in the return air ducts or mounted at a height of

approximately 5 feet off the floor near the door are used to monitor room temperature.
In addition to temperature, humidity may add additional stress to animals and can affect an animal's ability to efficiently lose heat. Many animals, such as rats,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_792.html[2010/10/28 18:47:54]

mice, dogs, and certain domestic farm animals, cannot sweat and as such cannot take advantage of evaporative cooling (26, 337). These animals must use insensible heat loss through the respiratory track or alterations in blood supply to heat radiating structures, such as the tail, soles of the feet, and tips of the ears to dissipate excess heat or to protect against excessive heat loss (110, 111). Some animals, such as dogs, can increase the frequency of their respiration (panting) to further lose heat. If the humidity in the environment is high, evaporative heat loss through insensible means is decreased and internal temperatures build. At very low humidities there is significant, insensible water loss that must be compensated for in order to maintain adequate fluid balance. Within recommended temperature ranges, however, the effects of relative humidity appear to be minimal. There is some human epidemiological evidence relating low relative humidity to increased susceptibility to certain respiratory diseases (16). Unfortunately, convincing evidence relating humidity to respiratory disease in animals is not available.

In rodents, low relative humidity has been suggested to cause ringtail (an annular notching of the tail that can lead to necrosis) in young rats and mice. Studies conducted on this condition indicate that it occurs at a high environmental temperature (81°F) with a low relative humidity (less than 30°) (93, 235, 314). While possible, these conditions are unlikely to occur under most laboratory animal housing conditions. Moreover, in those studies that have been reported, a variety of other factors, including diet and caging type, can effectively eliminate the condition (93, 235). When the condition is seen, there generally are very few animals affected and often there is no correlation to relative humidity.

The concept of thermal neutrality as a desirable state in which to maintain animals on study has been explored (35, 336). In theory, a temperature or temperature range exists for any given animal species in which oxygen consumption is minimal and no energy is expended to heat or cool the animal in order to maintain a constant body temperature. Ambient temperatures above the range result in increases in metabolism, physiologic alterations, and behavioral changes that favor heat loss. Conversely, temperatures below the range result in adjustments in the same systems designed to produce or conserve heat. Ambient temperatures outside of the thermal neutral zone can result in observable changes, such as alternations in feed consumption, activity, reproduction, and growth. When coupled with relative humidity, climatograms can be constructed in which it is presumed that animals are most comfortable (336). In practice, such optimal conditions are hard to determine for various species of animals, and there is evidence that climatograms may vary significantly with age, reproduction, and other factors (336).

BEDDING

Although many toxicologic studies are conducted on animals housed on suspended wire flooring with no contact bedding, there is increased use of contact bedding for many studies. This is due principally to the increase in bioexclusion housing that uses cage level containment. Even in the case of animals housed on suspended wire flooring, bedding often is placed below the flooring to absorb the moisture from urine and feces. Bedding can influence experimental data and animal well being (41, 239, 253, 254, 312).

Bedding is constructed of natural products, most commonly wood, paper, or corncobs. No bedding is ideal for all occasions and all species, but must be chosen based upon its characteristics. There have been a number of descriptions of the desirable characteristics of different types of bedding, as well as methods for evaluating various bedding types based upon these characteristics (27, 149, 169, 261, 309, 335). Of all the characteristics of bedding, absorbency would seem to be the most important. It is the purpose of bedding to absorb moisture to keep the environment dry and thereby minimize the growth of microorganisms that would otherwise flourish on the organic material and moisture within the cage. Moreover, by diluting feces and urine with bedding, the animals within the cage have less contact with excreta and hence have less chance of being soiled by it.

Wood products, although probably the most common form of bedding, are not the most absorbent, with their absorbency being directly related to their total surface area. The finer the wood product bedding, the more surface area and hence the more moisture it can retain. Paper product bedding, unlike wood product, tends to absorb large amounts of water directly into the material, which cause it to swell. The absorbency of paper product bedding can be much greater than wood product bedding. Unfortunately, some forms of paper product bedding lose their structural integrity when wet, making them difficult to manipulate, which can be a problem if used under suspended catch pans. To address this, some types of paper product bedding have a thin plastic backing, which makes them easier to remove from catch pans.

Another important factor with respect to bedding is its potential for introducing contaminants. Wood product bedding is obtained as a waste product from the milling of lumber. Wood chip bedding is

composed of the small wood chips produced by sawing lumber with coarse saws. Prior to processing, it may contain a range of chip sizes, including very coarse and very fine materials, such as saw dust. Wood from which bedding is produced may come from a variety of locations with different histories of exposure to compounds and microorganisms. Raw wood chips are processed by first screening out large debris and then heating them to a temperature of 140°F

to 150°F in an air convection furnace for approximately 20 minutes. This dries the product, which reduces bacterial contamination and the potential for growth, and also drives off volatile oils. The wood chip bedding is then run through a series of screens to develop products of varying sizes. After being screened, it is placed in bags and made available for animal housing.

Wood shavings are the product of planing kiln-dried lumber. Lumber is dried in large ovens maintained at a temperature of 140°F for periods of up to 14 days. The lumber is then run through shaping planes that produce shavings. These shavings are then bagged and used for bedding.

Both hardwood and softwood bedding are available as processed products. Storage conditions for these products are critical to preventing contamination. Certain softwoods, such as cedar, are no longer used for bedding for laboratory animals, with their use being relegated primarily to bedding for pets. Studies using softwood bedding have shown that volatile oils in them have the ability to induce liver microsomal enzymes, which can alter drug metabolism (56, 86, 320, 321, 322, 324, 334) and increase the incidence of neoplasia (146, 323). Softwood bedding that is kiln dried and hardwood bedding are both much less likely to produce hepatic microsomal effects, as essential oils associated with these inductive effects are driven off in the drying process. Hardwood beddings have not been shown to induce liver microsomal enzymes but may have other effects (309). If autoclaving or other heat treatments are applied to the bedding after receipt, the chance of essential oils producing any inductive effect are even further reduced (70, 260). In general, any such induction takes 3 or more days to occur and is rapidly lost when animals are removed from bedding materials, such as unprocessed cedar.

Paper bedding can come in a variety of shapes and sizes. Flat cardboard-like sheets, as well as plastic-backed absorbent pads, are commonly used in bedding trays under suspended wire cages. Paper chips and shredded paper products that may be bleached or unbleached provide a highly absorbent, contaminant-free contact bedding. Recently, compressed pads of paper that are cut to the size of individual cages have been introduced. These materials can come presterilized and are inserted into the cage at changing. When placed in the cages bedded with this material, animals scratch up the paper product into a loose bedding that is highly absorbent. This activity by the animals is considered by some to be a form of psychological enrichment. Similarly, the ability to burrow in contact bedding is also considered to be beneficial to some rodents.

Corn cob bedding is produced from coarsely ground corn cobs that have been heat treated. Their absorbency is similar to wood product bedding. The bedding itself is of irregular shape, is not easily compressed, and retains its structure when wet. There has been little indication that this bedding can cause significant research interactions; however, it is not widely used (259).

Larger animals, such as swine, dogs, cats, and other species, may also benefit from the use of contact bedding. In general, the use of such bedding is designed primarily to aid in cleaning of the cages, however, in the case of swine, it may assist in providing for their natural routing behavior.

A number of problems have been associated with varying types of bedding. Nude mice and SKH-1 mice that do not have eyelashes have a tendency to collect debris under their eyelids. This effect is less noticeable with screened wood product bedding; however, paper product bedding appears to release many more fines that are capable of lodging under the eyelids and causing swelling, and in the presence of the right microorganism, produce abscesses. Corn cob bedding seems to be similar to wood product bedding in this regard.

The ingestion of bedding can be problematic for newborn animals. If the particles are too small or do not easily pass the GI tract, newborn animals can ingest the bedding and develop fatal gastrointestinal tract obstructions.

It is important to periodically assess bedding materials for the presence of toxic and carcinogenic materials. Whereas some of these materials may be driven off during the processing of the bedding, others may be more stable.

Bedding, especially contact bedding, needs to be changed frequently based on a variety of factors, including the wetness of the bedding, the amount of feces present, the number of animals in the cage, and a variety of other factors. In the case of large animals or group-housed animals, bedding change often is required several times a week. Smaller animals or individuallyhoused animals may require less frequent bedding change. Failure to change the bedding and replace it with new bedding can result not only in an unhealthful environment, but can also increase the concentration of materials excreted in the feces and urine within the animal's environment, making ingestion or inhalation much more likely. There is also evidence that a soiled environment may also affect liver metabolism, which could interfere with toxicologic research (322).

WATER

Access to a sufficient quantity of clean, potable water is essential for normal hydration of the animal and for the maintenance of normal physiologic and metabolic processes. Water consumption and drinking patterns of laboratory animals vary with the species (311). Water supplied to toxicologic laboratories may be either from municipal sources or from privately owned wells. In either

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_794.html[2010/10/28 18:47:55]

case, the potential exists for contaminants to be introduced into animal holding facilities or for significant variation to occur in water quality over time.

To address this problem, animal facility drinking water, as well as water used for other husbandry tasks, is treated in order to adjust chemical and biologic characteristics. Water treatments may include one or more of the following: filtration, ion exchange, ultraviolet (UV) disinfection, halogenation (chlorination or iodination), reverse osmosis, or ozonization. At the local or room level, water may be acidified using mineral acids. Acidification usually is reserved for treatment of water used in water bottles although it is occasionally used in automatic drinking water systems.

Water filtration can be done using either depth or membrane filters. Depth filters are used for coarse filtration and involve passage of water through a coarse medium, such as sand. Finer filtration, down to 0.1 μm, can be obtained using a series of membrane filters often constructed out of paper or synthetic materials. These filters are only reliable for removing nonviable particulates, as many bacteria that collect on such filters can grow through them. If membrane filters are to be used for bacterial filtration, some regular means of disinfecting the filters must be employed. Some chemical components in water, such as suspended gases and certain organic compounds, can be removed by charcoal filters. These filters consist of canisters of activated charcoal that have varying degrees of retentivity for different compounds. These filters must be changed regularly and suffer from similar problems with respect to microbiological growth as membrane filters. Ion exchange resins can be used to remove inorganic compounds but offer no biological treatment.

Often, reverse osmosis is applied to animal water supplies. This treatment involves placing water under pressure on one side of a membrane that is designed to exclude all but a few types of molecules and collecting the water that passes through the membrane in an area of lower pressure on the opposite side of the membrane. To be effective in animal facilities, the capacity of the reverse osmosis equipment must be large enough to accommodate the necessary water usage. This entails either many such units or very large units. Water produced by reverse osmosis is devoid of all minerals and hence is chemically very aggressive to surfaces. Over time, water treated by reserve osmosis can recapture metal from stainless steel surfaces and other materials. Because the reverse osmosis process depends on an intact membrane, absolute bacteriologic or viral exclusion is only possible if there are no deficits in the membrane that might allow untreated water to pass through. Although water produced by reverse osmosis, in theory, should be free of microorganisms, in practice this is not always the case.

UV disinfection is a common and rapid means of killing a variety of microorganisms that might be found in water supplies. Because the process involves the exposure of water to UV light, the water must be reasonably free of minerals so that deposits do not form inside the exposure chambers. Moreover, light intensities of UV-producing fixtures decrease over time, and hence the effectiveness of the process. For this reason, regular measurements of the irradiance level of the light source, as well as regular replacement of the light source, must be done.

Halogenation, most commonly chlorination, is a relatively simple but effective means of disinfecting water supplies (133). Chlorine is effective against a wide range of microorganisms (21). Depending on the chlorine species being measured, ranges of effective concentrations have been established that will not adversely affect animals but still accomplished disinfection. It is important to realize that a certain minimum contact time is required for the chlorine or any chemical disinfectant to be effective. For this reason, chlorination usually is done centrally with the treated water being held in a contact tank for a period of several minutes to several hours in order to ensure adequate disinfection.

Depending on the form of chlorine being used, the chlorine reacts in variable fashion with organic materials present in the water, causing the generation of halogenated organic compounds (225). The importance and the likelihood of such occurrence is difficult to assess. It should be noted, however, that chlorine-based compounds are the most commonly used disinfectants for water and for husbandry practices in animal facilities, as well as for the treatment of drinking water for humans. The use of chlorine to disinfect drinking water has an important advantage over filtration and reverse osmosis methods in that it provides residual disinfection within watering systems. This prevents build up of bacteria in the watering systems as the result of back flow into water bottles or automatic watering devices of saliva and feed debris during drinking.

Ozonization is another means of assuring microbiological decontamination of water supplies and the destruction of dissolved organic compounds in the water. Such systems use an ozone generator to produce ozone gas and bubble it into a water contact tank. Contact periods of less than 90 seconds are required in order to adequately sterilize water. The resulting water is highly aggressive to pipes and surfaces, requiring that the ozone be broken down into less aggressive oxygen-containing compounds.

This is done either by exposure to UV light or by the addition of chlorine-containing compounds (sometimes both). Water that has been ozonated is devoid of any residual disinfection capacity and hence must be treated with halogen-containing compounds (e.g.,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_795.html[2010/10/28 18:47:56]

chlorine) in order to have residual disinfection capabilities.

Acidification of drinking water was first used to control the growth of pseudomonas in the drinking water in water bottles used for mice that had been irradiated (94, 184, 187). Water of a low pH (acidic) is bacteriostatic to certain vegetative forms of some bacteria. To be most effective, acidification should be at pH 2.3 or lower (127). Usually this is done with mineral acids; however, such acids have little buffering capacity, and hence the addition of saliva or other alkaline containing compounds may rapidly increase the pH of the drinking water.

The use of acidification, as well as other forms of water treatment, are not without potential research effects (91, 119). Any water treatment should be considered an experimental variable and should be well-understood by the toxicologist (58, 127). Usually it is necessary to group together a number of different water treatments in order to provide a water system that is capable of not only adjusting the chemical composition of the water, but also to ensure that it is free from harmful microorganisms.

FEED

Feed is considered by some to be one of the principal uncontrolled variables in toxicology today. Many textbooks and articles, as well as guidelines, have been written on nutrition for laboratory animals (209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 220, 221, 230, 226). There are numerous examples of how diet composition or administration can affect the outcome of toxicological research either directly or indirectly (30, 57, 144, 227, 232, 237, 292, 340). There also are examples of individual nutrients either in excess or deficiency producing a wide range of metabolic, morphologic, or physiologic conditions that have influenced the outcome of studies (8, 44, 229, 231, 330). It is not the purpose of this review to cover all of these. The reader is encouraged to pursue such information from available texts, reports, and journal articles, as well as seek the advice of those skilled in laboratory animal nutrition for specific recommendations. Subcommittees of the National Research Council's Committee on Animal Nutrition have published reviews of the nutrient requirements of laboratory animals that can be used as a guide in assessing the adequacy of specific formulations (209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 220, 221).

Feed provided to laboratory animals should be palatable, nutritionally complete, and free of contaminants unless the lowering or removal of a nutrient or the addition of other compounds is required by the study design. The feed should be provided in sufficient quantity and be of the necessary quality to assure normal growth and provide for the overall health of the animal (46, 222). Increased demands of reproduction and lactation may require slightly different feed formulations. Many commercially available diets are calorie dense, protein rich, and often are fed ad libitum. Such practices encourage feed wastage and may adversely affect some toxicology studies (159).

The physical and taste characteristics of laboratory animal feed can be important variables in study design. Some common laboratory animal species, such as nonhuman primates, guinea pigs, and rabbits, have well-developed taste and dietary consistency preferences. Guinea pigs, for example, do not easily accept changes in the texture of the diet or in its taste. These animals may need to be habituated to changes in diet by gradual introduction of the new diet during the course of feeding a previously accepted diet. This can prove challenging when artificial diets need to be substituted for natural ingredient diets.

Laboratory animal feeds can be classified as natural ingredient diets, semipurified (or purified) diets, or chemically defined diets (273). These classifications are based on the ingredients used to construct the feed. Natural ingredient diets are composed of unprocessed or crudely processed materials, such as cereal grains, milk products, and animal product meals, such as fishmeal or meatmeal. Semi-purified diets (also referred to as synthetic, semi-synthetic, and purified) are constructed of processed ingredients that are refined so as to be uniform in content. Examples of such ingredients include casein, dextran, soy protein, hemicellulose, and fats, such as corn oil. Chemically defined diets are composed of chemically pure compounds, including specific amino acids, fatty acids, inorganic salts, vitamins, and sugars, such as glucose and fructose (351).

Natural ingredient diets can be pelletized (extruded), expanded (baked), or processed as a meal (powdered). They can also be suspended in agar or other types of hydrocolloids, providing both feed and a source of water. Semi-purified and chemically defined diets are provided in either a powdered or liquid form. Experimental compounds can be incorporated in any of these physical forms, but as a rule are usually fed as a gel or in liquid or powdered form.

The exact formulation of specific feeds may or may not be available to the toxicologist. Open-formula diets are diets that are manufactured to published specifications based on quantities of specific ingredients (165, 166). The quantitative and often qualitative ingredient compositions of open-formula

diets are readily available from the manufacturer. Open-formula diets usually are made from natural ingredients, and as such may easily suffer from variability due to differences in source of ingredient supply, harvest times, and storage conditions (234). Detailed ingredient analysis prior to manufacture in both open- and closed-formula diets is seldom done, and when

analysis is conducted, it usually is done for only a few key constituents. For this reason, open-formula diets can still exhibit significant variability between suppliers and within any given supplier.
Closed-formula diets are those manufactured by feed companies who hold the exact composition of the diet in terms of the quantities of specific ingredients as proprietary information. They will provide a list of the ingredients used and usually will provide a calculated analysis. Closed-formula diets are often less costly than open-formula diets, as the manufacturer can adjust the formula periodically, based on the availability and costs of various ingredients. It must be remembered that like open-formula diets, closed-formula diets may have variable nutrient levels. The calculated analysis on such products is not the same as a laboratory analysis of an individual batch of closed-formula diet.
Recently, the concept of constant nutrition or variable-ingredient diets has been introduced. This is a natural extension of closed-formula diets in that the manufacturer is allowed to select the type and quantity of various natural product ingredients to be used in a diet formulation based on availability and cost. The maximum percentage that any given ingredient can constitute in the diet is limited by published specifications; however, the final product must have analyzed nutrient levels that fall within prescribed ranges. Generally, constant nutrition diets are coupled with regular analysis by the manufacturer of the product for an extensive list of nutrients in order to assure that the product provides the specified levels of such nutrients as set forth in the diet specifications. Given the inherent variability with both open- and closed-formula diets, as well as the lack of regular laboratory analysis for specific nutrients in such diets, constant nutrition diets provide a means for standardizing diets between locations as well as suppliers.
Certain basic analyses are required for interstate shipment of dietary ingredients in the United States. Analyses for up to five constituents, including protein, are made, and certain minimal levels based on the guaranteed analysis stated on the feed container must be met (17). It is important to realize that the actual level of these nutrients is not guaranteed, only that the level is not less than that listed. Similarly, diets can be certified with respect to levels of certain toxic and carcinogenic compounds. This process involves holding in a secured location a batch of feed from which samples are taken for analysis of 15 or more toxic or carcinogenic compounds. The analysis for that particular lot of feed is used to certify the diet as containing specific levels of these compounds which may interfere with some toxicologic research (80, 100, 227, 230, 296, 350). Certification of feed does not imply a laboratory analysis for specific nutrients, only that the material does not contain more than a stated level of certain compounds as determined by the analyses. Hence, a certified diet could be deficient in nutrients and yet still be certified (57, 117, 228, 267, 352, 353).
For convenience in feeding and to minimize wastage, diets often are pelletized (97). During this process, the diets are briefly exposed to temperatures exceeding 60°C. The process of pelletizing diets is one of compression and extrusion. The amount of time that the pellet is exposed to elevated temperatures is very brief, and hence there is no assurance that vegetative or nonnegative forms of bacteria or other microorganisms are consistently killed.
Expanded diets undergo a process of prolonged mixing and heating with added liquid in a manner similar to mixing a cake batter. This material is mixed with air and expanded through a die into pellets that are dried with heated air. This process forms a much harder and durable product. The process also exposes the mixture to temperatures in excess of 100°C for periods of 15 minutes or more. This causes some reduction in microorganisms; however, the product itself is not sterile. Contamination can occur in both pelletized and expanded diets after processing. Expanded diets have a lower specific gravity, and hence a lower caloric density than pelletized or powered diets of equal volume. Hence, to obtain the same caloric intake, animals will consume greater volumes of an expanded diet.
A number of applications in toxicological research require the decontamination or sterilization of feed (204). If true reductions in bacteria and viruses are to be achieved in feed products, feed can be treated by application of steam under pressure (autoclaving), dry heat, or irradiation. Heat applied in these processes can destroy certain labile ingredients within the diets (62, 96, 242). Irradiation produces very little elevation in temperature and hence is less likely to require additional fortification if sterilization is contemplated (66, 356).
Any process used to sterilize feed must be calibrated and carefully controlled. Minor items, such as variation in stacking patterns of bags of feed within an autoclave or the magnitude and number of vacuum pulses, can yield significant differences in the total reduction of microorganisms during the autoclaving process (222). Equipment used for such feed treatment must be regularly calibrated. The use of indictor tapes or other sterilization indicators in a single spot does not assure the adequacy of the process. Moreover, cycles designed for pelletized feed seldom are effective in processing powdered feed

or other forms of diet.

When irradiation is used, it is important to specify dosages based on the minimum dosage received throughout the entire load or container. Once an item has been treated, it should be labeled as to the date of treatment so that judgments can be made as to the appro

priate time in which the product should be used. Feed should be sealed in durable and preferably water-resistant packaging prior to irradiation.

With or without heat or radiation treatment, certain liable components within diets will degrade over time (102, 242). Diet manufacturers place milling dates on containers of diet using either sequential dating codes or Julian dating. As a general rule, natural ingredient, dry laboratory-animal diets that have been stored properly can be used for 180 days after manufacture (222). Some diets that contain supplemental vitamin C or other very labile ingredients should be used in approximately 3 months from milling unless special stabilized forms of these especially labile nutrients are added to extend the shelf life (222). Supplemental vitamins and other labile ingredients can be provided separately through the use of drinking water supplements, sprayed on dietary additives, or in the case of nonhuman primates and certain other species, by the feeding of fruits and vegetables.

Feeding can also be used as part of a psychological enrichment program for certain species of animals. In the case of nonhuman primates, specialized feeders, the use of a variety of different types of food items, and the presentation of feed in a way that foraging is required can all be used to stimulate these animals and reinforce natural behaviors. For the purposes of toxicologic research, maintaining constancy in a diet is important. Varying the diet with a wide selection of unbalanced foods, as might occur through nonstructured supplementation of diets, can cause health-related problems (195). It is also important to minimize abrupt changes in diet because in many species these can lead to digestive and metabolic disturbances.

The storage of feed and other dietary ingredients should be done in areas that are regularly cleaned and enclosed to prevent entry of pests. In general, feed should be stored off of the floor and care should be taken to prevent exposure of these items to temperatures above 70°F for prolonged periods of time (102, 228, 272). Containers used to hold loose feed should be covered and constructed of materials that prevent the entrance of vermin and other pests.

The presentation of feed to animals is another important variable. With few exceptions, feed should be administered to animals in feeders that allow easy access to the feed while minimizing the possibility of contamination with feces or urine. Feeders should also minimize wastage, which is particularly important with powdered diets. The size and number of openings in feeders, as well as the location of the feeder, can affect the animals' consumption of feed. Some designs of feeders can actually restrict an animal's access to the feed, resulting in caloric restriction.

Dogs, cats, nonhuman primates, and certain other species are commonly "meal" fed such that feed is pro vided one to three times a day in limited quantities (178). Rodents are more commonly fed *ad libitum*. Feed consumption can be influenced by the light cycle, with some species preferring to consume more feed in the dark part of the light cycle than others. Rodents consume feed both in the light and dark portions of the light cycle, with more feed being consumed during the dark part of the cycle than the light. Poultry consume feed primarily during the light cycle, as do many other nonrodent species. Hamsters characteristically horde feed, and for that reason will tend to remove feed from feeders in order to form feed piles on the floor. To minimize injury associated with this behavior, hamsters are commonly fed off of the floor when pelletized diets are used (122). The ready availability of a water source is also important in feeding behavior for many animals. Many species eat and drink at the same time.

Of all the variables associated with feed, perhaps that which has the greatest impact on toxicologic studies, other than outright nutritional deficiency, is overfeeding (159). Animals will consume feed until an internal caloric limit is reached. The imposition of mild to moderate caloric restriction in all species, including rodents, can increase longevity, postpone the development of spontaneously occurring neoplasms, decrease the incidence of background lesions in the kidneys, cardiovascular, and endocrine systems, and cause other changes that in aggregate can produce a more consistent model for toxicologic research (3, 23, 24, 52, 53, 183, 319). To adequately interpret data from long-term studies on animals using caloric restriction, other primary studies, including range-finding studies for dosages, need to be conducted in calorically restricted animals.

Caloric restriction or limited feeding is not a new concept (225, 226, 227, 274, 302, 303, 304, 305, 306, 317). The effects produced by this procedure have been recognized for decades (63, 150, 182). A number of publications have reviewed various segments of this relatively large body of literature (123, 124, 156, 157, 158, 357). The phenomena appears to be closely correlated with total calories and not with specific nutrient concentrations, such as protein levels (170). The technique appears to be most easily applied to those studies in which compounds are administered by gavage; however, there is little reason to believe that it could not be applied to studies in which the compound was administered by

other routes. Errors associated with administering compounds incorporated into the diet and administered under a caloric restriction regimen may not pose any greater error than those associated with similar administration using *ad lib* feeding, which assumes a consistent intake on a daily basis and a consistent level of wastage.

The usefulness of caloric restriction in group-housed animals, however, still needs to be explored (55). It has been assumed that any dominance hierarchy estab

lished within a group would lead to significant differences in diet consumption between members of the group with, perhaps, the introduction of unwanted variation, however, any such dominance hierarchy that already exists within the group will still result in variation even when feed is available *ad libitum*. This problem could be further magnified if one or more members of the group died during the course of a study. The interaction of group size, sex, and caloric restriction still needs additional investigation.

The decision of the toxicologist to use caloric restriction as a means of decreasing the variability encountered in product registration studies using rodents must be based on a careful examination of the literature and a dialogue with regulatory authorities. Caloric restriction in rodents is used by a growing number of pharmaceutical companies and has gained acceptance by regulatory bodies, provided that adequate control data are provided.

HEALTH AND HEALTH MONITORING

Animals used in toxicologic research come from several different categories of sources. A limited number of animals are occasionally obtained from either wild populations or open colonies in which there is little attempt to control the introduction of adventitious organisms. Such conventional or random source animals have the potential for significant interindividual variability with respect to health status.

A second-source classification are closed colonies of animals in which the introduction of new animals is minimized or eliminated and certain control measures are put in place either by means of vaccination, antimicrobial therapy, or anthelminthic treatment to control and, in some cases, eliminate a limited number of microorganisms. Interindividual variability in health profiles may still exist; however, the maintenance of these control measures at the toxicology laboratory can provide some assurance that certain organisms have been eliminated.

The last source classification of animals are animals from colonies that have originated through procedures designed to totally eliminate unwanted microorganisms and parasites, usually caesarean section or embryo transfer. These animals are maintained within bioexclusion systems, such as barrier production facilities, that are designed to prevent contamination with species-specific pathogens and, in the case of some bioexclusion systems, even common opportunistic organisms that could pose unwanted research interference (315).

The availability of any species in any one of these source categories may be limited or even nonexistent. Larger domestic animals, such as dogs, cats, and farm animals, and nondomestic animals, such as nonhuman primates, generally are not available in a highly defined microbiological status. Health programs designed to control or improve the health status of these animals will not eliminate the possibility of species-specific or opportunistic disease that may interfere with toxicologic research using these animals.

Health monitoring programs for nonbarriermaintained or random source animals depend heavily upon a comprehensive initial quarantine and screening process that is supplemented by individual and/or colony health data available from the supplier (84, 85). Some organisms that are seldom found in barrier-reared animals are not uncommon in many research facilities (147). Routine vaccination and anthelmintic therapy, as well as the application of antimicrobial agents, may all be used to control or eliminate undesirable organisms. The toxicologist must be aware that during the course of a study, individual animals may develop clinical illness or may exhibit individual variation as a result of underlining infectious processes. The frequency of such occurrences cannot be predicted, and allowances must be made for this in the study design when using such animals.

To minimize the impact of health issues on toxicologic research, each institution must develop an institutional philosophy with respect to the impact of certain organisms in their research animals. Not all organisms have a significant impact on research, and those that do may not interfere with certain types of research. Simplistically, organisms can be divided in terms of their relative importance and the amount of peer-reviewed information available to support their impact on research (Figure 16.1).

A number of reviews of microorganisms affecting laboratory animals have been assembled (29, 205, 206, 120, 247). Unfortunately there is no universally accepted list of organisms that should be excluded from all animals under all circumstances. Many adventitious organisms do not cause clinical disease. Instead they cause subclinical infections that do not produce histologic changes associated with their presence. In some cases they may have only limited or subtle research effects that are self-limiting and cease after protective antibodies are formed (344). In a few instances more significant effects occur only when the organism is first introduced into a naïve population (epizootic phase of infection). After the organism becomes established and protective antibodies are present either through maternal transfer or the development of a controlled infection, clinical signs or research effects may disappear. Often, agents that are commonly recommended to be screened for have been selected on a historical

basis rather than through an analysis of their potential to cause effects or the prevalence of the organism.

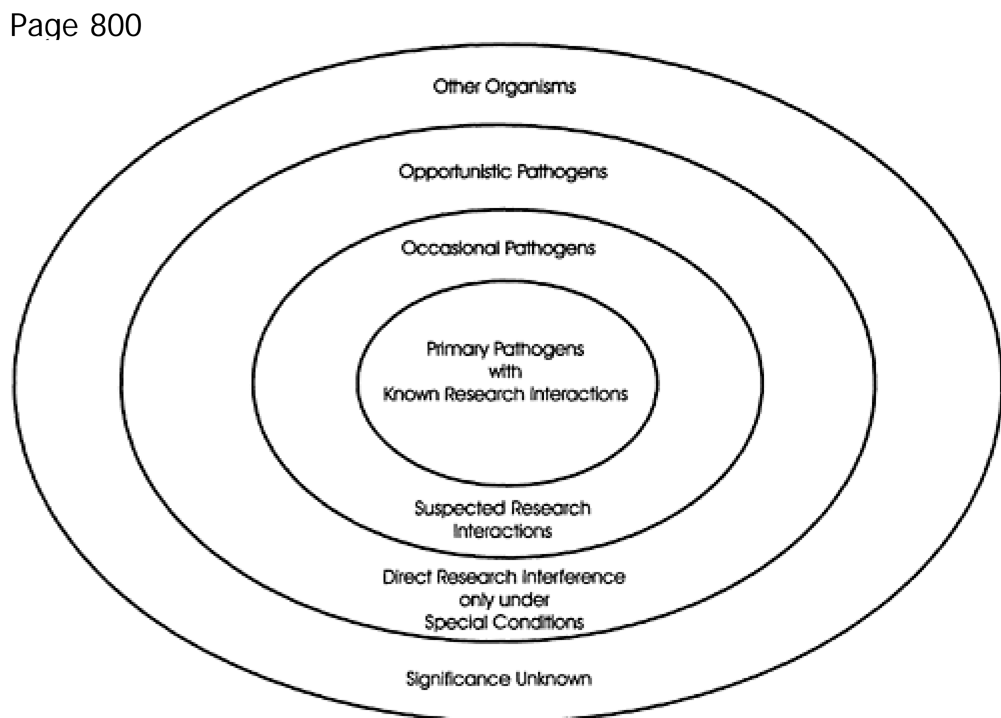

FIG. 16.1. Classification of organisms by their significance and impact on research.

Suppliers of barrier-produced animals have developed exclusionary lists of organisms that define the status of the animals that they produce. These exclusionary lists set forth microorganisms that are to be screened for on a regular basis and whose presence is deemed to be a cause for the supplier to eliminate that colony of animals from production. In some cases, an additional group of opportunistic microorganisms may be screened for by suppliers to document the presence of these organisms in the event that they might interfere with certain types of research. These opportunistic organisms may have little potential to cause research interaction and are not a cause to eliminate colonies. These organisms may be common human or environmental commensals that can only be excluded by very specialized bioexclusion housing techniques that may be impractical in the toxicologic research environment.

Animals free of one or more specified microorganisms are termed *specific pathogen free* (SPF) (206). There is no universal definition of SPF with respect to what organisms are to be excluded from each common laboratory species. Proprietary terms or abbreviations may be used to designate a particular supplier's or research institution's definition of SPF.

In developing an institutional health standard for laboratory animals to be used in toxicologic research, the advice of a competent veterinary professional with experience in laboratory animal medicine science should be sought. Decisions on which organisms to exclude and to test for will need to be based on the nature of the research being conducted, species being utilized, a realistic assessment of the facilities and equipment available for maintaining animals, and a thorough review of peer-reviewed literature with respect to the disease-causing potential, host range, and research interactions posed by specific microorganisms. Table 16.2 lists a number of organisms that may infect common laboratory animal species. This table includes species-specific organisms and some common environmental and human commensals whose exclusion might require extraordinary efforts although their presence may have little research impact; however, such opportunistic organisms may be considered for inclusion in the screening program if their presence would need to be documented in order to help

Page 802
explain unexpected variation in certain specialized studies (84). It is unrealistic for most toxicologic research facilities, however, to set as a goal the exclusion of all the organisms on this list, as the likelihood of long-term success, unless extraordinary measures are used, is quite low (344).

No matter what institutional exclusionary list is decided upon, each organism on the list should have documentation in the peer-reviewed literature to support its inclusion. Moreover, in developing an exclusionary list, consideration should be given to the formulation of a plan to address the potential discovery of positive findings in research populations within the institution. Development of an exclusionary list presumes that some method is available to limit the spread of the organism if it gains entrance into the facility and that some course of action, such as elimination of infected animals or the imposition of some form of control measures, such as drug therapy, will be used to eliminate it (344). Because the toxicologist will be impacted by the health and health monitoring program at the institution, it is important that he/she participate in the formulation of that program.

There are a number of microorganisms that can be carried by animals that have health implications for man. Zoonotic organisms that can be transmitted from animals to man are often included in the screening and control processes that are part of the health program for laboratory animals. Many of these organisms, such as herpes B virus (nonhuman primates), *Salmonella, Shigella,* Hantaan virus, and Lymphocytic Choriomeningitis virus, may be included in screening programs not because of their possible research effects, but because of their ability to cause disease in people who work with the animals (101, 138, 289).

Health monitoring programs require consideration of sample size and frequency; the type, availability, sensitivity, and specificity of assays for various microorganisms; biological characteristics of the microorganisms; sampling procedures and preparation; and the interpretation of results. Discussions of these subjects are beyond the scope of this review but are available elsewhere (10, 75, 84, 85, 176, 293, 325, 342). In light of all of these considerations, as well as the limitations of the health monitoring techniques currently available, it is imperative that no single set of results be used to make a determination of the health status of any group of animals used in toxicologic research. Any positive findings should be confirmed with alternative tests or additional samples. False-positive and false-negative results do, in fact, occur, and drastic actions taken without confirmatory data can cause irreparable damage to ongoing studies (342).

Special problems are imposed when immunocompromised animals are used in pharmacological research. The very property that makes these animals unique (i.e., defects in their immune system) makes them susceptible to many organisms that would not be of concern to animals with an intact immune system. Manipulation of these animals requires the use of aseptic technique and rigorous attention to detail to assure that they are not exposed to even common opportunistic organisms that could set up life-threatening infections or cause research interactions. Health monitoring programs for these animals often require the use of immunocompetent sentinel animals that are housed either on soiled bedding obtained from the immunocompromised animals or in direct contact with the animals themselves (73, 310, 342). Such animals must be obtained from suppliers in a microbiologically defined status that limits the microorganisms to which the animals are exposed to a small number of commensals that have no disease-causing capacity or research implications. Maintenance of these animals requires very special bioexclusion housing practices and modification of research techniques.

The collection of background data can be incorporated into the health monitoring program. In addition to documenting the presence or absence of various microorganisms, samples may also be collected for histopathology, clinical chemistry, and hematology using representative animals obtained from the same populations as the animals participating in the study.

In some instances it may be necessary to eliminate one or more microorganisms from a group of animals in order to make it acceptable for introduction into a toxicologic research facility if alternatives to the use of these animals are not available. This process is referred to as rederivation and can be accomplished either by caesarean section with cross-fostering of young onto lactating females of the correct microbiological status or by hand rearing the young using the appropriate milk substitute. As an alternative, embryos collected from donor females can be transferred, after washing, to recipient mothers of the appropriate health status. Both of these techniques require considerable technical skill and extensive health monitoring after the procedures to assure that the appropriate health status of the rederived animals has been obtained. Each technique has advantages and disadvantages. Both of these procedures are expensive and time consuming, especially if they are to be applied to outbred animals that require relatively large founding populations.

In the case of a few viral agents, cessation of breeding and the elimination of naive individuals for a

period of 6 weeks or more, coupled with environmental disinfection, has been shown to eliminate certain viruses from infected populations (342). With some bacteria and parasites, medications can be used but usually are only practical when applied to small numbers of animals, as such therapies are seldom 100% effective.

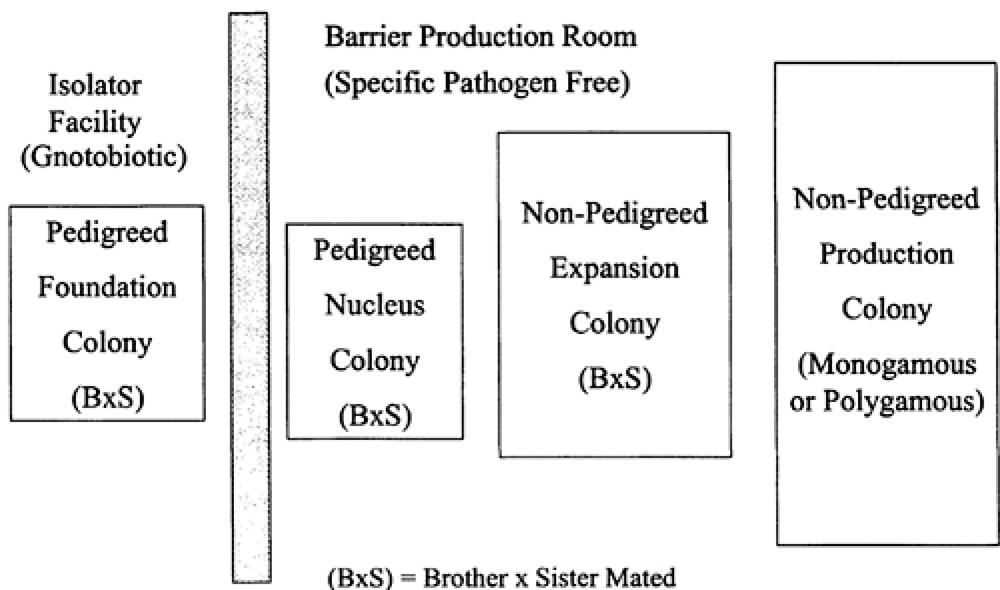

FIG. 16.2. Schematic representation of the segments of an inbred production colony.

GENETICS AND GENETIC MONITORING

Laboratory animals need to be appropriately identified in terms of nomenclature and genetics if studies are to be confirmed either at the same institution or at other institutions. Laboratory animals may be referred to by their common names as well as their scientific names for the purposes of description. In the case of laboratory rodents, specific rules of nomenclature exist for stock and strain designations that cover the genetic classification of the animal and identify its origins and its methods of derivation (87, 90, 142, 143, 207, 208). Listing of various stocks and strains, as well as other genetic classifications of animals, are periodically published (88,89). The correct designation of the animals used should be included in any reports or publications as well as other information regarding the source of supply.

The majority of rodents used in toxicologic research fall into three general genetic classifications: outbred/ random bred, inbred, and F1 hybrid. Transgenic animals can be produced on any of these backgrounds and represent a rapidly growing segment of rodents used in toxicologic research.

Inbred animals are produced as the result of 20 generations or more of brother-sister mating and possess more than 98% genetic homozygosity. They are produced by most breeders by means of a colony structure that allows breeding of large numbers of these animals that are, at most, separated from a brother-sister mating by no more than one generation (Figure 16.2). A gnotobiotic foundation colony is maintained in isolators or other bioexclusion systems and is periodically used to replace the pedigreed nucleus colony of animals within the production facility. The nucleus colony animals are brother-sister mated with pedigrees being maintained. The progeny from these matings form nonpedigreed brother-sister matings in an expansion colony that pro duces breeders for either a pair-mated or polygamous-mated production colony, the offspring of which are used in research.

Inbred animals are useful in toxicologic research in which genetic homogeneity is required. Inbred strains may differ significantly in their response to various compounds due to variations in their genotype and phenotype. They are particularly useful when studying pharmacological mechanisms. Conclusions drawn using a single inbred strain should be verified using other inbred strains or outbred stocks if the findings are to be applied to more genetically diverse populations, such as domestic animals or man.

F1 hybrids are produced from the mating of two inbred strains. Offspring are genetically identical at all alleles at

page_804

which the parental strains differ. F1 hybrids are not self-perpetuating in that breeding F1 hybrids to each other to yield F2 generation allows the various genes that were heterozygous in the F1 alleles to segregate. Commercial production of F1 hybrids requires maintenance of two inbred colonies. Use of F1 hybrids in toxicologic research is limited; however, they do exhibit greater genetic diversity than inbred strains.

Outbred or random-bred animals posses a high degree of individual genetic diversity. The term *random bred* refers to a system of mating by which there is no conscious selection for specific traits or kinships. Unfortunately, random mating assumes that a population is of infinite size and that all reproductively fit members of the population participate in the mating program. It also assumes that no conscious or unconscious selection process issue is used when new matings are set up. Even under the most careful circumstances, these assumptions cannot be fulfilled. Random mating programs, especially those that start with small numbers of individuals, will rapidly result in an increasing level of inbreeding or loss of heterozygosity. Because random-bred or outbred animals are presumed to be useful in toxicology and because of their great degree of individual diversity, loss of this diversity through random mating diminishes their usefulness.

Outbred animals are produced using a purposeful system of mating that seeks to retain the heterozygosity within a group of animals. A number of rotational systems for outbreeding have been devised, as have systems based on the coefficient of inbreeding of pedigreed groups of breeders (114, 163, 257). The latter system provides the greatest assurance of continued genetic diversity, provided that the colony is started with a sufficiently large number of genetically unrelated individuals.

Because established colonies of outbred animals undergo independent genetic assortment of polymorphic alleles and will independently fix certain nondeleterious mutations, different colonies of outbred animals separated by time as well as by geographic location will undergo genetic divergence even if they were started from the same colony of animals. To minimize this genetic divergence, breed stock can be traded between colonies of the same stock within the same supplier's organization. Systems for linking colonies in this fashion have been described. These rely on well-established population genetic techniques (125).

The genetic authenticity of inbreds and F1 hybrids can be monitored by assaying a variety of polymorphic alleles located on multiple chromosomes (126, 238). If mismatings occur, variations in this allelic profile will be found indicating a genetic contamination. Any polymorphic marker can be used, including biochemical, immunologic, and DNA assays.

The authenticity of outbred stocks or of individual outbred animals cannot be determined. Populations of outbred animals can be compared using markers similar to those used for inbreds and F1 hybrids, but large enough groups from a population must be sampled to characterize the allele frequency within the population. Using this allele frequency data, population genetic calculations can be made that will allow the similarity of different populations to be compared (48, 125).

In the case of transgenic animals, the presence of a transgene can be determined using PCR or other DNA analysis techniques in order to verify its presence and zygosity. This information can be used to adjust the breeding program or to authenticate a transgenic animal. Finding the presence of a particular transgene, however, does not determine if it has any functional significance.

SANITATION

Sanitation refers to the cleaning processes required for the maintenance of environmental conditions that are conducive to health. Sanitation of the animal's primary and secondary enclosure includes bedding change and cage cleaning and disinfection. The act of cleaning, either by manual or mechanical methods, removes excessive amounts of dirt and debris from surfaces while disinfection reduces or eliminates unacceptable concentrations of microorganisms that can interfere with toxicologic studies (222). The frequency with which these processes of cleaning and disinfection are done, as well as the methods used, depends on a number of factors, including species, age, and size of the animals; the type, construction, and size of the enclosure; the nature and quantity of the feces, urine, or debris soiling the environment; the temperature and relative humidity; the rate at which the surfaces of the enclosure becomes soiled; and the normal behavioral and physiological characteristics of the animals housed in the enclosure (222, 322).

To facilitate cleaning, the surfaces of both the secondary and primary enclosures should be impervious to liquids and smooth to allow easy application of cleaning materials and disinfectants. The surfaces should also be capable of withstanding scrubbing and should be free of cracks or other deficits that may inhibit the cleaning process (177). The use of agents designed to mask animal odors should not be used in animal facilities designed to support toxicologic research. Such agents expose the animals to chemical

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_804.html[2010/10/28 18:48:02]

compounds that may interact with metabolic or physiologic processes involved in drug uptake and metabolism. Such agents simply obscure poor sanitation practices or inadequate ventilation. Conversely, characteristic animal odors released from the decomposition of urine or feces cannot be used as the sole criteria for the adequacy of sanitation practices or ventilation. Some studies suggest a relationship between

certain decomposition products of urine and feces (principally ammonia) and the potentiation of the effects of certain disease-causing organisms (36, 104, 179).

The sanitation of cages and associated equipment, such as watering devices and feed containers, can be done either manually or with mechanical equipment. The frequency of cleaning is dictated by cage type and the husbandry program. The use of wire-bottom or perforated-bottom cages, the use of regularly changed contact or noncontact bedding, and regular flushing of catch pans suspended under certain types of caging, coupled with the number, size, and type of animals in the cage, will influence how often the cage will need to be washed and sanitized. Hamsters, guinea pigs, and rabbits produce urine that contains high concentrations of minerals and proteins that can adhere to caging equipment. Regular cleaning will minimize the build up of such materials on the caging; however, pretreatment with acid solutions prior to cleaning may be required in order to remove such deposits from cages housing these species of animals (223).

Disinfection of caging can be accomplished, with hot water or chemicals applied either singly or in combination. The conditions under which these disinfection regimens are used must be adjusted so that they adequately kill vegetative forms of common bacteria and other organisms to be controlled by the sanitation program. It must be remembered that cage-washing practices, including the use of disinfectants in the cage-washing regimen, will not necessarily produce sterilized equipment nor guard against contamination after the disinfectants have been rinsed off the surfaces. The process of disinfection with chemicals must be carefully controlled in terms of preparation of the agent, method of application, conditions of application, properties of the agent, and contact time (13, 31, 180).

The use of hot water to disinfect surfaces must also be done in a controlled fashion. It is the combination of the temperature of the water, coupled with the length of time that the surfaces are exposed to a given water temperature (cumulative heat factor), that must be controlled. The same total exposure in terms of time and temperature can be obtained by washing at lower water temperatures for longer periods of time (327). Water temperatures ranging from a 140°F to 180°F have been used effectively in mechanical cage washers for disinfection with hot water alone. If detergents and/or disinfectants are combined with the hot water washing process, it is important that these compounds be thoroughly rinsed from all surfaces, as residual materials may interfere with some types of studies. If manual washing of cages is undertaken, as might be necessary in some specialized housing facilities, special care must be given to standardize the washing process and to assure that personnel are provided with the necessary personal protection equipment to minimize their exposure to hot water or chemical agents (222).

Although conventional methods for washing cages may be satisfactory for most toxicologic studies, the use of specialized bioexclusion systems, such as microisolation caging, may require a greater level of assurance of disinfection. In such cases, wrapping caging after cleaning in steam-permeable materials and autoclaving may be required to achieve the necessary level of decontamination.

Runs and pens may be sanitized by using high-pressure water coupled with detergents and/or disinfectants. Some organisms, such as gastrointestinal parasites, may not be eliminated by such treatments and may require periodic application of chemical disinfectants for prolonged periods of time. In all cases, thorough rinsing of the enclosures is critical so that carry over of materials that might adversely affect the animals or research does not occur.

Secondary enclosures, such as animal holding rooms, hallways, and support areas, should also undergo regular cleaning and disinfection. These areas can easily become contaminated with infectious organisms that can reinfect clean and disinfected caging. Contamination of secondary enclosures can also allow the spread of organisms from one area of a facility to another. To break the cycle, it is necessary to regularly clean the floors, walls, and other surfaces in the room using agents similar to those used in the cage-washing process.

The choice of disinfectants to use in an animal facility is difficult, may not be limited to a single agent, and will rely on a variety of factors. Discussion of disinfection principles is beyond the scope of this text, but useful information that will aid in selecting agents can be found in a number of references (13, 31, 180). For general purpose disinfection, agents should be active both by direct contact and in the vapor phase. The agent should have a broad spectrum of activity, including the ability to kill spores and nonenveloped viruses. Halogen-based compounds, most commonly those containing chlorine, appear to have the widest range of activity and are commonly selected. Care must be taken when using such agents, as regular use of any aggressive disinfectant can also damage surfaces.

PEST CONTROL

Animal facilities by their very nature generate large amounts of waste and use significant amounts of

feed and bedding. Their complex design and extensive mechanical systems provide excellent harborages for rodent and insect pests. Pests can serve as vectors for the introduction into research animal colonies of unwanted parasites and pathogenic microorganisms. Inappropriate

application of materials designed to kill pests can pose a risk to toxicologic research either through direct toxic effects on the animals or by interaction on a molecular level with experimental protocols (98, 155, 329).

Pest control is best conducted by professionals who can design an integrated pest management system that puts in place control methods and monitoring systems to track the effectiveness of the program. The use of potentially toxic chemicals should be avoided whenever possible in favor of nonchemical control measures (73, 105, 109, 164, 223). Application of pesticides should only be conducted with the knowledge of the animal care and research staff and done in compliance with federal, state, or local regulations (222).

WASTE DISPOSAL

Animal facilities generate large amounts of waste in either solid or liquid form. These wastes can either be nonhazardous or hazardous in nature. Depending on the country, wastes from animal facilities may be regulated and may have to be tracked and disposed of in a prescribed manner (244). In the United States, the Medical Waste Tracking Act (MWTA) of 1988 charged the EPA with tracking certain potentially hazardous wastes. Additional state and local regulations may also be imposed, causing the complexity of research waste management to vary from state to state (282). Although these regulations were designed to limit exposures to biohazardous wastes, all animal wastes may be subject to specific tracking and disposal procedures, depending on the interpretation of these regulations. For this reason, a local safety committee with expertise in these regulations should oversee the disposal process and ensure that all personnel handling waste are properly trained.

Some forms of waste may require special handling and may be incinerated on site. The operation of an on-site incinerator is heavily regulated in most countries and is not available at all research facilities. More commonly, contract waste handlers are used to dispose of research/medical waste using methods that comply with existing regulations. Waste water from cage washing, room cleaning, and flushing of pens and runs is flushed into drains to be subsequently treated either on site using local sewage treatment facilities or sent to municipal treatment systems.

Bedding constitutes the largest waste component in animal facilities. This is seldom treated on site and usually is removed either as bagged waste or in large containers for off-site disposal. Final disposal of noninfectious waste bedding is often by composting, land application, or landfills. Noninfectious animal carcasses and carcasses exposed to infectious or other hazardous materials are commonly refrigerated or frozen in plastic bags for sub sequent incineration (222). Recently, cost-effective chemical digestion methods for carcasses and other solid biological wastes have become available, allowing on-site treatment of such items with minimal environmental impact. Wherever possible, waste that is known to contain infectious or heat-liable hazardous materials should be treated by autoclaving or other destructive methods prior to storage for final disposal. Care should be taken to ensure that biological materials with a high liquid content, such as carcasses, are placed in sturdy leak-proof containers that can be sealed to minimize the potential spread of contamination (222).

Areas in which wastes are stored should be adequately ventilated and appropriately labeled. Individual waste containers should also be labeled as to the contents and any hazardous materials that they might contain. In the case of biological materials that are being collected for disposal, refrigerated or freezer storage may be required; in such instances a properly labeled, dedicated refrigerator or freezer should be available.

ANESTHESIA, ANALGESIA, AND SURGERY

Some toxicologic research protocols involve the surgical modification of animals or may subject animals to procedures that are likely to cause pain. Such procedures have been an important focus of the animal use oversight processes in most countries that have legislation regulating the use of animals in research. The researcher bears ultimate responsibility for the use of the appropriate procedures and the administration of the necessary drugs in such circumstances to assure the welfare of animals. Many references are available to assist the toxicologist in developing an appropriate surgical, anesthetic, or analgesic regimen (39, 68, 69, 152, 168). Assistance in this process should be sought from veterinarians experienced in laboratory animal medicine. The conduct of surgery in a research setting usually is a team effort requiring advanced planning, training to acquire the necessary skills, the appropriate facilities and equipment, and regular evaluation of outcomes and objective oversight of the entire surgical process (39, 40, 69).

Because both infection or lack of appropriate materials to successfully complete the surgery can result in the failure of the surgical procedure with the subsequent loss of animals, it is important that all aspects of the surgical procedure, from the selection of the animal through its preparation, anesthesia, surgical

manipulation, and postoperative recovery, be carefully planned in detail and all necessary supplies, equipment, and assistance be provided (14, 15, 222, 291). It is well established that animals are no less susceptible to infection than humans (20, 32, 68, 332, 333); For this reason, any materials or

equipment used in the operative procedure must be appropriately disinfected or sterilized and techniques be used to maintain the critical components of surgical supplies and equipment in aseptic condition throughout the surgical procedure (25, 151, 270, 279, 290).

The complexity of this task varies with the size and number of animals that must undergo a surgical procedure. Large animals often require a much larger surgical field from which hair is removed and the skin is scrubbed, disinfected, and covered by sterile drapes (132, 348). Often the incision site is quite large and the procedures undertaken may be more complex and require more instrumentation than those conducted on small laboratory rodents (69). Personnel must be provided with appropriate operating attire that is decontaminated or sterile. The surgeon's hands and arms should be disinfected by scrubbing with an antibacterial soap and water, and the necessary clothing and gloves should be packaged in a manner that will allow them to be put on by the surgeon in a location and manner so they do not become contaminated. The extent of surgical clothing required will vary with species of animals being used and will be proportional to the size of the operative site and incision (51, 248, 348). In the case of surgery involving rodents, the use of sterile gloves, a face mask, and a clean garment that covers the upper torso including the arms may be all that is required, whereas surgery on larger animals, such as rabbits, dogs, or nonhuman primates, may require much more extensive coverage of the surgeon with disinfected/sterile attire (38, 67, 69).

It is critical to review in detail each component of the procedure to determine if assistance is needed either from a person who is in surgical attire and capable of manipulating instruments or tissues in the operative field or by personnel who are not in full surgical attire and can handle materials that have not been disinfected or sterilized, conduct anesthesia, or aseptically dispense surgical supplies.

To be qualified to conduct the surgical procedure, the toxicologist must undergo training. Most commonly, this is done using a combination of techniques, including assisting in similar surgical procedures, observing others performing the surgical procedure, practicing on cadavers, or in the case of basic surgical technique, using training aids to acquire the necessary skills to conduct the surgery (1). The surgeon should also be prepared to deal with possible complications, including anesthesia difficulties, hemorrhage, difficulties in wound closure, and other similar, unwanted occurrences that could be associated with the procedure.

The postoperative recovery of the animal should be carefully planned and the clinical parameters that would signal need for additional intervention, including supportive therapy, which might consist of supplemental heat, administration of fluids, use of parental drugs (antibiotics, analgesics), nutritional support, or resuscitative procedures, prepared for. The criteria for a successful surgical outcome should be determined, as should the criteria for terminating a process when the outcome is unsuccessful. The toxicologist should have planned for and be trained in appropriate methods of euthanasia if and when it is required (7, 160, 181).

When new procedures are being developed, veterinary assistance and oversight may be necessary to further refine techniques and minimize failures. If animals die unexpectedly or unfavorable outcomes occur, the process should be analyzed and steps taken to improve it. Often critical to this is a comprehensive diagnostic examination of the animals that have undergone the procedure, either at the end of the study or when unexpected deaths or failure of the procedure occurs. Postmortem examinations, including histopathology and, where appropriate, other diagnostic measures, are essential to this process.

Surgical procedures can be classified as either recovery or nonrecovery and further subdivided as major or minor (222). Each requires respect for the animals being used and provision of adequate anesthesia. There are many complex issues in selecting the appropriate anesthetic regimen for any surgical procedure. Anesthetic techniques, equipment, and drugs are constantly being refined. With few exceptions, most techniques that can be applied to man can be applied to animals. Most anesthetic regimens used in toxicologic research, however, tend to be relatively simple and effective. Commonly, only one or two drugs are administered, and agents are favored that are easy to administer and whose use is well characterized in the species selected.

Because most toxicologic research involves small rodent species, agents that can be given intraperitoneally or by inhalation are easiest to administer and are commonly used. Selecting a few anesthetic regimens and being skilled in their use in a particular species often proves to be the most successful approach for the toxicologist. Switching between new anesthetic regimens without adequate training can lead to undesirable outcomes. Conversely, if an anesthetic regimen does not work well in a particular species or for a specific procedure, the toxicologist should not be reticent to seek an alternative technique that is more successful.

If inhalational agents are used, care must be taken to minimize human exposure, especially to women of childbearing age. Simple systems have been devised to scavenge waste anesthetic gases, and devices exist to monitor personnel exposure. Many anesthetic agents and analgesics are categorized as controlled substances that require secure storage, record keeping, and licensure.

When administering anesthesia, it is necessary to be cognizant of the signs and reflexes used to gauge the depth of anesthesia and what dosages will be used to re-dose the animals should additional anesthesia be required.

Similarly, a number of important factors can influence the course of anesthesia, including the state of hydration of the animal, decreases in the animal's core temperature due to loss of heat into its surroundings, the route and site of administration of the agent, and variability in the depth of anesthesia associated with failure to fast the animal. Techniques have been described to address all of these issues as well as others (168, 346).

Once an animal has recovered from anesthesia, there may be instances in the postoperative period where analgesics may be required. Similarly, in some studies, pain may result from nonsurgical procedures or conditions that may need to be relieved for the study to continue. The diagnosis of pain in animals is difficult and does not rely on any single clinical sign (135, 299). Analgesics have not been well studied in laboratory animals. It is clear that animals can and do experience pain and that analgesics can provide relief from pain, as evidenced by alterations in parameters such as weight gain, feed consumption, and activity measurements (219). Determination of the presence or absence of pain in small laboratory animals is particularly difficult, as is the assessment of the effectiveness of various analgesics administered prior to or following the onset of pain. Because the information available for choosing analgesics is limited and in some cases relatively subjective, the toxicologist should seek to assess the effectiveness of any drug or regimen selected through measurement of clinical parameters that are affected by pain.

ACQUISITION, QUARANTINING, AND CONDITIONING ANIMALS

The choice of a particular species for use in toxicologic research may be based on past work using the species, evaluation of metabolic, physiologic, or morphologic characteristics of a given species, the incidence of the development of certain spontaneous lesions, conditions, or an assessment of other biologic parameters, including lifespan, reproductive cycles, and behavioral characteristics that would make them suitable for a particular type of toxicological study. Laws and guidelines in many countries require consultation of literature or other sources of information to verify the appropriateness of a particular species to assure unnecessary duplication of work and to determine if alternatives to painful procedures exists. Other factors, such as the availability of a particular species and its conservation status, may also impact the decision.

When ordering animals, the only truly verifiable specifications are weight and sex. With the exception of nonhuman primates, dogs, and cats, there are very few instances in which a complete clinical or historical record is kept on individual animals. In some cases, a vaccination history and records of preshipment conditioning programs, including dosing with anthelminthic and antimicrobial treatment, may also be available for cats, dogs, and nonhuman primates, as well as limited colony health history, as previously discussed.

Commercially bred rodents and rabbits maintained under defined microbiological conditions by large commercial breeders are easily obtainable, but care must be taken when ordering these animals. Most commercial breeders produce rodents and rabbits in large numbers, often using polygamous or harem mating systems. Stock animals are maintained after weaning either in weight groups or in age groups by week of birth. Animals are seldom held by day of birth unless specific arrangements are made to set aside groups of animals for this purpose.

When ordering, animals usually are specified by weight or age but seldom both. With outbred animals and, to a lesser extent, with inbred and F1 hybrid animals, the weight range at any given age can be relatively broad and significantly overlap weight ranges for other age groups. Hence, it is possible to have animals of two different ages have the same weight. These overlaps can span several weeks of growth. Suppliers construct growth charts that can be used to estimate age based on weight within specific weight ranges. These are useful when a specific weight range of animals is required for a particular study, but some assurance still needs to be given that this represents a certain age range. If both an exact age and a specific weight range are selected, only a small portion of an outbred population of animals (and to a lesser extent, inbred and F1 hybrid animals) will be represented, resulting in unconscious selection for certain traits associated with animals within the population that fall within this specific age/weight range. Such overselection can adversely skew study populations and can lead to circumstances where findings cannot be repeated. For these reasons, it is best to specify animals by either age or weight.

When selecting animals for a study, it is important that the toxicologist carefully determine the size of the study group to be used. If very small groups of outbred animals are used, it is possible to select, purely through sampling error, a nonrepresentative group of animals from a much larger population (125). Attempts to repeat the findings of the study with another small group or even with larger groups may yield different results purely due to inappropriate sampling. It is also a reason why care must be

taken to adequately randomize the assignment of animals to both test and control groups. Populations of animals are dynamic and constantly changing their profile of expressed phenotypes. This occurs to a much smaller degree with inbred animals and F1 hybrids but can occur, as previously described, through the process of fixation and assortment of natural mutations. The problem is magnified in outbred col

onies due to random genetic drift (125). Hence, the toxicologist should expect that historical controls will vary over time in an unpredictable fashion and that such variation will occur regardless if the same colony is used for a source of animals for subsequent studies or if alternative colonies are selected. It is also important to appreciate that while different suppliers may produce strains or stocks of similar designations, perhaps derived from a common source, the longer the time interval from the point of stocking until the present, the more the groups of animals have likely drifted apart genetically and the more likely they are to have different phenotypic expressions, either through continual genetic reassortment and fixation or through the development of new allelic polymorphisms. Switching sources of supply of animals can cause changes in historical controls as well as in standardized assays. These changes usually are not dramatic but can be a source of concern for those assuming that there is some consistency between different populations of animals.

Animals are transported from suppliers to toxicology laboratories in shipping containers that are designed to meet national and certain international standards (141). Depending on the country, various regulations may be applicable to the control of animals in transport. Animals containing infectious agents or whose genetic material has been altered, and animals that have been exposed to hazardous materials of a noninfectious nature, must be shipped in conformance to regulations that can differ significantly between countries. Commercial animal suppliers are experienced in shipping animals in conformance with these requirements; however, if the toxicologist intends to ship animals between institutions, it is important to work with experienced brokers or other shipping agents who can assist in making the necessary arrangements and acquire the necessary shipping containers to legally conduct this process.

For the most part, animals are shipped in new, disposable containers that often are filtered to prevent the incursion of microorganisms. Containers are sometimes sterilized or disinfected, as may be the bedding, feed, and water used in shipping, depending on the supplier and the animals being transported. Most transportation either entirely or in part is done by truck. Most large laboratory animal suppliers maintain independent trucking routes and dedicated vehicles that are disinfected between shipments that transport animals. Some animal suppliers have only limited trucking capabilities and rely on air shipments. All suppliers ship some portion of their animals by air to supply customers not served by truck routes or to accommodate special conditions or orders that cannot be handled by truck. Unless very special shipping containers are used, shipment of animals by air allows the possibility of excessive stress and contamination during shipment (190, 222, 223). Moreover, the supplier does not have control of the shipment while it is being handled by the air carrier, and hence the control of environmental conditions may vary depending on the circumstances.

It is generally good practice to process animals immediately upon receipt at the research institution. Disinfection of the outside of the containers with solutions of general-purpose disinfectants is often a prudent step, especially if the animals have been shipped by air. Animals should be removed from their containers and examined upon arrival to confirm their clinical condition and to verify order specifications. They should be placed in appropriate caging that has been labeled to identify the animals, and they should be given access to feed and water as soon as possible after arrival. Most toxicologic research facilities provide a period of stabilization and/or quarantine for newly arrived animals. During quarantine periods, animals are observed for clinical signs of disease, samples are taken for health assessment, and in some cases, vaccinations, treatment with antimicrobials, or treatment with anthelminthics may also be undertaken (222). Other forms of diagnostic testing may also be conducted during the quarantine period. The length of quarantine can vary considerably, depending on the institutional exclusionary list of organisms for a particular species and health monitoring program.

A stabilization period differs from quarantine in that a stabilization period is designed to allow the animals time to recover from the stress of transportation, become rehydrated, and to gain back weight that may have been lost during transportation (2, 74, 78, 148, 326). This period of acclimation also allows the animal to become accustomed to using the water and feed sources and to adapt to any changes in diet (112, 173, 262, 313). In the case of group-housed animals, it allows the establishment of both social hierarchies and other behavioral adaptations. Stabilization and quarantine should be done concurrently. Some institutions do not have a quarantine period in which health monitoring is conducted, but rather, health monitoring information from the animal supplier is used to determine the fitness of the animals for incorporation into the research program. A stabilization period, however, may be instituted for the group to allow the necessary acclimation to occur prior to use. Typical stabilization periods range from 3 to 7 days for most species and are based upon some limited work to suggest that periods of 48 or 72 hours are necessary to overcome the stress of transportation (173, 286, 318).

QUESTIONS

1. What housing systems can be used to minimize the risk of introduction and spread to animals of unwanted microorganisms that could alter toxicologic research?
2. What microorganisms that infect animals have the ability to alter toxicologic research results?
3. If outbred (non inbred) rodents are used in toxicologic research or product registration studies, what factors associated with their breeding methods and source colonies, as well as ordering specifications, can cause variation in research results?
4. What are the differences between closed formula, open formula, and constant nutrition natural ingredient diets used to feed research animals?
5. What laws, regulations, and guidelines affect the use of laboratory animals in toxicological and product registration research?
6. What constituents of the research animals' environ ment can cause variation in toxicologic research results?

Genetic toxicology, as a subspecialty of toxicology, involves the identification and analysis of agents with toxicity directed toward the hereditary components of living organisms. A large proportion of human disease is either directly or indirectly associated with genetic dysfunction. Many agents are able to produce genetic damage at high exposure concentrations following the induction of acute, nonspecific cytotoxic effects across a wide range of cellular processes, however, the ultimate objectives of genetic toxicologists are to detect and access genetic hazard from agents that are highly specific for nucleic acids and are capable of producing genetic damage at subtoxic concentrations. Such agents are classified as *genotoxic*.

The term *genotoxic* is a general descriptor and is used to distinguish chemicals that have an intrinsic affinity for DNA from those that do not. Genotoxic substances have several common chemical or physical properties facilitating their interaction with nucleic acids (i.e., electrophilicity). A report of the International Commission for Protection Against Environmental Mutagens and Carcinogens (ICPEMC) provides a more detailed definition of genotoxic and emphasizes that categorization of a chemical as genotoxic is not a priori indication of a health hazard (46).

Mutagens comprise a subset of genotoxicants and are characterized by their ability to induce specific classes of stable changes in (a) the nucleotide sequence of genes, (b) chromosome structure, or (c) chromosome number. Changes in nucleotide sequence are described as point mutations, and chromosomal damage is referred to as clastogenicity. These two major classes of genetic damage are responsible for a large proportion of the array of human genetic diseases and contribute significantly to congenital malformations.

Because the original goal of genetic toxicology was to protect the human gene pool from increases in

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_819.html[2010/10/28 18:48:11]

mutational load, the discipline of genetic toxicology initially focused on transmissable damage. Test methods employed during this early period were primarily in vivo and focused on measuring damage to mammalian germ cells. Later, reports from several independent groups of investigators were published showing a correlative relation between mammalian carcinogens and mutagens (3, 14, 18, 60, 93).

Table 17.1 Basic biochemical characteristics of all double-standard DNA

DNA consists of two purines (guanine, adenine) and two pyrimidines (thymine and cytosine).

A nucleotide pair consists of one purine and one pyrimidine (adenine/thymine (AT) or guanine/cytosine (GC)).

Nucleotide pairs are connected to a double helix molecule by sugar-phosphate backbone linkages and hydrogen bonding.

The AT base pair is held by two hydrogen bonds and the GC is held by three hydrogen bonds (see Figure 17.2).

The distance between each base pair in a molecule is 3.4 Å, producing 10 nucleotide pairs per turn of the DNA helix.

The number of adenine molecules must equal the number of thymine molecules in a DNA molecule. The same relation exists for guanine and cytosine molecules. The ratio at AT to GC base pairs, however, may vary in DNA from species to species.

The two strands of the double helix are complementary and antiparallel with respect to the polarity of the two sugar-phosphate backbones, one strand being 3′-5′ and the other 5′-3′ with respect to the terminal OH group on the ribose sugar.

DNA replicates by a semiconservative method in which the two strands separate, and each is used as a template for the synthesis of a new complementary strand.

The rate of DNA nucleotide polymerization during replication is approximately 600 nucleotides per second. The helix must unwind to form templates at a rate of 3600 rpm to accommodate this replication rate.

The DNA content of cells is variable (1.8×109 daltons for *Escherichia coli* to 1.9×1011 daltons for human cells).

Thus, genetic toxicology has evolved to play a dual role in safety evaluation programs. One role is the implementation of testing and risk assessment methods to determine the impact of genotoxic agents found in the environment on the integrity of the human gene pool. The second role is the application of genetic test methods to the detection and mechanistic understanding of carcinogenic processes.

BASIC GENETIC CONCEPTS

Gene Structure

The hereditary informational molecules of all living systems, with the exception of some viruses that use RNA, are composed of DNA, and those organisms which store their hereditary information in RNA go through a DNA intermediate during replication. Some common characteristic features of DNA molecules are listed in Table 17.1. The mechanisms of information storage and gene expression are similar for all organisms with DNA composition.

The simplest complete functional unit in a DNA molecule is termed a *gene*. Most of the early knowledge concerning structure and operation of genes was acquired from studies with bacteria or bacteriophages. During the past 10 years, development in molecular biology of mammalian cells has resulted in equivalent information in this cell type. The differences between the genes of prokaryotic (bacteria) and eukaryotic (plant and animal cells) organisms center primarily on the number, location of the respective chromosome, and mechanisms of gene regulation (Table 17.2). In prokaryotic cells there is a single *chromosome* with little or no differentiation along the DNA molecule so far as function is concerned. Eukaryotic cells, on the other hand, have DNA with nonfunctional, repeated sequences of some genes; these cells also have regions of noncoding DNA, called *introns*, inserted between coding sequences called *exons*. The exact function of repeated DNA sequences and intron regions is not known.

The nucleotide composition and the mechanisms by which information encoded in a gene is transformed into gene products is universal. Universality was confirmed by recombinant DNA genetic engineering studies in which genes continue to function properly after having been transplanted from human cells to bacterial cells or from bacterial cells to plant cells (15, 53).

In eukaryotic cells, the process of gene expression follows the pattern shown in Figure 17.1. Enzymes located in the nucleus of the cell excise intron regions and splice the coding sequence back together. The resulting mRNA is then transported to ribosomes outside the nucleus for translation. Intron regions are not present in prokaryotic cells, and the gene is read in one sequence. DNA repair processes are also influenced by transcription activity. Important to a full appreciation of the functions of genes coding for structural proteins and enzymes is the identification of regulatory genes that control gene expression.

Somatic and Germ Cell Characteristics

From a genetic perspective, multicellular eukaryotic organisms are composed of two cell types: somatic cells and germ cells. Somatic cells constitute the major portion

Page 821

Table 17.2 Characteristics of DNA in prokaryotic and eukaryotic cell types

Prokaryotic Cells	Eukaryotic Cells
Primarily haploid	Primarily diploid
DNA uncomplexed	DNA complexed with proteins forming chromosomes
DNA nonlocalized in the cell cytoplasm	DNA localized primarily within the nucleus of the cell
No morphologic stages in DNA replication	DNA replication described by mitotic cycle consisting of specific cytologic stages
DNA often found as a closed circle	DNA found in linear chromosomes
Replication not associated with cellular organelles	Replication and separation of chromosome associated with cellular organelles called centrioles
All genes encoded in the DNA are functional	Repetitive, nonfunctional gene sequences are common
Spacer sequences have not been identified	Noncoding spacer sequences identified as introns occur along the DNA molecule

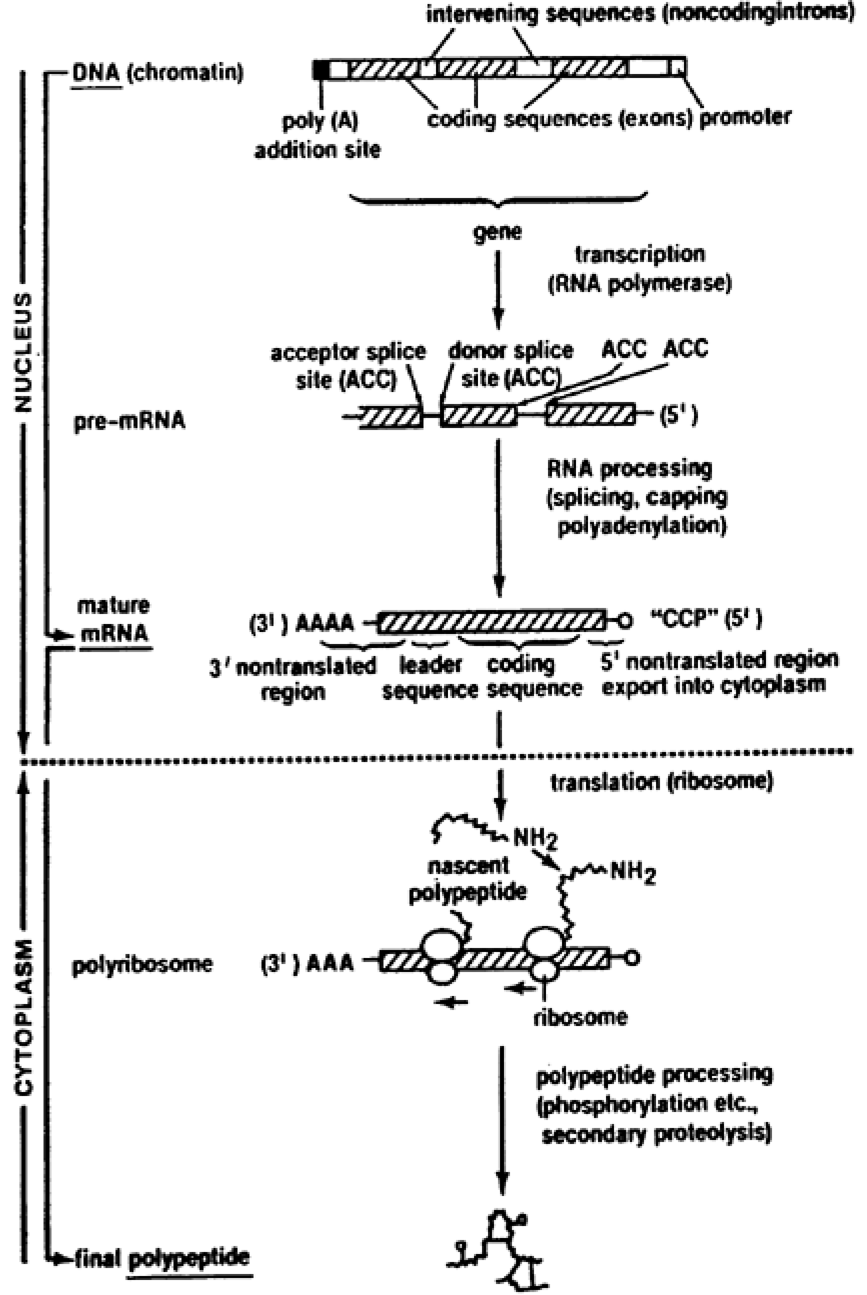

FIG. 17.1 Transcription and translocation of mammalian genes.

of the mammalian organism. The *genomes* of most somatic cells are *diploid* (two complete sets of chromosomes), and genetic alterations in somatic cells are not transmissible to subsequent generations. Virtually all in vitro mammalian cell assays used in genetic toxicology employ somatic cell types. Germ cells (sperm and eggs) are a special cell population in multicellular organisms. Their function is to form the next generation. Mutations carried in these cells produce a broad array of heritable genetic diseases, congenital malformations, and other disorders. Germ cells are derived from diploid stem cells in gonadal tissues following meiosis and carry a *haploid* set of chromosomes. *Mutations* carried in germ cells are classified as recessive or dominant, dependent on their expression in the diploid state. A large proportion of human genetic diseases are associated with recessive mutant genes that are expressed only when two mutant alleles (one contributed by each parent) are present in the homozygous condition. Recessive mutations are maintained at a constant level in the gene pool in the heterozygous state and are carried in that configuration by individuals who appear phenotypically normal. The inability to identify heterozygous from normal individuals is one of the primary reasons that the human genetic burden has not been reduced. Table 17.3 summarizes the spectra of mutations in humans for germ cell and somatic cell effects.

DNA ALTERATIONS RESULTING IN GENOTOXIC EFFECTS IN CELLS

DNA synthesis and replication are not flawless processes, and in rare instances, genetic alterations occur

Table 17.3 Mutational spectrum in humansa

Mutation Type	Examples of Inherited Effects	Examples of Somatic Effects
Single base changes	Sickle cell disease, Phenylketonuria	Epithelial cancers, activation of *ras* oncogenes
Small deletions and/or translocations	Haemophilias, Duchenne muscular dystrophy	Lymphomas, leukemias, enhanced activation of *myc, abl* oncogenes
Whole chromosome losses or gains	Down's syndrome, Turner's syndrome	Loss of tumor suppressor genes, retinoblastoma, Wilms' tumor, breast cancer

a From Reference 35.

spontaneously during normal cell division. In addition, endogenous oxidative metabolism produces reactive species capable of damaging DNA. The occurrence of intrinsic damage follows a predictable rate per gene and forms the basis of "background" or "spontaneous" mutation frequencies. In addition to errors in replication or repair, the origin of spontaneous mutations may arise from unavoidable environmental exposures (e.g., background radiation, diet).

Classification Scheme for Genotoxic Effects

DNA damage may be classified into several broad categories based on the nature (presumed mechanism) of the DNA change. The following is one type of such classification:

A. DNA disruption damage involves the breakage of and/or interchange of DNA segments between chromosomal structures. This type of damage may be visible through cytologic analysis of condensed chromosomes. Although genotoxicants such as alkylating agents induce DNA disruption damage, a characteristic of DNA disruption damage is that it may also be caused by secondary mechanisms (e.g., processes that result in cell stress such as high temperature) that do not target nucleic acids specifically (43, 16).

B. DNA microlesions are nonvisible alterations occurring at the nucleotide level. Nucleotide damage generally produces point mutations through base-pair substitution or insertion/deletion or it may induce recombination between sister chromatids. Microlesions generally are induced by agents that specifically target nucleic acids (e.g., electrophilic agents).

In addition, some genotoxic effects may be induced by other mechanisms that do not fall readily into either of the two mechanisms defined previously. Examples of such genotoxic damage are aneuploidy/polyploidy that may be caused by damage to chromosome movement proteins and morphological cell transformation resulting from altered gene expression patterns.

Processes Leading to Mutation

The expected DNA base pairings are shown in Figure 17.2: adenine and thymine form two hydrogen bonds, and guanine and cytosine form three. Hydrogen bonds are weak electrostatic forces involving oxygen and nitrogen atoms at specific sites on the purine and pyrimidine molecules. If electrophilic chemical species covalently bind to portions of the DNA bases involved in the formation of hydrogen bonds (Figure 17.3), these covalently bound species *(adducts)* can produce electron shifts from the H-bonding sites to areas within the molecules, giving opportunities for short-lived mispaired bases (e.g., A:C

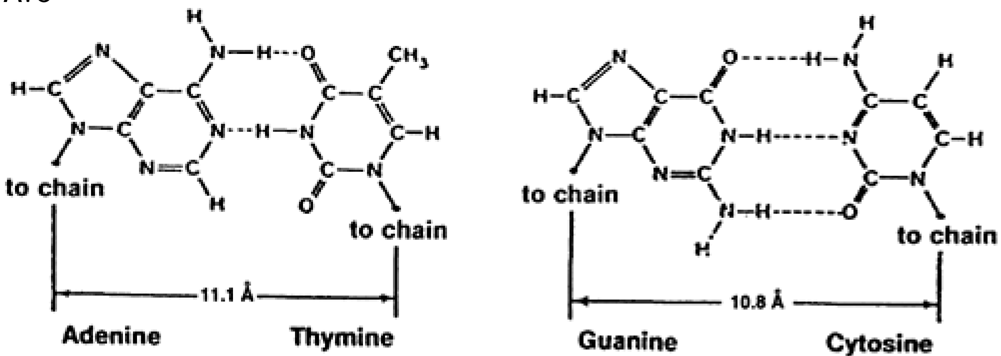

FIG. 17.2. Hydrogen bonding of nucleotides normally found in DNA.

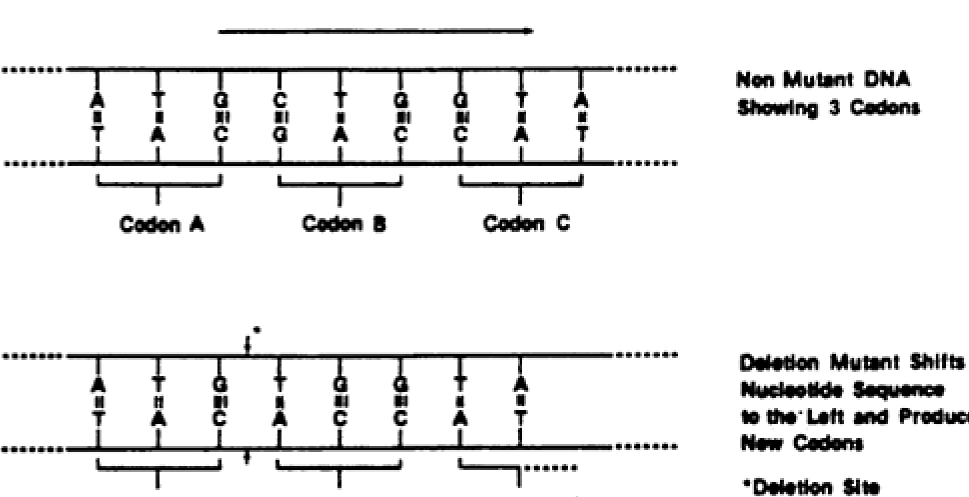
FIG. 17.3. Two examples of DNA chemical adducts. (Top) an aromatic amine adduct to guanine. (Bottom) a benzo[a]pyrene metabolite adduct to guanine.

or G:T). If this mispairing occurs before or during a DNA replication cycle, the result may be the substitution of an incorrect base pair for the original pair. The cycle of DNA replication to fix base-pair substitution mutations is called the "expression period" in in vitro mutation assays.

Base-pair addition-deletion mutations, also called *frameshift mutations*, result from the addition or deletion of one or a few nucleotide pairs from the nucleotide sequence in an exon or gene. Because the codon sequence reads in one direction and is nonpunctuated, the loss or gain of a single base pair changes the reading frame of the gene—hence frameshift mutation. This type of mutagenic mechanism is illustrated in Figure 17.4. Both frameshift and *basepair substitution* gene mutations result in alterations in translation of mRNA into the proper sequence of amino acids in the gene products (See Figure 17.1) and produce a mutant cell or organism. Mutations or DNA methylation in regulatory genes are capable of modulating the production of functional gene products (44).

DNA is visible microscopically as a chromosome. Figure 17.5 illustrates the generalized anatomy of a chromosome. The chromosome illustrated is typical of a metaphase structure and the anatomy shows distinctive bands as a result of giemsa staining. Mammalian chromosomes have a constriction known as the *centromere*. To either side of the centromere are the chromosome arms that terminate in structures called *telomeres*. The dark G+ bands represent highly condensed DNA and are areas of little or no gene expression (transcription). The light G− bands represent active genomic areas where gene expression (transcription) is occurring. The telomeric regions at the ends of the chromosome struc



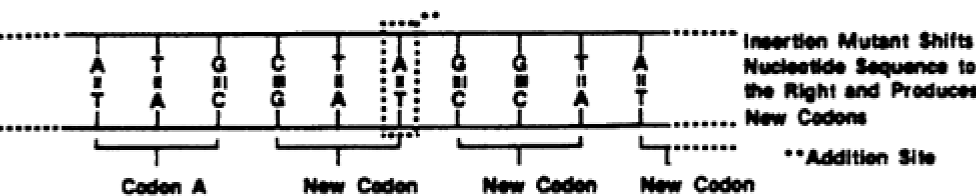


FIG. 17.4. The base pair changes involved with frameshift mutations. An insertion or deletion of a base pair results in the shift of the gene or exon reading frame.

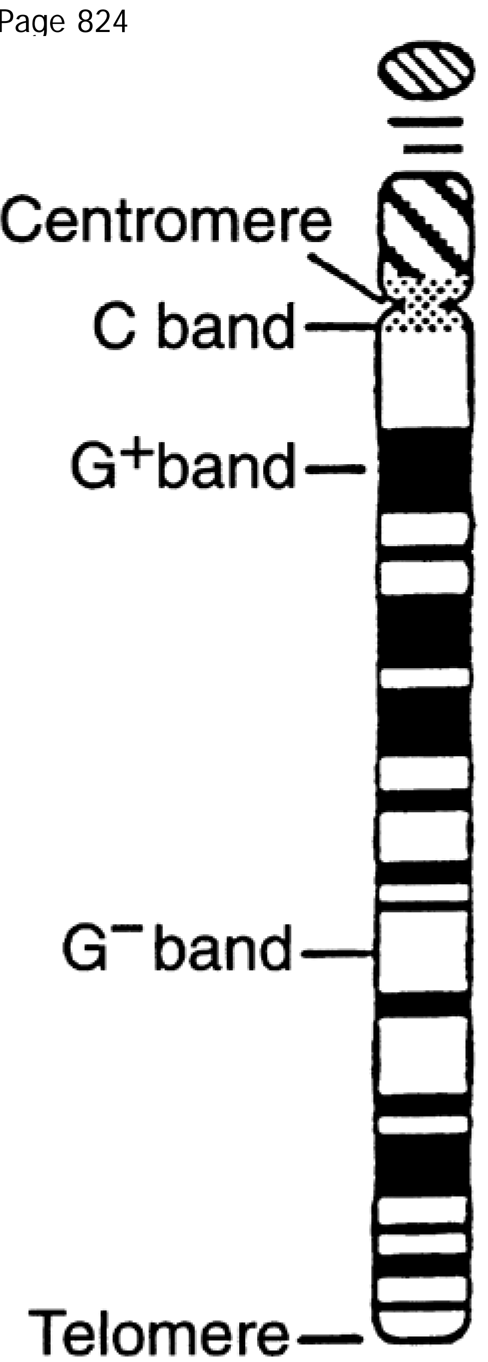

FIG. 17.5. The anatomy of a typical chromosome to show active (unstained) and inactive (stained) regions.

tures are important for chromosome stability. Telomeres consist of repeat units of a small number of nucleotides that stabilize the linear DNA molecule. At each cell division, chromosomes lose small amounts of telomeric DNA. The ability of the cell to replace the lost DNA with telomerase determines whether the cell continues to proliferate or, if the DNA loss reaches a critical level, stops dividing (28). Microscopically visible DNA disruption damage is subdivided into changes in chromosome number (gain or loss of single chromosomes or sets of chromosomes) and changes in chromosome structure (breaks, deletions, rearrangements). Each type of chromosome change has a characteristic morphometric description so that a reasonably high degree of uniformity can be maintained when scoring them microscopically. Variations in chromosome number can result from incomplete dissociation of single or entire sets of chromosomes at metaphase, resulting in aneuploidy or polyploidy (34). A wide range of in vitro and in vivo genetic test methods are designed to assess chromosome breakage and numerical changes. Chromosome breakage can be induced by several mechanisms (e.g., disruption of DNA synthesis or DNA cross-linking) that result in double-strand breaks. In addition to the tests that

specifically measure nucleotide substitutions and chromosome alterations, a third group of tests to measure other mechanisms of genotoxicity has been employed in screening. Included in this group were tests for DNA binding and repair, DNA strand breakage, sister chromatid exchange (SCE), and mitotic recombination. These methods were categorized as tests for measuring primary DNA damage. Few testing guidelines specify primary DNA damage tests any longer, as these tests have been found to lack adequate specificity and sensitivity. In some instances they may be useful biomarkers of exposure to genotoxicants.

A significant amount of research has focused on the induction and measurement of DNA adducts. The initial hope of this technology was to use adduct formation as a method to demonstrate exposure and calculate cancer risk. To date, that hope has not been fulfilled. Adduct formation remains a sensitive method to demonstrate exposure; however, we still do not know enough about adduct processing and repair to use this information to define genetic or cancer risk except for a small number of agents. Binding sites on DNA vary with the compound and are influenced by complex factors that are not yet understood. What is known is that organs/tissues in mammals have different capacities for repairing adducts and that some adducts, such as the O-alkyl adducts, are repaired inefficiently and probably produce most of the mutagenic damage responsible for tumor cell initiation.

Repair of DNA Damage

The fidelity and integrity of genetic information in organisms are maintained by several types of enzymatic DNA repair. The characteristic of self repair is unique to DNA and illustrates how important the integrity of this molecule is to the survival of an organism. Table 17.4 summarizes the major classes of DNA repair that exist in virtually all higher organisms. DNA repair kinetics are variable, but, in general, highest rates of DNA repair are associated with gene transcription processes (i.e., transcription-coupled-repair (TCR)).

DNA damage is induced by environmental agents and normal cellular proceses of DNA replication or oxidative stress. Some estimates of endogenous damage and repair capacities for human cells are given in Table 17.5. As indicated, endogenous cellular repair capacities are more than adequate to compensate for background DNA

Table 17.4 Classification and properties of DNA repair processes

Class	Properties
Base excision repair	Elimination of single nucleotide through cleavage of the glycosyl bond connecting the altered base to the deoxyribose sugar, resulting in an abasic site in the DNA followed by resynthesis using the opposite strand as template.
Nucleotide excision repair	Removal of bulky DNA adducts from DNA. Process involves 20 proteins that remove up to 100 nucleotides associated with damaged region. Repair synthesis using the opposite strand as template fills in repair patch.
Mismatch repair	A "second chance" repair system that corrects mismatch base pairs post-DNA replication. This process catches lesions missed by nucleotide excision repair and base excision repair (BER) processes.
Recombinational repair	This process acts on double-strand DNA breaks and/or DNA crosslinks, where both DNA strands are damaged.

damage; however, massive or frequent exposures to exogenous genotoxic agents may saturate the DNA repair capacity leading to human genetic disease, aging, and cancer (83).

The most important feature of most repair processes is the ability to enzymatically remove and replace damaged segments of DNA with higher fidelity. If a DNA lesion can be repaired prior to mutation fixation, the net effect of the DNA damage to an organism may be nil. This is especially true following intermittent, low-level exposures to genotoxicants, where repair enzymes are not fully saturated by excessive numbers of damaged DNA sites. DNA adducts are not all recognized or repaired equally by excision repair. The size and effect that an adduct has on the conformation of DNA determines how readily it is detected by the repair enzymes and is excised. As a consequence of this situation, it is not advisable to use the number of adducts per cell as a predictor of damage or genetic hazard unless definitive information is available about the elimination kinetics for the specific adducts (99).

Test systems measuring some parameter of the DNA repair process have been used as genotoxicity screens for detection of primary DNA damage (80, 103). Normal organisms are capable of some type of DNA repair

Table 17.5 Estimates of human endogenous DNA damage and repair processes[a]

Type of Damage	Estimated Occurrences of Damage per Hour per Cell[b]	Maximal Repair Rate, Base Pairs per Hour per Cell
Depurination	1000	–[c]
Depyrimidination	55	–[c]
Cytosine Deamination	15	–[c]
Single-stranded breaks	5000	2×10^5
N7-methylguanine	3500	Not reported
O6-methylguanine	130	10^4
Oxidation products	120	10^5

[a] Modified from data in Reference 69.
[b] Might be higher or lower by a factor of 2.
[c] Not reported, but the rates are at least 10^4, based on concentration of repair activities in cell extracts.

activity following chemical insult; thus, stimulation or induction of repair activity following chemical treatment at sublethal concentrations is a good indicator that the target organism has experienced DNA-directed toxicity. These tests are generally identified as measures of unscheduled DNA synthesis (UDS).

Studies of DNA repair kinetics indicate that once permutational lesions have been induced in the DNA, both error-prone and error-free repair processes are activated. Error-prone repair processes generate nucleotide mismatches (i.e., A:C or G:T) that produce mutations de novo. Error-free repair replaces the damaged DNA site with a correct nucleotide sequence. The fidelity of repair depends on the degree to which the two different processes are involved. Factors that determine whether error-prone or error-free pathways predominate include (a) the target species, (b) cell type involved, (c) chemical mutagen, and (d) the specific DNA lesion induced. Some data suggest that the error-free repair pathways predominate at low exposure levels, and error-prone pathways come into play only following saturation of the error-free enzymes.

The basic processes of Nucleotide Excision Repair (NER) and Base Excision Repair (BER), the primary repair mechanisms for chemical damage, are shown in Figure 17.6. The enzyme complex responsible for NER of bulky adducts requires more than 20 proteins and consists of several steps (63). One step is an

endonuclease activity that cleaves the DNA at the site of the damage; an exonuclease cuts out the damaged region, including nucleotides to either side. The correct bases are replaced by a DNA polymerase using an editing function to ensure that the correct bases are incorporated into the repair patch. DNA ligase seals the repair patch. Occasionally, even in error-free repair, incorrect bases are incorporated

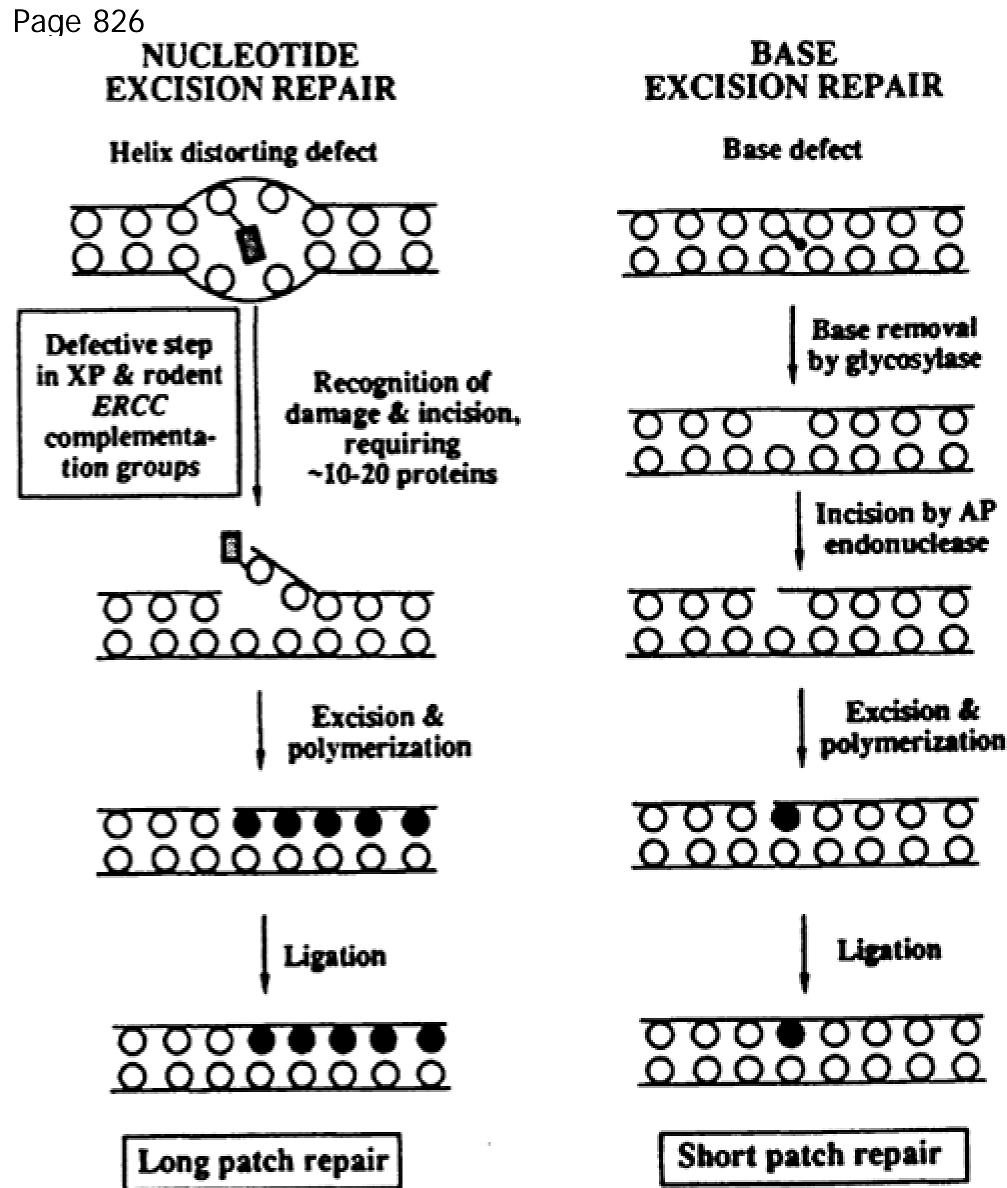

FIG. 17.6. Long and short patch excision repair processes.

by the polymerase, resulting in mismatched bases that do not properly hydrogen bond. In BER, a number of different glycosylases catalyze release of the inappropriate base, followed by replacement and ligation (38).

Mismatch repair (MR) enzymes recognize nonhydrogen bonding base pairs. A short segment of the DNA duplex is excised and filled by the repair polymerase. This is a second-chance repair process that occurs after BER and NER and improves the accuracy of those processes. Finally, recombinational repair acts on double-strand breaks and interstrand cross links, resulting in damage to both strands of the DNA. Collectively, these processes maintain integrity of DNA against endogenous and exogenous sources of damage.

Repair of mutational damage has been shown to be inducible by low-level exposures to DNA-damaging agents (79, 105). Inducibility of repair processes above constitutional levels will increase the magnitude of exposure required to exceed the intrinsic capacity producing a “threshold” for mutation and produce a protective effort for subsequent exposures. Theoretical assumptions and data from studies of repair support the belief that at background or low-exposure levels, an error-free removal of alkyl groups from DNA can be virtually 100% effective. Thus, one observes survival shoulders and nonlinear kinetics for mutation induction in repair-proficient cells and the loss of apparent “no effect” regions in repair-deficient cells.

Because of the influence that species- and cell-specific genetic background have on repair capacity, an appreciation of the variability of DNA repair in somatic and germ cells of humans as well as the animal

models is essential in assessing genetic risk (36, 71). Several general characteristics of mammalian DNA repair are summarized in Table 17.6.

RELATIONSHIP OF GENOTOXIC DAMAGE TO TOXICITY

The proposed sequence of events from DNA interaction to the expression of human toxicity is represented

Page 827

Table 17.6 DNA repair characteristics

DNA repair characteristics
DNA repair is tissue- and species-specific (e.g., human capacity approximately 10-fold greater than mouse)
DNA repair is increased in genes involved in transcription (e.g., chromosome loops)
DNA adducts are repaired with different efficiency (e.g., bulky >small)
Effects of DNA repair are tied closely to cell stringency and apoptosis (e.g., cell lines with low cycling stringency have higher error rates)

HUMAN DISEASE

FIG. 17.7. The hypothetical process from exposure to genotoxin to the induction of genetic disease in humans. Repair processes can eliminate the formation of mutations that produce disease.

in Figure 17.7. The nature of the toxicity or disease is dependent on which cells or tissues and genes are altered by the mutation.

Because of the fundamental role genes play in all aspects of organisms, the mutational basis for many human disorders and anomalies is well documented (61). The genetic disease burden in humans is estimated to be approximately 5% (Table 17.7), and its effects contribute significantly to the health care costs of most developed countries. The origin of the mutations in the gene pool is unknown, but Table 17.8 provides several probable sources. Animal experiments offer convincing evidence that environmental agents are capable of inducing permanent, transmissible mutations in either somatic or germ cells and support the assumption that humans are susceptible to genetic risk factors in the environment (76, 77). Other types of toxic phenomena appear to be determined or influenced by somatic cell genotoxicity. Among these endpoints are the following:

1. Oncogenesis-inherited and induced forms (12, 54).
2. Teratogenesis (49).
3. Sterility or semisterility (23).
4. Atherosclerosis (47).
5. Aging (20).

Tests for DNA binding and repair, point mutation, and clastogenicity have been used to monitor human populations, putatively exposed to genotoxic agents, for evidence of somatic cell genotoxicity (27). In many studies there have been strong associations between somatic cell toxicity and the production of primary DNA damage 127–138. PAH exposure, DNA adducts, and tumor incidences are highly associated in human populations, but DNA adducts are not general predictors of carcinogenesis (57); however, the consistency between cancer and other types of DNA damage, such as chromosome aberrations, SCEs, or micronuclei in humans exposed to carcinogens, is not sufficient for routine human monitoring (11).

Carcinogens and Mutagens

During the early 1970s, the introduction of a *Salmonella* assay detecting reverse mutation, combined with an in vitro metabolic activation system, appeared to offer a rapid, inexpensive solution to the identification of chemical carcinogens (4, 58). The Ames test was the forerunner for an array of submammalian and mammalian cell assays proposed as rapid screens for carcinogens (73, 74). The rationale for the use of these methods consisted of several investigations demonstrating that properties associated with the transformed (malignant) cell phenotype were encoded in the DNA. During the late 1970s, studies were published showing that DNA isolated from transformed mouse cells could be

purified of other contaminants, cut into discrete fragments by bacterial restriction enzymes, transfected into "normal" cells resulting in the conversion of "normal" cells into a transformed phenotype (101). Investigators conducting these experiments ultimately identified a series of genes in the restriction fragments (proto-oncogens) responsible for transforming the cells (12, 75). Proto-oncogens are highly conserved genes found in most eukaryotic organisms, and some, such as the *ras, myc,* and *neu* genes, are known to be activated by base-pair substitution mutations or chromosome aberrations (34). Additional loci have been discovered that code for tumor suppressor molecules. The suppressor molecules, which prevent cell proliferation, become inactive following mutation in the genes coding for them (45). *Oncogenes* and *tumor suppressor* have been studied in humans and in rodents used for experimental carcinogenesis studies (7). It has been established that some strains of animals carry activated oncogenes in their germ line and are predisposed, therefore, to specific tumor types following exposures to promoting agents alone (55). Apoptosis is an important cellular process that functions

in the immature and adult animals. In adult animals it is responsible for elimination of potentially preneoplastic cells by nuclear degredation (97). The p53 tumor suppressor gene is a major apoptosis-inducing protein. Elimination or reduction in the expression of p53 by mutation is believed to be a critical step in the process of neoplasia.

Support for genotoxicity as a means of carcinogen detection was derived from studies correlating the results of specific genotoxicity tests (or batteries of tests) on chemicals with tumor responses, for the same chemicals, in long-term tests using mice or rats. The animal cancer classifications were usually consensus responses derived from multiple tests employing several rodent species or strains. During the early 1970s, concordance between rodent carcinogenicity and results reported for chemicals in the Ames test ranged from 90% to 95% (89); however, by 1984 the concordance on a wider base of data had dropped to just over 60%. There are several reasons for this reduction in concordance (9); however, the factor that had the most influence was the selection of chemicals

Table 17.8 Origin of mutations in the human gene pool

- The majority are inherited
- A small number arise from spontaneous events that occur during normal DNA replication and repair
- Unavoidable environmental exposures (radiation, products of combustion, mycotoxin, pesticides, manufacturing emissions, etc.)
- Therapeutic treatments that are directly mutagenic (e.g. radiation)
- Successful treatment of individuals with lethal genetic diseases, thereby elevating the gene frequency in the reproducing population

used in the comparisons (17). Reports in the early to mid-1970s showing high concordance employed groups of chemicals highly biased toward electrophilc carcinogens (72). Reports with lower concordance employed groups of chemicals (a) not selected for electrophilicity and (b) with a greater proportion of noncarcinogens. A good comparison of the two approaches is summarized in Table 17.9, which compares the results of the EPA Gene-Tox analysis of concordance and the National Institute of Environmental Health Sciences (NIEHS) National Toxicology Program (NTP) analysis of concordance (52). The EPA Gene-Tox analysis, which demonstrated high positive correlations between mutagens and carcinogens, used published data heavily skewed toward positive responses in both the cancer and genotoxicity tests (Table 17.10). Consequently, it is impossible to exclude chance as an explanation for the high concordance found in the EPA Gene-Tox assessment.

Another outcome of the cancer concordance analyses has been the use of genotoxicity tests to help interpret the mechanism of rodent carcinogens. Carcinogens with positive effects in genetic tests are considered to act through direct genotoxic effects on DNA in contrast to carcinogens with predominantly negative results in genetic tests. Thus, a classification scheme of genotoxic and nongenotoxic carcinogens has been proposed by some individuals as a method to interpret the mechanisms of tumor initiation and aid in the selection of the most appropriate data extrapolation model for cancer risk assessment (84). A genotoxic mechanism implies a no-threshold mechanism, and risk data would be analyzed with more conservative methods than would data from nongenotoxic carcinogens. While conceptually this scheme appears reasonable, a better understanding of carcinogenic processes is necessary to support its general appreciation to risk assessment. With the correlation between carcinogens and mutagens averaging about 70%, the appropriate integration of genetic toxicology results into toxicological assessments is less than certain.

The use of genetic tests as part of an assessment for carcinogenic potential may be justified by mechanistic considerations alone and may not have to be supported by high correllations. New mutation models, such as the in vivo *transgenic* models developed for measuring

mutation, may offer a much more relevant assessment of carcinogenicity than in vitro assays (78). Two transgenic models for mutation detection employing transgenes from the bacteria *lac* operon have been developed and partially validated (64, 85). Other transgenic mouse models with altered tumor suppressor genes (p53 heterozygote) or activated proto-oncogenes (TG:AC) are currently under validation in short-term bioassays for chemical carcinogens. The p53 model is used for genotoxic agents as the mode of action for enhanced tumorigenesis is inactivation of the normal p53 allele by chemical-induced mutation, deletion, or rearrangement (98).

EFFECTS OF MUTAGENS ON THE HUMAN GENE POOL

Induction of damage to the germ-line DNA of plant and animal species has the potential to create serious adverse consequences for the health and survival of those organisms. In humans, genetic damage is a cause of hereditary diseases, cancer, congenital anomalies, and even reduced life expectancy (94).

The genes needed to produce the current human population were all acquired from the previous generation's *gene pool*. The gene pool is the sum total of genes, at a given point in time in the reproductively active population of a species, available for transmission to the next generation. Deleterious genes are present in the gene pool at a set frequency, as evidenced by predictable rates of recurring genetic diseases in the human species. The origin of this genetic burden (genetic load) is not known, but it is imperative that the current caretakers of the gene pool use all precautions to transmit it to the next generation in no worse shape than it was received.

Genetic disease in humans appears to be produced by the same types of mutations identified in animal models:

Table 17.11 Examples of human diseases and conditions caused by mutations in germs cellsa

Genetic Disease or Condition	Estimated No. of Cases in the United States
Dyslexia	15,000,000
Manic depression	2,000,000
Schizophrenia	1,500,000
Juvenile diabetes	1,000,000
Adult polycystic kidney disease	500,000
Familial Alzheimer's disease	250,000
Multiple sclerosis	250,000
AAT deficiency (emphysema)	120,000
Myotonic muscular dystrophy	100,000
Fragile X chromosome syndrome	100,000
Sickle cell anemia	65,000
Duchenne muscular dystrophy	32,000
Cystic fibrosis	30,000
Huntington's chorea	25,000
Hemophilia	20,000
Phenylketonuria	16,000
Retinoblastoma (childhood eye cancer)	10,000

a From Reference 96

(a) chromosome abnormalities resulting in stable changes in chromosome number or structure, (b) dominant gene mutations in which only a single mutant allele (of the normal gene pair) is required to produce the disease, (c) recessive gene mutations in which both alleles of the pair must be mutant for

expression of the trait, or (d) polygenic mutations in which the mutant trait is determined by the interaction of several genes.

Table 17.11 provides examples of human genetic diseases as well as the frequency of these disorders in the United States population. The examples given in the table represent only a small portion of the total human diseases and defects known to be of genetic origin (61). It is estimated that the human genome consists of approximately 140,000 genes controlling all aspects of an organism's biology and behavior. Of the total number of genes, we currently know the function for about 1500 to 2000 genes (30). The current human genome project plans to complete sequencing the entire human genome by 2001; however, it will be many more years before all gene functions are mapped to a physical structure.

The degrees of impact to the gene pool from the separate categories of germ cell alterations (listed in Table 17.7) are not equivalent; for example, most of the chromosome abnormalities, other than balanced translocations, result in cell lethality, and if induced in either the ova or sperm, generally produce dominant lethal effects not transmitted to the next generation.

Dominant viable mutations will be expressed in the first generation after induction and may contribute only moderately to the genetic burden. The impact of these mutations on the gene pool may be limited because the affected individuals are aware that they are carrying the mutant form of the gene and that there will be a 50% probability of transmitting the trait to their children if married to an unaffected (normal) individual. Thus, depending on the severity of the effect, the parents can decide, prior to reproducing, if the risk associated with transmission is acceptable.

Recessive mutations are not expressed unless both alleles of the gene in a diploid organism are defective or if the mutation is on the X chromosome in male offspring. Therefore, two normal-appearing heterozygous carriers for an autosomal mutant allele could produce offspring (25% incidence) exhibiting a recessive disease. Consequently, increases in new recessive mutations pose the most serious threat to the gene pool because they would tend to accumulate, over time, in the gene pool as expressed heterozygotes. Due to this latent period, the ultimate expression of a new recessive mutation in the population will have no apparent association with the environmental exposure that induced it. This situation severely limits the opportunity to use human epidemiological studies for proof of human genetic risk.

Intrinsic Differences Affecting Susceptibility to Genotoxic Effects

Unlike the genetic uniformity intrinsic in the animals used as experimental models in toxicology testing, humans exhibit a broad range of variability in their capacity to process and repair DNA damage (30, 41, 63). Studies on DNA repair capacity in mice also indicate a substantial decrease in global DNA repair capacity compared with humans (40).

As described previously, DNA repair in organisms, including humans, is controlled by a complex genetic system of structural and regulatory genes involving almost 50 different proteins. Human *polymorphisms* exist for many of these genes. Individual DNA repair capacity may range as low as 65% of the normal average level (63), placing such individuals at a different risk to mutagens than most of the population. Additional information about repair genes comes from studies of human genetic diseases, such as xeroderma pigmentosum (XP). Diseases such as XP are caused by mutations in NER genes. Individuals with XP lack one of the enzymes in the repair process, and affected individuals, with as little as l%-2% of the normal repair capacity, usually experience high levels of intrinsic DNA damage (63). Cancer susceptibility among XP cases is believed to be a consequence of the genetic damage and can be as much as 1000 times greater than non-XP individuals. Other human syndromes associated with reduced repair capacity (e.g., ataxiatelangiectasia, Bloom Syndrome, and Fanconi anemia) are inherited traits that also exhibit increased cancer risk (64). Thus, it is unlikely that genetic damage induced in genetically homogenous animal models with uniform repair will be easily extrapolated to human populations because factors such as DNA repair exhibit such broad response ranges. It is also clear from this illustration that quantitative estimates of hazardous or safe exposures to genotoxic chemicals based on results from animal data are likely to have large margins of error.

Pharmacogenetics

In addition to DNA repair polymorphisms, other allele variations confer important differences that will influence the impact of genotoxic agents. Some of these differences affect metabolic conversion kinetics. Individuals genetically predisposed to be either a fast or slow metabolizer of specific chemicals may be at higher risk from the parent compound or metabolite. Determination of an individual's genotype can be made with only a small sample of their DNA (15).

Identification of single gene polymorphisms (one nucleotide change), which influence the susceptibility of an individual to the pharmacologic/toxic effects of therapeutic agents, has developed into a major field of medical genetics (107). Institutions have assembled alleles from hundreds of polymorphic genes, and large human populations can be screened for single gene polymorphisms with automated high through-put screening systems employing techniques such as DNA binding and transcription activation. Integration of such information into a genetic profile may eventually be used to direct an individual's lifestyle optimization. Studies in humans exposed to carcinogenic hydrocarbons documented a genotypic influence on the level of adducts. Polymorphism in GSTMI 2 (gluthathione transferase), CYP1A1, and CYP2D6 alleles all affected the formation of DNA adducts found in white blood cells of exposed individuals (21).

Life Style and Exposure to Genotoxicants

There are numerous examples of heritable cancer, where acquisition of specific genes confer a high risk of cancer (e.g., retinoblastoma, colon cancer, breast cancer). These alleles may contribute to as much as 5% of the total cancer incidence, the other 95% is a product of life style. It is well documented that occupation and life style can influence genetic hazard (48, 86).

See References 2, 66, 67, and 68 for general discussion.

Tobacco smoke contains a broad range of mutagenic agents detectable in human lymphocytes and urine (51). Consumption of alcoholic beverages has been associated with genetic alterations in humans (69). Diet is also an important source of mutagens. The average human consumes about 10 tons (dry weight) of food by the age of 50 (92), and the list in Table 17.12 illustrates that many food items normally consumed by humans contain substances found to be mutagenic in microbial assays. Many of these agents are also mutagenic when tested in mammalian cell systems.

Other ubiquitous materials that have been reported to produce positive effects in mutagenicity tests include cosmetic ingredients, drugs, food additives, and pesticide residues (1, 5, 6, 87). At present, it is not possible to assess, in quantitative terms, the relevance, if any, of these agents to the mutational or cancer risk in humans.

In addition to tobacco smoke, alcoholic beverages, and consumption of preformed mutagens in or on food products, other life style factors that may be important are less subject to individual control. Exposure to ultraviolet light and ionizing radiation are common. Ambient air contains carbonaceous particles coated with agents producing mutagenic responses in a range of assays (57). The level of particle loading is location dependent, and exposures encountered in urban areas or in certain occupations (e.g., coke oven workers) are considerably higher than exposures in more rural areas.

Ames (2) hypothesized that endogenously formed mutagens and intermediates found in various plants are significant contributors to genotoxic risk. He reported the formation of numerous mutagens resulting from lipid peroxidation of fatty acids. The agents include aldehydes, peroxides, and other free radicals. Considerable efforts are currently under way to evaluate the relative contributions of dietary, environmental, and endogenously formed mutagens to the human disease burden, as well as the modulating influence of antimutagenic agents (e.g., antioxidants) on mutation expressions and cancer (48, 91).

Methods for Assessing Genetic Hazard and Risk

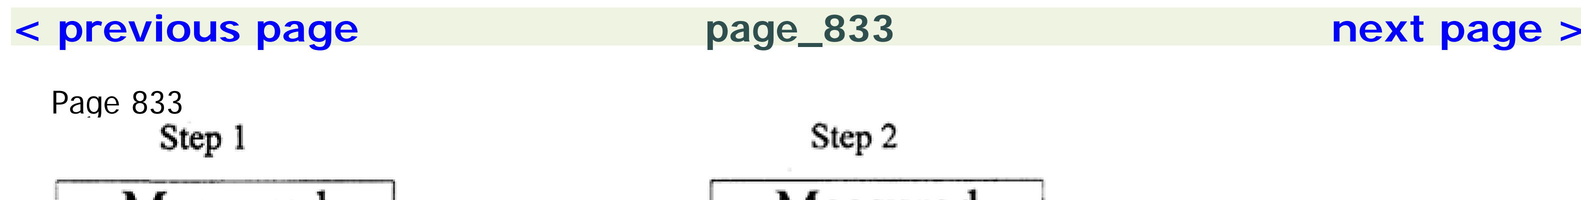
Observations of "new" dominant mutations in human populations and experimental induction of mutations in the germlines of mice indirectly document the fact that mammalian species, including humans, are susceptible to induced mutation. The ability to demonstrate genetic toxicity to human populations through epidemiological methods has been limited by

1. the small number of instances in which sufficient induced sentinel mutations were induced that could be detected in an epidemiology study;
2. the small number of genetic diseases or marker genes identified with specific genetic diseases;
3. the difficulty in identifying reproductively active populations exposed to biologically significant levels of mutagenic agents.

In 1992, the United Nations Environment Program (UNEP) reviewed the status of and methods available for genetic risk assessment (95). The report outlined the situations in which genetic risk assessment might be appropriate and the criteria for selection of risk assessment strategies. Risk information can be developed using qualitative methods resulting in the assignment of a classification, such as "human mutagen" and "probable human mutagen," based on a set of test results criteria. This classification method has been proposed for environmental health uses due to the absence of sufficient in vivo germ cell data to perform quantitative assessments.

When information is limited or when only a general characterization of risk is required, a qualitative assessment can be made. The results are expressed as a ranking for classification based on the test results from a predetermined scheme in which exposure and intrinsic bioactivity are known (Figure

17.8). In most cases, this type of classification is adequate for making risk management decisions (90). When essential, quantitative risk analysis for genetic damage can be performed using dose response results from animal models such as the mouse-specific locus test or the mouse heritable translocation assay. From these data, the population incidence of mutation can be calculated for anticipated exposure levels and expressed as the probability of new disease occurrence in the population. The same problems that confound the production of cancer risk estimates from animal studies affect the ability to generate accurate genetic risks (i.e.,



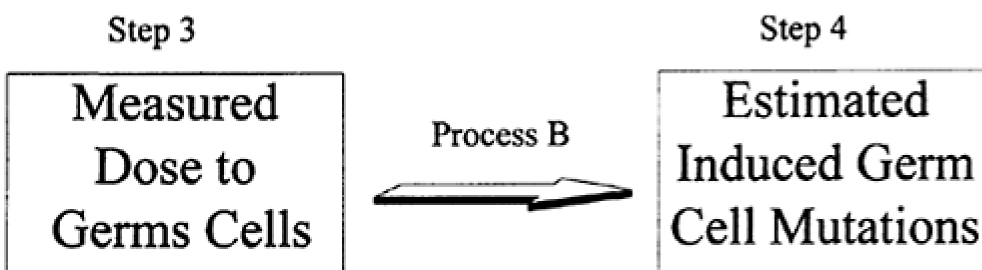


FIG. 17.8. Diagrammatical representation of the parallelogram method of estimating germ cell risk using somatic results and target site dosimetry. This method has been used with rodent and human data to develop probable mutation risks.

Table 17.13 Risk estimates for somatic and germ cell mutations for selected mammalian mutagensa

understanding the dose response kinetics, species differences in susceptibility, and factors that influence the phenotypic expression of new mutations). A few quantitative genetic risk assessments have been made (30) using data from mouse models for mutation and clastogenesis (Table 17.13). The major deficiencies in current risk assessment models are the lack of accurate methods to extrapolate animal mutation data to estimates of anticipated new disease incidences in exposed human populations. Mutagens are not as site specific (i.e., organ or tissue) as carcinogens.

INTERPRETING THE RESULTS OF GENETIC RISK ASSESSMENTS

Assessing human germ cell risk to mutagenic substances represents a formidable task, and no chemicals have been proven to induce new mutations in offspring of exposed individuals. Animal mutagens have been detected in rodent germ cells, and quantitative estimates of induced mutation rates per gene locus or the dose required to double a specific mutation rate have to be calculated from results of the in vivo-specific locus or

Page 834

heritable translocation assays (37). These estimates may be of limited value in calculating human risk or in setting safe exposure levels because they are based only on male gametes and, in the case of specific locus assay, generally on premeiotic stem cells (spermatogonia). The data do not reflect the risk to later cell stages in spermatogenesis or in female germ cells. Estimates of mutation in postmeiotic sperm and from female gametes will become available; but even so, other important biological variables would interfere with reliable risk estimates and extrapolation across species boundaries. Factors such as differences in endocrine profiles, gene structure, mutation specificity, DNA repair, mutation expression, and disease homology between rodents and humans will make extrapolation tenuous. In addition, postzygotic repair of damaged sperm has been demonstrated in mice and is a factor that may affect genetic risk.

Exposure assessment is a critical component of risk assessment. Exposure may occur by different routes and duration; however, most in vivo mutagenicity studies used in hazard assessment are dosed acutely by oral or intraperitoneal routes. Information derived from the physical/chemical properties of the agent, its concentration in environmental matrices, and exposure modeling are important factors that must be included in the development of quantitative genetic risk assessments. Table 17.14 outlines the variable factors essential for an accurate genetic risk assessment.

GENETIC TOXICOLOGY TESTING STRATEGIES AND DATA EVALUATION

Genetic toxicology assessments seldom consist of a single assay. Due to the multiplicity of mechanisms involved in mutation induction, most evaluations are made using a battery of several tests (102). Test batteries may consist of screening tests (in vitro), hazard assessment tests (in vivo), or both. It is important at the outset of testing to carefully define the objectives desired in a testing program. Screening to prioritize agents for further testing will require different types of tests than would be used to quantify somatic cell hazard to humans.

After conducting the tests, the more complex task is that of interpreting the results generated from the test battery. A genotoxic compound may be defined as

"an agent that produces a positive response in a bioassay measuring any genetic endpoint (e.g., mutation, unscheduled DNA synthesis (UDS) or chromosome breakage)."

Table 17.14 A list of required information for genetic risk analysisa

Endogenous DNA Repair: Capacities and mechanisms for repairing damaged DNA differ among organisms.

Metabolic Specificity: Many agents are not mutagenic themselves but require conversion to a chemical form that can react with DNA and cause mutation. This conversion is called metabolic activation and is accomplished by enzymes which vary in specificity and amount among (a) species (b) individual organisms within a species, and (c) different tissues in an organism.

Background Mutation Rate: All organisms and genes have an inherent background rate of mutations. Genetic factors that alter normal error rates in repair will alter this among individuals.

Age: Somatic mutations may accumulate during the lifetime of an organism. An older organism may thus be more vulnerable to disease, due to a greater body burden of background and induced mutations, than a younger organism.

Diet: Deficiencies in the levels of some vitamins, such as folate, may increase susceptibility to chromosomal mutations. Many foods contain both mutagens and antimutagens. Consumption of large quantities of mutagenic foods may account for the occurrence of certain types of cancer.

Economic and Sound Factors: Poor diet, inadequate health care, prevalence of infectious diseases, and excess exposure to known environmental mutagens, such as cigarette smoke and sunlight, could interact to increase susceptibility to mutagens.

Duration of Exposure: Duration of exposure to a mutagenic substance may affect the resulting genetic risk, depending on the form of the dose-response curve and the specificity of the agent for particular stages of germ-cell development.

Germ Cell Specificity: Acute exposure to chemicals that induce mutation in late stages of germ-cell growth will result in a transitory genetic risk, confined to conceptions resulting from the gametes exposed during the sensitive stage. Acute exposure to chemicals that induce mutation in early stages of germ-cell growth will result in a permanent genetic risk.

Page 835

Although this definition considers virtually all forms of damage to DNA to classify an agent as genotoxic, genotoxicity should not be interpreted, a priori, as an indication of hazard/risk. The label genotoxic is only a convenient method of classifying chemicals, according to their DNA reactivity, into genotoxic or nongenotoxic subgroups. Additional experimental information beyond this initial classification is necessary to resolve concerns of genetic hazard to somatic or germ cells.

Test results are interpreted on both an individual test basis (i.e., positive or negative in a specific assay) and on a test battery basis. Most decisions made for regulatory purposes are based on the response profile from a battery of tests specified by regulations or guidelines. The international scientific community has proposed a number of genetic test batteries for the evaluation of new chemicals, pesticides, food additives, and pharmaceutical products.

CONSIDERATIONS FOR ASSAY SELECTION

Regulatory Guidelines

Standard study designs for the routine genetic toxicology assays have been published by the EPA (32), Organization for Economic Co-operation and Development (OECD) (70), Canadian Health and Welfare (22), and European Economic Community (EEC) (29). Table 17.15 summarizes many of the recommended testing schemes for nonpharmaceuticals. Most test batteries include, at a minimum, (a) the Ames test, (b) a test for in vitro cytogenetic analysis, and usually (c) an in vivo test for cytogenetic damage. Other tests may be included to expand the profile on the agent if there were positive results or if human exposure was anticipated to be very high. It is also possible to add tests that may be particularly informative for special chemical classes. The EPA (33) has proposed guidelines for the interpretation of data, including in vivo tests. These guidelines provide a general framework for qualitative evaluation of results using a weight-of-evidence approach but do not define criteria to class agents as nonmutagenic.

A standard core battery of tests for pharmaceuticals has been developed under the ICH (officially, the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use). The ICH process resulted in two guidelines: (1) guidance and recommendations for the conduct of genetic tests and (2) establishment of a standard genotoxicity test battery. This battery consists of the Ames test modified by the addition of an *Escherichia coli* tester strain, the mouse micronucleus test, and either the Mouse Lymphoma test (with colony sizing) or an in vitro test for chromosome aberrations (Table 17.16). Adoption of the battery has been completed by the European Union, Japanese *MHW* (Ministry of Health & Welfare), and the U.S. Food and Drug Administration.

Development of a standard core battery of the type recommended by ICH has raised a number of issues regarding which genotoxic endpoints are relevant to hazard assessment, and which tests should be conducted. The two tests agreeable to all participants in the harmonization process were the Ames test for gene

Table 17.15 Testing requirements and guidelines other than for pharmaceuticals

AGENCY	AMES	IN VITRO	IN VIVO	OTHER
U.S. EPA FIFRA	+		+	Mouse lymphoma[a]

Industrial Chemicals	+	+		
Food Additive	+	+	+	Mouse lymphoma
JAPAN				
Industrial Chemicals	+	+		

a The mouse lymphoma must be conducted with colony sizing. Alternatively, the mouse lymphoma or CHO/HGPRT assay plus in vitro cytogenetics may be used.

b Usually conducted on extracts.

In most instances, where the mouse lymphoma is designated, the CHO cell HGPRT assay may be substituted.

Protocol designs for the tests in Table 17.16 follow the most recent OECD guidelines except for the mouse lymphoma assay, which should follow the ICH design.

Table 17.16 ICH test battery

Study	OECD Guideline Design	Testing Expectations
Bacteria reverse mutation assay	471/472	*Salmonella* and *Escherichia* tester strains Maximum concentration of 5 mg/plate or 5 μl/plate Equivocal response requires further testing Negative response confirmed on a case-by-case basis
In vitro chromosome aberration test	473	Maximum concentration of 5 mg/ml or 10 mM Test into the insoluble range Toxicity should exceed LC50 One harvest time at 1.5×normal cell cycle length If negative/-S9, do continuous treatment for 1.5 cycles Record polyploidy and endo replication when seen Equivocal responses require further testing Negative response/-S9 need to be confirmed on a case-by-case basis
Mouse lymphoma assay	476	Maximum concentration of 5 mg/ml or 10 mM Test into the insoluble range Toxicity should achieve 80%-90% Duplicate treatments or eight concentrations Sizing of mutant colonies required Equivocal responses require further testing Negative results must be confirmed on a case-by-case basis
Rodent micronucleus assay (mouse or rat)	474	Maximum dose of 2 g/kg Single sex is sufficient, if toxicity is similar in both May do acute or multiple dosing regimen Three dose levels For acute dosing, harvest high dose at 48 h; the rest at 24 h Must have 5 scorable animals/group Score 2000 PCE/animal Equivocal results should be clarified by further testing

mutation and the in vivo micronucleus for chromosome breakage. The use of in vitro tests for chromosome analysis and gene mutation were more controversial. The use of the mouse lymphoma assay was accepted, in part, because it could serve as both an in vitro measure of gene mutation and chromosome aberrations, and because induction of mutation at the target gene (thymidine kinase) can be induced by either base-pair substitution mutation at the mutant site on the normal chromosome or by deletions of the allele through chromosome breakage. The former mechanism results in large colony mutants and the latter mechanism produces small mutant colonies. Consequently, use of the mouse lymphoma assay for ICH purposes requires colony sizing. Chromosome analysis using cultured cell lines or human lymphocytes is an acceptable alternate to the mouse lymphoma assay.

NEW TECHNOLOGY AND ITS PLACE IN GENETIC TESTING

Limitations of Current Testing Strategies

By 1980, over 150 different tests for genotoxicity had contributed data to scientific journals. Many of the tests were redundant (i.e., measured same endpoint in a different organism or cell type) but each method had a champion who attempted to define the unique value of the particular technique or target organism. The following decade saw extensive efforts to validate and evaluate the best test or set of tests for the purposes of detecting relevant genotoxicant (carcinogens and/or germ cell mutagens). In the process, several valuable lessons were learned:

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_836.html[2010/10/28 18:48:22]

1. Many test methods are very sensitive and respond positively to rodent carcinogens; however, the tests do not discriminate agents based on DNA reactivity and they also respond to agents that are not carcinogenic or mutagenic. Examples of such tests are (a) in vitro SCE measures and (b) alkaline elution and other measures of single- and double-strand breakage. The use of these tests in genetic toxicology evaluations has dropped dramatically.
2. Several test methods worked extremely well in the laboratory of the inventor but did not reliably transfer to other testing laboratories. Some of the most difficult methods to transfer from lab to lab are the in vitro morphological cell transformation assays. Currently, only the Syrian hamster embryo (SHE) assays are used as a short-term test for carcinogenicity, and extensive standardization is required to acheive interlaboratory agreement on scoring colonies.
3. The array of mechanisms detected by the available tests may not include mechanisms that are relevant to genetic hazard in mammals. Examples of such deficiencies are tests that reliably measure aneuploidy, induction of tandom repeat errors, transposons, or effects from DNA methylation.
4. Commonly used tests, such as in vitro cytogenetic analysis and the Mouse Lymphoma assay, are susceptible to false-positive responses generated by (a) nonphysiological treatment conditions; (b) chemical-induced cytoxicity, and (c) reactive oxidation species generated by S9 mix chemistry (19).

Several actions were taken in an attempt to resolve the issues listed. The most dramatic was a reduction in test methods requested by regulatory agencies. Genetic toxicology testing schemes were simplified for the purposes of regulatory toxicology safety testing. Most agencies now expect to see the results from a limited test battery consisting of tests for gene mutation and chromosome aberrations before asking for further tests. The ICH core battery of tests is an example of this approach, and this battery is expected, over time, to become the international standard for most testing requirements. Other tests, such as in vitro cell transformation, DNA breakage and repair, mitotic recombination, and DNA adduct formation, are now used in research or as supplemental methods to support or explain findings from core battery assessments. Finally, treatment conditions and confirmatory testing were spelled out in more detail and have been structured to minimize false-positive responses.

Weight-of-evidence methods have been developed to evaluate complex response patterns from test batteries. Some of the methods, such as the Mutagenic Activity Pro files created by ICPEMC, have been validated with large data sets and encoded into computer software (62).

The technological deficiencies indicated in the prior list have not been resolved. The tests included in the ICH battery do not provide a full coverage of mechanisms known to operating in higher mammals and can potentially fail to detect agents that may be relevant to elements of the human genome. In addition, there are no routine methods capable of detecting gene mutation in vivo. This is a serious deficiency when attempting to confirm or extrapolate the results from the Ames test to organisms with eukaryotic DNA and chromosome structure.

Use of alternative methods for carcinogenicity testing, such as the p53 and TG:AC transgenic mice, may tend to reduce reliance on genotoxicity tests because these tests detect tumor endpoints and are both faster and more information rich than conventional rodent cancer bioassays, however, there will continue to be a need to assess the hazard to somatic and germ cell DNA from exposure to new products.

Proposed New Methods for Genetic Testing

Table 17.17 lists several technologies that have become widely available during the past 5 years and appear to be directly applicable to gaps identified in the existing methods used in genetic toxicology. Specific tests have been developed as a consequence of the technology. These new methods are currently being evaluated and validated as either replacements or additions to the current test batteries. Their primary advantage is that they allow more testing to be conducted in vivo using DNA from virtually any tissue.

Transgenic Models for in vivo Mutation Analysis

Transgenic animals for mutation detection were developed in 1990 using shuttle vector technology (40, 86). The two models that are commercially available today are summarized in Table 17.18. A third model that is based on the *lac Z* gene integrated in plasmid DNA was developed by Boerringter and co-workers (13) and is in commercial development. In all commercial models, a gene from the lactose operon of *E. coli* was combined with DNA sequences from lambda phage to form a recoverable shuttle vector (Figure 17.9). The transgenic animals were generated following micro-injection of the vectors into fertilized mouse ova that were subsequently replaced back into the uteri of psuedo-pregnant dams. Founder animals with integrated shuttle vectors were recovered and used to develop stable homozygous strains of mice (and rats) from which the target *lac* genes can be recovered and analyzed for mutation

in vivo exposure. This technology offers an ideal model for in vivo mutation detection and molecular analysis (Figure 17.10).

The recoverable shuttle vector containing the *lac* gene can be isolated from virtually any cell type in the treated animal (Table 17.19). Validation studies with transgenic models have demonstrated that they generally are reliable. For example, studies of known rodent carcinogens have demonstrated tissue-specific mutation associated with the target organs associated with induced tumors (98). Both transgenic models show very close con cordance with the Ames test for known genotoxic carcinogens (>90%), and may, therefore, serve as a confirmatory test for the Ames or other in vitro gene mutation screens.

All of the currently available models employ either *lac I* or *lac Z* target genes. The genes are not transcribed but appear to respond in a similar fashion to endogenous genes (96). The primary difference is associated with the ability of the transgenes to detect large deletions. Approximately 1%–1.5% of the spontaneous mutants from Big Blue or MutaMouse models are deletions of 50 base pairs or larger (98, personal communication); however, the *lac Z* plasmid model developed by Borringter and co-workers (13) is able to detect large deletions, and approximately 50% of the spontaneous mutations are due to deletions of 50 base pairs or larger. Recent development of positive selection methods for target genes has made the transgenic models faster and much less expensive to conduct.

Transgenic models for mutation have been used to show that many organ-specific carcinogens show a parallel organ specificity for mutation induction (35). These models are excellent models for the study of mutagenic specificity, as both *lac I* and *lac Z* genes can be sequenced. They may also prove to be good models to investigate the mechanisms of antimutagens and tumor promotors. Transgene sequences can be easily recovered from germinal tissue, making these models potentially ideal for genetic risk assessments. Validation studies for heritable risk analysis have not been conducted with transgenic models.

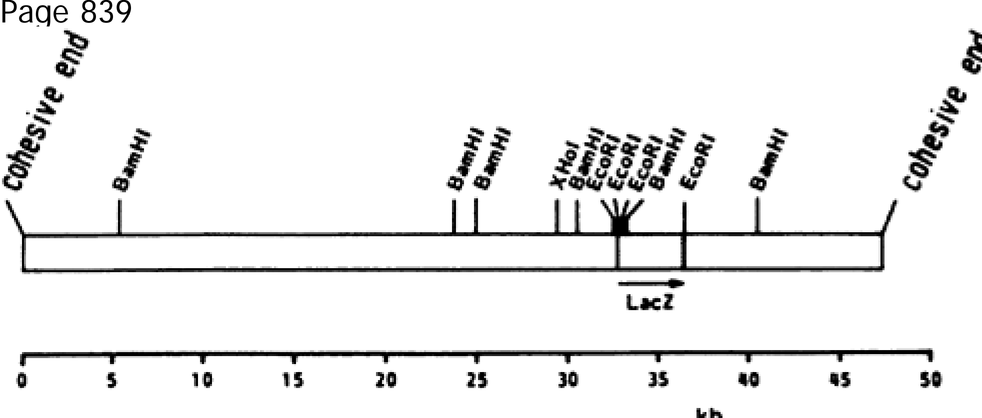

FIG. 17.9. The shuttle vector used to produce the MutaMouse transgenic model for mutation detection. The vector consists of the *lac Z* gene from *E. coli* with Lambda phage genes on either end. The vector is rescuable from mammalian DNA with lambda packaging extracts.

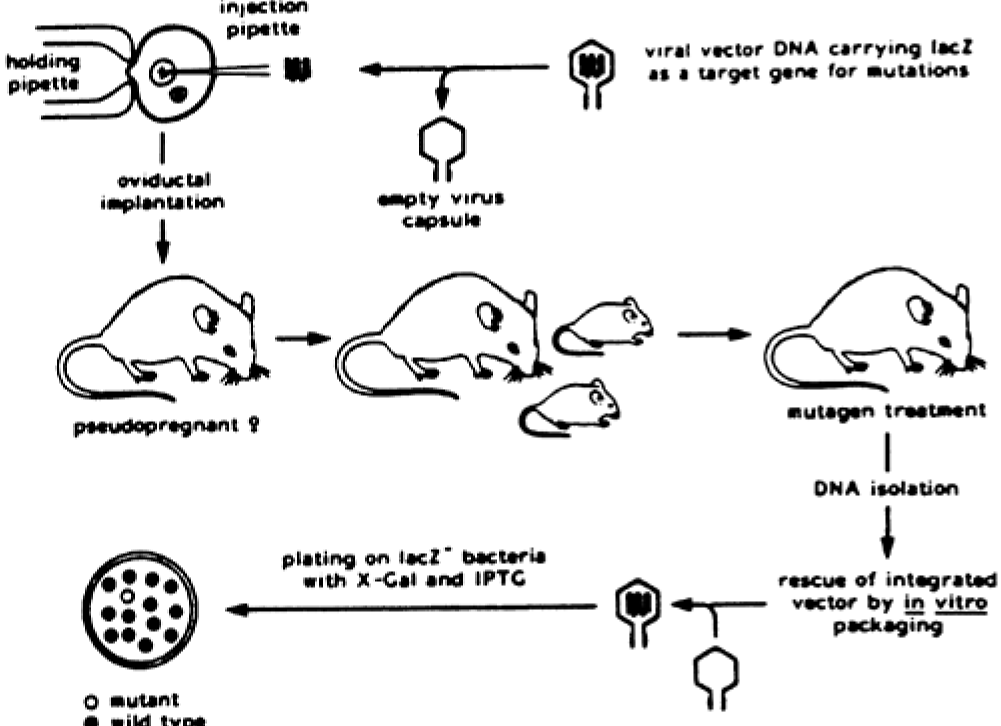

FIG. 17.10. The steps involved in the use of the MutaMouse transgenic mutation model. Exposure can be by any desired route. DNA can be recovered and analyzed from any tissue. The mutation detection part of the process is an in vitro technique.

Acetic acid	Inc.					
TPA	−					
Diethyl nitrosamine		−	+			
Ethylmethane sulfonate		+				
Mitomycin C		+	Inc.			
1,3-Butadiene		−	−	+		

+—mutagenic effects reported;−—no mutagenic effect using conventional study design; Inc.—mutagenic effects reported but inconclusive based on small sample sizes.

Transgenic models have not been introduced into testing schemes but are under intense review by regulatory agencies worldwide. It is likely that one or more of these models will be used as (a) a method to confirm in vitro gene mutation screening in vivo, or (b) replacements for many of the current in vitro gene mutation models.

Gene Amplification Approaches to Mutation Detection

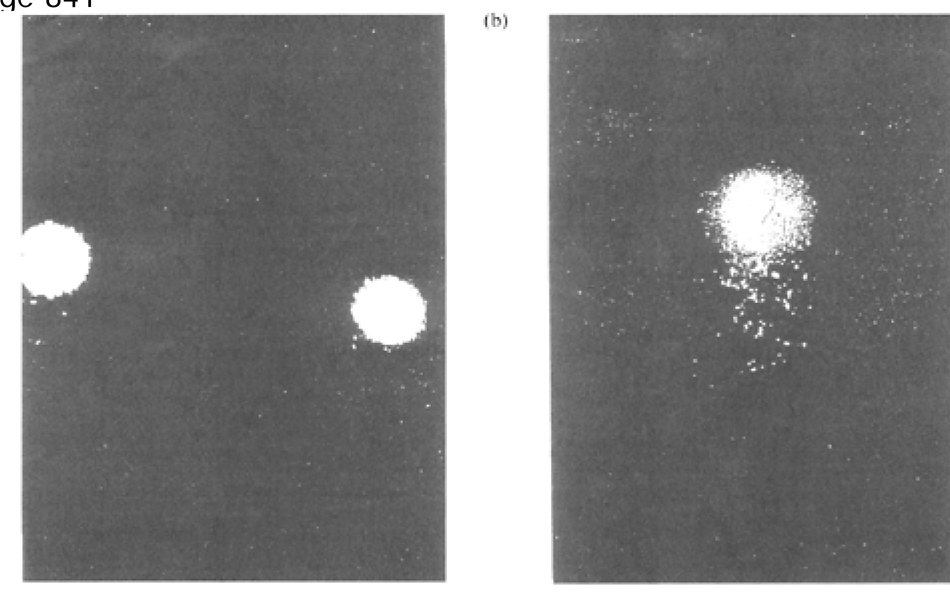
Development of polymerase chain reaction (PCR) has resulted in the ability to select specific DNA sequences and create millions of copies of them rapidly and inexpensively. Although PCR technology has had its greatest impact in other areas of biotechnology, it has been used to develop some new methods of mutation analysis (Table 17.17). Two such models appear promising as methods to detect mutation in vivo, and are compared to the transgenic model. The advantages of these methods over transgenic models are that (a) the target DNA sequences are endogenous in orgin rather than transplanted from other organisms, (b) the technology can be applied to any mammalian system from mouse to primate, and (c) the types of damage detected are relatively unrestricted to specific mechanisms (although DNA deletions are not detected). The first method involves the isolation of splenic T cells from treated rodents and subjecting these cells to 6-thioguanine resistant cells, amplification of the DNA by PCR, and classification of the mutations by sequence analysis. This technique works very well, but the mutation target is lim ited to the spleen. A second method, called single-strand conformational polymorphism, allows mutations to be detected in a larger selection of tissues. In this method, DNA from specific sites (e.g., targeted exons of the gene of interest) can be amplified by PCR. The amplified DNA is then subjected to denaturation and placed on nondenaturing polyacrylamide gel electrophoresis. DNA damage as small as single base changes will alter the mobility of the amplified sequences separating mutant DNA from nonmutant DNA. The shifts will be visible on stained gels. The mutant DNA bands can be removed and sequenced to classify the DNA changes. This method has been used to study organ-specific mutations in various regions of the p53 tumor suppressor gene.

Single Cell Gel Electrophoresis (COMET) Assay

This technique is dependent on the analysis of DNA integrity in single cells. The advantages of this technology are that the source of the cells is almost unrestricted. The basis of the test is that if single- or double-strand breaks are induced in DNA in situ, when cells are isolated, treated to denature nucleic acids, and placed in an electric field, DNA will migrate from the negative to the positive charge at a rate related to the length of the DNA. Fragmented DNA pieces migrate rapidly and, when stained, form a tail on the cells similar to that of a comet (Figure 17.11). The COMET assay is a very versatile technique that can be used in vitro or in vivo (88).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_840.html[2010/10/28 18:48:24]

Page 841



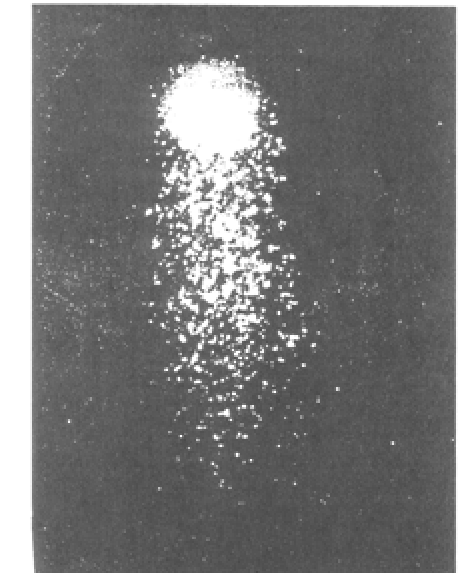


FIG. 17.11. Development of a "tail" in the COMET assay. A normal nucleus (a), followed by some leakage of broken DNA (b) forming ultimately a "tail" of DNA (c). The length of the tail is indicative of the amount of DNA damage.

The COMET assay has been used to screen for genotoxicity under the in vivo exposure conditions. The types of exposures have ranged from radio frequency radiation and agricultural and industrial chemicals to pharmaceutical products. Because the analysis can be conducted with small cell populations, studies of tissue-specific genotoxicity have been published (81). The method may also be applied directly to human populations. Wojewodzka and co-workers (104) studied a group of men and women with chronic low level exposure to radiation and reported that cells from blood cultures showed significant increases in DNA breaks compared to matched controls.

The use of this method increased dramatically from 1994 through 1996, but has slowed somewhat due to the technical problems associated with the sensitivity of the method to stress-induced positive effects occurring during the isolation and fixation steps of the methods. Interpretation of the results from this test might be compromised by cytotoxic effects from normal processes, such as programmed cell death (apoptosis). Extreme care must be taken during these steps of the procedure to eliminate false-positive effects. Some of the limitations and advantages of the COMET assay are listed in Table 17.20.

The introduction of one or more of these in vivo methods or others that are currently in development

Table 17.20 Potential advantages and limitations of the COMET assaya

Advantages

Studies can be conducted in vivo in almost any tissue

The endpoint is developed rapidly and seen visually as increased tail length

The endpoint is nonspecific and should respond to any agent causing DNA breakage

Measurement of the endpoint is sensitive and quantitative

Limitations

Cytotoxicity and induction of programmed cell death (apoptosis) can lead to false responses

The test is sensitive to physiological changes in vivo and stress alone may induce increased tail lengths

The endpoint is an indicator of reparable damage and may not be useful in quantifying risk or impact on germ cell DNA

a Either the mouse lymphoma assay or in vitro cytogenetics is required

Precipitates—if no toxicity is seen, the highest dose may use the lowest precipitating concentration. If toxicity is evident at precipitating concentrations, the high dose should be based on toxicity.

Exposure confirmation in vivo—demonstration of bone marrow exposure is essential for acceptability of negative results.

Mouse lymphoma repeat tests—if the results of the initial trial are negative, the treatment time in a repeat test (−S9) should be increased to 24 h.

would significantly improve the relevance of test batteries such as the ICH core battery. In vivo data from the mouse micronucleus and, for example, a transgenic mutation assay conducted using the anticipated route of human exposure, coupled with toxicokinetic data from the site of cell harvest, could provide a realistic set of results upon which quantitative hazard/risk decisions might be developed.

SELECTED STUDY DESIGNS AND GENETIC TESTING

This section contains a set of study designs that will meet the ICH guideliness for the United States, EC, and Japan. Although not fully described in every protocol, it is recommended that each test article be examined for several chemical, physical, and biological parameters. Included in this preliminary assessment is an examination of the test article's solubility, volatility, and light sensitivity, as well as its stability in the recommended solvent. A preliminary toxicity study is performed to establish a maximum concentration or dose level. Careful selection of concentrations is important. Because of the potential for artifacts produced by excessive ionic levels or low pH levels (19), these parameters should be monitored during the exposure period of in vitro procedures. The protocols all contain specific criteria related to interpretation of toxicity, but it is often possible to save time and materials by knowing the approximate concentration range needed to achieve the desired toxicity.

This group of protocols does not represent the entire repertoire of methods available to genetic toxicologists. It provides, however, the essential test's needed for routine screening for most new compounds under development for use in commerce.

Tests Measuring Gene Mutation

Protocol 1: Salmonella-Eschericia colil mammalian-microsome Reverse Mutation Assay

The objective of the bacteria/microsome assay is to evaluate the test article for mutagenic activity in a bacterial reverse mutation system with and without a mammalian S9 activation component. The assay design is based on OECD Guideline 471–472 (1997 version).

Materials. The strains of *Salmonella typhimurium* and *E. coli* that are used routinely in the plate assay are described in the following table:

Table 17.21 Strains used in the plate assay

Tester Strains	*Target Group*	*Additional Mutations*		
Salmonella				
TA1535	*his* G46	*rfa*	*uvr B*	–
TA1537	*his* C3076	*rfa*	*uvr B*	–
TA98	*his* D3052	*rfa*	*uvr B*	+R
TA100	*his* G46	*rfa*	*uvr B*	+R
Escherichia				
WP2	*trp*		*uvr A*	–

An S9 homogenate is used as the activation system. The 9000×g supernatant fluid is prepared from SpragueDawley adult male rat liver induced by Aroclor 1254 (5). The components of the S9 mix are described in (4).

Test procedures. An appropriate number of tubes of molten overlay agar (at least three per control or concentration level) are prepared. An equivalent number of Vogel Bonner plates also are prepared and properly labeled.

The test article is weighed or measured and diluted in a solvent to set up the stock solutions. The test article and other components are prepared fresh and added to the overlay. The contents then are mixed and poured on the surfaces of the Vogel Bonner plates. For activation studies, 0.5 ml of the S9 mix is added to each overlay tube. For highly reactive chemicals that might have short half-lifes in aqueous environments, a liquid preincubation method has been developed (107). The entire test consists of nonactivation and activation (+S9 mix) test conditions, each with appropriate negative and positive controls.

The plates (once the overlay has solidified) are incubated at 37°C for 36 to 72 h and scored for numbers of revertants per plate. Colonies are selected at random for verification of histidine independence by growth on minimal agar medium.

For the standard plate test, at least five dose levels of the test article, dissolved in a suitable solvent, are added to the test system. Triplicate plates per dose per strain are used in all standard assays. The test concentrations should be based on preliminary toxicity dose selection tests conducted both with and without S9 mix at 10 concentrations ×1 plate each. When no toxicity is observed, concentrations of up to 50 *µ*l or 5000 to 10,000 *µ*g per plate should be employed.

The chemicals that may be used as positive control agents are given in Table 17.22.

Assay acceptance criteria. Several methods for statistical analysis of the Ames test are suggested in the EPA Gene-Tox work group report for *S. typhimurium* mutation assay (50). Plate test data consist of direct revertant colony counts obtained from a set of selective agar plates seeded with populations of mutant cells suspended in a semisolid overlay. Because the test article and the cells are incubated in the overlay for 36 to 72 h, and because a few cell divisions occur during the incubation period, the test is semiquantitative in nature. Although these features of the assay reduce the quantitation of results, they provide certain advantages not contained in a quantitative suspension test:

1. The small number of cell divisions permits potential mutagens to act on replicating DNA, which is often more sensitive than nonreplicating DNA.
2. The combined incubation of the test article and the cells in the overlay permits constant exposure of the indicator cells for 36 to 72 h.

Surviving populations. Plate test procedures do not permit exact quantitation of the number of cells surviving chemical treatment. At low concentrations of the test article, the surviving populations on the treatment plates are essentially the same as that on the negative control plate. At high concentrations, the surviving population usually is reduced by some unknown fraction. This protocol normally employs several doses ranging over two or three log concentrations; the highest of these doses is selected to show toxicity as determined by subjective criteria, such as background clearing or a reduction in

Table 17.22 Positive control agents for the standard plate test

Assay	*Chemical*	*Solvent*	*Concentration per plate (µg)*	*Responding* Salmonella *strains*
Nonactivation	Sodium azide	Water	1	TA-1535, TA-100
	2-Nitrofluorene	DMSO	10	TA-1538, TA-98
	9-Aminoacridine	Ethanol	50	TA-1537
	4-Nitroquinoline	Oxide	1	*E. coli*
Activation	2-Anthramine	DMSO	2.5	All strains of *Salmonella*
	2-Anthramine	DMSO	25	*E. coli*

the number of spontaneous colonies on treated plates compared with the solvent control.

Dose-response phenomena. The demonstration of a dose-related increase in mutant counts is an important criterion for establishing mutagenicity. A factor that might modify dose-response results for a mutagen is the selection of doses that are too low (usually mutagenicity and toxicity are related). If the highest dose is far lower than a toxic concentration, no increase may be observed over the dose range selected. Conversely, if the lowest dose employed is highly cytotoxic, the test article may kill any mutants that are induced, and thus does not appear to be mutagenic. Occasionally, high levels of toxicity produce microcolonies (not mutants), which can be confused for revertants by inexperienced investigators.

Control tests. Positive and negative control assays are conducted with each experiment and consist of direct-acting mutagens for nonactivation assays and mutagens that require metabolic biotransformation in activation assays. Negative controls consist of the test article solvent in the overlay agar together with the other essential components. The negative control plates for each strain give a reference point to which the test data can be compared. The positive control assay is conducted to demonstrate that the test systems are functional with known mutagens.

Replication. OECD guidelines require independent repeat of all tests for confirmation of both negative and equivocal responses.

Assay Evaluation acceptance criteria. Because the procedures used to evaluate the mutagenicity of the test article are semiquantitative, the criteria used to determine positive effects are inherently subjective and based primarily on a historical database. Most data sets are evaluated using the following criteria:

1. Strains TA-1535 and TA-1537. If the solvent control value is within the typical range for the laboratory, a test article that produces a positive dose response over three concentrations, with the highest increase equal to three times the solvent control value, is considered mutagenic.
2. *Strains TA-98, TA-100, and WP2uvrA.* If the solvent control value is within the normal range for the laboratory, a test article that produces a positive dose response over three concentrations, with the highest increase equal to twice the solvent control value, is considered mutagenic. Occasionally, a doubling is not necessary for TA-100 if a clear dose-related pattern is observed over several concentrations.
3. *Pattern.* Because TA-1535 and TA-100 are derived from the parental strain (G-46), and because TA-1538 and TA-98 are derived from the same par ental strain (D3052), to some extent there is a built-in redundancy in the microbial assay. In general, the two strains of a set respond to the same mutagen, and such a pattern is sought. Generally, if a strain responds to a mutagen in nonactivation tests, it does so in activation tests.

The preceding criteria are not absolute, and other extenuating factors may enter into a final evaluation decision, however, these criteria can be applied to most situations and are presented to aid individuals not familiar with this procedure. It must be emphasized that modifications of the procedure involving preincubation conditions or source of S9 mix are necessary for evaluation of specific chemicals or classes of chemicals. Attached to reports should be results of analytical chemical analyses for stability and dose-verification. Laboratory historical control ranges should also be included.

Protocol 2: Forward Mutation at the TK Locus in L5178Y Mouse Lymphoma Cells

This method is developed from OECD protocol 473 (1997 version). The objective of the mouse lymphoma assay is to evaluate a test article for its ability to induce forward mutation in the L5178Y TK +/− mouse lymphoma cell line, as assessed by colony growth in the presence of 5-trifluorothymidine (TFT).

Thymidine kinase (TK) is a cellular enzyme that allows cells to salvage thymidine from the surrounding medium for use in DNA synthesis. If a thymidine analog such as TFT is included in the growth medium, the analog is phosphorylated via the TK pathway and incorporated into DNA, eventually resulting in cellular death. Cells that are heterozygous at the TK locus (TK+/−) may undergo a single step forward mutation to the TK−/− genotype, in which little or no TK activity remains. Such mutants are as viable as the heterozygotes in normal medium because DNA synthesis proceeds by *de novo* synthetic pathways that do not involve thymidine as an intermediate. The basis for selection of the TK−/− mutants is the lack of any ability to use toxic analogs of thymidine, which enable only TK−/− mutants to grow in the presence of TFT. Cells that grow to form colonies in the presence of TFT are therefore assumed to have mutated to the TK−/− genotype either spontaneously or by the action of a test article.

Materials.

Indicator cells. The mouse lymphoma cell line used in this assay, L5178Y TK+/−, is derived from the Fischer L5178Y line. Stocks are maintained in liquid nitrogen and laboratory cultures are periodically

checked for the absence of *Mycoplasma* contamination and karyotype stability. To reduce the negative control frequency (spontaneous frequency) of TK−/− mutants to

< previous page page_844 next page >

as low a level as possible, cell cultures are exposed to conditions that select against the TK−/− phenotype and then returned to normal growth medium for 3 days or more before use.

Media. The cells are maintained in RPMI 1640 or Fischer's mouse leukemia medium supplemented with L-glutamine, sodium pyruvate, and horse serum (10% by volume). Cloning medium consists of the preceding growth medium with the addition of agar to achieve a semisolid state. Selection medium is cloning medium containing 3 μg/ml of TFT (25).

Control articles. A negative control consisting in assay procedures performed on cells exposed to solvent in the medium is assayed as the solvent-negative control article to determine any effects on survival or mutation caused by the solvent alone. For test articles assayed with activation, the solvent-negative control articles include the activation mixture.

Reference substances for use as positive control articles should be based on the historical data from the laboratory performing the assay. The positive control articles listed below are chosen because of the large database available and because both chemicals detect both small and large colonies (108).

Methyl methanesulfonate (MMS) can be used at concentrations of 10.0 to 15 nl/ml as a positive control for nonactivation studies. Ethylmethane sulfonate is highly mutagenic via alkylation of cellular DNA and may be used at 0.25 to 0.50 μl/ml as a positive control article for nonactivation studies. 3-Methylcholanthrene requires metabolic activation by microsomal enzymes to become mutagenic and may be used at 1.0 to 4.0 μg/ml as a positive control article for assays performed with activation.

Sample forms. All types of test articles can be evaluated in the mouse lymphoma assay. Solid articles can be dissolved in water, if possible, or in dimethylsulfoxide (DMSO), ethanol, or acetone unless another solvent is requested. Liquids can be tested by direct addition to the test system at predetermined concentrations or following dilution in a suitable solvent.

Experimental design.

Dose selection. The solubility of the test article in water or an organic solvent is determined first, and then a wide range of test article concentrations are tested for cytotoxicity, starting with a maximum applied dose of 1 to 5 mg/ml for a solid test article or 1 to 5 μl/ml for a liquid test article and using twofold dilution steps. After an exposure time of 4 h, the cells are washed and a viable cell count is obtained the next day. Relative cytotoxicities expressed as the reduction in growth compared to the growth of negative control cells are used to select 7 to 10 doses that cover the range from 0–50% to 80%-90% reduction in 24-h growth. These selected doses subsequently are applied to cell cultures prepared for mutagenicity testing, but only five or six of the doses may be carried through the mutant selection process. This procedure compensates for daily variations in cellular cytotoxicity and ensures the choice of five or six doses spaced from little or no survival to no apparent effect on cell growth.

Mutagenicity testing. The procedure used for the nonactivation assay is based on that which has been reported (1, 24, 25). Cultures exposed to the test article for 4 h at the preselected doses are washed and placed in growth medium for 2 to 3 days to allow recovery, growth, and expression of the induced TK−/− phenotype. Cell counts are determined daily and appropriate dilutions made to allow optimal growth rates.

At the end of the expression period 3×104 cells for each selected dose are seeded in soft agar plates with selection medium, and resistant (mutant) colonies are counted after 10 to 14 days incubation. To determine the number of cells capable of forming colonies, a portion of the cell suspension is also cloned in normal medium (nonselective). The ratio of resistant colonies to total viable cell number is the mutant frequency.

The activation assay can be run concurrently with the nonactivation assay. The only difference is the addition of the S9 fraction of rat liver homogenate and necessary co-factors (CORE) during the 4-h treatment period. CORE consists of NADP (sodium salt) and isocitric acid. The final concentrations of the activation system components in the cell suspension should be 2.4 mg NADP (sodium salt)/ml, 4.5 mg isocitric acid/ml, and S9/ml. The optimal concentration of S9 (usually 10 to 50 μl S9/ml) should be determined in a pretest with control and MCA-treated cells.

Preparation of 9000g supernatant fluid (S9). Sprague- Dawley or Fischer 344 male rats are normally used as the source of hepatic microsomes; the S9 can be obtained commercially. Briefly, induction with Aroclor 1254 or another agent is performed by injection 5 days prior to killing. After decapitation and bleeding, the liver is immediately dissected from the animal using aseptic technique and placed in ice-cold buffer at pH 7.4. When an adequate number of livers are obtained, the collection is washed twice with fresh buffer and completely homogenized. The homogenate is centrifuged for 10 min at 9000g in a refrigerated centrifuge, and the supernatant fluid (S9) from this centrifuged sample is retained and frozen at −80°C until used in the activation system.

Test materials identified as mutagenic should have representative control and mutagenic selection plates recounted to permit mutant colony sizing. Selection plates are recounted using the Artek colony counter at size settings between 0.0 to 4.0 in increments of 0.2.

If the initial trial is determined to be negative or equivocal, a report test of the nonactivation portion of the assay is conducted with a 24-h exposure period. It is suggested that the activation portion be repeated using a different dose range.

Assay acceptance criteria. An assay is considered acceptable for evaluation of test results only if all of the criteria in the following list are satisfied. The activation and nonactivation portions of the mutation assays usually are performed concurrently, but each portion is in fact an independent assay with its own positive and negative controls. The activation or nonactivation assays are repeated independently to satisfy general acceptance and evaluation criteria:

1. The average absolute cloning efficiency of the negative controls (average of the solvent and untreated controls) is 100%±30%. Assay variables can lead to artificially low cloning efficiencies in the range of 50%–70% and still yield internally consistent and valid results. Assays with cloning efficiencies in this range are conditionally acceptable and dependent on the scientific judgment of the investigator. All assays below 50% cloning efficiency are unacceptable.
2. The average negative control suspension growth factor is not less than about eight. The optimal value is 25, which corresponds to fivefold increases in cell number for each of the 2 days following treatment of the experimental cultures.
3. The background mutant frequency (average of the solvent and untreated negative controls) is calculated separately for concurrent activation and nonactivation assays, even though the same population of cells is used for each assay. For both conditions, the normal range of background frequencies for assays performed with different cell stocks is 20 to 120×10^{-6}. Assays with backgrounds outside this range are not necessarily invalid and should be considered in the context of the historical data in the laboratory performing the assay.
4. A positive control is included with each assay to provide confidence in the procedures used to detect mutagenic activity. The normal range of mutant frequencies induced by MMS (nonactivation assay) is 200×10^{-6} to 800×10^{-6}; for MCA 4.0 μg/ml (activation assay), the normal range is 200×10^{-6} to 1000×10^{-6}. An assay is considered acceptable in the absence of a positive control (loss due to contamination or technical error) only if the test article clearly shows mutagenic activity as described in the evaluation criteria.
5. For test articles with little or no mutagenic activity, an assay must include applied concentrations that reduce the relative growth to between 10% and 20% of the average solvent control or reach the maximum applied concentrations given in the evaluation criteria. This requirement is waived if a dose increment of about 1.5 or less causes excessive toxicity.
6. An experimental treatment that results in fewer than 3.0×10^{-6} cells by the end of the 2-day growth period is not cloned for mutant analysis.
7. An experimental mutant frequency is considered acceptable for evaluation only if the relative cloning efficiency is 10% or greater and the total number of viable clones exceeds 20.
8. Mutant frequencies are derived normally from sets of three dishes for both the mutant and the viable colony count. To allow for contamination losses, an acceptable mutant frequency can be calculated from a minimum of two dishes per set.
9. The mutant frequencies for six treated cultures are normally determined in each assay. A required number of various concentrations cannot be explicitly stated, although a minimum of four analyzed cultures is considered necessary under the most favorable test conditions to accept a single assay for evaluation of the test article.

Assay evaluation criteria. The minimum condition considered necessary to demonstrate mutagenesis for any given treatment is a mutant frequency that is at least two times the concurrent background frequency. *Background frequency* is defined as the average mutant frequency of the solvent controls. The minimum increase is based on extensive experience that indicates that the calculated minimum increase is often a repeatable result.

The observation of a mutant frequency that meets the minimum criterion for a single treated culture within a range of assayed concentrations is not sufficient evidence to evaluate a test article as a mutagen. The following test results must be obtained to reach this conclusion for either activation or nonactivation conditions:

1. A dose-related or toxicity-related increase in mutant frequency is observed. It is desirable to obtain this relation for at least three doses, but it depends on the concentration steps chosen for the assay and the toxicity at which mutagenic activity appears.
2. An increase in mutant frequency may be followed by only small or no further increases at higher concentrations or toxicities; however, a decrease in mutant frequency to values below the minimum

criterion is not acceptable in a single assay to classify the test article as a mutagen. If the mutagenic activity at lower concentrations or toxicities is large, a repeat assay is performed to confirm the mutagenic activity.

3. If an increase of at least four times the background mutant frequency is observed for a single dose near

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_846.html[2010/10/28 18:48:28]

the highest testable toxicity, as defined in the Assay Acceptance Criteria section, the test article is considered mutagenic. Smaller increases at a single dose near the highest testable toxicity require confirmation by a repeat assay.

4. For some test articles the correlation between toxicity and applied concentration is poor. The proposition of the applied article that effectively interacts with the cells to cause genetic alterations is not always repeatable or under control. Conversely, measurable changes in the frequency of induced mutants may occur with concentration changes that cause only small changes in observable toxicity. Therefore, either parameter—applied concentration or toxicity (percent relative growth)—can be used to establish if the mutagenic activity is related to an increase in effective treatment. A negative correlation with dose is acceptable only if a positive correlation with toxicity exists. An apparent increase in mutagenic activity as a function of decreasing toxicity is not acceptable evidence for mutagenicity.

A test article is evaluated as nonmutagenic in a single assay only if the minimum increase in mutant frequency is not observed for a range of applied concentrations that extends to toxicity causing 10%–20% relative suspension growth. If the test article is relatively nontoxic, the maximum applied concentrations are normally 5 mg/ml (or 5 μl/ml) unless limited by solubility. If a repeat assay does not confirm an earlier, minimal response as discussed previously the test article is evaluated as nonmutagenic in this assay system.

Tests Detecting Chromosome-Breaking (Clastogenic) Agents

Protocol 4: Chromosome Aberrations in Chinese Hamster Ovary Cells

This design meets the OECD Guideline 473 (1997 version). The objective of the Chinese hamster in vitro assay is to evaluate the ability of a test article to induce chromosome aberrations in Chinese hamster ovary (CHO) cells.

Indicator cells. Cells to be used in this assay can be obtained from the American Type Culture Collection Repository No. CCL61 (Rockville, MD). The original cells were obtained from an ovarian biopsy of a Chinese hamster. It is a permanent cell line with an average cycle time of 10–12 h.

The CHO cells for this assay are grown in Ham's F12 medium supplemented with 10% fetal calf serum. The cells are split back to 3×10^5 per 75 cm^2 plastic flask and fed 24 h prior to treatment with 10 ml of fresh medium.

Control articles. The solvent for the test article is used as the solvent vehicle for the control article. Ethylmethane sulfonate, a known mutagen and chromosome-breaking (clastogenic) agent, may be dissolved in the culture medium and used as a positive control article for the nonactivation studies at a final concentration of 0.5 μl/ml.

Experimental design. Toxicity and dose determination. The solubility, toxicity, and doses for the test article are determined prior to screening. The effect of each test article on the survival of the indicator cell is determined by exposing the cells to a wide range of article concentrations in complete growth medium. Toxicity is measured as the loss in growth potential of the cells induced by a 4-hour expression period in growth medium. Doses are selected from the range of concentrations by bracketing the highest dose that shows no loss in growth potential with at least one higher and three lower doses. Otherwise, a half-log series of doses are employed, with the highest dose being perhaps limited by solubility, but in any case not to exceed 5 mg/ml. The doses cover at least four orders of magnitude, and all doses that yield sufficient numbers of scorable metaphase cells are considered in the analysis. Alternatively, inhibition of cell cycling (BrdU staining, discussed later) can be used to set dose levels.

Cell treatment. For the nonactivation assay, approximately 10^6 cells are treated with the test article at predetermined doses for 3 h at 37°C in growth medium. The exposure period is terminated by washing the cells twice with saline. Four replicate cultures per dose are employed in this assay; all receive fresh medium after washing, and 5-bromo-2′-deoxyuridine (BrdU) is added to two of the four replicates (10 μM final concentration). Incubation is continued in the dark for 20 h. Colcemid is added for the last 3 h of incubation (2×10^{-7} M final concentration), and metaphase cells are collected by mitotic shake-off. These cells are swollen with 0.075 M KCl hypotonic solution, washed three times in fixative (methanol/acetic acid, 3:1), dropped onto slides, and air dried.

For the activation assay, the test article is tested in the presence of an S9 rat liver activation system. This assay differs from the nonactivation assay in that the S9 reaction mixture is added to the growth medium, together with the test article, for 3 h. The S9 mix is the same as that used in the mouse lymphoma assay. The exposure period is terminated by washing the cells twice with saline. From this point, they are treated as described for the nonactivation assay.

If the 3-h exposure studies are equivocal or negative, a repeat nonactivation study employing a 17.5-h exposure will be conducted to confim the negative results. It is

suggested that the activiation test also be repeated using a different dose range.

Staining and scoring of slides. Slides are stained with 10% Giemsa at pH 6.8 for subsequent scoring of chromosome aberration frequencies. About 50 to 100 cells are scored from each of two replicate cultures per dose.

Standard forms are used to score and record gaps, breaks, fragments, and reunion figures, as well as numerical aberrations such as polypoid cells. The complete list of aberrations to be scored are as follows:

Chromatid gap
Chromosome break
Chromosome gap
Chromosome break
Chromatid deletion
Fragment
Acentric fragment
Translocation
Pulverized chromosomes
Pulverized chromosomes
Pulverized cells
Complex rearrangement
Ring chromosome
Dicentric chromosome
Minute chromosome
More than 10 aberrations
Triradial
Quadradial
Polypoid
Hyperdiploid

For control of bias, all slides are coded for scoring.

Assay evaluation criteria. A number of general guidelines have been established to aid in determining the meaning of CHO chromosome aberrations. Basically, an attempt is made to establish if a test article or its metabolites can interact with chromosomes to produce gross lesions or changes in chromosome numbers and if these changes are of a type that can survive more than one mitotic cycle of the cell. All aberration figures detected by this assay result from breaks in the chromatin that either fail to repair or repair in atypical combinations.

It is anticipated that many of the cells bearing breaks or reunion figures would be eliminated (i.e., fail to divide again) after their first mitotic division and, as a corollary, that those cells that survive the first division would primarily bear balanced lesions. The detection of these lesions, and hence a complete risk evaluation usually must rely on additional testing. In general, a cell bearing configurations such as small deletions or reciprocal translocations may be perpetuated and therefore constitutes a greater risk to an individual than one with large deletions or complex rearrangements.

Data are summarized in tabular form and evaluated. Gaps are not counted as significant aberrations unless they are present at a much higher than usual frequency. Open breaks are considered indicators of genetic damage, as are configurations resulting from the repair of breaks. The latter includes, for example, translocations, multiradials, rings, and multicenters. Reunion figures such as these are weighed higher than breaks and may lead to stable configurations.

The number of aberrations per cell are also considered significant. Cells with more than one aberration indicate more genetic damage than those containing evidence of single events. Frequently, one is unable to locate sufficient suitable metaphase spreads. Possible causes appear to be related to cytoxic effects, which alter the duration of the cell cycle, kill the cell, or cause clumping of the chromosomes. Additional information can be gained from the mitotic index, which appears to reflect cytotoxic effects, as well as from the frequencies of M1, M2, and M3 cells.

Comparison with a concurrent negative control that shows an unusually low frequency of aberrations can suggest undue statistical significance. Therefore, treatment data are considered against historical control data. In either event, the type of aberration, its frequency, and its correlation to dose trends within a given time period are all considered when evaluating a test article as being mutagenically positive or negative.

Statistical analysis employs a two-tailed t-test. This test can be performed on the number of breaks per

chromosome in treated and control samples. Dose regression analysis also is useful.

Protocol 5: Rodent Bone Marrow Micronucleus Assay

This assay design is based on OECD Guideline 474 (1997 version). The objective of the mouse micronucleus assay is to evaluate a test article for clastogenic activity in polychromatic erythrocyte (PCE) stem cells in treated mice. The micronucleus test can serve as a rapid screen for clastogenic agents and test articles that interfere with normal mitotic cell division (42, 82). Micronuclei are believed to be formed from chromosomes or chromosome fragments left behind during anaphase and scored during interphase because they persist. Thus, the time involved in searching for metaphase spreads in treated cell populations is eliminated. Test articles affecting spindle fiber function or formation, as well as clastogenic agents, can be detected through micronucleus induction.

Materials (This design will describe a study in mice). Adult male and/or female mice, strain CD-1, from a randomly bred closed colony may be used as well as other strains or species. A healthy, random-bred strain

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_848.html[2010/10/28 18:48:29]

is selected to maximize genetic heterogeneity and at the same time ensure access to a common source. Animals usually are 8–10 weeks old at the time of dosing.

Trimethylene melamine (TEM) at 1.0 mg/kg may be used as the positive control article and is administered via a split-dose intraperitoneal injection. The negative control consists of the solvent or vehicle used for the test article and is administered by the same route as, and concurrently with, the test article in volumes equal to the maximum amount administered to the experimental animals.

Experimental design.

Animal husbandry. Animals are group-housed 7 mice per cage. A commercial diet and water are available *ad libitum* unless contraindicated by the particular experimental design.

Five animals per dose level are uniquely identified and assigned to study groups at random. Prior to study initiation, animals are weighed to calculate dose levels. The volume of test article administered per animal is established using a mean weight unless there is significant variation among individuals; in this case, individual calculations are made.

Sanitary cages and bedding are used. Personnel handling animals or working within the animal facilities are required to wear suitable protective garments. When appropriate, individuals with respiratory or other overt infections are excluded from the animal facilities.

Dose selection. If acute toxicity information (e.g., LD50) is available, it can be used to determine dose levels. If it is not available, dose levels can be determined using five groups of six animals each in a toxicity study. For nontoxic agents, a limit dose of 2000 mg/kg is employed. For toxic agents, the high dose is selected based on some evidence of toxicity (e.g., clinical signs, death, depression in bone marrow cell maturation). Two lower doses at 1/2 and 1/4 of the high dose will be selected. An attempt is made in mutagenesis studies, as well as other toxicology work, to evaluate the extremes of dosage as well as values close to the use level.

Dosing schedule and route of administration. The test article administered may be in one of two groups: (1) animals may be treated once or (2) two or more daily doses are given 24 h apart. The single-dose administration is the most common. In the event that test article characteristics preclude oral gavage, intraperitoneal injection may be employed. These routes of administration are the ones most commonly used for this test procedure.

Extraction of bone marrow. For the single-dose regimen, sampling times will be at 24 and 48 hours after compound administration. Animals are killed with CO2 and the adhering soft tissue and epiphyses of both femurs removed. The marrow is aspirated from the bone and transferred to centrifuge tubes containing 5 ml fetal calf serum (one tube for each animal).

Preparation of slides. After centrifugation to pellet the tissue, the supernatant fluid is drawn off and portions of the pellet spread on slides and air-dried. The slides are then stained in May-Gruenwald solution and Giemsa, followed by clearing in distilled water.

Screening the slides. One thousand PCEs per animal are scored. The frequency of micronucleated cells is expressed as percent micronucleated cells based on the total PCEs present in the scored optic field. The frequencies of other bone marrow cell types are recorded for analysis of cytotoxic effects (reduced production of specific blood cell types).

Evaluation criteria. In tests performed for this evaluation, only PCEs are scored for micronuclei. Mature erythrocytes and other cells in the field are recorded but not scored. Loss of nucleated cells is an indication of cytotoxicity. The dose levels are established to ensure that a nontoxic level of the test article is scored. Dose-response data are not necessary to define a test article as active. Responses considered active are assumed to reflect clastogenic and related activities of test articles. Agents that break chromosomes and induce nondisjunction, as well as other events that produce structural or numerical changes in chromosomes, can produce micronuclei.

The data generated in this study may be analyzed by a two-tailed *t*-test. Individual animal results are used as data points in the analysis. The set of micronuclei frequencies among the controls are compared to the set for each treatment level. Male and female animal data are combined unless there appears to be a sex difference, in which case the data are analyzed separately. Increases above the negative control frequency that are significant at $p<0.01$ are considered indicative of an active agent.

For control of bias, all slides are coded prior to scoring and scored blind.

QUESTIONS

1. Would transcription-coupled DNA repair (TCR) be more active in an exon or an intron?
2. Which type of gene mutation would be corrected by mismatch repair: a basepair substitution or a frameshift mutation?
3. Which part of a chromosome is believed to influence cell mortality: the centromere, the telomere, or

the centriole?
4. Which short-term test shows the best overall concordance with animal carcinogenicity: SCEs, the Ames test, or the mouse micronucleus test?

5. The p53 gene is a member of which class of genes: an oncogene, a dominant gene, or a tumor suppressor gene?
6. A disruption in the nucleotide sequence of which of the following is likely to result in a mutation: a codon, a gene, or a chromosome?
7. Which of the following technologies was critical to the development of the transgenic mouse models for mutation: shuttle vector, PCR, or gel electrophoresis?
8. Chemically-induced heritable mutations have not been documented in which of the following species: fruit fly, mouse, or human?

The methods and principles of evaluating two categories of hazards, acute systemic toxicity and eye irritation, both resulting from a single or very short-term exposure, are described in this chapter. In

recent years, economics and concerns over animal welfare have raised many issues in animal testing. Alternate methods for acute toxicity and eye irritation are being developed and, in some cases, accepted by regulatory agencies for hazard assessment purposes. This chapter describes the classical methods for determining acute systemic toxicity and eye irritation, and the more modern methods requiring fewer animals are also discussed. In addition, criteria have been put in place for the validation and regulatory acceptance of alternative tests and these will be reviewed.

PRINCIPLES OF ACUTE TOXICOLOGY

Acute toxicity testing began nearly a century ago when physicians and pharmacologists were concerned with potent poisons and drugs. In 1927, Trevan (355) introduced the concept of a median lethal dose (LD50) for the standardization of digitalis extracts, insulin, and diphtheria toxin. He recognized that the precision of the value was dependent on many factors such as seasonal variation and the number of animals used in a test. High-precision LD50 values can only be established with a large number of animals.

The list of extraneous factors that affect the precision of the LD50 has increased since Trevan's work and

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_853.html[2010/10/28 18:48:33]

now includes, among other factors, sex, species, strain, age, diet, nutritional status, general health conditions, animal husbandry, experimental procedures, route of administration, stress, dosage formulation (vehicle), and intra- and inter-laboratory variations. In spite of the many variables affecting the LD50 determination, many government agencies still regard the LD50 as the sole measurement of the acute toxicity of all materials, though a change in this attitude has emerged.

It is important to obtain a sound measurement of the killing power of highly toxic substances because a small difference in exposure can distinguish a safe from a lethal situation. However, a precise LD50 is not necessary for less toxic materials such as pesticides and consumer household products. For these substances, an approximate measurement of the killing ability is sufficient and still desirable, since overexposure to these products is possible and lethal cases are not uncommon. There are errors inherent in the determination of LD50 values, some of which cannot be controlled by the experimenter, and it is therefore not scientifically sound to obtain a precise LD50 on low to moderate toxic substances. Many methods have been developed over the years to calculate LD50 values and to evaluate the acute toxicity of chemicals with a small number of animals. These methods are discussed later in this chapter. Many scientists have advocated changes in the emphasis of acute toxicity testing. To date, there is a general consensus among toxicologists in academia, industry, and government that a change in the emphasis of acute toxicity testing is needed (24, 122, 132, 208, 227, 262, 321, 339). The value of a precise LD50, except for highly toxic substances, is being de-emphasized and the focus is now on obtaining as much information as possible on the toxic manifestation and mechanism with the smallest number of animals. Undoubtedly, such information will be for physicians more useful than the LD50 in treating overexposure.

Even though the emphasis of acute toxicity testing is changing, the principles of dose-response and development of signs of toxicity remain the basis of the science of toxicology. This section refreshes the knowledge of the experienced and introduces the novice to these general concepts.

Definition of Acute Toxicity

Toxicity is defined as the harmful effect of a chemical or a drug on a living organism. Various expert groups have defined acute and subchronic toxicities. The Organization for Economic Cooperation and Development (OECD) defines acute toxicity as "the adverse effects occurring within a short time of (oral) administration of a single dose of a substance or multiple doses given within 24 hours" (275). In terms of human exposure, this definition of acute toxicity refers to life-threatening crises such as accidental catastrophes, overdoses, and suicide attempts.

Dose-Response Relationship

Toxicologists often obtain two types of data, quantal and graded. The quantal response is called the "all-or-none" response; it either happens or it does not happen. On the other hand, the graded response can be determined quantitatively and it is continuous. Mortality and incidences of pharmacotoxic signs are examples of quantal data, whereas enzyme activity, protein concentration, body weight, feed consumption, and electrolyte concentration are quantitative parameters. However, many apparently quantal responses are quantitative. If technical measurements permit, they may be graded. For example, the severity of a pharmacotoxic sign can be graded if detection methods are available.

At the molecular level, the graded dose-response relationship often can be explained by the receptor, a relatively old concept but still a valid one. Let S be a particular substance that produces a specific response by interacting with a target protein molecule, the receptor R, in the body to form a substance-receptor complex, SR. Assuming the reaction is reversible and there is only one binding site on every target receptor molecule, this process can be described by the following expression:

$$\mathrm{S} + \mathrm{R} \underset{K_2}{\overset{K_1}{\rightleftarrows}} \mathrm{SR}$$

and the mass equation for this reversible process is

$$\frac{K_2}{K_1} = k_d = \frac{[\mathrm{S}][\mathrm{R}]}{[\mathrm{SR}]} \quad (1)$$

where [S] [R], and [SR] are the concentrations of the substance, the receptor, and the substance-receptor complex at any particular time, respectively, and *Kd* is the dissociation constant of the process. Let [R]O be the initial concentration of the receptor, which is usually very small and constant in number when compared with the concentration of the substance. Then

[R]0=[R]=[SR]

thus

$$[R]=[R]_0-[SR]$$

Substituting the above into the mass equation [(Eq. (1)]

page_855

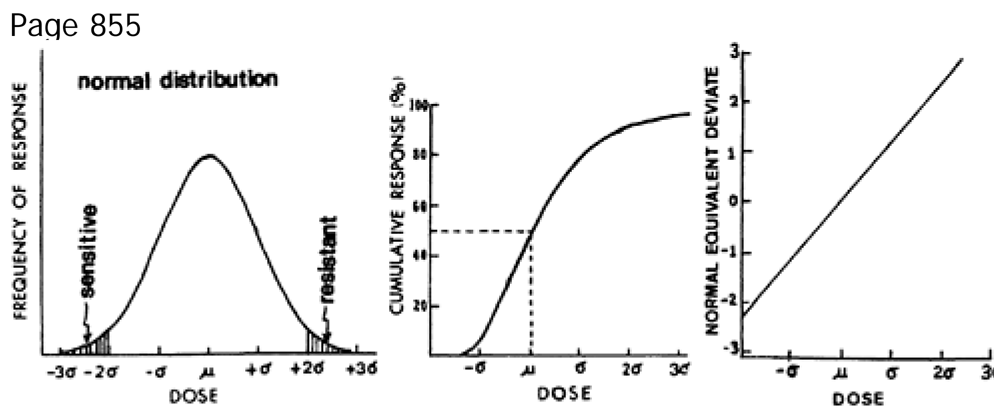

FIG. 18.1. Normal distribution of dose-response relationships: frequency of response, cumulative response, and cumulative response in terms of normal equivalent deviate.

and rearranging:

$$[SR]K_d = [S]([R]_0 - [SR])$$

or

$$[SR](K_d + [S]) = [R]_0[S]$$

which can be rearranged to

$$\frac{[SR]}{[R]_0} = \frac{[S]}{k_d + [S]} \quad (2)$$

SR/[R]O is the fraction of receptor that has reacted with the substance to form the substance-receptor complex. If we assume that the response *(E)* resulting from the interaction of the substance with the receptor is dependent on the fraction of total receptor concentration that has reacted with the substance, then

$$E = \frac{[S]}{k_d + [S]} \quad (3)$$

Equation (3) is a hyperbolic function; therefore, the response *(E)* is related to the concentration of the substance in a hyperbolic function relationship. If the concentration of the substance at the receptor site is dependent on the dose, then the response is dependent on the dose administered. This phenomenon is perhaps the simplest version of the receptor kinetic concept relating the dose of the chemical to a biological response. The kinetics of the receptor-substrate interaction may be more complicated, and different dose-response relationships could be drawn based on these complicated kinetics. Readers who are interested in different receptor-substance kinetics are referred to Ferdinard (135).

The quantal dose-response relationship often is difficult to conceptualize based on the receptor theory. However, quantal response also can be viewed as a graded response if the whole population is considered as an individual. This relationship can best be explained in terms of a probability distribution. For a particular response, members of a population, for example, all the rats in the world, respond differently to a particular stimulus such as exposure to a chemical. Some rats will be highly sensitive and others will be very resistant. If these different responses are distributed normally within the population (i.e., with most members of the population being neither extremely sensitive nor resistant), the well-known bell-shaped population distribution curve results. If the probability of dose-response is expressed in terms of cumulative response, a sigmoidal curve can be obtained, as shown in Figure 18.1. However, most biological response distributions are not exactly normal and tend to be skewed to the higher dose, that is, extreme resistors have a larger *range of dose* to response than the extremely sensitive portion of the population. In general, a logarithmic dose transformation can normalize the distribution (i.e., convert the skewed distribution to a normal distribution) (Figure 18.2). After this logarithmic dose transformation, if the probability of the log dose-response is expressed cumulatively, the sigmoidal response curve is obtained (Figure 18.2). How is this lognormal transformation related to a regular dose-response curve? Is there justification or basis for a log dose transformation? To answer these questions, let us again look at Eq. (3). This equation can be arranged to

$$E = \frac{[S]}{k_2/k_1 + [S]}$$

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_855.html[2010/10/28 18:48:34]

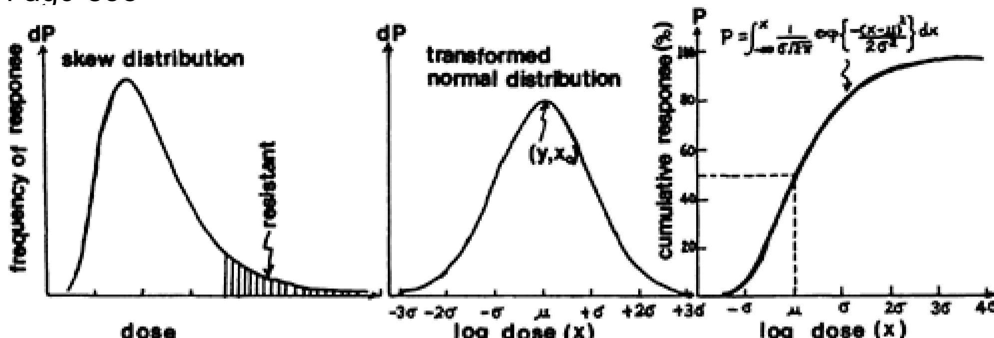

FIG. 18.2. Skew of dose-response can be normalized by log-dose transformation.

which can be rearranged to

$$E = \frac{k_1[S]}{k_2 + k_1[S]} \tag{4}$$

Over a certain concentration range, Eq. (4) will produce a curve very similar to the logarithmic function $E=K1 \log (k2 [S]+1)$ (77). Therefore, there may be justification for the log transformation besides simply a mathematical convenience.

Because a sigmoidal curve is more difficult to analyze than a straight line, many experts feel that further transformation of the log dose-response hyperbolic function is necessary to obtain a *straight-line* function curve. Perhaps the most widely used transformation is the normal equivalent deviate (NED) or the similar probit transformation (34, 78, 82, 95, 105, 138, 242). This technique involves the log dose transformation and the transformation of the cumulative response probability to the NED or probit. After both the probability and the dose are transformed, their transformed values are directly related to each other. A brief derivation of the straight-line direct function relationship between the log-dose and NED or probit is presented later in this chapter.

LD50and Its Determination

Definition

The LD50 in its simplest form is the dose of a compound that causes 50% mortality in a population. A more precise definition has been provided by the OECD panel of experts as the "statistically derived single dose of a substance that can be expected to cause death in 50% of the animals" (275). In other words, an LD50 of a compound is not a constant, even though it has been treated that way by many; rather, it is a statistical term designed to describe the lethal response of a compound in a particular population under a discrete set of experimental conditions.

The significance of LD50 values has been examined by many scientists (24, 122, 132, 208, 227, 262, 321, 339) who have arrived at similar conclusions: the LD50 is an imprecise value, it is not a biological constant and should be de-emphasized for most materials. They agree, furthermore, that approximate LD50 values often are sufficient for all practical purposes and that more emphasis should be placed on signs of toxicity, target organs, and other factors.

The numeric value of the LD50 has been used to classify and compare toxicity among chemicals. The extent of involvement of the LD50 in safety evaluation has almost reached a level of abuse. Although determining the LD50 under a set of experimental conditions can provide valuable information about the toxicity of a compound, the numeric LD50 per se is not equivalent to acute toxicity. One must always remember that lethality is only one of many reference points in defining acute toxicity. The slope (response/dose) of the dose-response curve, the time to death, pharmacotoxic signs, and pathological findings are all vital or even more critical than the LD50 in the evaluation of acute toxicity. Therefore, defining acute toxicity based only on the numeric value of an LD50 is inappropriate.

As pointed out previously, lethality is a quantal response, and the probability of a cumulative response is related to dose in a hyperbolic (sigmoidal) function. The cumulative probability of response is directly related to the standard deviates of a log dose population (Figure 18.1). Therefore, the slope of the log dose-response curve will indicate the relationship between the range of dose and the lethal response. This relationship is more important in risk assessment than the numeric value of the LD50 because more insight is available about the intrinsic toxic characteristics of a compound.

Sometimes the slope can give a clue to the mechanism of toxicity. For example, a steep slope may indicate rapid onset of action or faster absorption. A large margin of safety is predicted when a compound has a flat slope, that is, only a small increase in response with a large increase in dose. With the slope, it often is possible to extrapolate the response to a low dose (e.g., LD0, LD1) or even to a no-observed-effect level. It is especially important to know the slope when comparing a set of compounds. Two compounds may have identical LD50 values but different slopes and thus have quite different toxicological characteristics depending on the range of doses. Parallel dose-response curves may indicate a similar mechanism of toxicity, kinetic pattern, and probably similar prognosis. Neither the LD50 nor the slope can reveal absolutely a specific mechanism, but with pharmacokinetic and other biochemical studies elucidation of the mechanism of toxicity may be possible.

*Determination of LD***50**

Many methods are available for the determination of the LD50. They can be grouped into two categories, the *normal population assumption* and *the normal population assumption-free* methods. The former usually can be analyzed by graphic procedures.

The normal population assumption-free methods are represented by Thompson's moving average interpolation (353, 372) and the "up-and-down" method (51–54, 77, 98). The former method is widely accepted, and convenient tables (105, 372) are available for estimation of the value of the LD50 with confidence limits when either 0 or 100% mortality incidences are observed. However, there are some restrictions on the use of this method, that is, four doses at equal log dose intervals and the number of animals per dose level must be equal. The up-and-down or the pyramid method is designed to estimate the LD50 with a small number of samples. It has a relative cost advantage because fewer animals are needed, but the test may be time-consuming and require excessive test material. Because of the advantage of using only a few animals, this method is popular when the test has to be conducted in large animals such as cows or sheep or expensive animals such as monkeys. A study comparing LD50 values obtained by the up-and-down method and other methods revealed an excellent agreement (52). There are apparently two shortcomings for this method—it is not adequate for estimating the incidence of delayed deaths, and a dose-response of mortality or signs of toxicity cannot easily be obtained. However, Weil (373) has adapted the up-and-down method to calculate the slope of acute toxicity response.

The normal population assumption method is represented by the probit analysis approach, which can be performed either by graphic means (138) or by mathematical calculation (139). Because the probit analysis is used widely in evaluating acute toxicity data, the priniciples are discussed briefly. This method involves the transformation of both the cumulative response probability and the dose.

When the dose is transformed into a log dose (x), the frequency of response versus log doses follows a normal distribution (Figure 18.2), which can be expressed mathematically as

$$dP = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(\frac{-(x-u)^2}{2\sigma^2}\right) \tag{5}$$

where σ^2 and u are the variance and the mean of the population, respectively, and P is the probability corresponding to each value of x (Figure 18.2). The LD50 is defined as the log dose that can produce 50% mortality in a population (i.e., P=0.5 or 50% cumulative response). Let x be the log LD50; then P=0.5 will correspond to the area under the log normal distribution curve from $-\infty$ to x_0; or P=0.5 will correspond to the integration of Eq. (5) from $-\infty$ to x_0: That is,

$$P = 0.5 = \int_{-\infty}^{X_0} \frac{1}{\sigma\sqrt{2\pi}} \exp\left(\frac{-(x-u)^2}{2\sigma^2}\right) dx \tag{6}$$

The solution of Eq. (6) is $x=u$, the true mean or the median of the log normal distribution. One way to solve this equation is by a graphic method. The integration of Eq. (5) from $x=-\infty$ to $+\infty$ can be represented graphically by a sigmoidal curve as illustrated in Figure 18.2. Analysis of the sigmoidal curve is more difficult than a straight line. One way to transform the sigmoidal curve to a straight line is by NED analysis or, similarly, by probit analysis. For a detailed description of this analysis, the reader should consult Finney's text (138). A brief derivation of the straight-line function between log dose and the transformed probability of response is described below.

Probability *(P)* is normally expressed in terms of percentage or with values between 0 and 1; but Gaddum (152) has proposed to measure the probability of response on a transformed scale called the normal equivalent deviate (NED), or the standard deviation of a normal distribution, which can be

described mathematically by Eq. (5). In a particular case, the normal distribution of response with mean equal to 0 and the standard deviation equal to 1, Eq. (5) can be written as

$$dP = \frac{1}{\sqrt{2\pi}} \exp\left(\frac{-x^2}{2}\right) dx$$

Similarly, if this distribution of response is plotted on the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_857.html[2010/10/28 18:48:36]

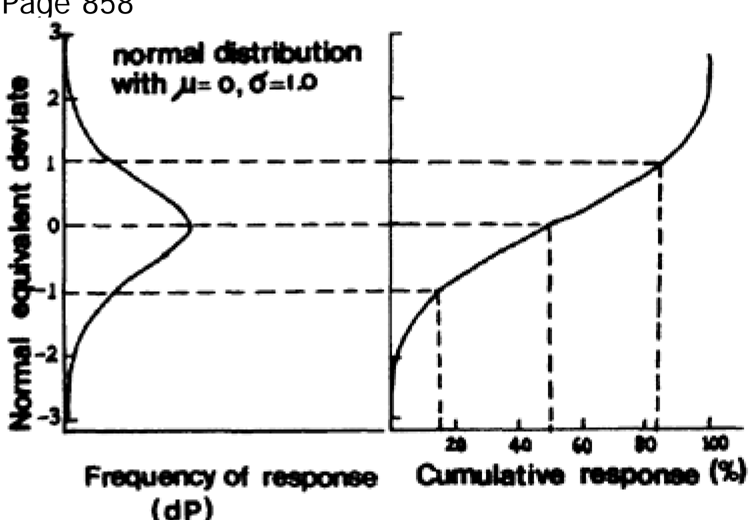

FIG. 18.3. Probability of response can be expressed in terms of percentage of the population or the NED of a normal distribution with mean=0 and standard deviation=1.

y axis (Figure 18.3), then

$$dP=\frac{1}{\sqrt{2\pi}}\exp\left(\frac{-y^2}{2}\right)dx \quad (7)$$

The probability in such a case is defined by a value on the *y* axis of Figure 18.3, that is, the integration of Eq. (7) from −∞ to *y:*

$$P=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{y}\exp\frac{-y}{2}dy \quad (8)$$

In other words, for each value of *y* (from −∞ to +∞) expressed in terms of the standard deviation of a normal distribution with the mean equal to 0 and the standard deviation equal to 1, there is a corresponding value of probability *(P)* expressed in terms of percentage or having a value ranging from 0 to 1. Thus, equivalent values on the *y* axis can be used to define the value of *P* or vice versa; *y* and *P* define each other. This relationship is illustrated in Figure 18.3.

The particular probability of response to a particular log dose value *x,* as described in Eq. (6), will be

$$P=\int_{-y}^{-x}\frac{1}{\sigma\sqrt{2\pi}}\exp\left(\frac{-(x-u)^2}{2\sigma^2}\right)dx \quad (9)$$

where *u* and *σ* are the mean and standard deviation of the log dose, respectively.

If *P* is expressed by a value of *y* on the *y* axis (standard deviations), then

$$P=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{y}\exp\left(\frac{-y^2}{2}\right)dy$$

$$=\int_{-\infty}^{x}\frac{1}{\sigma\sqrt{2\pi}}\exp\left(\frac{-(x-u)^2}{2\sigma^2}\right)dx$$

The solution of this equation is $x=u+\sigma y$ or

$$y=\frac{(x-u)}{\sigma}-\frac{1}{\sigma}x-\frac{u}{\sigma} \quad (10)$$

Therefore, the probability when expressed in terms of *y* (the NED scale) is related linearly to *x,* the log dose. If *x* is plotted against the corresponding *y,* a straight line with slope=1/*σ* will be obtained. To further facilitate calculation, Bliss (33) suggested a slightly different NED unit called the probit, such that the new *y* value is equal to $[(x-u)/\sigma]+5$. This procedure eliminates the negative values of NED when *P* has a value of less than 50%. Therefore, the probit is equal to the NED plus 5. The linear relationship between probits and log dose is similar to the relationship between NED and log dose. Thus, when *y*=5, from Eq. (10),

$$5 = \frac{(x-u)}{\sigma} + 5$$

and $x=\mu$ (i.e., the median log dose which has a probability of response of 50%).

Logistic Transformation

Waud (371) suggested a logistic approach to calculate the LD50. Thus

$$P = \frac{D^E}{(D^E + K^E)}$$

where P is the probability of response, D is the dose, E and K are scale and location parameters, respectively, and K corresponds to the LD50. With the procedure of iteration, K and E can be estimated with a range of confidence. The derivation of this equation is beyond the scope of this chapter, and interested readers are referred to the original article by Waud (371).

Nonlethal Parameters

Although the LD50 and the slope of the dose-response curve can provide valuable information on the toxicity of a compound, the LD50 *is not equivalent to toxicity*. Chemicals can induce damage to the physiological, biochemical, immunological, neurological, or anatomical systems. Depending on the severity and the extent of the disturbance of the normal biological functions, the animal may survive the toxic response but some irreversible damage may occur. These nonlethal, adverse effects are as undesirable as lethality and certainly should be taken into consideration in the risk assessment of a chemical.

The major problem in the analysis of nonlethal responses is that the data often are not quantal. For example, dermal toxicity ranges from slight to severe.

< previous page page_858 next page >

These polychotomous data may be handled by RIDIT analysis, which was designed to analyze quantal responses with more than two outcomes (2, 50, 176).
Although toxic effects may contribute to lethality, any attempt to correlate a particular nonlethal response to mortality may be irrational (340) unless that response is the only one responsible for the eventual death of the animal. Identification of the response or responses related to mortality is not often a straightforward matter. Nonlethal responses that affect the general well-being of an animal should be considered in the risk assessment of a compound. If nonlethal responses can be viewed as true quantal data, the *median effective dose* (ED50) and the corresponding dose-response curve may apply. The ED50, which often is used in the standardization of a biologically active compound such as a drug, has a meaning similar to the LD50 except that it is designated to examine nonlethal parameters such as pharmacological responses and other nonlethal adverse effects. The ED50 is defined as a statistically derived single dose of a substance that can be expected to cause a particular effect to occur in 50% of the animal population. The therapeutic index (TI), defined by the ratio of LD50/ED50 or LD1/ED99, has been applied to establish the safety margin of some biologically active drugs. The higher the index, the greater the margin of safety with the drug, that is, a large difference exists between the amount of compound predicted to kill 50% of the animals and the amount of compound predicted to elicit a particular response in 50% of the animals. The TI gives an even greater estimate of safety when the LD1 is compared with the ED99.

Reversibility of Nonlethal Parameters

In general, reversible responses are those that diminish with elimination of the chemical from the body. A true reversible response will cause no residual effects when the chemical is completely eliminated from the body. Such responses are commonly seen in drugs used at therapeutic dose levels. As the amount of drug in the body increases, the magnitude of the effect also increases. If it is truly reversible, the effect will wear off when the drug is completely eliminated.
The reversibility of a particular response is dependent on the organ or system involved, the intrinsic toxicity of the chemical, the length of exposure, the total amount of the chemical in the body at a specific time, and the age and general health of the animal. If the amount of chemical in the body is high enough, the intensity of the response may overwhelm a particular organ. Effects indicated through hormonal imbalance such as thyroid effects generally are reversible unless the threshold is surpassed. Damage in rapidly regenerating organs such as the liver is usually more likely to be reversible than damage in nonregenerating tissues such as nerves. A good example is the delayed onset of neuropathy caused by many organophosphate insecticides. The chemical may be completely eliminated from the body before the effect manifests itself. Animals with renal or liver diseases are often more susceptible to damage (reversible or irreversible) by a chemical insult because of their decreased ability to eliminate the chemical. Exposure to a chemical at an early age may induce irreversible damage more easily than at an older age because of the limited development of the kidneys and/or functional capacity of other organs such as the liver.
In risk assessment, it is important to know whether a toxic effect is reversible. Irreversible effects seen in animals obviously are weighted more heavily in reaching a conclusion on the toxicity and hazard a chemical may pose for humans.

ACUTE TOXICITY TESTING

The objectives of acute toxicity testing are to define the intrinsic toxicity of the chemical, predict hazard to nontarget species or toxicity to target species, determine the most susceptible species, identify target organs, provide information for risk assessment of acute exposure to the chemical, provide information for the design and selection of dose levels for prolonged studies, and, most important and practical of all, provide valuable information for clinicians to predict, diagnose, and prescribe treatment for acute overexposure (poisoning) to chemicals. Acute studies often are called the “first line of defense” in the absence of data from long-term studies. These data help industrial, government, and academic institutions formulate safety measures for their researchers and for limited segments of their worker population during the early stage of the development of a chemical. From a regulatory standpoint, acute toxicity data are essential in the classification, labeling, and transportation of a chemical. From an academic standpoint, a carefully designed acute toxicity study can often provide important clues on the mechanism of toxicity and the structure-activity relationship for a particular class of chemicals.
Many acute toxicity studies have been conducted solely for the purpose of determining the LD50 of a chemical. However, the reader is reminded that acute toxicity is not equivalent to the LD50, and that the LD50 is not an absolute biological constant to be equated, as many investigators have, with such chemical constants such as pH, pKa, melting point, and solubility. The LD50 is only one of many indices

used in defining acute toxicity. A well-designed acute toxicity study should include consideration of the dose-response relationship of both lethal

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_859.html[2010/10/28 18:48:37]

and nonlethal parameters, as discussed above. Sometimes biochemical measurements in an acute test can aid in elucidating the mechanism of toxic actions. Histopathology of organs may be helpful in determining the cause of death and identifying the target organs.

Types of Acute Testing

Because acute toxicity data may provide the first line of defense, a battery of tests under different conditions and exposure routes should be considered. In general, these tests should include oral, dermal, and inhalation toxicities, and skin and eye irritation studies. Other tests such as acute pre-neonatal and neonatal exposure, dermal contact sensitization, and phototoxicity should be considered. Depending on sound scientific factors, which may vary from one chemical to another, the number and kind of acute tests needed to establish the initial toxicity database may not be the same. For example, when inhalation exposure is not expected to occur because of the physical properties of the chemical, inhalation testing may not be needed. Such a case is not uncommon if respirable particles cannot be generated, even under the most favorable laboratory conditions. Nonetheless, for most purposes, oral, dermal, skin, and eye tests should be considered in the initial acute investigation. These four tests are often sufficient for regulatory purposes, labeling, and classification of a chemical, although increasing concerns also are placed on inhalation and skin sensitization studies. This chapter is concerned only with acute oral and dermal toxicity and eye irritation.

Acute Oral Toxicity

Principles

The test substance, undiluted or diluted with the appropriate solvent or suspending vehicle, is given to several groups of animals by gavage with a feeding needle or by gastric intubation. A vehicle control group is included if needed, but generally this group is not necessary if the toxicity of the vehicle is known. Clinical signs, morbidity, and mortality are observed at specific intervals. Animals that die or become extremely moribund during the study are subjected to necropsies. Animals that survive the test period are killed and necropsied at the end of the observation period. Tissues may be saved for histopathological examination to facilitate the understanding of the acute toxicity of the compound. To increase the reproducibility of the study, all experimental conditions and procedures should be standardized, and the study should be conducted according to generally recognized good laboratory practices (GLP) outlined by the U.S. Environmental Protection Agency (EPA) and the OECD (120, 121, 281).

Animal Species

The responses elicited by a compound often vary greatly among species. Ideally, toxicity tests should be conducted with an animal that will elicit compound-related toxic responses similar to those that occur in humans, that is, an animal that metabolizes the compound identically to humans and that has the same susceptible organ system(s). Under such conditions, the animal data may be extrapolated to humans. Unfortunately, finding such an ideal animal is a difficult if not impossible task.

A less ideal but more manageable approach is to conduct acute toxicity studies in a variety of animal species under the assumption that if the toxicity of a compound is consistent in all the species tested, then a greater chance exists that such a response may also occur in humans. Even though the response in different species is not consistent, it generally is considered better to err on the safe side with the risk assessment being based on the most sensitive species unless there is justification that such responses are less likely to occur in humans, for example, because of dissimilarity in metabolism between the less sensitive animal species and humans. Although these are logical assumptions and generally quite reliable, the danger of underestimating or overestimating the response in humans still exists. Therefore, there is no absolute criterion for selecting a particular animal species. However, priority should be given to species with metabolism or other physiological and biochemical parameters similar to humans. Animal species also should be selected on the basis of convenience, economic factors, and the existing database for the animal. Rats, mice, rabbits, and guinea pigs are most commonly chosen for acute toxicity studies.

Other Animal Variations

Acute toxicity, even within a particular species, can vary with health conditions; age; sex; genetic makeup; body weight; differences in absorption, distribution, metabolism, and excretion of the compound; and the influence of hormones (101). A conscientious investigator should be aware of the possible interaction of chemical treatment with these parameters. For example, immature animals may lack an effective drug-metabolizing enzyme system; this may contribute to higher toxicity of the compound in an immature animal if an enzyme is responsible for detoxification of the compound, or to decreased toxicity if an enzyme is responsible for activation of the compound. Obesity may affect the

distribution and storage of a compound, especially when it is highly

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_860.html[2010/10/28 18:48:38]

lipophilic. Sex hormones may be the target, or sex hormones may modify a particular toxic response which then may account for different toxic responses between sexes. Liver and renal diseases associated with old age may contribute to higher toxicity. Variations in genetic makeup among different strains may alter metabolism or other parameters, which may affect the toxicity of a particular compound. It is therefore important to document all data on animals: age, sex, body weight, strain, general health condition, and source. In general, healthy, young adults should be used. For example, if a rat is the test animal, then young adults weighing between 150 and 250 g should be used. The weight variation among animals should not exceed ±20% of the mean body weight.

Animal Numbers and Sex

The precision of the acute test is dependent to a large extent on the number of animals employed per dose level. Historically, 10 rats (5 male and 5 female) have been recommended in most regulatory guidelines (109, 124, 125, 275, 337), although more recently modified protocols are acceptable using as few as three animals per dose level (278, 279). The degree of precision needed and, in turn, the number of animals per dose group needed depend on the purpose of the study. In screening tests or tests designed to define the range of toxicity, fewer animals per dose level or fewer numbers of dose levels may be considered. In rare situations where a fairly precise LD50 is needed, the number of dose levels (at least three dose levels) and animals per dose group may need to be increased. The number of animals and dose levels should be based on sound scientific judgement.

In 1986, the OECD updating committee recommended that acute toxicity studies be conducted first in the male and at one dose level in females. If a marked sex difference appears when one dose level is used, then the test should be cross-checked. This approach reduces the number of animals used in acute toxicity testing. The more recent guideline (279), which is even more effective in reducing the number of animals used, specifies that in the absence of information suggesting that males are more sensitive, only females should be used. Literature surveys have shown that when there are sensitivity differences between the sexes, females, in general, are more sensitive (225).

Animal Housing and Environment

Studies should be conducted in a controlled environment. The temperature (22±3°C), relative humidity (30–70%), light and dark cycle (12 h dark, 12 h light), diet, and quality of drinking water should be standardized and maintained continuously. Animals may be caged in groups by sex or caged individually, depending on the species and size of the animals and on the needs of the particular study. Rodents can be caged in groups, usually not more than three per cage, but larger animals such as rabbits and dogs should be housed individually.

Dose levels. In general, the dose levels should be sufficient in number to allow a clear demonstration of a dose-response relationship and to permit an acceptable determination of the LD50, if required. Three dose levels generally are sufficient. The selected dose levels should bracket the expected LD50 value with at least one dose level higher than the expected LD50 but not causing 100% mortality, and one dose level below the expected LD50 value but not causing 0% mortality, when the probit analysis method is applied to estimate the LD50. However, with a method such as the moving average under some specific conditions (at least four dose levels with equal logarithmic intervals between each dose level, and with equal numbers of animals in each dose group), the LD50 can be estimated even with 0% mortality at the lower dose levels and 100% mortality at the two higher dose levels.

In any event, three or more dose levels with a wide range of toxicity responses are recommended if no other toxicity data are available. A pilot study may be needed for the selection of dose levels. Fewer animals per dose level and wider logarithmic intervals between dose levels usually are selected for the pilot study to ensure bracketing of the expected LD50 value. For example, if one desires an equal log interval of 0.6 between dose levels, and if the lowest dose is 1 mg/kg (log dose=0), the next log doses would be 0+0.6, 0.6+0.6, 1.2+0.6, and so on, corresponding to dose levels of antilogs 0.6, 1.2, 1.8 (i.e., the dose levels are: 1, 4, 16, 64, etc., in a geometric progression ratio of 4).

Dosages. If necessary, the test substance should be dissolved or suspended in a suitable vehicle, preferably in water, saline, or an aqueous suspension such as 0.5% methyl cellulose in water. If a test substance cannot be dissolved or suspended in an aqueous medium to form a homogeneous dosage preparation, corn oil or another solvent can be used. If the toxicity of the vehicle is not known, a vehicle control group should be included in the test. The animals in the vehicle control group should receive the same volume of vehicle given to animals in the highest dose group.

The test substance can be administered to animals at a constant concentration across all dose levels (i.e., varying the dose volume) or at a constant dose volume (i.e., varying the dose concentration). However, the investigator should be aware that the toxicity observed by administration in a constant

concentration may be different from that observed when given in a constant dose volume. For instance, when a large volume of corn

< previous page page_861 next page >

oil is given orally, the gastrointestinal motility is increased, causing diarrhea and decreasing the time for absorption of the test substance in the gastrointestinal tract. This situation arises when a highly lipid-soluble chemical is tested. A large fraction of such a material may quickly pass through the gastrointestinal tract and remain unabsorbed. Local irritation of a test substance generally decreases when the material is diluted. If the objective of the study is to establish systemic toxicity, the test substance should be administered in a constant volume (diluted concentration) to minimize gastrointestinal irritation that may in turn affect the absorption of the test substance. On the other hand, the test substance should be administered undiluted to assess the irritation potential of the test substance. The choice of constant concentration versus constant dose volume should be based on sound scientific judgment. The OECD guideline suggests a constant dose volume approach (275). The maximum dose volume in rodents should not exceed 10 ml/kg body weight for non-aqueous vehicles or 20 ml/kg body weight for aqueous solution or suspension. In any event, for scientific and humane reasons the dose volume should be as small as possible.

Observation. As has been discussed previously, the emphasis in acute toxicity studies is on the determination of the dose-response and the onset of toxic signs. The observation period should be flexible depending on the purpose of the study. This period should be based on the onset of signs, the nature of the toxicity, time to death, and the rate of recovery. For most highly toxic substances, the onset of toxic signs and the time to death may be very short, and prolonged observation may not be necessary. The slope of the dose-response curve for such test substances is usually very steep, and the treated animals either die or survive within a very short time. For other substances, the onset of signs and the time to death may be delayed for a few days to a few weeks or longer. Obviously, a longer observation period is needed to detect these delayed acute effects. The observation period also should be long enough for the determination of reversibility or the recovery of an adverse effect. Under specific circumstances the observation period might be longer, but it normally does not exceed 14 days.

Test limit. All chemicals can produce toxicity under some experimental conditions; for instance, if a sufficiently large dose is given. It is therefore scientifically misleading and inhumane to conduct acute toxicity studies at unreasonably high dose levels for the sake of demonstrating lethality and/or toxicity, which may be irrelevant to the compound itself. For example, an extremely high dose of a practically nontoxic compound can cause gastrointestinal blockage, which, in turn, can result in gastrointestinal tract dysfunction. Toxicity in this case is not related to the intrinsic characteristic of the test substance, because it is a direct result of the physical blockage caused by the biologically inert substance. There must be a point, however, at which an investigator can conclude that a test substance is practically nontoxic or nonlethal after an acute exposure. The traditional test limit for acute oral toxicity was considered to be 5.0 g/kg body weight. If no mortality was observed at this dose level, a higher dose level generally was not necessary. The more recently accepted protocols for acute toxicity (277–279) have a test limit of 2.0g/kg-body weight.

Testing methods and procedures. The purpose of this section is to describe practical experimentation in detail, but it is not the authors' intention to list all technical procedures. A manual is available that describes technical procedures such as handling and dosing animals (286). Since the Good Laboratory Practices Act has been implemented in both the United States and most OECD countries, all experimental procedures should be documented and the studies conducted by trained personnel. For more details on GLP guidelines, the reader may consult several EPA, OECD, and Japanese publications (120, 121, 281, 337). The Japanese guidelines contain some unique requirements that are not duplicated by other countries.

Grouping, randomization, and preparation of animals. Animals not previously treated with test substances in other studies should be identified individually by coded marks, metal ear tags, or tattoos. The animals then should be quarantined for at least a week prior to dosing to acclimatize them to the conditions of the animal room. The animals should be fasted prior to administration of the test substance if the route of administration is oral. The purpose of fasting the animal is to eliminate feed in the gastrointestinal tract, which may complicate absorption of the test substance. Rats usually are fasted overnight. Because mice have a higher metabolic rate, withholding feed for 3–4 h may be adequate. Over-fasting small animals with a high metabolic rate may induce undesirable effects.

The animals should be randomly assigned to dose groups. Randomization, needed not only in acute toxicity studies but also in subchronic and chronic studies, ensures a homogeneous population and can minimize errors due to sampling bias. All animals with body weights and health conditions out of the normal range should be eliminated prior to the randomization procedure. With computer-generated random digit numbers or with tables of random digit numbers such as the one below, animals can be

randomly assigned to groups by cage number or by individually assigned animal number.

Random numbers

	00–04	05–09	10–14	15–19	20–24
00	01826	72696	67261	13748	57834
01	70371	12890	90395	45245	71282
02	46616	84522	17249	78172	14197
	25–29	30–34	35–39	40–44	45–49
00	27748	47492	43428	85524	19311
01	15960	02749	86763	80564	02631
02	84272	53226	96719	83462	05628

For example, by using a random number table, 30 rats from a total of 60 rats are assigned to 3 dose groups of 10 rats each. Assume that 12 rats will be excluded from the study because of overweight, underweight, or other health problems; this leaves 48 rats, from which 30 would be chosen. One method of randomization is to arbitrarily number the 48 rats from 1 to 48. The random number table gives the following series of random numbers (row 00): 01826, 72696, 67261, 13748, 57834, 27748, 47492, and 43428. Because there are only 48 rats, the numbers should be two-digit numbers. The first group of rats would be rat numbers 01, *82, 67,* 26, *96, 67, 26,* 11, 37, *48, 57, 83,* 42, *77, 48,* 47, *49,* 24, 34, and 28. The italicized numbers should be discarded because they are either repeated numbers or greater than 48. The second group of rats would be chosen similarly. The same procedure is repeated until 30 rats have been assigned to the 3 dose groups.

When the number of animals to be grouped is small, a large number of random numbers may be required to complete the grouping. Another way to use the random number table under such circumstances is by cycling. For example, 6 rabbits are assigned to 2 groups of 3 rabbits each from a total of 10 rabbits. From the second row of the same random digit number table, the first 3 two-digit numbers are 70, 73, and 11. Dividing these numbers by the total number of rabbits (i.e., 10), the remainders of these three numbers are 0, 3, and 1. If the remainder is zero, the denominator (in this case 10) will remain. Therefore, the 3 rabbits in the first group would be rabbit numbers 10, 3, and 1. Again, if the remainder numbers are repeated, they would be discarded. Also, if the number is smaller than the total number of animals, the number would be used and no division is needed. For the second group, the next series of numbers from the table are 28, 90, 90, 39, 54, 52, 45, 71, 28, 21, 59, 60, 02, 74, 98, and 67, and the corresponding numbers are 8, 0, 0, 9, 4, 2, 5, 1, 8, 1, 9, 10, 2, 4, 8, and 7. Therefore, the 3 rabbits in the second dose group would be rabbit numbers 8, 9, and 4. If a third group is needed, the 3 rabbits in this group would be rabbit numbers 2, 5, and 7. In general, the following rules apply when using the cycling method:

1. When the number from the random number table is less than the total number of animals to be chosen from, no division is needed.
2. When the number is greater than the total number of animals, the random number is divided by the total number of animals, and the remainder is used.
3. When the remainder is zero, the denominator is used.
4. No numbers or remainders should be allowed to repeat: any repeated numbers should be discarded.

The entry (the starting point) in the random number table should *not* be consistent. Thus, the entry should be made at a different point each time the random number table is used (one can start along the rows or the columns).

Calculation and Preparation of Doses

Doses in general are based on the body weight of the animal (expressed as weight of the test substance per kilogram of body weight of the animal), although for larger animals, the surface area may be more appropriate. The weight (or dose) of the test substance often is expressed in milligrams or grams of active ingredient if the test substance is not 100% pure. Ideally, only 100% pure sample should be tested; however, impurity-free samples are difficult to obtain. Although some toxicologists strongly advocate the use of pure samples in toxicity testing, others see the appropriateness of using technical samples, formulations, or crude products. It is acceptable to study the test substance in its pure form or in its technical or product form; however, the toxicity of impurities should be examined separately if the investigator feels that the impurities may contribute significantly to the toxicity of the test substance.

Selection of doses often is based on a pilot study, on existing toxicity data in other species, or on data obtained with a similar analog of the test substance. In an example based on the traditional LD50 determination, if 0 of 3 and 3 of 3 rats died at dose levels of 500 and 1000 mg/kg, respectively, in the pilot study, the expected LD50 numeric value would be between these two dose levels. If the investigator decides to select five doses that will bracket the expected LD50, the logical approach would

be to set the LD50 at 750 mg/kg for the definitive study with the following dose levels: 520, 625, 750, 900, and 1080 mg/kg. The dose levels progress by a value of the antilog 0.08 (i.e., multiplied or divided by 1.2 of the assumed LD50). Although more modern methods

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_863.html[2010/10/28 18:48:40]

may require fewer dose levels, the following procedure for calculation and preparation of doses is similar.

If the test substance contains only 75% active ingredient and the investigator chooses a constant dose volume of 10 ml/kg body weight across all dose levels, it will be more convenient to prepare a stock solution so that when 10 ml/kg of this stock solution is given to the animal, the dose will be 1080 mg/kg (active ingredient). The concentration of this stock solution would be

$(1080 \text{ mg}/10 \text{ ml}) \div 0.75 = 144$ mg of test substance/ml.

Aliquots of the test substance for other dose levels can be prepared by dilution of the stock solution. For example, the solution concentration for the 900 mg/kg dose is

$(900 \text{ mg}/10 \text{ ml}) \div 0.75 = 120$ mg of test substance/ml.

This solution can be prepared by diluting the stock solution 1.2 times, that is, for each ml of the 120 mg/ml solution to be prepared,

$$\frac{120 \text{ mg/ml} \times 1 \text{ ml}}{144 \text{ mg/ml}} = 0.833 \text{ ml of the stock solution should be diluted to a final volume of 1 ml with the vehicle.}$$

The vehicle should be one with limited or no toxicity. In preparing dosage solutions or suspensions, the vehicle of choice is water; other choices include an aqueous suspending vehicle such as 0.5% (w/v) methyl cellulose (Methocel) in water; corn oil; or other solvents such as aqueous ethanol, propylene glycol, or diluted DMSO in 5.0% $NaHCO_3$ solution. Magnetic stirring bars, micromills, or homogenizers can be used in preparing suspensions. Sometimes a small amount of a surfactant such as Tween 80, Span 20, or Span 60 is helpful in obtaining a homogeneous suspension. If surfactants are used, one must be aware of the potential effect of these surfactants on the absorption of the test substance.

On many occasions, it is desirable to prepare the dosage in an aqueous medium because of the undesirable effect of corn oil or other vehicles on the animals. In this case, one may try to prepare the dosage in a simple, watersuspensible, uniform formulation even though the test material is not soluble or cannot be suspended in aqueous medium. For example, a formulation can be prepared by dissolving a specific amount of the test material in an adequate amount of acetone, followed by mixing the acetone solution with a known amount of small particle size and biologically inert dispensing agent such as HiSil, and evaporating to dryness under a hood. In the resulting formulation, the test material is uniformly coated on the small particles. Then, a dosage in a uniform suspension can be prepared from the formulated test substance. This procedure has been used successfully in many studies.

Administration of the Dose

The test substance can be administered as a solution or suspension as long as it is homogeneous. The solution or suspension is gavaged to the animal with a suitable stomach tube or feeding needle attached to a syringe. For most acute oral toxicity studies with a test limit of 2.0 g/kg, the dose can be administered with one treatment. If unusual circumstances require a total dose that is too large to be administered at a single time, it should be divided into equal doses with 3 or 4 h between each administration. Feed should be withheld until the last dose, which should be within 24 h of the first dose.

Observations

Clinical examination, observation, and mortality checks should be made shortly after dosing, at frequent intervals over the next 4 h, and at least once daily thereafter. The intervals and frequency of observation should be flexible enough to determine the onset of signs, onset of recovery, and the time to death. The mortality checks should be frequent enough to minimize unnecessary loss of animals due to autolysis or cannibalism. The cage side observation should include any changes in the skin, fur, eyes, mucous membranes, circulatory system, autonomic and central nervous systems, somatomotor activities, behavior, and so on. Any pharmacotoxic signs such as tremor, convulsions, salivation, diarrhea, lethargy, sleepiness, morbidity, fasciculation, mydriasis, miosis, droppings, discharges, or hypotonia should be recorded. The most common pharmacotoxic signs are listed in Tables 18.1–18.3.

Individual body weights should be determined just prior to dosing, once weekly, and at death or at termination. The body weights of animals found dead generally are not as useful as the body weights of live animals. Necropsies should be performed on animals that are moribund, found dead, and killed at the conclusion of the study. All changes in the size, color, or texture of any organ should be recorded. Any gross change observed at necropsy should be described according to the size, color, and position of the lesion. Definitive pathological diagnostic terms should be avoided. Even though a complete

microscopic examination of tissues and organs is ideal and would be helpful in defining acute toxicity, economic and time factors may preclude such a study. If the investigator feels that microscopic examination of a lesion is essential, tissues from the lesion should be preserved in an appropriate fixative such as 10% buffered formalin.

Table 18.1 Common signs and observations in acute toxicity tests

Clinical observation	Observed signs	Organs, tissues, or systems most likely to be involved
I. Respiratory blockage in the nostril, changes in rate and depth of breathing, changes in color of body surface	A. Dyspnea: difficult or labored breathing, essentially gasping for air, respiration rate usually slow	
	1. Abdominal breathing: breathing by diaphragm, greater deflection of abdomen upon inspiration	CNS respiratory center, paralysis of costal muscles, cholinergic
	2. Gasping: deep labored inspiration, accompanied by a wheezing sound	CNS respiratory center, pulmonary edema, secretion accumulation in airways, increased cholinergic
	B. Apnea: a transient cessation of breathing following a forced respiration	CNS respiratory center, pulmonary-cardiac insufficiency
	C. Cyanosis: bluish appearance of tail, mouth, foot pads	Pulmonary-cardiac insufficiency, pulmonary edema
	D. Tachypnea: quick and usually shallow respiration	Stimulation of respiratory center, pulmonarycardiac insufficiency
	E. Nostril discharges: red or colorless	Pulmonary edema, hemorrhage
II. Motor activities: changes in frequency and nature of movements	A. Decrease or increase in spontaneous motor activities, curiosity, preening, or locomotions	Somatomotor, CNS
	B. Somnolence: animal appears drowsy, but can be aroused by prodding and resumes normal activities	CNS sleep center
	C. Loss of righting reflex, loss of reflex to maintain normal upright posture when placed on the back	CNS, sensory, neuromuscular
	D. Anesthesia: loss of righting reflex and pain response (animal will not respond to tail and toe pinch)	CNS, sensory
	E. Catalepsy: animal tends to remain in any position in which it is placed	CNS, sensory, neuromuscular, autonomic
	F. Ataxia: Inability to control and coordinate movement while animal is walking with no spasticity, epraxia, paresis, or rigidity	CNS, sensory, autonomic
	G. Unusual locomotion: Spastic, toe walking, pedaling, hopping, and low body posture	CNS, sensory, neuromuscular
	H. Prostration: immobile and rests on belly	CNS, sensory, neuromuscular
	I. Tremors: involving trembling and quivering of the limbs or entire body	Neuromuscular, CNS
	J. Fasciculation: involving movements of muscles, seen on the back, shoulders, hind limbs, and digits of the paws	Neuromuscular, CNS, autonomic
III. Convulsion (seizure): marked involuntary contraction or seizures of contraction of	A. Clonic convulsion: convulsive alternating contraction and relaxation of muscles	CNS, respiratory failure, neuromuscular, autonomic

voluntary muscle	B. Tonic convulsion: persistent contraction of muscles, attended by rigid extension of hind limbs	CNS, respiratory failure, neuromuscular, autonomic
	C. Tonic-clonic convulsion: both types may appear consecutively	CNS, respiratory failure, neuromuscular, autonomic
	D. Asphyxial convulsion: usually of clonic type but accompanied by gasping and cyanosis	CNS, respiratory failure, neuromuscular, autonomic
	E. Opisthotonos: tetanic spasm in which the back is arched and the head is pulled toward the dorsal position	CNS, respiratory failure, neuromuscular, autonomic

Clinical observation		Observed signs	Organs, tissues, or systems most likely to be involved
IV.	Reflexes	A. Corneal eyelid closure: touching of the cornea causes eyelids to close	Sensory, neuromuscular
		B. Primal: twitch of external ear elicited by light stroking of inside surface of ear	Sensory, neuromuscular
		C. Righting: ability of animal to recover when placed dorsal side down	CNS, sensory, neuromuscular
		D. Myotact: ability of animal to retract its hind limb when limb is pulled down over the edge of a surface	Sensory, neuromuscular
		E. Light (pupillary): constriction of pupil in presence of light	Sensory, neuromuscular, autonomic
		F. Startle reflex: response to external stimuli such as touch, noise	Sensory, neuromuscular
V.	Ocular signs	A. Lacrimation: excessive tearing, clear or colored	Autonomic
		B. Miosis: constriction of pupil regardless of the presence or absence of light	Autonomic
		C. Mydriasis: dilation of pupils regardless of the presence or absence of light	Autonomic
		D. Exophthalmos: abnormal protrusion of eye in orbit	Autonomic
		E. Ptosis: dropping of upper eyelids, not reversed by prodding animal	Autonomic
		F. Chromodacryorrhea: red lacrimation	Autonomic, hemorrhage, infection
		G. Relaxation of nictitating membrane	Autonomic
		H. Corneal opacity, iritis, conjunctivitis	Irritation of the eye
VI.	Cardiovascular signs	A. Bradycardia: decreased heart rate	Autonomic, pulmonary-cardiac insufficiency
		B. Tachycardia: increased heart rate	Autonomic, pulmonary-cardiac insufficiency
		C. Vasodilation: redness of skin, tail, tongue, ear, foot pad, conjunctivae, sac, and warm body	Autonomic, CNS, increased cardiac output, hot environment
		D. Vasoconstriction: blanching or whitening of skin, cold body	Autonomic, CNS, decreased cardiac output, cold environment
		E. Arrhythmia: abnormal cardiac rhythm	CNS, autonomic, pulmonary-cardiac insufficiency, myocardiac infraction
VII.	Salivation	A. Excessive secretion of saliva: hair around mouth becomes wet	Autonomic
VIII.	Piloerection	A. Contraction of erectile tissue of hair follicles resulting in rough hair	Autonomic
IX.	Analgesia	A. Decrease in reaction to induce pain (e.g., hot plate)	Sensory, CNS
X.	Muscle tone	A. Hypotonia: generalized decrease in muscle tone	Autonomic
		B. Hypertonia: generalized increase in muscle tension	Autonomic
XI.	Gastrointestinal signs: Droppings (feces)	A. Solid, dried, and scant	Autonomic, constipation, GI motility
		B. Loss of fluid, watery stool	Autonomic, diarrhea, GI motility
	Emesis	A. Vomiting and retching	Sensory, CNS, autonomic (in rat, emesis absent)
	Diuresis	A. Red urine	Damage in kidney
		B. Involuntary urination	Autonomic sensory

XII. Skin	A. Edema: swelling of tissue filled with fluid	Irritation, renal failure, tissue damage, long-term immobility
	B. Erythema: redness of skin	Irritation, inflammation, sensitization

Table 18.2 Autonomic signs

Sympathomimetic	Piloerection
	Partial mydriasis
Sympathetic block	Ptosis
	Diagnostic if associated with sedation
Parasympathomimetic	Salivation (examined by holding blotting paper)
	Miosis
	Diarrhea
	Chromodacryorrhea in rats
Parasympathomimetic block	Mydriasis (maximal)
	Excessive dryness of mouth (detect with blotting paper)

Table 18.3 Toxic signs of acetylcholinesterase inhibition

Muscarinic effects[a]	Nicotinic effects[b]	CNS effects[c]
Bronchoconstriction	Muscular twitching	Giddiness
Increased bronchoconstriction		Anxiety
	Fasciculation	Insomnia
Nausea and vomiting (absent in rats)	Cramping	Nightmares
	Muscular weakness	Headache
Diarrhea		Apathy
Bradycardia		Depression
Hypotension		Drowsiness
Miosis		Confusion
Urinary incontinence		Ataxia
		Coma
		Depressed reflex
		Seizure
		Respiratory depression

a Blocked by atropine.
b Not blocked by atropine.
c Atropine might block early signs.

Other Nonroutine Determinations

The cause of death in acute poisoning generally involves the nervous, cardiovascular, or respiratory systems. Effects on other organs such as the liver or kidney sometimes are masked by lethality or cannot be detected without special determinations. Clinical laboratory studies (hematology, clinical chemistry, or specific functional tests) may be needed to identify these adverse effects. Because these laboratory tests are costly, they are only justifiable when there is evidence indicating that a particular laboratory test would be helpful in identifying the target organ or mechanism of toxic action. For example, if the test substance has a chemical structure that belongs to a class of hepatotoxins, clinical chemistry measurements may be conducted to verify its hepatotoxicity.

Histopathology can be very valuable in identifying a target organ. Like clinical laboratory tests, histopathological examination of organs is expensive. However, the cost should not be the limiting factor in deciding whether histopathological examination is needed; rather the limiting factor should be whether there is evidence that a particular organ is involved.

Data Processing

All signs of toxicity, onset of signs, time to recovery, time to death, mortality, and necropsy findings can be summarized in tabular form. If a defined LD50 is required, it may be determined by an acceptable method (226, 353, 373). Although most laboratories are equipped with calculators or computer programs to facilitate the estimation of LD50 values, fiducial limits, and the slopes of the dose-response curve, the reader is advised to review the manual estimation procedure for two widely adopted methods, the probit analysis and the moving average method. The graphic procedure of the probit analysis is rapid and is sufficient for most purposes. But for a more precise estimate of the LD50, mathematical calculation may be necessary, and the reader is referred to the maximum likelihood estimation described in Finney's text (138).

*Graphic estimation of LD*50 *by probit analysis.* The basic linear equation for the probit analysis as described in the previous section is

$$y = 5 + \frac{1}{\sigma}(x - u)$$

where y is the probit, (σ is the standard deviation of a log normal distribution with mean u, and x is the log dose. This equation is linear with respect to y and x often can be expressed as a linear equation, for example, $y=\alpha+\beta x$, where $\beta=1/\sigma=$ slope, and $\alpha=5-(u/\sigma)$. When $y=5$, $(x-u)/\sigma=0$; thus $x=\mu$ (the median log dose). Further, y is related to P (the probability of response which has a value of 0 to 1 by the following equation:

$$P = \frac{1}{\sqrt{2\pi}} \int_{-x}^{y} \exp\left(\frac{-y}{2}\right) dy$$

The reader should bear in mind that both the u and x are in log dose scale.

The following steps should be taken for graphic estimation of LD50 by probit analysis.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_867.html[2010/10/28 18:48:42]

1. Convert response probabilities to probit units by a probit transformation table (96, pp. 54–55).
2. Convert all doses into log dose units (e.g., log10 dose=*x*). (Steps 1 and 2 may be eliminated if probit-log graphic paper is available.)
3. Using the probit as the abscissa and log10 dose as the ordinate, plot the response probit units against the log10 dose.
4. Draw a straight line such that the vertical deviations of points (the probits) at each *x* value are as small as possible. Extreme probits, for example, those outside the range of probit 7 and 1, carry little weight in the fitting of the probit-log dose-response line and thus should be excluded.
5. From the regression of the probit-log dose line, extrapolate the log dose corresponding to probit units of 5, which also correspond to the P=0.5. Thus, this extrapolated dose should be the median lethal *log dose,* and the LD50 value would be the *antilog* of this log dose value.
6. Calculate the slope of the probit-log dose line. This slope, $\beta=1/\sigma$, is defined as the number of increases in probit units for a unit increase in log dose. The slope defined by Litchfield and Wilcoxon (226) is equal to

$$\frac{1}{2}\left(\frac{LD_{84}}{LD_{50}}+\frac{LD_{50}}{LD_{16}}\right)=\sigma$$

This slope is different but related to the slope described here, thus, the larger the slope value, the steeper the probit-log dose response. The opposite is true in the Litchfield and Wilcoxon definition.
7. A *x*2 test should be conducted to determine if the fitted line is adequate. A small value of *x*2 statistic (within the limits of random variation) may indicate satisfactory agreement between the theoretically expected line and the fitted line. A significantly large *x*2 statistic may indicate either that the animals do not respond independently or that the fitted line (probit-log dose) does not adequately describe the dose-response relationship of the test substance. If the latter is true, forms of the dose-response curve other than the probit-log dose linearity may exist, and further transformation may be needed (138). If the former is the case, then precision of the line is reduced.
8. Determination of precision is by weighting the coefficient. The standard deviation of a binomial distribution is, $\sqrt{PQ/n}$, where *P* and *Q* are the mean probabilities, *P* equals (1–0, and *n* is the number of test subjects. Thus, the variance is *PQ/n,* the square of the standard deviation. It is obvious that the variance (i.e., the spread of a distribution) is inversely related to *n*. This relationship means that the larger the number of test subjects, the smaller the variance and the better the precision. The reciprocal of the variance is invariance, which measures the weight, *nW*. Here, *W* (weighting coefficient)=*Z2/PQ,* where $Z=(1/\sqrt{2\pi})$ exp(−*y*2/2) dand is related to the normal frequency function corresponding to the NED. A table of weighting coefficients (see 96, p. 53) corresponding to probits *(y)* is available (139). The standard error for the log LD50 is given by

$$\sigma/\sqrt{\Sigma nW}$$

if the estimated log LD50 does not greatly differ from the true mean log LD50, because this estimation does not take into consideration the error in the estimation of σ for the probit-log dose-response line. A better equation for the estimation of the variance of the estimated log LD50 is given by

$$V(m)=\sigma^2\left(\frac{1}{\Sigma nW}+\frac{(m-\bar{x})^2}{\Sigma nW(x-\bar{x})^2}\right)$$

where *V(m)* is the variance of LD50, $\bar{x}$ is the weighted mean log dose, *m* is the median log dose, *x* is the log dose, and $1/\sigma=1/1\Sigma nW\ (x-\bar{x})$. If the χ2 is large, indicating that the test subjects do not respond inde- pendently to the dose, the estimation of variance of log LD50 may not apply, and adjustment due to the sampling variation of the slope (1/σ) of the probit-log dose line may have to be made (138). For a quick estimation of the LD50 this adjustment may be dropped, and the standard error would be the square root of the variance, i.e., $\sqrt{V(m)}$. One must remember that the dose is expressed in log dose; therefore, the estimation of the standard error (SE) for the LD50 in the original dose unit (e.g., mg/kg) is impossible. However, an approximation is given:

$$SE(LD_{50})=(10^m)\cdot([\log_e(10)\cdot(S_m)]$$

where *Sm* (which equals $\sigma/\sqrt{\Sigma nW}$ or $\sqrt{V(m)}$) is the estimated standard error for the median log dose

m (i.e., m=log LD50 or 10^m=LD50).
A more rapid approximation of the standard error of log LD50 was given by Litchfield and Wilcoxon (226) as

$$S_m = \frac{S}{N'/2}$$

where S is the difference between two log doses of expected effects (as indicated by the probiting dose

line) that differ by one unit of probit and *N′* is the total number of animals between the log dose limits, corresponding to the expected probit 4.0–6.0 (i.e., the 16% and 80% responses).

9. *Fiducial limits.* The concept of fiducial limit is similar to the confidence limit. The value of the two may be the same, but they are not always identical. The fiducial probability *F*(e.g., *95%*) can be defined as the situation when the true value of a parameter lies between the calculated upper and lower limits, which would not be contradicted by a significance test at the 1/2(1–*F*) probability level. These higher and lower limits are called the fiducial limits. For rapid analysis, the fiducial limits at the *F*=95% level can be estimated by log LD50±1.96 *(Sm)*. A more detailed estimation can be obtained by the maximum likelihood estimation (138).

Another simple approximation of the fiducial limits is given by Litchfield and Wilcoxon (226) as LD50/*f*LD50 or LD50×*f*LD50 for the lower and upper limit, respectively, where LD50 is defined as the LD50 factor equal to *(s)* $^{(2.77/\sqrt{N'})}$. Here *s* is the slope, which is defined as

$$\frac{1}{2}\left(\frac{\mathrm{LD}_{54}}{\mathrm{LD}_{50}}+\frac{\mathrm{LD}_{50}}{\mathrm{LD}_{16}}\right)=\frac{1}{2}(3.55+3.55)=3.55$$

in this example, and *N′* is the total number of animals used between response probabilities 16% and 84% (i.e. probit 4 and *6,* equal to 30 in this example). Then *f*LD50 equals 1.896. Therefore, the lower fiducial limit is equal to 8.91/1.896=4.70, and the upper fiducial limit is equal to 8.96×1.896=16.90.

For all practical purposes, the graphic method should be sufficient to estimate the LD50. Nonetheless, because computer programs are available to handle the mathematics, the more detailed maximum likelihood estimation (98, 138) is used in many laboratories. Indeed the up-and-down procedure (52–54, 279) (See Alternative Methods for Oral LD50 Test), which is one of the more modern methods of estimating the LD50, is based on the maximum likelihood method. Calculations can be performed using either SAS (316) or BMDP (99) computer program packages which are available to many toxicology laboratories. Other examples of programming for the estimation of the LD50 with a small computer have been reported (223, 311).

Acute Dermal Toxicity

Dermal exposure is an important route of exposure. The objective of conducting an acute dermal toxicity study is the same as an acute oral toxicity study. Such testing may provide information on the adverse effects resulting from a dermal application of a single dose of a test substance. The acute dermal test also provides the initial toxicity data for regulatory purposes, labeling, classification, transportation, and subsequent subchronic and chronic dermal toxicity studies. Comparison of acute toxicity by the oral and dermal routes may provide evidence of the relative penetration of a test material.

Although the general experimental design and principles of acute dermal toxicity testing are similar to those of acute oral testing, there are differences. These differences include selection of the animal species, number of animals per dose level, preparation of animals, dosage, and administration of the test substance. Only differences in the acute dermal test are described in this section.

Animals

The same concern about animal factors raised in connection with acute oral toxicity testing, such as species, age, health conditions, body weight, sex, and housing environment, can affect the outcome of an acute dermal test. The three most commonly used animal species are young, healthy adult rabbits (2–3 kg), rats (200–300 g), and guinea pigs (350–450 g). Other species can be used. The animals should be housed individually in a controlled environment. Quarantine, acclimatization, and randomization are as described for acute oral studies. The back of the animal or a band around the trunk should be clipped free of hair. When clipping the hair, care must be taken not to abrade the skin. If abraded skin is called for, a needle may be used, but care must be taken not to damage the dermis. Increasingly, investigators have come to question the value of conducting tests on abraded skin, and many consider such tests to be irrelevant. To date, almost all testing guidelines call for conducting the dermal test only on intact skin (109, 124, 125, 275, 337). Fasting the animals overnight is not necessary for the dermal test. Generally, five animals per dose level per sex is sufficient to allow for an acceptable estimation of the dermal LD50. Smaller numbers of animals can be used.

Doses

Dose selection is similar to the acute oral test. Higher doses do not need to be tested when a test substance at 2000 mg/kg has not produced test substance-related mortality.

While a control group generally is not needed, a vehicle control group should be included in the study if the toxicity of the vehicle is not known. Its influence on dermal penetration of the test substance should

be fully established prior to the study.

Preparation of Dosage and Dosing Procedure

The test substance should be applied uniformly to approximately 10% of the body surface of the animal (e.g., 4 cm×5 cm for rats, 12 cm×14 cm for rabbits, 7 cm×10 cm for guinea pigs). This area may vary. For example, the area of application for highly toxic substances may be small because a smaller volume is applied. Liquid test substances generally are applied undiluted. If the test substance is a solid, it should be pulverized, weighed, placed on a plastic sheet or porous gauze dressing, moistened to a paste with normal saline (one part test substance for one part saline) or with the appropriate solvent, and spread evenly on the closely clipped skin to ensure uniform contact with the skin. Grinding of the solid test substances may not be needed under some conditions. For example, when a granular formulation is tested, it may be more relevant to test the substance in its formulation state than to destroy the formulation by grinding.

Because rabbits are the most widely used animal for acute dermal testing, the dosing procedure for the rabbit is detailed, especially for liquid substances. Dermal application of the test substance ranges from occlusive to semiocclusive to unocclusive.

The choice of the application method depends on what the most likely exposure pattern is in humans. Skin irritation is usually the worst after occlusive exposure, followed by semiocclusive and unocclusive exposure. Skin irritation may not only cause stress to the animal but also may increase dermal penetration. For unocclusive application, the application site remains uncovered but the volume of liquid test substance that can be applied to the skin may be limited depending on the volatility of the liquid. Immobilizing the animal or using a device such as a collar is needed to prevent ingestion through licking the application site. For occlusive or semiocclusive application, the application site is covered with an impervious material such as a plastic sheet, or with a porous gauze dressing as described in the following paragraph. The volume that can be applied with the occlusive or semiocclusive patch generally is larger than that of the unocclusive method.

Dosing procedures for liquid test substances. Rabbits are clipped free of hair with an electric animal hair clipper. The rabbit may have to be restrained by tightening the hind legs to a secured post and holding the nape of the neck during clipping. The area of skin to be clipped should be based on the need of the experiment and generally involves the entire band around the trunk between the flank and the shoulders if the dose exceeds 5.0 mg/kg. If abraded skin is to be tested (generally not required), abrasions to the stratum corneum may be made with a hypodermic needle (201/2 G) 2–3 cm apart longitudinally over the appli cation site. A plastic cuff in a cylindrical shape (approximately 12–15 in. long and 10 in. in diameter) open at both ends can be used. The cuff is put on the trunk of the rabbits, covering the application site. With the help of another investigator, the plastic cuff is folded around the trunk and secured at the thorax and flank of the rabbit with surgical adhesive tape. Care should be exercised so that the cuff is sufficiently secured but not too tight to affect breathing. Using a long feeding needle, the correct amount of the liquid test substance is drawn into a syringe of appropriate size. The needle then is placed under the cuff and half of the dose is delivered evenly on each side of the vertebral column. After withdrawal of the needle, the test substance is evenly distributed over the application site by gently rubbing the top of the plastic cuff. A piece of cloth of appropriate size is then wrapped around the plastic cuff and taped in place to absorb any test substance that may spill off the cuff. After dosing, the investigator should observe the animal for a moment to see if breathing is affected, prior to putting the animal back into the cage. In the semiocclusive method, a porous gauze dressing replaces the plastic cuff. In unocclusive exposure, the test substance is applied uniformly over the skin: care must be taken to minimize run off from the skin, especially for aqueous dosing solutions. Applying the test substance in small amounts at a time may help.

Dosing procedure for solid test substances. If the test substance is a solid, it should be ground with a mortar and pestle unless there is justification not to pulverize it. The correct dose of the ground solid is weighed, placed in the center of a plastic sheet of appropriate size, and moistened with sufficient normal saline or another appropriate vehicle. If a vehicle other than saline or water is used, the effect of the vehicle on the skin penetration of the test substance should be considered, and its toxicity should be known. The type of vehicle selected should be based on the expected mode of exposure of the test substance and should be mixed into a paste. The paste then is spread evenly around the center of the plastic sheet. With one person holding the rabbit by grasping it at the back, another person moistens its belly and its back with paper towels soaked with saline. Then the rabbit is placed with its belly on the test substance paste on the plastic sheet, and another investigator wraps the sheet around the trunk of the rabbit. The plastic cuff is secured in place with surgical tape at the thorax and the flank. A piece of cloth of appropriate size then is wrapped around the plastic cuff and secured in place in the same

manner. In the semiocclusive method, a porous gauze dressing replaces the plastic sheet.

Dosing procedures for rats and guinea pigs. Similar dosing procedures can be applied to rats and guinea pigs. Liquid samples should be placed on the back instead of the belly or on the lateral trunk. If unocclusive

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_870.html[2010/10/28 18:48:44]

exposure is called for in rats, the test substance should be applied to the skin as near to the head as possible to prevent ingestion by preening of the application site. A plastic collar may be used to further limit access to the treatment site. Generally, the plastic collar produces more stress in the rat, as indicated by chromodacryorrhea (red stain around the eye), than in the rabbit. To minimize stress in rats, small collars can be handmade from light cardboard. The collar is lined with cut rubber tubing around the neck area and stapled in place. The cardboard collar is lighter and easier to place on small animals. It can readily be replaced if needed (the collar placed on the neck usually will last about three days), and it is more economical than the commercially available plastic collars.

Exposure Period and Removal of Cuff

Almost all testing guidelines (109, 124, 125, 275, 337) call for 24-h continous exposure. After the 24-h exposure, the cuff is removed and the application site is gently wiped with a paper towel soaked with saline, water, or any appropriate solvent to remove residual test substance remaining on the application site.

Observation Period

As in the acute oral toxicity test, the observation period and intervals should be flexible enough to establish onset of signs, time to death, and time to recovery, but should be frequent enough such that the loss of animals due to autolysis and cannibalizing is minimal. In addition, skin irritation should be assessed according to a scoring system such as the one described by Draize et al. (102).

Data Processing

Data should be analyzed and handled as in the acute oral toxicity test. Because the exposure period in a dermal toxicity study is longer than in a skin irritancy test, the skin irritation resulting from the 24-h exposure may not be relevant for assessing the skin irritancy potential of the test substance but may be considered as the worst case if the occlusive or semiocclusive method is used.

Test Limit

If no test substance-related mortality is observed at 2000 mg/kg, testing at higher doses may not be necessary because additional test substance may only be applied on top of the test substance layer already present. This layering may form a physical barrier to prevent further absorption of the test substance from the application site.

ALTERNATIVE METHODS FOR ORAL LD50TEST

Animal testing has been widely debated. Many regard the issue as no more than animal protectionism and solely

Table 18.4 Summary of current recommendations on acute oral toxicity testing

Provisions	EEC and OECD	U.S. EPA	U.S. CPSC	U.S. FDA	U.S. DOT
Use of LD50	Discourages	Same as OECD	Strongly discourages	Does not require	Same as OECD
Limit test (2g/kg Dose)	Recommends	Same as OECD*a*	Same as OECD	Refers to	Recommends

NS, not specified.

a Under current policy and regulations for pesticide products, precautionary statements may still be required unless there are data to indicate the LD50 is greater than 5g/kg.

based on humanitarian reasons. Aside from valid scientific concerns on the usefulness of classic LD50 values (e.g., uncertainty in species extrapolation, seldom needed for potent drug standardization), there are broader issues on animal testing, some political in nature and others economically based. The cost of animal testing has been increasing at a skyrocketing rate over the last decades, and even without animal rights activism, the scientific community will need less costly alternatives to cope with the increasing demand for safety evaluation of a vast number of existing and new chemicals.

The approach to animal testing today is being altered by the so called Three Rs: reduction, refinement, and replacement. Reduction of the number of animals used in testing and refinement of existing testing methods to minimize pain and suffering of animals represent the short-term objective. Replacement of animal testing with non-animal-based methods, e.g., in vitro ("in glass," i.e., test tube) methods, is the ultimate goal. However, genuine, validated, and regulatory accepted nonanimal alternative methods to replace whole animal acute toxicity testing are still more of a goal than a reality, even though the concept has been widely accepted by scientists from industry, professional societies, and certain regulatory bodies (10, 240, 338, 339).

As far as the oral LD50 test is concerned, a number of these classical, precise tests, using large number of animals, have been conducted for the purpose of labeling and classification of chemicals. Recently, there have been many positive developments in the reduction and refinement of acute oral toxicity tests. For example, the limit test (151), the British Society of Toxicology method (49), the up-and-down method (52–54), the fixed dose procedure (359), and the acute toxic class method (309), can achieve reduction in the number of animals. These methods, in general, have been endorsed by the scientific and regulatory communities and animal advocates alike (10, 240, 338, 339), and some have been adopted as regulatory guidelines for the testing of chemicals (277–279). However, the classification and labeling schemes of many regulatory bodies around the world still use the LD50 value, and it may be some time before the classical, more precise test, using large numbers of animals, is eliminated. Perhaps it is time for regulatory bodies to redefine the scheme for classification and labeling of chemicals on the basis of reduced and refined acute toxicity testing results. An international study using the fixed dose procedure has shown that this is possible (359).

Modified LD50Tests

The aim of these tests is to obtain adequate information on toxic signs, approximate LD50 values, and, in some,

Table 18.5 Approximate lethal dose (ALD) versus conventional rat LD50 (g/kg)

	Conventional		Approximate	
Chemical	n	LD50	n	ALD
Tetraethyllead	36	20	5	26
Methomyl	53	40	5	26
Hexachlorophene	46	165	11	90
Adiponitrite	65	301	7	300
Caffeine	40	483	8	450
N-Butylhexamethylene amine	35	536	7	1000
Hexamethylene diamine	92	1127	5	1500
Bromobenzene	35	3591	8	3400
Carbon tetrachloride	105	10,054	5	7500

Adapted from Reference 208.

the slope of the dose-response. Many studies have shown that adequate acute toxicity and lethality information can be obtained by using fewer animals than in the classical LD50 studies. DePass (93) and Lipnick et al. (225) have reviewed several modified LD50 tests. Although the main endpoint remains lethality, these tests generally fulfill the goal of reducing the number and suffering of animals and in some cases provide adequate information for hazard classification and labeling. The key alternative tests are described below.

Approximate Lethal Dose Method

This method involves sequential dosing until the lowest lethal dose is obtained. Initially, an arbitrary dose is given to an animal. If the animal survives, a second animal is given 1.5 times the initial dose, and, sequentially, several animals are given increasing doses in the same manner until a lethal dose is achieved. This dose is the approximate lethal dose (ALD). In general, only 6–10 animals are required to achieve the ALD. Comparison of classical LD50 values and the ALD indicates that the ALD can be used to closely predict the LD50 (Table 18.5).

The Up-and-Down Method

Animals are dosed one at a time, starting at an estimated LD50 dose. If the first animal survives, the next one receives a higher dose. If the first animal dies, the next one receives a lower dose. The spacing of doses generally is adjusted by a factor of 1.3 up or down depending on the outcome of the previous animal. Comparison of classical LD50 values to the up-and-down-derived LD50 shows close agreement (Table 18.6). This test has been adopted by the OECD as an alternative to the more traditional methods of LD50 determination (279). The

OECD guideline also contains the provision for a limit test. The upper-limit dose is 2000 mg/kg (5000 mg/kg). If the first animal survives the upper-limit dose, then the second animal receives the same dose. If three animals survive the limit dose, then three animals of the other sex are tested at the limit dose. If all survive, the test is terminated.

The British Society of Toxicology (BST) Protocol

This protocol starts with three doses (5, 50, and 500 mg/kg) with five animals per sex per group, to minimize pain and suffering observed typically at the higher doses. The three initial doses generally will produce toxicity but no mortality. Depending on the response from the initial doses, subsequent doses can be increased or decreased by a factor of 10. Based on survival and toxic signs at a given dose, substances are placed into one of four categories. At least one study showed that classification of chemicals based on the BST protocol and the standard OECD protocol produced good agreement, but only use 74% of the animals and produce 87% less mortality than the OECD protocol (360).

The Fixed Dose Procedure

This modification of the BST protocol has been described by Van den Heuvel et al. (359). Basically, this procedure calls for testing at a dose selected from a series of pre-set doses (5, 50, 500, and 2000 mg/kg) for discriminating classification of the test substance into toxicity categories. The selected dose (discriminating dose) should be nonlethal, nonpainful, nonstressful, but toxicityevident. It could be selected by using available information, or by conducting a "sighting study" using three or four animals. The focus of the test should not be limited to mortality (found dead or killed for humane reasons), but should include other toxicity endpoints such as time course of signs of toxicity and necropsy findings. These data and the "discriminating dose" should provide adequate data for hazard assessment, comparative reference, and labeling classification (Table 18.7).

A multinational validation study in 33 laboratories with 20 materials using the fixed dose approach produced consistent results on the time course of signs of toxicity which was adequate for acute toxicity risk assessment and acute toxicity classification based on the European Economic Community (EEC) criteria. Fewer animals were used and less stress occurred (359). This test has been adopted by the OECD as an alternative acute oral toxicity method (277).

The Acute Toxic Class Method

This method has been described by Roll et al. (309) and is based on the assumption that using a minimum number of animals in a stepwise procedure will provide enough information on the acute toxicity of a substance to allow classification according to the most commonly used classification schemes. Three animals of one sex are used for each step; either sex can be used. The initial dose is selected from one of three fixed levels, 25, 200, or 2000 mg/kg body weight, and should be chosen to produce some mortality. If existing information suggests that mortality is unlikely at the 2000 mg/kg dose, then a limit test at that level may be conducted with three animals of each sex. If deaths occur, further testing at the lower dose levels may be necessary. This method was evaluated in national and international validation studies (319, 320), and has been adopted by the OECD as an alternative acute oral toxicity method (278).

Current Regulatory Status of Acute Oral Toxicity Testing

The current regulatory status of acute oral toxicity testing is in a state of flux. Although some form of acute toxicity information is required, most international regulatory agency guidelines are being revised to accept alternative methods based on the principles of reduction and refinement. A new regulatory philosophy is emerging which discourages the use of the classical LD50 test except when specifically

justified for reasons of scientific necessity. Indeed, the OECD has agreed to phase out its Guideline 401 —Acute Oral Toxicity, which requires an LD50 with 95% confidence interval, dose-mortality curve and slope, and to replace it with the more recently approved Acute Oral Toxicity Guidelines (277–279). Various regulatory agency recommendations on acute oral toxicity testing are compared in Table 18.4. For specific information on regulatory agency requirements,

Table 18.7 Investigation of acute oral toxicity using the fixed-dose method of interpretation of results

Fixed dose	Results	Interpretation
5 mg/kg[a]	Less than 100% survival[b]	Compounds that may be very toxic if swallowed
	100% survival but evident toxicity	Compounds that may be toxic if swallowed
	100% survival; no evident toxicity	Retested at 50 mg/kg if not already tested at that level
50 mg/kg	Less than 100% survival[b]	Compounds that may be toxic or very toxic if swallowed; retested at 5 mg/kg if not already tested at that level
	100% survival but evident toxicity	Compounds that may be harmful if swallowed
	100% survival; no evident toxicity	Retested at 500 mg/kg if not already tested at that level
500 mg/kg	Less than 100%, survival[b]	Compounds that may be toxic or harmful if swallowed; retested at 50 mg/kg if not already tested at that level
	100% survival but evident toxicity	Compounds that do not present a significant acute toxic risk if swallowed
	100% survival; no evident toxicity	Retested at 2000 mg/kg if not already tested at that level
2000 mg/kg[c]	Less than 100% survival[b]	Compounds that may be harmful if swallowed; retested at 500 mg/kg if not already tested at that level
	100% survival with or without evident toxicity	Compounds that do not present a significant acute toxic risk if swallowed

Adapted from Reference 359.

a Where a dose of 5 mg/kg produces significant mortality, or where a sighting study suggests that mortality will result at that dose level, the substance should be investigated at a lower dose level. The level chosen should be one that is likely to produce evident toxicity but no mortality.

b Includes compound-related mortality and humane kills but not accidental deaths.

c Testing mortality at this dose level is carried out primarily for risk assessment purposes. However, where no evident toxicity is seen at 500 mg/kg its results are relevant to classification if there is greater than 50% mortality (including humane kills).

the reader is encouraged to check the most recent regulatory guidelines that apply.

Refining the Acute Oral Toxicity Test

Humane Endpoints

Refinement of the acute oral toxicity test to minimize pain and suffering of animals, is an area that is also receiving considerable attention. Current OECD Test Guidelines require that animals which are moribund or in obvious pain and distress should be humanely killed. An ad hoc working group has been established to develop an OECD guidance document to provide a more humane perspective on when to euthanize animals used in toxicity studies. The final document will give specific criteria to determine when an animal is in moribund condition or experiencing significant pain and distress. Although the guidance document has not been finalized, the working group has agreed that a harmonized approach to defining humane endpoints in acute toxicity testing is essential. For additional information, the reader is referred to the accumulating literature on the subject of humane endpoints (217, 252–256, 319, 359).

Quantitative Structure-Activity Relationship (QSAR) Analysis

Analysis of the structure-activity relationships within a class of chemicals can yield valuable information and may reduce the number of bioassays conducted. QSAR analysis is particularly useful during the discovery stage for selection of chemicals for further development. QSAR also can be used for prioritization of chemicals for various actions related to health and safety and environmental assessment. The elements generally needed for QSAR include: a verified bioassays database for the endpoint to be predicted; a set of chemical-physical parameters which describe the chemical structures so that the endpoint can be modeled in terms of these parameters; statistical techniques, that is, principally multivariate regression and discriminant analysis for weighing these parameters in a near-optimum fashion for the explanation of the endpoint; and computer technology to make it all practical (119). Using QSAR, Enslein (119) has analyzed 2066 chemical structures and found that the oral rat LD50 of almost 50% of the compounds examined was predicted within a factor of 2, and 95% within a factor of 8.

Obviously there are limitations for the QSAR approach to predict a complex toxic response in whole animals. These include a limited database on which to base a QSAR model, the temptation to extrapolate beyond the confines of the model, and the noise inherent in the bioassays on which the models are based (119). The results from QSAR have to be used with caution, and at this stage, QSAR is useful during the discovery stage and for prioritizing chemicals.

Cytotoxicity Tests

Recent interest has focused on the use of in vitro cytotoxicity assays as predictors of human acute toxicity. The relationship between acute toxicity and cytotoxicity is not only intuitively appealing, but its relevance may be explained by the *basal cytotoxicity concept* (113). This concept derives from classifying all chemical toxicity to humans into three categories:

(1) organizational or extracellular toxicity;
(2) organ-specific cytotoxicity; or
(3) basal cell toxicity or chemical injury to structures and functions which are common to all human cells.

Because the mechanism of action of most toxic chemicals is related to basic biochemical processes found in all cells, it is postulated that there should be some correlation between toxic concentrations determined in vitro as well as in vivo.

An international program, the Multicenter Evaluation of In Vitro Cytotoxicity (MEIC), organized by the Scandinavian Society of Cell Toxicology, was designed to evaluate the relevance of in vitro toxicity assays for human acute toxicity (36, 112, 114, 366). In this program, 29 laboratories tested 50 reference chemicals with known human toxicity (acute lethal blood concentrations as taken from clinical and forensic medicine handbooks) in 61 different in vitro assays (116). These assays comprised human and animal cell lines and primary cultures, fish cell cultures, other ecotoxicological systems, and cell free systems. In vitro IC50 values (geometric average 50% inhibitory concentrations) were compared to human mean lethal serum concentrations using multivariate partial least squares (PLS) analysis. To provide a benchmark for measuring the predictivity of in vitro assays to animal tests, rodent and human toxicity data were compared (115) and an evaluation of rodent LD50 values contrasted to human acute lethal dose was also conducted (116). Results indicated that rat and mouse LD50 values predicted human acute lethal doses with correlation coefficients (r2) of 0.61 and 0.65, respectively. In contrast, the various in vitro assay predictions of human lethal blood concentrations ranged from r2=0.69 (all human cell lines combined) to r2=0.34 (all plant systems combined). These correlative findings show that for the 50 reference chemicals studied, in vitro tests using human cell lines are equivalent to rodent LD50 determinations in predicting human lethal blood concentrations.

Although this simplistic approach ignores most metabolic and toxicokinetic aspects operative in the intact organism, the results support the continued evaluation of the basal cytotoxicity concept and suggest that the use of human cell lines in in vitro cytotoxicity assays as predictors of human acute toxicity should be given serious further consideration as alternative methods to acute lethality studies in rodents. Although substantial gains have been made, in vitro replacement methods for acute toxicity testing are difficult to define. Some investigators have proposed a battery of in vitro tests as a strategy to replace whole-animal acute toxicity tests (266).

ASSESSMENT OF EYE IRRITATION INDUCED BY CHEMICALS

The eye captures visible energy and converts the energy to neurosignals, which are transmitted to the intricate central nervous system in which they form neuroimages (vision). The importance of having this ability to perceive the external environment through vision is a giant step in the evolutionary process. In humans, vision along with hearing is vital for the development of speech, learning, and intelligence. Loss of vision can greatly curtail normal living.

There are three basic components of vision: optics, photoreceptors, and conducting nerves. All three components must function properly to form a clear and sharp neuroimage in the visual cortex. The optics of the eye (cornea, aqueous humor, iris, lens, and vitreous humor) must remain transparent and be able to refract and focus light on the right position on the photoreceptors. The photoreceptors (the cones and rods) of the retina must be able to undergo photolysis and convert light energy to neuropotential impulses. The optic nerves must be able to carry these neuroimpulses to the visual cortex.

Because the eye is constantly exposed to the external environment, the cornea must be protected from drying, dust, and microorganisms. The eyelids, the lacrimal system, and the somatosensory response of the cornea all work together to protect this outermost structure of the eye. Like other organs, the major portion of the eye is nourished by blood vessels. The retinal, circumcorneal, and uveal vessels also

nourish and help maintain the eye. These vessels are so arranged and constructed that they normally do not alter the transparency of the ocular optics. Nutrients reach the transparent

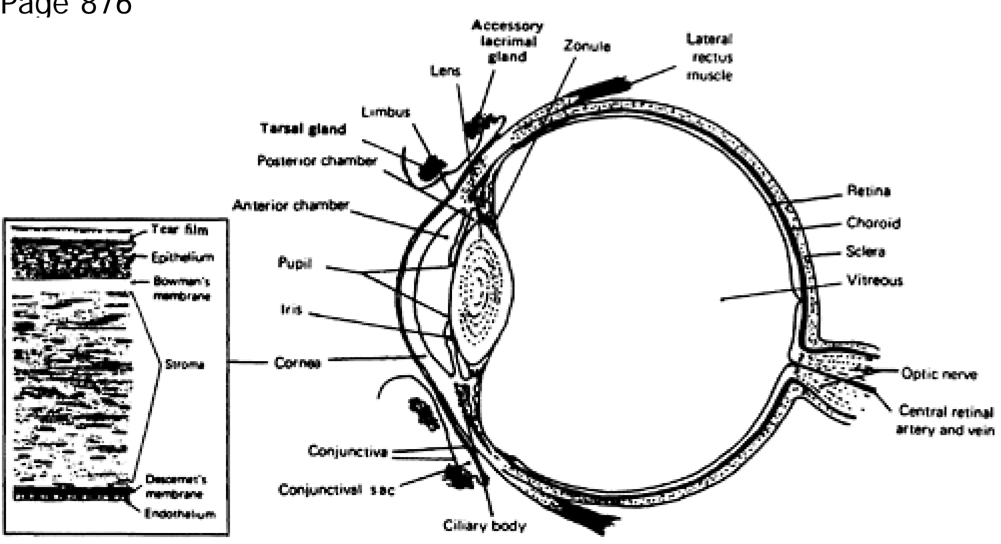

FIG. 18.4. Schematic illustration of the eye.

tissues of the eye via tears, the aqueous humor, and vitreous fluids.

Normal ocular functions are in delicate balance and are interdependent. Any traumatic insult, chemical or physical, can upset one or many of these ocular functions, thus creating a disturbance in vision. Depending on the extent of the traumatic injury (ranging from drying of the tear film to corneal ulceration or optic nerve damage), partial or complete loss of vision can result. Ocular injury not only can result from accidental physical trauma, but, also, from radiation and chemicals.

Chemicals can cause ocular damage locally by accidental exposure to the eye, or systemically by ingestion of chemicals such as food contaminants and drugs. Because many chemicals can produce ocular damage either locally or systemically (170, 180, 241, 308), it is important to test products for ocular effects before exposing workers during manufacturing and, ultimately, before subjecting consumers to products on the market. Ocular effects resulting from systemic exposure are beyond the scope of this chapter. This section focuses on eye irritation resulting from direct ocular contact.

Conducting ocular tests in humans is not only impractical but also unethical. Consequently, many methods and techniques have been developed over the years for testing ocular effects in animals. This section describes the methods for detecting potential eye irritants and discusses their limitations. In recent years, in vitro methods intended to replace eye irritancy tests in animals have evolved. The pros and cons of alternative methods are discussed.

Testing for potential eye irritancy is required for labeling and classification of chemicals by most regulatory agencies worldwide. The test protocol, interpretation of results, and classification scheme vary among countries. The differences among major industrial countries also are discussed.

Definition of Chemically Induced Eye Irritation and Corrosion

Irritation can be defined as reversible inflammatory changes in the eye and its surrounding mucous membranes following direct exposure to a material on the surface of the anterior portion of the eye. Corrosion is irreversible ocular tissue damage following exposure to a material. From a practical point of view, the distinction between reversible and irreversible changes sometimes is limited by the length of the observation period. Therefore, the term "eye corrosion" should be reserved for gross tissue destruction of the eye, which generally occurs rapidly following exposure. When interpreting results from an eye irritation study, one must take into consideration the biological significance of the ocular changes. For example, redness of the conjunctiva is considered a mild ocular effect. Even if it does not disappear completely within a specific time period

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_876.html[2010/10/28 18:48:48]

(e.g., 21 days), one can hardly justify classifying the material as corrosive.

Normal Physiology and Anatomy of the Eye

A brief description of the normal physiology and anatomy of the eye is essential for understanding the development of eye irritation. Details can be found in a variety of textbooks and reviews (137, 238, 298).

Functionally, the eye can be divided into three basic parts (Figure 18.4). From posterior to anterior, they are:

- *Photoreceptors (retina):* The part of the eye that connects to the central nervous system via the optic nerve
- *Optics:* Structure that focuses visible light (image) onto the retina; it includes (from anterior to posterior) the cornea, iris, aqueous humor in the anterior chamber, the lens, and its related organelles such as the zonules and ciliary body (muscles), and the vitreous in the posterior chamber
- *Protective, lubricating, and nutritional structures:* These include the anterior eyelids and conjunctiva and associated secretory glands, the sclera and its outside layer (the fibrous tunic) and inside layer (uvea-vascular), and the ciliary body (secretory).

For chemically induced eye irritation, the main concern is generally on the directly exposed organelles such as the cornea, conjunctiva, and the iris. Effects on these structures can easily be detected by gross observation. If the chemical can penetrate deeper into the eye, other organelles also can be affected. Detection of the effects on these deeper structures requires special aids.

Cornea

The cornea is composed of, from anterior to posterior, the epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. The epithelium is about five cells deep in the transitional zones at the periphery. The basal cells are columnar, the other cells are squamous, and the cells between the two layers are polygonal (wing cells). The Bowman's membrane (12 μm) is an acellular layer of collagen and ground substance which provides a functional interface between the stroma and epithelium. An intact Bowman's membrane and the epithelial basal cell layer are vital to the regeneration of damaged epithelium. Damage to Bowman's membrane may predispose the cornea to fibrosis. The stroma consists of lamellae of collagen fibrils and fibroblasts supported by ground substances. The stroma forms most (nine-tenths) of the cornea and is limited on its inner surface by Decemet's membrane.

In addition to the organization of sheets of fibrils, other unique features such as proper hydration also contribute to corneal transparency. The Descemet's membrane (5–10 μm), like the Bowman's membrane, is an acellular layer which is the basement membrane of the endothelium. The endothelium is a single layer of cells which completely covers the posterior surface of the cornea. The cells are hexagonal with large nuclei. This layer of the cornea is particularly rich in the active transport enzyme adenine triphosphatase (ATPase). The maintenance of proper hydration of the cornea has been attributed to the activity of this enzyme, which catalyzes an active sodium-potassium pump (38, 203, 228). The limbus is a transitional region between the cornea and the sclera. This region, rich in vascularization, is the source of fluid and infiltration cells during corneal injury.

The epithelium and the overlying tear film provide the intrinsic protection for the cornea. Other layers have almost no intrinsic resistance to injury. Penetration into deeper layers of the cornea and other structures of the eye is limited by chemicals' solubility and lipophilicity. Chemicals that are lipophilic and water-soluble penetrate more rapidly and probably deeper into the eye than other chemicals.

The cornea is always covered with a film of tears, which consists of several oily and aqueous layers. Proper tear formation and drainage as well as the stability of the precorneal tear film are important for a normal precorneal optical surface, proper lubrication, nutrition for the cornea, removal of bacteria and debris from the cornea, and activity on the cornea. Reduction of tear formation can lead to a dry eye, mechanical friction, irritation, or infection. A discussion of the assessment of tear film formation, stability, and drainage is available (73).

The cornea is a powerful refractive biological optic. Its refractive power is dependent on its being transparent and on proper hydration. Maintenance of proper transparency and hydration is dependent on many mechanisms, for example, proper tear flow, absence of deposits and blood vessels, proper arrangement of collagen fibrils, unimpaired nutritional supply for the metabolic active pump (Na^+-K^+), and proper intraocular pressure. Decreased transparency or hydration can be a result of corneal scars (decreased corneal thickness) or corneal edema (increased corneal thickness). Corneal edema can be caused by epithelial damage, endothelial damage, increased intraocular pressure, lack of oxygen, or inhibition of the electrolyte balance pump (Na^+-K^+-activated ATPase), which is located mainly in the

endothelial membrane, but is also found in the epithelium. Methods for measuring corneal curvature, corneal thickness, intraocular pressure, blood/aqueous humor barrier, and corneal endothelium damages have been reviewed (73).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_877.html[2010/10/28 18:48:49]

Conjunctiva

The conjunctiva is part of the eyelid. It is the delicate membrane that lines the eyelid (palpebral conjunctiva) and covers the exposed surface of the eyeball (bulbar conjunctiva). Histologically, the conjunctiva is an aqueous, nonkeratinized epithelium with numerous mucussecreting cells. Accessory lacrimal glands are present in the conjunctiva, which contribute to the aqueous layer of a precorneal tear film. The Meibomian gland, a specialized sebaceous gland in the eyelid, secretes the outer oily layer of the tear film.

The main function of the eyelid is to protect the eye, especially the cornea, from external trauma through proper blinking reflexes and secretion of tears. Normal secretory and excretory functions of the tear are also important for normal optical function of the eye. The precorneal tear film can form an optically uniform layer over the microscopically irregular surface of the corneal epithelial cells. The tear flow continuously flushes cellular debris or foreign bodies from the eye, lubricates the corneal surface from mechanical friction caused by blinking, provides nutrients to the cornea, and induces antibacterial activities by proteolytic enzymes and immunoglobulin. All of these functions are important to maintain an optically intact corneal surface. Substances that affect the stability of the precorneal tear film by interfering with the secretory/excretory functions or with the blinking mechanism can cause serious damage to the cornea and may even cause corneal ulceration.

The nictitating membrane or the third eyelid is an important and prominent structure in many species of animals, including the rabbit, but is not as important in humans and nonhuman primates. It aids in protecting the conjunctiva and the cornea when the eyeball is retracted. The nictitating membrane, like the conjunctiva, also contains lacrimal glands and its secretion contributes to the aqueous layer of the precorneal tear film. In addition, the nictitating membrane helps to support the position of low eyelids and forms the lacrimal lake in the medial canthus. Vascularization in the conjunctiva generally consists of superficial and deep groups, mainly in the bulbar conjunctiva.

Three endpoints generally are associated with irritation in the conjunctiva: redness, chemosis, and discharge. In response to an irritant, the eyelids blink, the tear secretion increases, and the conjunctiva vessels dilate. Blinking and tearing (discharge) aid in removing the irritant from the eye, and tear flow also may reduce the acidity or basicity of the irritant. Vessel dilation may be triggered by histamine, prostaglandins, or other inflammatory mediators, resulting in an apparent increase in vascularity (redness) in the conjunctiva. If irritation is severe, the dilation of the vessel increases and vascular fluid and proteins leak into the conjunctiva resulting in edema (chemosis). If the edema is severe, bulging may hinder normal functioning of the eyelids.

Iris

The iris forms the pupil and functions in regulating the amount of light that may reach the retina. High-intensity light causes constriction of the diameter of the pupil and low-intensity light dilates it. It does so by two sets of muscles acting opposite each other to control the diameter of the pupil. These muscles, circulatory and radiating, are innervated by both the autonomic and sympathetic nervous systems. The set of muscles forms the distinct characteristic of iridic furrows of the iris.

The iris is anatomically located posterior to the cornea, and is a very vascular structure made of loose connective tissues, muscle, and pigmented cells. The amount of pigment in the iris varies. Heavily pigmented cells are found in most species, except albinos. Only a small amount of pigment is found in the albino rabbit eye. This is an advantage in ocular studies because it allows easier and better examination of the iridal vessels, lens, and retina.

The observation endpoints of local iridic injury are increased vascularity, edema (increased thickness of the stroma/swelling), reaction to light, aqueous flare, and gross destruction of tissue. These are the manifestations of an inflammatory process (iritis) responding to an irritant. Like the conjunctival vessels, the iridic vessels dilate and leak vascular fluid in response to irritants. Dilation of vessels and leakage cause edema and apparent changes in vascularity such as injection of iridic vessels (hyperemia). Aqueous flare is a result of protein leaking from the iridic vessels into the aqueous humor of the anterior chamber. Protein leakage into the anterior chamber alters the refractive index of the aqueous humors. Light beams entering the anterior chamber are scattered, giving the anterior chamber a cloudy appearance which contrasts with a clear appearance in normal eyes as a light beam passes through the pupil and the anterior chamber, for example, during examination with a slit lamp. This is called the aqueous flare or Tyndall phenomenon which is usually not noted during routine gross examination of the eye. In a more severe form of iritis, tissue destruction may result and nerve innervation may be disrupted, causing the pupil to be unresponsive to light. Failure to react to light, from a practical standpoint, is the most reliable observation of a severe iridic reaction since severe iritis is usually

accompanied by severe opacity in the cornea, which may obscure the visible detection of changes on the iris.

THE DRAIZE TEST

The Draize test was developed in 1944 by Draize et al. to study eye irritation (102). The test was based on the

original work of Freidenwald et al. (148). For years, the Draize test has been used as the animal test to identify human eye irritants. It is a simple and generalized test. It is easy to conduct and requires no special instruments. Even though simplicity is probably the main reason for its popularity, it is also the limitation of the test per se. Undeniably, the Draize test can adequately identify most of the moderate-to-severe human eye irritants, but the test may fail to detect mild or subtle ocular irritation even with proper modification.

In the original Draize test, a standard 0.1 ml or 0.1 g of test substance is applied to the conjunctival sac of an albino rabbit's eye. The eyelid is held together for a few seconds and then released. The degree or extent of opacity on the cornea, the redness on the iris, and the chemosis and discharge on the conjunctiva are scored subjectively according to an arbitrary scale at preselected intervals (1, 24, 48, and 96 h) after exposure. Scoring is based on the degree of effects caused by the testing substance. More emphasis is placed on the opacity of the cornea, which has a maximum score of 80, whereas emphasis is progressively less with other effects: conjunctival changes (maximum score of 20) and iritis (maximum score of 10) (62, 165, 232).

The Draize test has been a subject of controversy among animal rights groups (178, 313) and even in the scientific community (28, 62, 165, 172, 181, 232, 304, 374). It has been criticized on the bases of dose volume, use of animals as models, methods of exposure, irrigation, number of animals, observation and scoring including laboratory procedure variability, and interpretation of results, all of which are discussed below.

Dose Volume

The 0.1 ml dose volume used in the original test was based on the volume used earlier by Friedenwald et al. (148) to study the mechanism of acid- and base-induced ocular damage. This dose volume was selected arbitrarily as a standard volume for intraocular injection. Draize et al. (102) adopted it solely for convenience which unfortunately has set a seemingly unchangeable doctrine for years even though the 0.1 ml dose volume lacks a scientific basis and, in conjunction with the conjunctival dosing method, often overpredicts the eye irritancy of a chemical.

Proponents of the 0.1 ml dose volume argue that this dose is a maximized test for the worst case and that it can better predict human eye irritants. The Draize test is basically a safety test. Its main purpose is to predict what would happen to human eyes *within* the expected range of exposure. The 0.1 ml dose is out of the range of human exposure. The maximal volume the cul-de-sac of a rabbit's eye can hold is only 30–50 μl (246); thus, even though one desires a maximal test, the dose volume should not be more than 50 μl. Any volume over this absolute maximum simply falls from the eye. Furthermore, the worst case is not necessarily the best case. Constantly overrating eye irritation will have a desensitizing effect on consumers' and workers' awareness of potential eye irritation. This will defeat the purpose of eye irritancy testing which is to protect them.

There are no data to substantiate the argument that the 0.1 ml dose can better predict human eye irritants. On the contrary, in at least one survey, there was little correlation between human accidental exposure experience and data generated by the traditional 0.1 ml maximal dose. The survey did not support the general presumption that rabbit eyes are more sensitive than human eyes (68). Simply reducing the dose volume has produced data closer to eye irritation experienced in humans. For example, comparison of human eye irritation resulting from accidental exposure to many consumer products has revealed that lower dose volume predicts the eye irritancy potential much better than the 0.1 ml dose vol ume (147, 172). In one of the studies, the time needed for recovery from eye irritation in consumers or factory workers is compared with animal tests in monkeys and rabbits (147). This survey clearly demonstrated the modified Draize test (Federal Hazardous Substances Act (FHSA) protocol with a dose volume of 0.1 ml) was the poorest predicting test, whereas the low dose volume and the monkey tests were better predictors even though all three animal tests overpredicted the eye irritancy experienced in humans.

In 1977, a panel on eye irritancy test of the National Academy of Sciences (NAS), formed at the request of the Consumer Product Safety Commission (CPSC), recommended lowering the dose volume (267). Subsequently, even smaller dose volumes ranging from 0.003 to 0.03 ml were proposed by others because they predict human eye irritants more accurately, cause less pain to animals, and can discriminate slight-to-moderate eye irritants (172, 174, 380). Williams et al. (380) showed that direct corneal application in a dose volume of 0.01 ml increased the response on the cornea when compared with the standard 0.1 ml dose but did not change the response on the conjunctiva. These results in the absence of compounding effects of a high dose volume suggest that the lower dose volume is just as sensitive a method for eye irritancy testing as the higher dose volume.

Animal Models

As with other toxicological tests in animals, the primary issue of testing for ocular irritancy in animals is predictability for humans. Recognizing that there are anatomical, physiological, and biochemical differences

between human and animal eyes, researchers are confronted with the difficult task of selecting the appropriate animal model and suitable test conditions to identify potential human eye irritants. The corneal thickness of dogs and rhesus monkeys is similar to that of humans (approximately 0.5 mm) (232, 236, 247); rabbit corneal thickness is somewhat thinner (0.37 mm) (232). There is a lack of a recognizable Bowman's membrane in rabbits, but they have a well-developed nictitating membrane (an additional target tissue), thick fur around the eyes, loose eyelids susceptible to mild irritants, an ineffective tear drainage system, and a poorly developed blinking mechanism (267). There are also species differences in biochemistry (e.g., variation in enzyme content (216)) and different penetration rates of various substances (231).

Even though there are shortcomings and exceptions in predictability, the rabbit has been used for most eye irritancy studies. There are some obvious advantages for choosing the rabbit: a wide database, economy, availability, ease of handling, and large, unpigmented eyes suitable for various ophthalmological examinations. With some exceptions (171, 304), the rabbit eye is generally more sensitive to irritating materials than human or monkey eyes (25, 63). Thus, there are built-in safety factors for making extrapolation and assessment of hazard to humans.

In addition to rabbits, dogs and primates sometimes are used for ocular testing. Eye irritancy in primates generally is more closely correlated with the exposure experience in humans, although dogs also are suitable under certain circumstances (29). Because they are more expensive and less available, dogs and primates are only used occasionally to assess eye irritancy.

Regardless of which animal is used, the investigator should always have a good understanding of the animal eye being observed. Background ocular findings, if not observed prior to exposure, can be recorded falsely as chemically induced damage.

Methods of Exposure

Basically, there are two ways of applying a test sub stance to the eye: (a) applying the test material into the cul-de-sac of the conjunctiva or (b) applying it directly onto the cornea. The conjunctival exposure method has been adopted historically because of the ease of application. It also has been perceived as being accurate in dosing. However, some have experienced (29, 172) that conjunctival exposure is inappropriate under many circumstances, especially when the test material is a solid powder. The possibility exists that the test material will be trapped in the conjunctival sac, producing some undesirable mechanical effects and making the interpretation of the results more difficult. It is also evident that a considerable amount of the standard 0.1 ml or 0.1 g dose (especially as a solid powder) either falls or is blinked from the eye once the animal's eyelids are released. The claim that conjunctival dosing is more accurate may not be valid.

The corneal exposure method, on the other hand, mimics more closely the actual accidental exposure experience in humans. When assessing the hazard of most chemical accidents, this method should be considered except when the chemical is intended for pharmaceutical use (267). Applicators developed for the corneal exposure method have been used in some studies (25, 63). A more uniform corneal lesion was observed, resulting in less observation variability (25). For a study as specific as corneal wound healing, a corneal applicator is recommended (258). However, for hazard assessment, it is desirable to apply the test substance directly onto the cornea while the lids of the test eye are gently held open. The eyelids are closed for a second and then released to allow blinking; this action more closely mimics actual human exposure (172).

Irrigation

Washing the eye is a typical emergency remedy after accidental exposure to chemical substances. In experimental studies, the treated eye usually is irrigated 20–30 sec after exposure to the test substance. Water is rapidly but gently squeezed from a plastic bottle to produce a constant gentle stream of water irrigating the entire treated eye. Irrigation should last for at least 1 min.

The effect of irrigation on the interpretation of test results has been the subject of many studies (25, 27, 28, 37, 89, 140, 171, 173, 285, 322). While irrigation of the treated eye right after exposure can prevent or minimize eye irritation in rabbits, the effectiveness of irrigation is dependent on the chemical, the concentration, the time lag between exposure and initiation of the irrigation, and the volume of irrigation. Early washing (less than 1 min) generally is recommended to reduce irritation (89, 140, 173, 322), but in some cases, increased irritation has been observed after irrigation with water (153, 322). In other cases, ocular damage was almost instantaneous if irrigation did not begin after a few seconds (89).

Number of Animals

It is generally true in experimental studies that the larger the group size the more precise the test

results. Sometimes, the desired precision may be offset by animal-to-animal variabilities. Economic considerations also are important in determining the number of animals used in a test group. A balance between economic considerations and reliability of test results should determine the number of animals tested in a study.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_880.html[2010/10/28 18:48:50]

For eye irritation studies, a group size of 9 rabbits was recommended in the original Draize test, and group sizes of at least 6, 3, 3, and 4 rabbits have been recommended by the FHSA, Interagency Regulatory Liaison Group (IRLG), OECD, and NAS, respectively. The relationship of variability, classification, and group size is addressed in the literature (27, 173, 375). With larger group size, smaller variability has been noted (375), whereas with a decreased group size, lesser differentiation of irritancy has been suggested (27). Recognizing these facts, Guillot et al. (173) suggested a compromised approach. They suggested that with 3 rabbits in an initial study, there was a 96% chance that a positive or negative eye irritation result would be obtained. A similar conclusion was obtained in another study conducted with 67 petroleum products each with 6 rabbits (94). The eye irritation scores for the petroleum products based on all 6 rabbits were compared statistically with the scores from 2, 3, 4, or 5 animals. The comparison showed that a subsample size of 2, 3, 4, and 5 rabbits correctly classified (compared with the original 6 rabbits/test classification) the chemicals at 88, 93, 95, and 96% accuracy, respectively.

Observation and Scoring

Reversibility and severity are the two major criteria used to measure eye irritancy in the Draize test. Reversibility refers to the time needed for the ocular effects to disappear and for the eye to return to its normal state. To determine this reference time, treated eyes are examined periodically at 24-h intervals, on day seven after exposure, or at longer intervals if needed to establish reversibility (102). The observation period varies for different guidelines. For example, the FHSA uses 24-, 48-, and 72-h time spans (136); the OECD uses 1-, 24-, 48-, and 72-h, and, if needed, extended observations (276); and the NAS recommends 1, 3, 7, 14, and 21 days (267). The observation period should be flexible so that one can confidently assess the persistence of ocular effects and fully characterize the degree of involvement, because the onset and healing of ocular effects often are unpredictable (171).

The assessment of severity of different ocular effects is subjective. This subjective evaluation is the major source of error for intra- and inter-laboratory variation (374). Therefore, to minimize at least the intra-laboratory variability in scoring, uniformity in scoring techniques must exist among investigators regardless of which scoring system is followed. Pictorial references such as those prepared by the FDA (131) and the Consumer Product Safety Commission (CPSC) (85) can be extremely helpful in the standardization of scoring eye irritation.

The types of ocular effects observed in the Draize test involve the cornea, iris, nictitating membrane, and conjunctiva. A grading system (Table 18.8) was originally

Table 18.8 Scale of weighted scores for grading the severity of ocular lesions

Lesion	Score[a]
I. Cornea	
A. Opacity—degree of density (area which is most dense is taken for reading)	
Scattered or diffuse area—details of iris clearly visible	1
Easily discernible translucent areas, details of iris clearly visible	2
Opalescent areas, no details of iris visible, size of pupil barely discernible	3
Opaque, iris invisible	4
B. Area of cornea involved	
One-quarter (or less) but not zero	1
Greater than one-quarter—less than onehalf	2
Greater than one-half—less than threequarters	3
Greater than three-quarters—up to whole area	4
Score equals A×B×5	
Total maximum=80	
II. Iris	
A. Values	
Folds above normal, congestion, swelling. circumcorneal injection (any one or all of these or combination of any thereof), iris still reacting to light (sluggish reaction is positive)	1
No reaction to light; hemorrhage, gross destruction (any one or all of these)	2
Score equals A×5	
Total maximum=10	
III. Conjunctivae	
A. Redness (refers to palpebral conjunctivae only)	
Vessels definitely injected above normal	1
More diffuse, deeper crimson red, individual vessels not easily discernible	2

Diffuse beefy red	3
B. Chemosis	
Any swelling above normal (includes nictitating membrane)	1
Obvious swelling with partial eversion of the lids	2
Swelling with lids about half closed	3
Swelling with lids about half closed to completely closed	4
C. Discharge	
Any amount different from normal (does not include small amounts observed in inner canthus of normal animals)	1
Discharge with moistening of the lids and hairs just adjacent to the lids	2
Discharge with moistening of the lids and considerable area around the eye	3
Score equals (A+B+C)×2	
Total maximum=20	

From Reference 62.

a The maximum total score is the sum of all the scores obtained for the cornea, iris,and conjunctivae.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_881.html[2010/10/28 18:48:51]

Table 18.9 Grades for ocular lesions

Lesion	Grades	Lesion	Grades
Cornea		Conjunctivae	
No ulceration or opacity	0	Redness (refers to palpebral and bulbar conjunctivae excluding cornea and iris)	
Scattered or diffuse areas of opacity (other than slight dulling of normal luster), details of iris clearly visible	1*a*	Vessels normal	0
		Some vessels definitely injected	1
Easily discernible translucent areas, details of iris slightly obscured	2	Diffuse, crimson red, individual vessels not easily discernible	2*a*
Nacreous areas, no details of iris visible, size of pupil barely discernible	3	Diffuse, beefy red	3
		Chemosis	
Complete corneal opacity, iris not discernible	4	No swelling	0
Iris		Any swelling above normal (includes nictitating membrane)	1
Normal	0	Obvious swelling with partial eversion of lids	2*a*
Markedly deepened folds, congestion, swelling, moderate circumcorneal Injection (any of these separately or combined); iris still reacting to light (sluggish reaction is positive)	1*a*	Swelling of lids about half closed	3
		Swelling of lids more than half closed	4
No reaction to light, hemorrhage, gross destruction (any or all of these)	2		

a Lowest grade considered positive.

proposed by Draize et al. (102), and subsequently a number of modifications were proposed (85, 131, 267). In the Draize system, the intensity and area of involvement on the cornea are graded separately on a scale of 0–4. The product of the two scores is multiplied by 5 to obtain a weighted corneal score. The congestion, swelling, circumcorneal injection, hemorrhage, and iridic failure of reactions to light are graded collectively on a scale of 0–2, and the score is multiplied by 5 to obtain a weighted iridic score. The redness, chemosis, and discharge of the conjunctivae are graded on scales of 0–3, 0–4, and 0–3, respectively. The sum of the conjunctival scores is multiplied by 5 to obtain a weighted conjunctival score. Other lesions also are recorded, such as pannus (corneal neovascularization), phylyctena, and rupture of the eyeball.

In the guidelines set forth by the EPA, CPSC, FHSA, OECD, EEC, and Japan's Ministry of Agriculture, Forestry and Food (MAFF) (85, 109, 124, 136, 337), only the degree (intensity of cornea damage, iritis, and redness and chemosis [swelling]) of the conjunctivitis is scored (Table 18.9). The area involved on the cornea as well as the discharge of the conjunctiva are not taken into consideration in scoring. Various aids are used at times to facilitate or increase the resolution power of these observations. These aids include fluorescein staining and ophthalmoscopic or slit lamp microscopic examinations. A scoring system has been developed for the slit lamp and fluorescein staining examination (267) (Table 18.10). Other scoring systems have been proposed for lacrimation, blepharitis, chemosis, injection of conjunctival blood vessels, iritis, kerectasis, and corneal neovascularization (9).

Interpretation of Results

There are essentially four categories of data, generated by the Draize test, to be considered when interpreting the results of ocular testing:

(a) kind of ocular effects,
(b) severity,
(c) reversibility, and
(d) rate of incidence.

Weighting the scores in the original Draize test has, to some extent, to take the first category into consideration, yet it biases toward the cornea, one of the most critical ocular tissues. Severity is measured according to a graded scoring system, and reversibility is expressed as the time needed for the affected ocular tissue to return to the normal state. Incidence is the number of animals that show

some kind of ocular effect during the study. Interpretation of the data is a multiple and factorial undertaking. All four categories of data

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_882.html[2010/10/28 18:48:52]

Table 18.10 Scoring criteria for ocular effects observed in slit lamp microscopy

Location of observations	Grades	Location of observations	Grades
Corneal observations		*Iridal observations (cont'd)*	
Intensity		Aqueous flare (Tyndall effect)	
Only epithelial edema (with only slight stromal edema or without stromal edema)	1	Slight	1
		Moderate	2
		Marked	3
Corneal thickness 1.5×normal	2	Iris hyperemia	
Corneal thickness 2×normal	3	Slight	1
Cornea entirely opaque so that corneal thickness cannot be determined	4	Moderate	2
		Marked	3
Area involved		Pupillary reflex	
≤25% of total corneal surface	1	Sluggish	1
>25% but <50%	2	Absent	2
>50% but <75%	3	Maximal iridal score	11
>75%	4	*Conjunctival observations*	
Fluorescein staining		Hyperemia	
≤25% of total corneal surface	1	Slight	1
>25% but <50%	2	Moderate	2
>50% but <75%	3	Marked	3
>75%	4	Chemosis	
Neovascularization and pigment migration		Slight	1
≤25% of total corneal surface	1	Moderate	2
>25% but <50%	2	Marked	3
>50% but <75%	3	Fluorescein staining	
>75%	4	Slight	1
Perforation	4	Moderate	2
Maximal corneal score	20	Marked	3
Iridal observations		Ulceration	
Cells in aqueous chamber		Slight	1
A few	1	Moderate	2
A moderate number	2	Marked	3
Many	3	Maximal conjunctival score	12

are somewhat interrelated; the individual scores do not represent an absolute standard for the irritancy of a material (273).

In one study, interpretation of eye irritation was not considered to be the major factor contributing to interlaboratory variability (374). This finding is not surprising, if one assumes that everyone adheres to the same interpretation criteria. However, the question is what are the appropriate criteria for interpreting eye irritation results that would have an impact on placing eye irritants into different categories? The individual scores do not represent an absolute standard for the irritancy of a material (275).

Many classification systems for eye irritants have been proposed. Some have been published in the literature (171, 173, 202, 267), and in various testing guidelines (109, 136, 337), and many others are used in individual laboratories. There is general agreement among investigators on how to classify test substances when no irritation is observed or when severe irritation or corrosion is seen, but there is little agreement on how to classify irritancy that falls between these two extremes. The manner in which data are evaluated directly affects the conclusions reached.

Because of the complexity of eye irritancy data and their interdependence, some investigators have chosen to simplify the interpretation to a pass-or-fail approach. For example, in the FHSA guideline (136), if four or more of the six test rabbits show ocular effects within 72 h after a conjunctival sac exposure (0.1 ml or 100 mg of the test material), the test material is considered to be a positive eye irritant. The ocular effects in consideration are "ulceration of the cornea (other than a fine stippling), corneal opacity (other than a slight deepening of the nor

mal luster), inflammation of the iris (other than deepening of folds), an obvious swelling with partial eversion of the lids, or a diffuse crimson red with individual vessels but not easily discernible." If only one of the six tested animals shows ocular effects within 72 h, the test is considered negative. If two or three of the six tested animals show ocular effects, the test is repeated. The test substance is considered to be a positive irritant if three or more animals show ocular effects in the repeated test; otherwise, the test is repeated. Any positive ocular effect observed in the third test automatically classifies the test substance as an irritant. A similar approach has been adopted in the IRLG guideline (192), but an option is given that declares a test positive when two or three of six rabbits tested show a positive ocular effect and the test is not repeated. The pass-or-fail interpretation is too simplistic, however, and it does not separate eye irritants, especially those that fall between the two extreme irritancy categories (from nonirritating to severely irritating). Gradation of potential eye irritation is important to denote an anticipated hazard and to convey to consumers or workers that a specific degree of precaution should be exercised whenever a potential exposure to the substance exists.
Green et al. (171) used a different approach. Eye irritancy was classified into four easily recognizable categories based on the most severe responder in a group:

- *Nonirritation:* Exposure of the eye to the material under the specified conditions causes no significant ocular changes. No tissue staining with fluorescein was observed. Any changes that did occur cleared within 24 h and were no greater than those caused by normal saline under the same conditions.
- *Irritation:* Exposure of the eye to the material under the specified conditions causes minor, superficial, and transient changes of the cornea, iris, or conjunctiva as determined by external or slit lamp examination with fluorescein staining. The appearance at any grading interval of any of the following changes was sufficient to characterize a response as an irritation: opacity of the cornea (other than a slight dulling of the normal luster), hyperemia of the iris, or swelling of the conjunctiva. Any changes cleared within 7 days.
- *Harmfulness:* Exposure of the eye to the material under specified conditions causes significant injury to the eye, such as loss of the corneal epithelium, corneal opacity, iritis (other than a slight infection), conjunctivitis, pannus, or bullae. The effect healed or cleared within 21 days.
- *Corrosion:* Exposure of the eye to the material under specified conditions results in the types of injury described in the previous category and also results in significant tissue destruction (necrosis) or injuries that adversely affect the visual process. Injuries persisted for 21 days or more.

This classification system has taken into consideration the kinds of ocular effects, the reversibility, and, to a certain extent, the qualitative severity, but not the incidence. The committee that revised the NAS publication 1138 (267) put forward a system of classification similar to that of Green et al. (171). The categories are named differently: inconsequential or complete lack of irritation, moderate irritation, substantial irritation, and severe or corrosive irritation. The classification also is based on the most severe responder, and incidence is not considered. A provision for repeating the test is given as an option to increase the confidence level in making a judgment in some borderline cases. This eye irritancy classification system has been widely adopted. One shortcoming of the NAS system is that too wide a spectrum is created for moderate irritancy, which may lead to overutilization of the cautionary term, *moderate*. Many investigators have experienced problems in interpreting results from fluorescein staining of the cornea when the NAS gradation system is used. The confusion arises mainly from the occasional artifacts inherent in fluorescein staining. Experience and sound scientific judgment are needed to properly interpret the fluorescein staining results (see the discussion on ophthalmological techniques).
Griffith et al. (172) disagreed with using the most severe responder for classification of eye irritancy, claiming that there was no epidemiological evidence to suggest that the most severe rabbit responder would correlate with the worst possible case of human exposure. Instead, these investigators used the median time for recovery for classification according to the same temporal criteria as in the NAS system. The underlying logic is that the incidence of responders is being considered indirectly.
The classification systems of Green et al. (171), Griffith et al. (172), and NAS (267) apparently have not taken into account the severity of irritancy. Although there is a perception of a direct relationship between severity and reversibility, if one examines the data of Griffith et al. (172), indeed, it can be shown that a direct correlation of median time to recovery and the severity of irritancy does occur.
Kay and Calandra (202) proposed yet another rating system based on the Draize scores, taking into account the extent and persistence of irritation and the overall consistency of the data. Another system was proposed by Guillot et al. (173). Here, the greatest mean irritation score within an observation period is identified. On the basis of this score, the test substance is classified into six categories, ranging

from nonirritating to maximum or extremely irritating. To maintain this initial rating,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_884.html[2010/10/28 18:48:53]

the data also must meet the arbitrary criteria for reversibility and frequency of occurrence, otherwise the rating is upgraded one category. The Kay and Calandra system has not been verified for correlation to human exposure experience, nor has it been compared with other classification systems. Guillot et al. (173) made an attempt to compare their rating with the OECD protocol. They claimed that one-third of the 56 materials tested could be classified into a lower category by the OECD protocol.

The most current modification of the OECD protocol (276) is an effort to minimize the number of animals used to produce data suitable for hazard classification. In this simplified scheme, a Draize eye test is conducted using one animal if severe effects are expected, or three animals if no severe eye irritation is anticipated. Scoring is based on ocular lesions that occur within 72 h of exposure and results are expressed in terms of the lesions and their reversibility (eye irritation) or irreversibility (eye corrosion). The EPA has recently revised its health effects test guidelines for acute eye irritation (126) to be more consistent with the OECD protocol. A revised EEC directive, based on the OECD approach, provides hazard classification corresponding to risk phrases (R 36—Irritating to eyes and R 41—Risk of serious damage to eyes). These risk phrases are assigned to the label of a chemical when two or more of the three animals exhibit scores within certain arbitrary numbers (110).

A summary of the current international classification systems and major features for eye irritancy testing is shown in Table 18.11. Despite such a range of classification schemes, there is little difference in the actual scoring system (basically adhering to the original Draize) (102).

SPECIAL OPHTHALMOLOGICAL TECHNIQUES

The Draize test is a generalized test concentrating on the effects of the material on the cornea, iris, and conjunctiva. Examination usually is performed under a hand light. Accurate observations are limited by the experience and training of the investigator. Subtle ocular changes may be missed. If these subtle changes are to be detected and ambiguous gross observations resolved, or if internal tissues (e.g., the lens and the retina) are to be examined, the investigator must rely on special techniques. Many such techniques have been developed over the years, most of which are more objective than the gross examination itself. A few comments on the fluorescein staining technique and several of the more objective methods are presented.

Fluorescein Staining for Corneal Damage

Fluorescein is a weak organic acid (Figure 18.5) and is only slightly soluble in water, but its sodium salt is moderately soluble in water. It is very efficient in absorbing ultraviolet light and emitting fluorescent light. The maximum absorption is 490 nm (excitation) in the violet region, and its maximum emission is 520 nm in the green region of the spectrum. Its un-ionized form is less fluorescent than its ionized form. At pH 7.4, fluorescein does not seem to bind to tissue and is nontoxic in animals, making it an ideal marker for an ocular fluid dynamics study. Because fluorescein is a deeply colored and highly fluorescent chemical, it can be detected at very low concentrations in biological tissues or fluid; however, its detection sensitivity often is limited by the background fluorescence of biological tissues.

Because sodium fluorescein is a polar molecule, it does not readily traverse lipophilic membranes but easily diffuses into aqueous medium. For example, if ulceration occurs on the cornea, the lipophilic membrane barrier is broken down and the fluorescein diffuses freely through the ulcerated area of the cornea and either is dissolved or suspended in the aqueous medium of the stroma. More detailed information on the chemical and biological properties of fluorescein is provided in two excellent reviews (235, 249).

Since its first use in studying the origin of aqueous humor secretion a century ago (111), fluorescein has become an important aid in ophthalmology. It has been used as a marker in detecting obstructions in the nasolacrimal drainage systems, for studying changes in the flow dynamics of different ocular fluids, for demonstrating leakage of retinal vessels in angiography, for estimating permeability of the cornea and lens, and for identifying ulcerations on the cornea (235). Among these, its use in detecting subtle changes on the corneal epithelium (80, 183) has been a routine procedure in animal eye irritation studies.

The corneal epithelium is a lipophilic barrier to sodium fluorescein, but such a barrier is broken when there is an ulceration or change in membrane structure. Some amount of fluorescein applied on the cornea will penetrate into the intercellular spaces of the stroma, which constitute a water-soluble layer of the stroma. When light is cast on the cornea, fluorescence is detected on the damaged area of the epithelium. Once the fluorescein enters the stroma, it eventually will pass through Descemet's membrane and the endothelium into the aqueous humor.

Fluorescein staining usually is accomplished by solution or impregnated paper strips. Fluorescein is commercially available in 2, 1, or 0.25% sodium salt solutions. Preservatives to minimize bacterial

contamination are common in these commercially available sol

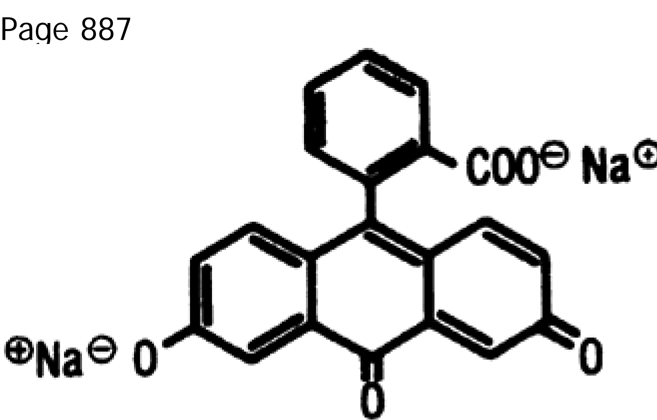

FIG. 18.5. Structure of fluorescein.

utions (71). A drop of the solution is instilled onto the eye and excessive fluorescein is flushed immediately with a sufficient amount of water. The eye then can be examined under a cobalt-filtered UV light for epithelial defects.

Fluorescein also is available in impregnated paper strips (210). These strips are free of contamination and easy to use. Moistened with collyria, a strip is touched lightly to the dorsal bulbar conjunctiva. The small amount of fluorescein should distribute uniformly on the cornea by either diffusion or blinking. Flushing is not usually necessary with the strips if applied properly. Nonetheless, if the strip touches the cornea, it becomes necessary for the cornea to be flushed with water before examination. Better results are obtained with the fluorescein-impregnated strip when examination is by slit lamp microscopy.

Fluorescein staining has two valuable applications in a routine eye irritation test. It can be used for screening eyes prior to the study to ensure that healthy eyes are being used. The other application is for the determination of total recovery from grossly observed damage on the cornea. Slight epithelial effects still can be detected by fluorescein even though they are not visible during gross observation. Even though most of these subtle effects on the cornea will disappear in a relatively short period of time, prolonged effects detected by fluorescein staining, but not by gross examination, should raise a concern over the healing process. However, when no gross lesions are detected at any time during a study (except for a few incidences of minor fluorescein staining on the cornea) one should not be overly concerned. If there are any effects on the cornea, they must be extremely minimal ones on the superficial epithelium for eye irritation to rate as nonirritating or inconsequential. If the staining is not an artifact, the minimal ocular effects detected under such circumstances should be readily reversible.

Although fluorescein staining can detect very subtle corneal epithelial changes, one can easily be misled by some very noticeable background staining. In addition, artifacts are quite common. For example, the apparent staining of the cornea can result from incomplete flushing of excessive fluorescein with water or even from reflected light. A strong jet of water during irrigation can cause mild damage to the cornea. Damage also can occur if the eye is not handled properly during gross examination. These changes are not related to the test compound but may be detected with fluorescein staining. Sometimes one may see haziness on the cornea after fluorescein staining even though a clear cornea is seen prior to fluorescein staining. Whether the hazy appearance of the cornea is a reflection of mild change or artifact depends on several factors. If the hazy appearance is also visible under a cobalt filter and is preceded by grossly visible lesions, it generally is considered to be a residual effect of mild severity that will disappear within a short time. However, if the hazy appearance is seen intermittently or is not preceded by ocular effects, it is likely an artifact. Proper training and experience are necessary to recognize artifacts and to obtain reliable, reproducible, and consistent results from fluorescein staining. In general, it is not necessary to stain lesions that are obvious and grossly evident. It is when lesions would otherwise go undetected by gross examination that fluorescein staining is of value.

Slit Lamp Microscopy

The slit lamp biomicroscope is an important instrument for studying ocular tissues, especially the cornea. As its name suggests, a slit lamp consists of a microscope that views optical sections of different layers of the cornea made by an intense light beam acting as a surgical knife or microtome, cutting through different layers of the eye. Many lesions that would remain undetected by gross examination can be observed with the slit lamp biomicroscope. Using recent models of slit lamp microscopes, one can observe not only the different layers of the cornea but, also, other transparent parts of the eye such as the aqueous humor, lens, and vitreous body.

The slit lamp biomicroscope consists of an illuminating light source and a microscope. Both components

are movable and adjustable, allowing the eye to be illuminated and observed from different angles and with different width and height adjustments of the slit light beam. An area of the cornea can simultaneously be illuminated and magnified by aligning the incidence of the light beam and the focus of the microscope. The light beam also can be directed at the area from different angles, providing several views of the same area.

Two types of slit images are used for illumination: parallelepiped and optical section (239). For the parallelepiped slit image, a rectangular light beam (approximately 1–2 mm wide and 5–10 mm high) is projected onto the cornea. The shape of the illuminated area is similar to a parallelepiped prism where the outer

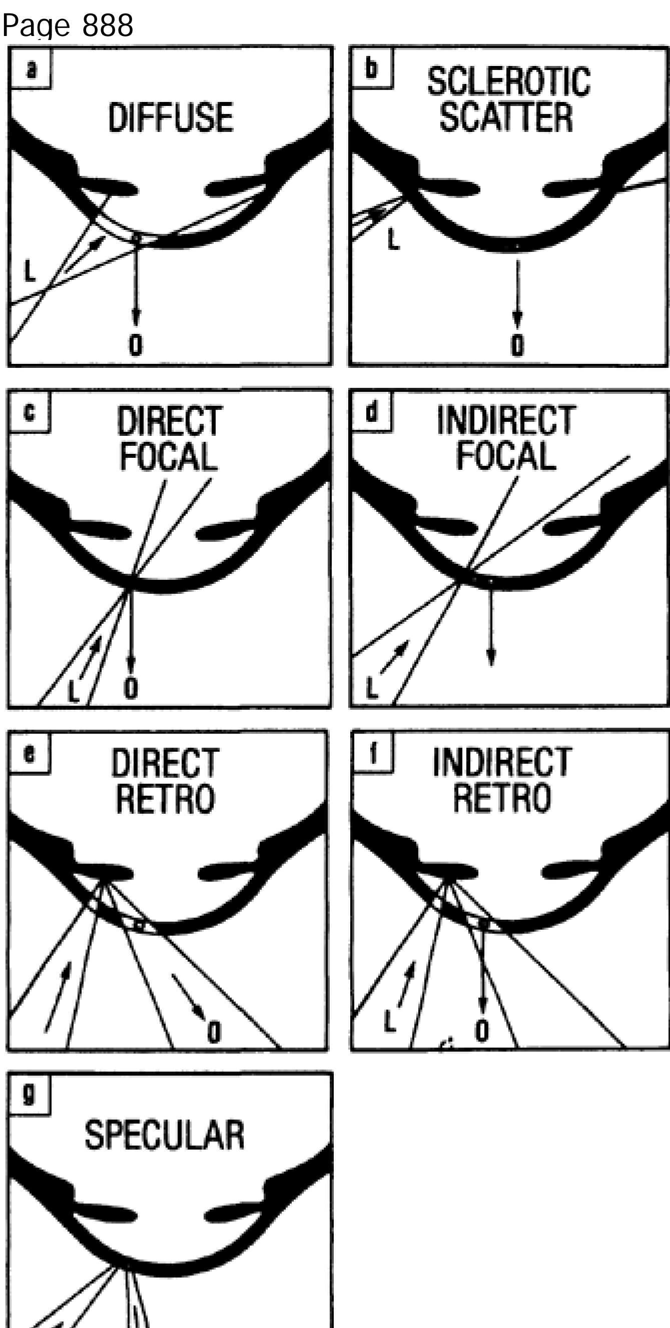

FIG. 18.6. Seven basic methods of illumination in slit lamp microscopy: (a) diffuse; (b) sclerotic scatter; (c) direct focal; (d) indirect focal; (e) direct retroillumination; (f) indirect retroillumination; (g) specular reflection. O=observer; L=illuminator light. Modified from Reference 239, with permission.

and inner surfaces are bent because of the shape of the cornea. For the optical section slit image, the width (20 μm) of the light beam is narrowed to its minimum and is projected onto the cornea, providing a sagittal view that is similar to a thin histological section.

There are several basic illumination techniques (Figure 18.6): diffuse illumination, sclerotic scatter illumination, direct and indirect focal illumination, direct and indirect retroillumination, and specular reflection (247, 346).

Diffuse Illumination

In diffuse illumination, a slightly out-of-focus wide beam is used to scan and localize any gross lesions of a large area of the eye. Usually the first step in examining the eye under a microscope is observing gross lesions and their extent of change. This technique is similar to observing the eye with a hand light, except that the observation is made under a microscope (Figure 18.6a).

Sclerotic Scatter Illumination

In sclerotic scatter illumination (Figure 18.6b), a narrow light beam is directed at the temporal limbus, and the microscope is focused centrally on the area of the cornea to be examined. The light reflected from the sclera will transmit within the cornea by total reflection. Under normal conditions nothing will be seen, but if even minor changes are present the reflected light will be obstructed and the damaged area (e.g., mild corneal edema) will be illuminated. This technique is useful for detecting minimal changes in the cornea.

Direct Focal Illumination

In direct focal illumination, the light beam and the microscope are focused sharply at the same point of interest in the same plane (Figure 18.6c). If a rectangular slit image is used for illumination and focused on the cornea, three general areas are seen when the parallelepiped is formed on the cornea: the epithelium (the anterior bright line), the stroma (the central clear marble-like area), and the endothelium (the posterior thin, bright line). If an optical section slit image is used for illumination, the corneal layers seen from anterior to posterior are a thin, bridge layer, a thin dark layer, a granular layer, and another thin bright layer. These correspond to the tear film, the epithelium, the stroma, and the endothelium, respectively. Altering the angle of incidence of the light beam decreases or increases the reflection. This allows for the detection of depth of the lesion. Opacities on the different layers can be detected easily as obstructions of the incident light beam.

Indirect Focal Illumination

Indirect focal illumination (Figure 18.6d) is accomplished by a narrow beam of light directed at an opaque area of the cornea. For example, changes in blood vessels at the cornea adjacent to the opaque area are illuminated and can be detected by focusing the microscope at these areas.

Direct and Indirect Retroillumination

In direct (Figure 18.6e) and indirect (Figure 18.6f) retroillumination, the light beam is directed at tissues behind the cornea, e.g., the iris or the fundus. The reflected light illuminates the area of interest of the corneal tissue and can be focused under the microscope. The microscope can be located directly on the path of the reflected light (direct retroillumination), thus permitting subtle changes to be observed against a con

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_888.html[2010/10/28 18:48:55]

trasting background. Any optical obstruction by lesions such as scars, pigment, or vessels located along the reflection light path will appear as darker areas on a brighter background. Lesions such as corneal edema and precipitates that can scatter the reflection light will show up as a brighter area against a darker background. When the microscope is located off the reflection light path (indirect retroillumination), the corneal structure is observed against a dark background such as the pupil or iris. Indirect retroillumination is better for observing opaque structures, whereas direct illumination often is used to detect corneal edema and precipitates.

Specular Reflection Illumination

Specular reflection (Fig. 18.6g) is most useful in studying the endothelium and precorneal tear film. This technique makes use of the difference in refractive properties between the corneal surface and the adjacent medium of the posterior and anterior surfaces of the cornea. The microscope is focused on the cornea adjacent to the path of the incident slit light beam. By alternating the angle of incidence, a point can be reached such that a total reflection is obtained on the junction between the aqueous medium and the most posterior corneal surface, thus illuminating endothelial cell patterns and the Descemet's membrane. Similar techniques can be performed on the anterior corneal surface to visualize precorneal tear film.

Scoring System for Slit Lamp Examinations

By using slit lamp microscopic techniques, many subtle changes can be observed that would not otherwise be evident from the Draize test. A different scoring system must be developed to reflect such subtle changes. Baldwin et al. (8) proposed a scoring system for the cornea, anterior chamber, iris, and lens. Subsequently, NAS (267) developed a scoring system for slit lamp examinations that is similar to the Draize system in placing emphasis on the cornea, iris, and conjunctiva. Basically, in the NAS system, the intensity and the area involved are the two main criteria for scoring. Using this scoring system, the investigator must have a good understanding of the physiology of the normal eye. Like the Draize score, the NAS system is based on corneal effects; total maximal corneal score is 20 as compared with 11 and 15 for iridic and conjunctival scores, respectively. A detailed scoring scale and criteria are listed in Table 18.10.

Corneal Pachymetry

Because corneal transparency is so important to vision (over 70% of the Draize score is derived from assessment of damage to the cornea) objective procedures to quantify corneal effects are an important element in eliminating intra- and inter-laboratory variability in assessing the effects of ocular exposure to exogenous agents. Corneal transparency, thickness, and hydration are related in a linear fashion (179). Therefore, changes in corneal thickness can be used as an indicator of irritant affects, which may impair normal corneal hydration and transparency. When corneal thickness is measured appropriately, it can be used to objectively quantify swelling of the corneal stroma, which is a typical early irritant response. The measurement of corneal thickness is called pachymetry, which comes from the Greek words *pachys* (thick) and *metry* (the process of measuring).

One method for measuring corneal thickness uses an optical pachometer attached to a slit lamp microscope. Optical pachometers provide essentially indirect measurements of apparent corneal thickness based on displacement of light beams bouncing off the endothelial and epithelial surfaces of the cornea. The principles of this method have been described previously (73).

Various investigators (66, 81, 207, 251), using a variety of substances from different chemical classes, have reported that corneal thickness is significantly correlated with the Draize corneal score. Moreover, Kennah et al. (207) clearly demonstrated a substantial reduction in the coefficient of variation when comparing corneal swelling to Draize scores for various surfactants, alcohols, ketones, acetates, and aromatic chemicals.

Recent advances in human ophthalmological procedures to correct visual acuity (i.e., radial keratotomy, eximer-laser photorefractive keratectomy) have resulted in the development of improved devices to measure corneal thickness which guide the practitioner both before and after the procedure, and provide a means to measure the effectiveness of the treatment. The ultrasonic pachymeter is such a device (35, 264, 352, 363) and it may have useful application to in vivo ocular irritation testing.

The ultrasonic pachymeter is an instrument with a hand-held probe that emits an ultrasonic signal of fixed velocity. The probe is placed directly on the anterior surface of the cornea and after signal emission, a sensor directly measures the time difference between echoes of signal pulses reflected from the front and back surfaces of the cornea. This time differential is directly proportional to the thickness of the cornea via a function that is computed as the product of the time delay between the two echoes (in seconds) and the velocity of sound in the corneal tissue (in meters/second). The optical pachometer

indirectly equates displacement of incident light to corneal thickness, and the ultrasonic pachymeter provides a direct measurement.

Comparative evaluations of the sources of variability in human corneal thickness measurements using optical and ultrasonic (162, 182, 224, 289, 315) or between various ultrasonic devices (377) have been reported and discussed.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_889.html[2010/10/28 18:48:56]

Salz et al. (315) found that sources of variation include intra- and inter-session variation, inter-observer variation, left/right eye variation, and variations due to alternate settings of ultrasonic sound frequency. They reported that the optical pachymeter had significant inter-session variation, significant inter-observer variation, and significant differences in left and right eye thickness measurements, while the ultrasonic pachymeter demonstrated high reproducibility, no inter-observer variation, and no left/right eye variation.

The ultrasonic pachymeter has many desirable features such as a relatively low cost, portability, ease of operation, and use requiring less operator skill and training than the optical pachometer. When used in humans, a topical anesthetic is employed, because the tip of the measuring probe must be in contact with the corneal surface before a measurement can be taken. However, it has been reported that because of a lower corneal sensitivity in rabbits (75, 243) an anesthetic is not necessary before taking corneal thickness measurements.

Because the velocity of sound can vary in different tissue, accurate readings for absolute corneal thickness require that the ultrasonic sound frequency of the instrument be matched to the tissue of interest. The velocity of sound in human corneal tissue has been variously reported as 1502 m/s (265), 1586 m/s (307), and 1610 m/s (272). Salz et al. (315), in their human cornea comparison of optical to ultrasonic pachymetry, used an approximate velocity of 1590 m/s and found good agreement between the two measurement methods. The velocity of sound in cat (224), rabbit (74), and bovine (283) corneal tissue was found to be 1590 m/s, 1580 m/s, and 1550 m/s, respectively. Empirical methods to determine the velocity of sound in corneal tissue have been described (224, 283).

The utility of ultrasonic pachymetry in measuring corneal thickness changes in rabbits (230, 263) and rats (230), after treatment with ocular irritants, has been reported. The findings, albeit limited to a small number of chemicals, support the continued pursuit of this method as a relatively inexpensive, objective way to measure corneal irritant effects.

Confocal Microscopy

The confocal microscope is another instrument that can be used to measure corneal thickness, as well as provide high-resolution microscopic images to study the cellular structure within corneal tissue. The first confocal microscope was described by Minsky (244, 245) in a 1957 patent application. This device had a pinhole and a lens (objective and condenser) located on either side of the specimen to be viewed. The intent of the design was to eliminate any scattered light that might pass through the specimen, thus concentrating all light at a point source that was the focal point. The term confocal originated because the objective lens and the condenser lens were focused on the same specimen point. The image seen in a conventional light microscope includes the in-focus image in the *x, y* (horizontal) plane and the out-of-focus image above and below in the *z* (vertical) plane, the confocal microscope only focuses in the *x, y* plane. Indeed, de-focusing a confocal microscope makes the image totally disappear rather than appear blurred. Reducing the out of focus signal above and below the focal plane results in enhanced resolution. In contrast to the light microscope, which is focused by moving the objective, moving the specimen focuses the confocal microscope. This feature provides an optical sectioning capability that allows thick tissue sections such as the cornea to be viewed in vivo or in vitro in both the horizontal and vertical planes. Because of the point source light illumination, however, scanning the specimen is necessary to produce a full field of view with the confocal microscope. Scanned images can be viewed through a video monitor on a real-time basis, imported into a video cassette recorder, or stored as a digital image (291) for later viewing and analysis. For a complete review of the principles and applications of the scanning confocal microscope see Petroll et al. (292).

By successively scanning the cornea and capturing a series of optical sections it is possible to reconstruct a three-dimensional image of the tissue. Methods for three-dimensional imaging of rabbit cornea in vitro (196, 233, 293) and in vivo (129, 196, 250, 290), have been described. These methods have been used to characterize the changes in area and depth of corneal injury of surfactant-induced eye irritation in the rabbit (234) and to examine the relationship between area and depth of injury to corneal cell death (195).

Mauer et al. (234) used in vivo scanning confocal microscopy to qualitatively and quantitatively characterize the initial changes occurring after treatment with surfactants known to produce slight, mild, moderate, and severe corneal irritation. Materials were applied directly to the corneas of 6 rabbits per group at a dose of 10 μl with macroscopic (Draize) and microscopic evaluations beginning at 3 h after treatment and continuing periodically through day 35. Microscopic three-dimensional images were obtained from the surface epithelium to the endothelium and measurements made for surface epithelial cell size, epithelial layer thickness, total corneal thickness, and depth of keratocyte necrosis. The

average Draize scores at 3 h for the slight, mild, moderate, and severe irritants were 6.0, 39.3, 48.5, and 68.7, respectively. Confocal microscopic images at 3 h showed that corneal injury with the slight irritant was limited to the epithelium (cell size and thickness 59 and 82% of control). The mild irritant had removed the surface

epithelium, increased the corneal thickness to 158% of control, and produced keratocyte necrosis to a depth of 4.3 μm. With the moderate irritant the epithelium was markedly attenuated, the corneal thickness was 156% of controls, and keratocyte necrosis extended to a depth of 19 μm. For the severe irritant, the epithelium was significantly thinned, the corneal thickness was 166% of controls and keratocyte necrosis extended to a depth of 391 μm.

The use of confocal microscopy in studies designed to provide semi-quantitative information on the nature and depth of injury to the cornea after chemical treatment has the potential to serve as an important link to the development of physiologically relevant and mechanistically based in vitro alternatives to the Draize eye test (234).

LOCAL ANESTHETICS

For humane and scientific reasons, guidelines such as those established by the IRLG and the OECD provide options for using local anesthetics in eye irritation studies. Tetracaine, lidocaine, butacaine, proparacaine, and cocaine have all been examined for their usefulness in eye irritation studies, with the results being mixed and inconclusive. Most of these anesthetics can alleviate pain, but they also can inhibit or reduce the somatosensory area of the eye and the blinking reflex. Tear flow is reduced, causing the test substance to be trapped and remain undiluted on the cornea instead of being blinked from the eye or diluted and flushed away by the tear flow. Especially among higher primates, the blinking and tearing reflexes are important defense mechanisms against accidental exposure to any substance (181). Some local anesthetics can cause delay in corneal epithelial regeneration and loss of surface cells from the cornea (174). Some such as procaine, lignocaine, piperocaine, amylocaine, amethocaine, and cinchocaine are cytotoxic to cultured human cells, including conjunctival cells (90). However, at least one study has shown that a 0.5% tetracaine solution apparently had no effect on corneal healing (294). Further research is needed to reveal the interaction of local anesthetics and chemically induced ocular effects. Local anesthesia is sometimes useful to induce akinesia of the eyelid during eye examination.

Local anesthetics are desirable to alleviate pain, but one must be aware of the potential physical, chemical, physiological, and toxicological incompatibilities before considering their use.

HISTOLOGICAL APPROACHES

Histological examination of the eyes has been included routinely in subchronic and chronic toxicity studies, but because it is time-consuming and costly, it is performed only occasionally in eye irritation studies. Results may be no more informative than those from observations and measurements by other techniques. However, histological examination of ocular tissue can reveal the type of damage, tissues involved, and certain subtle changes in ocular tissue.

Both electron and light microscopic examinations have been used to evaluate local ocular injury (171, 197, 198, 308, 350, 354, 367, see Henkes and Canta [1973] (180) for review). Although such methods sometimes can reveal morphological changes of different parts of the cornea, conjunctiva, lens, and retina, as well as visual nerve degeneration, shortcomings are not uncommon. Among the problems are sectioning the precise lesion, problems in slide preparation, and subjective interpretation of observations. Another problem is that histological examination generally is made on dehydrated tissue (65), which makes some lesions, such as corneal edema, difficult to detect. However, histological examination of ocular tissues in local eye irritation studies has been considered an objective method because of its high sensitivity in detecting very mild ocular effects (181).

ALTERNATIVE METHODS FOR THE ASSESSMENT OF EYE IRRITATION

Humane and scientific concerns regarding the use of animals in toxicology have prompted development of many in vitro methods as potential alternatives for animal tests. One area that has seen considerable activity is the development of new methods for use as alternatives in the assessment of eye irritation. The use of firstgeneration screening tests (26, 30, 42, 46, 106–108, 127, 184, 205, 206, 248, 258, 261, 300, 317, 331, 344, 364) has laid the foundation for continuing research with more sophisticated methods, many of which use human ocular cells as their basis (31, 32, 130, 149, 150, 156, 191, 199, 209, 219, 222, 268, 295, 310, 312, 336, 348, 356, 357, 368, 381). Although the majority of procedures that use human cells are employed in studies of ocular disease, some are finding applications in eye irritation hazard assessment. For a review of this research, see Kruszewski (214).

Organizations such as the Johns Hopkins Center for Alternatives to Animal Testing, the European Center for the Validation of Alternative Methods (ECVAM), the Fund for Replacement of Animals in Medical Research in England (FRAME), and the U.S. Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) have been active in promoting development of such alternative methods for animal testing.

Research on alternatives for assessing ocular irritancy has focused on development and validation of a number of in vitro tests. These methods can be grouped into functional categories according to test endpoint (146), which includes morphology, cell toxicity, cell and tissue physiology, inflammation/immunity, recovery/repair, and others (e.g., protein denaturation, computer-based structure-activity relationships, *Tetrahymena thermophila* motility, etc.). Most of these endpoints are indicators of cellular membrane integrity and/or cytotoxicity. Detailed reviews of these methods are beyond the scope of this chapter but are available (60, 306).

For the following discussion, the above classes of methods are grouped into four broad categories: ex vivo methods, cell-based assays, inflammation/immunity, and other methods.

Ex Vivo Methods

Several methods have been investigated which are based on morphological alterations to either whole eye tissue or isolated corneas. The enucleated perfused rabbit eye, enucleated chicken eye test, or isolated bovine or porcine cornea methods (17, 67, 117, 186–190, 237, 259, 260, 296, 382), are based on visible alterations of tissues as the endpoints. The effect of a chemical on the tissue is measured by corneal opacity, corneal thickness, or corneal fluorescein retention. These methods are complex, lack good correlation with in vivo results, and still require killing animals; however, eye tissue can be obtained from slaughterhouses, from animals processed for food (299).

The bovine corneal opacity and permeability (BCOP) test, developed by Gautheron et al. (154), is a more recent modification of the original isolated bovine procedure (260). In the bovine corneal opacity method, freshly excised bovine eyes obtained from a slaughterhouse are used. The test material is placed on the cornea for 30 sec, after which corneal lesions are scored. In the BCOP test two endpoints are determined:

(1) opacity, which is measured by change in light transmission passing through the cornea; and

(2) permeability to fluorescein dye, a measure of barrier function. This method is an improvement over the earlier procedures and has been used with a variety of chemicals and consumer product formulations to produce results that compare favorably when extrapolated to corneal effects in the rabbit eye test (69, 83, 155, 159, 302, 335, 358, 362). An expert working group has reported on the state of the art of the BCOP test (335).

Cell-Based Assays

Cytotoxicity Methods

These methods are based on cytotoxicity. Frazier et al. (146) grouped these methods under three categories according to the indicator of cytotoxicity. These are adhesion/cell proliferation (cellular growth), membrane integrity, and cell metabolism. Chemically induced cytotoxicity will interfere with cell growth and proliferation, which can be quantified by counting the number of viable cells, by assessing the adhesion or colony-forming ability of the cells, or by measuring the amount of macromolecules such as DNA, RNA, or protein. The endpoints investigated under the category of adhesion/cell proliferation include growth inhibition (BHK cells), colony-formation efficiency (BHK cells and SIRC cells), cell detachment (BHK cells), total protein (Balb/c 3T3 cells, BCL DI cells) (20, 270, 305, 330, 342, 370), or binding of certain dyes (the FRAME Kenacid Blue Test in 3T3-L1 cells) (79, 211), and a plant cell-derived pollen tube test (201). The cell lines generally are well characterized; some are corneal cell lines. Several of these procedures are discussed below.

Adhesion and proliferation. The *colony-formation efficacy test* involves establishing good viability and growth of cells, exposing BHK or SIRC cells to a test substance for a predetermined period of time (e.g., 1 h), washing the exposed cells, and reincubating for the time needed for cellular proliferation. After reincubation, the effect of the test substance on the ability of the cells to adhere and/or form colonies is determined by fixing and staining the cells. The number of functionally viable cells (i.e., with the ability to adhere and proliferate) in the chemically exposed group is compared with an unexposed control group. Ranking of ocular irritancy often is based on the IC50, the concentration of chemical at which functionally viable cells are only 50% of the unexposed control group. The correlation in ranking of irritancy of various surfactant and cosmetic formulations has been reported between this test and the in vivo rabbit eye irritancy test (39, 40, 158, 161, 271, 325).

The FRAME *Kenacid Blue (KB) Test* is based on the principle of a direct correlation between cell number, total protein, and the binding of certain dyes such as Kenacid Blue (Coomassie brilliant blue) (18, 79, 211, 330). Proliferating 3T3-L1 cells are exposed to a low concentration of chemical for 72 h (at least two cell cycles). Then exposed and unexposed cells are removed from the growth medium and dried in the air for 72 h, and the amount of protein in the cells is measured by the KB dye-binding assay. The method involves treating cells with a fixative (glacial acetic acid/ethanol/distilled water 1:50:49), then

staining with freshly prepared Kenacid Blue R solution, washing

the cells, and releasing the dye into a desorbing solution (approximately 10% potassium acetate in water/ethanol solution). The absorbency of the dye is measured at 570 nm against a cell-free desorbing solution. Absorbency correlates linearly with the amount of pro tein and the number of cells. This method has been used in projects sponsored by Cosmetic Toiletries and Fragrance Association (CTFA) and the Commission of European Communities (CEC). Correlation between in vitro ranking and in vivo Draize test ranking of salts, chlorides, and certain cosmetic formulations has been reported (9, 18, 158, 161).

The *pollen tube test* employs plant cells (201). It is essentially a cell proliferation assay. The endpoint is the amount of tube wall biomass *(Nicotiana sylvestris)* produced (through germination and growth) in vitro. After exposure to the test substance, the amount of biomass is determined by measuring optical density at 500 nm. Results are expressed as the concentration of test substance, which causes a 50% growth inhibition. Correlations between in vitro ranking and the in vivo Draize test ranking for certain cosmetic formulations and surfactant chemicals have been reported (158, 159, 161, 213).

Membrane integrity. Damaged membranes can cause a host of toxic responses including cell lysis and cell death, leakage of enzymes such as LDH, loss of certain cofactors such as Ca^{2+}, K^+, and NADPH, and alterations in substances being actively or passively transported across the membrane. Endpoints include dual-dye/fluorescent dye staining (LS cells, thymocytes), chromium isotope (^{51}Cr) release (RCE, SIRC, P815, YAC-1 cells), cell viability (L929 cells), hemolysis (bovine red blood cells), and transepithelial barrier integrity (MDCK or HCE-T cells) (100, 199, 206, 261, 317, 324, 325, 368). Alteration in the ability of substances being actively or passively transported across the membrane barrier (release or uptake) indicates membrane toxicity.

The *chromium isotope* (^{51}Cr) *release assay* has been used in several studies (39, 40, 161, 324, 325). In the presence of excess Cr in the growth medium, normal cells take up Cr, which binds to intracellular macromolecules. After changing to isotope-free growth medium, Cr-labeled macromolecules are transported actively across the membrane of normal cells into the extracellular medium at a slow rate. In cells exposed to cytotoxic agents (and if membrane integrity is altered), Cr-labeled macromolecules will diffuse passively across the membrane into the extracellular medium at a much higher rate. The increased release rate (difference between release rate of normal and chemically treated cells) of Cr-labeled macromolecules indicates membrane toxicity. Correlations have been reported between in vitro ranking and in vivo Draize test ranking for several surfactant (39, 40, 146) and certain cosmetic formulations (161).

The *Neutral Red Release (NRR) Test* also measures the cellular membrane integrity (303). It is based on the principle that living cells accumulate the dye (2-amino3-methyl-7-dimethyl aminophenazonium chloride) in lysosomes by an active metabolic process. If the membranes are damaged, the accumulated intracellular neutral red dye will be released into the extracellular medium. In this method, confluent 3T3-L1 cells are preloaded with neutral red dye, washed, replaced with fresh growth medium, and exposed to a high dose of the toxic substance for 1 min. The test substance is removed; the exposed and unexposed cells are washed and fixed with PBS, destained, and fixed with a glacial acetic acid/ethanol/distilled water (1:50:49) solution. The absorbance of the destained solution is measured at 540 nm against a cell-free destain reference solution. Results are expressed as NRR_{20}, NRR_{50}, or NRR_{80} (i.e., concentration of test substance, that causes 20%, 50%, or, 80% of the preloaded dye to be released). Correlations between in vitro ranking of certain classes of chemicals and certain cosmetic formulations and the in vivo Draize test ranking have been reported (158, 159, 161, 303).

A neutral red release method to test solid materials has been reported (365). The *agarose diffusion assay* uses a confluent monolayer of culture cells preloaded with the neutral red dye. The cells are overlaid with agarose. Test material placed on the agarose can diffuse through the agarose to the cells. Any damage caused by the test material to the cellular membrane will release the dye into the agarose. Scoring is based on the presence of a dye zone. (The size of the zone may or may not correlate with the degree of cytotoxicity). Correlations between in vitro ranking of certain cosmetic formulations or ingredients and the in vivo Draize test ranking have been reported (158, 159, 161, 365).

Membrane tight junctions between epithelial cells form a barrier for water movement across the corneal epithelium. When this barrier is damaged, water moves into the cornea, resulting in edema. The FRAME *fluorescein leakage (FL) test* is based on the principle that a damaged epithelial cell barrier will be more permeable to the nontoxic dye fluorescein than an undamaged barrier (327, 351). Canine kidney cells (MDCK cells, an epithelial cell line) are grown to confluence in tissue culture inserts. The confluent cell layer is washed, exposed to 100 μl of test substance for 1 min, and then the test substance is removed by washing with distilled water. The washed cells are placed in clean wells containing PBS medium.

Fluorescein (500 μl) in PBS (0.02%) is added to each cell insert. Cells are incubated for 1 h, and the leakage of fluorescein from the cells into the well is measured by absorbence at 492 nm. Results are expressed as FL20 and FL50 (concentration of test substance, which causes 20% and 50% of maximum leakage from inserts containing no cells) (327). A modification

of this method expresses results as FL10 and FL20 (concentration of test substance which causes 10% and 20% of maximum leakage) and measures recovery at 4, 24, 48, and 72 h after treatment (84). Comparison of in vitro response to the in vivo irritancy classification of various chemicals has been reported (84, 159, 327).

The *transepithelial permeability (TEP) and the transepithelial resistance (TER) assays* are barrier function tests based in the human corneal epithelial cell line, 10.014 pRSV-T (HCE-T cells) (199, 368, 369). This cell line has been used to develop a three-dimensional in vitro model of the human corneal epithelium (HCE-T model). HCE-T cells form a stratified culture when grown in serum-free medium on a collagen membrane at the air-liquid interface. Because it is a multilayer model, barrier function is a well-developed property in the HCE-T model which can be quantitatively measured by its retention of fluorescein (TEP assay) and the maintenance of high electrical resistance (TER assay). For these procedures, HCE-T cells are grown in 24 well plates to confluence (3–4 days) in low-calcium (0.15 mM CaCl2) keratinocyte growth medium (KGM), then airlifted in high-calcium (1.15 mM CaCl2) KGM until Day 7, when they are treated. Treatment consists of 100 μl of test substance in KGM for 5 min and then the test substance is removed by washing three times with D-PBS. The washed cells are placed in clean 24-well plates containing high-calcium KGM.

For the *TEP assay,* fluorescein (200 μl) in high-calcium KGM (0.02%) is added to each well. Cells are incubated for 30 min, and the leakage of fluorescein into the well is measured by absorbance at 490 nm. Results are expressed as FR85 (concentration of test substance, which causes fluorescein retention to decrease to 85% of control) (215).

For the TER assay, resistance measurements are taken using an epithelial voltohmeter, EVOM (World Precision Instruments) after treatment of the cells as per the TEP assay. The instrument probe is inserted into the culture insert and a reading is recorded after a 20-sec instrument stabilization period. Resistance is calculated based on an area of 0.64 cm2, which is the area of the culture insert. Results are expressed as R50 (concentration of test substance that causes the electrical resistance to decrease to 50% of control) (215). Correlations between these tests and the in vivo Draize test for various chemicals and certain cosmetic formulations have been reported (215).

Cellular metabolism. Even in viable cells, toxic substances can cause subtle metabolic changes in such cellular endpoints as plasminogen activator activity, ATP production, lysosomal activity, basic metabolic rate (measured as changes in acidic by-products), and amount of light produced by luminescent bacteria (43, 44, 64, 72, 204, 303, 328, 331). These changes can be quantified by techniques ranging from simple neutral red dye or 3-(4,5-dimethylthiazol-2-yl)-2,5-biphenyltetrazolium bromide (tetrazolium MTT) uptake into lysosomes (41, 43, 44, 200), silicon microphysiometer sensor for detecting changes in pH caused by acidic metabolic by-products (177), or output of light by luminescent bacteria (64).

The *neutral red uptake (NRU)* test is based on the principle that living cells absorb the dye and accumulate it in the lysosomes. Cytotoxic agents can disrupt the metabolic energy required for dye accumulation and thus decrease dye uptake. Such a change can be quantified by a simple method. A culture cell line (BALB/c3T3 mouse fibroblasts) is grown and exposed to various concentrations of the test substance for 24 h. After exposure, the medium is removed, and cells are washed with fresh growth medium. The neutral red dye is added and the cells are incubated for 3 h at 37°C. The medium is removed and the cells are washed and fixed with a formaldehyde-based fixative. The dye is extracted into an acetic acid/ethanol solution and the concentration of dye is measured spectrophotometrically at 540 nm. Results are expressed as either NR50, the concentration of test substance, that inhibits dye update by 50% compared to untreated cells, or HTD, the highest tolerated dose (41, 43, 44, 200). Correlations between in vitro ranking of several surfactant and certain cosmetic formulations and the in vivo Draize test ranking have been reported (39, 40, 120, 158, 159, 161).

The *MTT assay* measures the metabolic activity of mitochondria. It is based on the principle that only cells with respiring mitochondria can reduce significant amounts of MTT, a soluble, pale yellow dye, to the insoluble dark blue metabolite, MTT formazan (41). After incubating metabolically active cells (BALB/c3T3 mouse fibroblasts) with various concentrations of the test material for 24 h, cells are incubated with MTT for 3 h at 37°C in 96-well tissue culture plates. MTT formazan is solubilized in isopropanol and quantified by colorimetry. The concentration of MTT formazan as measured at 550 nm is related to the number of viable cells. Results are expressed as percentage difference from untreated cells. Correlations between in vitro ranking of certain cosmetic formulations and the in vivo Draize test ranking have been reported (158, 159, 161). MTT measurement in human epidermal keratinocytes after treatment with various chemicals, or personal care and cosmetic products has also been correlated to Draize test results (3, 128, 159, 301, 302).

The *microphysiometer* measures changes in the cellular metabolic rate. The changes are detected as small changes in the physical properties of the growth medium as a result of accumulation of acidic metabolic by-products (57, 177, 287). The results are expressed as concentration of test material, which causes a 50% drop in metabolic rate. Preliminary results are encouraging but limited to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_894.html[2010/10/28 18:48:59]

acidic metabolic by-products. Correlation between this test and the in vivo Draize test for various surfactants, household cleaning products, and cosmetic formulations has been reported (4, 57, 58, 70, 159).

The *luminescent bacteria test (LBT)* is based on the principle that light emission occurs in certain strains of bacteria during metabolic activity. Thus, the amount of light produced by the bacteria reflects its metabolic rate. Cytotoxic agents which decrease the metabolic rate of the bacteria also will decrease light production. Light output from the luminescent bacteria *Phytobacterium phosphoreum* is measured after incubation of the bacteria with various concentrations of the test material. Results are expressed as the concentration of the test material that causes a 50% reduction in light output. Correlation between this test and the in vivo Draize test for a few chemicals and certain cosmetic and toiletry formulations has been reported (64, 91, 159, 161).

Cellular morphology. The *Balb/c3T3 cell/morphological assay* (43–45, 329) is a simple method that measures morphological changes in cultured cells. In this assay, chemicals are ranked on the basis of the highest tolerated dose (concentration) at which no morphological change associated with exposure to the chemical is observed by phase contrast microscopy.

Other cytotoxicity tests. Cell or tissue physiology also has been used as an endpoint for screening ocular irritants. Examples include electrical conductivity of epidermal tissue slices (284) and inhibition of contraction in rabbit ileum (258). In general, these tests have not been as extensively studied as the other methods because they all require killing animals. Some investigators have reported correlation with in vivo eye irritation tests for a few materials.

Inflammation/Immunity

Because ocular irritation is an inflammation process, inflammation/immunity has been evaluated as an endpoint for alternative irritancy tests (146). These tests include morphological observations of inflammatory/morphological changes in the chorioallantoic membrane (CAM) of developing chick embryos (212, 218, 220, 221, 297), in vitro macrophage dynamics (chemotaxis method using Balb/c3T3 cells and leukocyte chernotactic factors using the bovine corneal cup model) (344), and quantitative measurement of release of inflammation mediators such as histamine (rat peritoneal mast cells and bovine eye cup), serotonin (rat peritoneal mast cells) (76, 193), prostaglandins (rat vaginal tissue) (103, 104), and leukotriene C4 (bovine eye cup) (118).

Chorioallantoic Membrane

In these methods, the endpoints are the subjective evaluation of vascular changes (hemorrhage or obstruction) and necrosis of the CAM, the vascularized, respiratory membrane just underneath the egg shell. This membrane was suggested to be equivalent to the conjunctiva of the eye (220). It enjoys the advantage of a viable membrane with the vasculature needed for an inflammatory response. However, recent studies have shown that responses to irritants in the CAM methods are morphological, rather than inflammatory, alternations. There are three variations of the CAM method: the CAM, the CAM vascular assay (CAMVA), and the hen's egg test-CAM (HET-CAM) method. Using a method similar to Leighton et al. (220) for acids, alkali, and surfactants, Parish (288) reported a correlation between CAM and Draize results. Correlation between this test and the in vivo Draize test for various chemicals, surfactants, household cleaning products, cosmetic formulations, and pesticides has been reported (3–7, 39, 40, 47, 61, 158, 159, 161, 163). However, these methods require living embryos and results in ranking irritants have been mixed due to false positives probably attributable to embryo toxicity rather than local irritancy. The HET-CAM test has also been used in combination with the BCOP test (39, 40, 57, 361, 376). Irritancy is ranked according to the most severe response from the two tests. Correlation between this test and the in vivo Draize test for various surfactants, household cleaning products, and cosmetic formulations has been reported (39, 40, 57). A modification of the HET-CAM test (HET-CAM-TSA), which uses microscopic evaluation and a special test substance applicator, has also been reported (164).

Macrophage Chemotaxis

The underlying principle of this method is that leukocytes migrate to the site of inflammation. Cultured Balb/c3T3 cells are treated with potential irritants for different periods. The treated cells are washed and re-fed with fresh medium. The chemotactic factors in the re-fed medium are detected by placing the medium in the bottom wells of a microchemotaxis chamber, covering the wells with a polycarbonate membrane (5 μm pore size), and adding about 105 mouse peritoneal macrophages in the upper wells. The system is incubated for 4 h at 37°C. After staining, the number of macrophages that migrated through the membrane are counted. This method has not been routinely used and no information is available regarding extensive correlation to the in vivo Draize test.

Other Alternative Methods

Other approaches include the *Tetrahymena* motility assay (332), protein denaturation (168, 169), ocular wound healing test (197, 333), and quantitative structure-activity relationship analysis (119).

Tetrahymena Motility Assay

The motility assay evaluates the effect of the test material on the characteristic swimming pattern of the fresh water protozoa *Tetrahymena thermophila.* Motility is examined under a microscope following exposure to the test material for 2 min at 21°C. Results are expressed as the highest tolerated dose, the concentration or dilution of the test material, that is characterized by 90% normal cell motility (332). Correlations between this test and the in vivo Draize test for various chemicals, household cleaning products, and cosmetic formulations have been reported (3, 39, 40, 158, 159, 161, 332).

Protein Denaturation Test

Protein denaturation is the basis of the commercially available Irritection (Eytex) system. The test is based on the principle that opacity (precipitation of the specially organized protein in the cornea) is the major contribution to ocular irritancy in the Draize test. The degree of opacity and irritancy can be predicted by assessing the degree of aggregation of a synthetic (nonanimal) aqueous protein matrix that mimics the protein matrix of the cornea (168, 169). The Irretection (Eytex) assay tests solutions and insoluble, immiscible, or opaque materials by using a special semi-permeable membrane bullet over the responding protein matrix. Correlation between Eytex results and the in vivo rabbit eye test for various chemicals and cosmetic formulations has been reported (92, 97, 158, 159, 161, 229, 314).

Ocular Wound Healing Test

Although reversibility is a key criterion in the Draize test, only a few in vitro studies have evaluated healing and repair of ocular lesions (197, 333). In such studies cultured rabbit corneal cells are grown to multilayer confluency. A wound is created using a liquid nitrogen chilled probe and the test substance is added to the wounded cells. After 24 h of incubation, the cells are fixed and healing assessed by measuring the size (using computerized planimetry) of the remaining wound area not covered by cells as compared to the initial wound size (333). Although these tests may give information on cell migration and proliferation at the wound, a process needed for initial wound closure, the multilayer cell culture is not the same as an intact corneal epithelium with a basement membrane. This method has not been routinely used and no information is available regarding extensive correlation to the in vivo Draize test.

Quantitative Structure-Activity Relationship (QSAR)

Quantitative structure-activity relationship (QSAR) analysis, widely used to predict various physiological and biochemical activities of novel chemicals, also has been used to predict eye irritancy of structurally related chemicals. Using QSAR, Sugai et al. (345) examined the eye irritancy (opacity and conjunctivitis) of 131 chemically heterogeneous chemicals. The accuracy was 86.3% for classifying irritancy of the chemicals. In another study, overall accuracy of 91% was reported (119). More recent research involving QSAR analysis for eye irritancy has been reported (21, 22, 86, 87). Although this approach may provide useful information on structurally related chemicals, its current utility for formulated products is questionable. The same limitations that impact the use of QSAR for acute toxicity applications are also applicable to acute ophthalmic irritation (See Alternative Methods for LD50 Test, Quantitative Structure-Activity Relationship [QSAR] Analysis).

Evaluation and Validation Programs

Since eye irritation is a process involving multiple mechanisms (347), it is not surprising that development of alternative in vitro tests for eye irritancy is an extremely complex issue. Although the current thrust in method development and validation is encouraging, many issues remain. The Johns Hopkins Center for Alternatives to Animal Testing (CAAT)/European Research Group for Alternatives in Toxicity Testing (ERGATT) Workshop on Validation of Toxicity Testing Procedures recognized the need for mechanistic similarity between an in vitro assay and the in vivo animal model (14). For screening purposes, mechanistic similarity may not be necessary if the empirical correlation/predictability criterion is met. However, mechanistic similarity is generally required if the alternative method is to be a replacement test.

Important issues must be addressed before alternative ocular irritancy test methods can replace current in vivo animal tests. For example, insolubility of certain chemicals remains an issue. Testing extracts may partially resolve this problem. Many in vitro assays are not suitable for testing materials that change the physiological pH of the test system. A major problem is the lack of correlation between in vitro and in vivo data. Correlation appears to be good only within certain classes of chemicals. Predictability is further confounded when testing complex mixtures and total product formulations. A battery of assays could possibly minimize these issues. Most in vitro techniques do not establish reversibility, which is extremely important in classification of eye irritants (123, 202). These and other issues are apparent when reviewing the results of recent multi-laboratory evaluation/validation studies with alternative methods for ocular irritancy.

In the United States, a number of programs have been launched to evaluate alternative tests. Two such programs organized by the Soap and Detergent Associ

ation (SDA) and the Cosmetic Toiletry and Fragrance Association (CTFA) have reported on their findings (3, 39, 40, 158, 159, 161). The CTFA program was designed to evaluate the performance (correlation with Draize test results) of a set of in vitro tests on materials used in the cosmetic and toiletry industry.

In Phase I of the CTFA program, 25 alternative tests (representing 12 different endpoints) were used to test 10 different hydroalcoholic cosmetic and toiletry products (161). Results indicated that 6 of the 25 assays demonstrated the least disagreement with the Draize test for these products. Predictability generally was better for materials with low, rather than high, irritancy potential.

In CTFA Phase II, 30 alternative tests (representing 14 different endpoints) were used to test 18 different oil/water emulsion cosmetic and toiletry products (158). Results indicated that 16 of the 30 assays demonstrated the least disagreement with the Draize test for these products. As in Phase 1, predictability generally was better for materials with low, rather than high, irritancy potential.

In CTFA Phase III, 23 alternative tests (representing 41 different endpoints) were used to test 25 different surfactant-containing cosmetic and toiletry products (159). Results indicated that no single in vitro endpoint exhibited relative superiority with regard to prediction of the Draize test results for these products. Overall, predictability of the in vitro assays was better in Phase I (hydroalcoholic products) than in Phase II (oil/water emulsion products) or in Phase III (surfactant-containing products).

In Phase I of the SDA program, 14 alternative tests (mostly cytotoxicity) were used to test 8 household cleaning product ingredients or formulations (39). Six assays were selected as having the best agreement with Draize test results.

In SDA Phase II, 9 in vitro assays were used to test 23 household cleaning product ingredients or formulations, 8 of which were tested in Phase I (40). Phases I and II results indicated that the combination of product alkalinity and in vitro data provide useful information on the ocular irritancy potential of alkaline and acidic household cleaning product ingredients or formulations.

In SDA Phase III, 9 in vitro assays were used to test 22 household cleaning product ingredients or formulations (3). When only nonalkaline materials were considered, the correlation coefficients of the 9 methods were not significantly different from one another, although none of the tests could accurately predict the relative irritation potential of the irritant materials. Various evaluation and validation programs also have been conducted in Europe and Japan, all with mixed results (17, 48, 155, 282, 341).

A formal validation study on the HET-CAM and NRU cytotoxicity test was conducted in Germany to determine whether these tests were capable of identifying chemicals that are severe eye irritants (341). The study was carried out in 10 laboratories with 200 test materials under blind conditions. Results suggested that this combination of methods was adequate to identify severe irritants.

An evaluation of the BCOP test was sponsored by the European Directorate General (DGXI) (155). The study included 12 laboratories testing 52 chemicals with a wide range of structure, physical form, and irritancy potential. Results indicated that the BCOP correctly predicted whether a material would be an irritant or nonirritant for 44 of the 52 materials.

A European validation study was coordinated by the European Commission/British Home Office (EC/HO) (17). In this study, 9 Draize test alternatives were evaluated in 37 laboratories using 60 coded chemicals. The goal was to establish whether any of the alternative methods could replace the Draize test for all severely irritating materials, all severely irritating materials belonging to a specific chemical class, or materials with or without regard to chemical class. With the possible exception of predicting the irritancy potential of surfactants, none of the 9 tests met any of the pre-defined performance criteria.

In Phase I of a Japanese Cosmetic Industry Association validation trial, 12 Draize test alternatives in 20 laboratories were used to evaluate 9 cosmetic ingredients (282). Many of the assays handled the surfactant materials adequately.

The European Cosmetics Association (COLIPA) conducted a validation study evaluating 10 alternative methods in 34 laboratories using 55 test substances (23 ingredients, 32 formulations) selected as representative of those commonly used in the cosmetics industry (48). Using the criteria of reliability and relevance as defined in the study, preliminary results indicated that none of the methods could be considered a valid replacement for the Draize test across the full irritation scale, although several satisfied at least one criterion of reliability or relevance.

At present, none of the in vitro techniques appears able to replace eye irritation testing in animals. However, some methods are useful in screening for ocular irritancy potential and can aid in selection of a final product for further development. In fact, many of the tests described above have been adopted as routine screening tests for product development and are well documented in the scientific literature. As efforts continue to develop appropriate alternatives, prudent science necessitates continued use of animals in safety testing. Nonetheless, protocol refinements and reduction in the number of animals

should continue

< previous page page_897 next page >

Page 898
where appropriate while validated alternative methods are sought.
Protocol Refinement
Because it is generally agreed that in vitro techniques will not replace animal testing immediately, efforts should be made to reduce the number of animals used and to minimize their pain. The precision of an eye irritancy test is a function of the number of animals used. The question arises as to whether it is justified to use a large number of animals to increase precision. The answer is no, because there is seldom an advantage to testing eye irritancy with more than three to six animals. The largest variable in an eye irritancy test is among animals, and the test itself is designed to be a bioassay. Therefore, to use a large number of animals in hopes of achieving a higher level of precision is neither realistic nor scientifically sound. A statistical analysis of 155 Draize irritancy studies with six-rabbit scores has shown that reducing the number of animals to five-, four-, three-, or two-animal scores retains, respectively, a 98, 96, 94, or 91% agreement with an irritant classification of these chemicals based on the six-rabbit scores (349). The correlation coefficients for randomly selected subsets of five, four, three, or two scores were 0.998, 0.996, 0.992, and 0.984, respectively. The results of this study show that sufficient accuracy can be obtained by reducing the number of animals used in the Draize test. A combination of lower test substance dose volume (one-tenth the Draize test dose volume) and fewer animals (three) also has yielded good correlation with the standard Draize test (59).
Another proposal is to test only for skin irritation. If the material causes severe skin irritation, it is presumed to be severely irritating to the eye as well. Thus, the argument concludes, an eye irritation test is not needed. Extrapolation from skin to eye is not always valid. In at least one study of 60 severe skin irritants, only 39 also caused severe eye irritation; 15 caused mild or no ocular effects, and the other 6 caused moderate eye irritation (378, 379). Nonetheless, this approach has been proposed as one element of a tier system to prevent conducting an eye irritancy test when other potentially relevant information is available (194).
Many company guidelines specify that materials with extremely high or low pH do not need to be tested for eye irritancy. This approach is fully justified, especially for highly basic compounds. Alkali compounds generally cause more severe eye irritation than acidic compounds.
Tier Testing Strategies
A variety of tier testing strategies have been proposed to reduce the number of animals in eye irritation testing (23, 175, 185, 194). These strategies usually begin with a weight-of-evidence approach, in an effort to review existing information that would allow classification and labeling a material as a severe ocular irritant without animal testing, or to conduct testing with a reduced number of animals. An example of this approach is shown in Figure 18.7, a tier testing scheme proposed by the OECD to support the harmonization of eye irritation testing and classification (280). Stages 1–3 involve information on the physicochemical characterization of the test material and use decision points to preclude animal testing such as: if the test material has a high or low pH (<2 or >11.5); is a known corrosive or severe dermal irritant; or if relevant information from structure-activity relationships (SAR) is available. If the weight-of-evidence suggests that the test material is a severe irritant, it should be so labeled. If information suggests that the test material is not a severe eye irritant, conducting an alternative test is the next step. If the results of the alternative test are indicative of a severe response, the material is classified as a severe irritant. If not, then testing in one or two animals is necessary before a final evaluation can be made.
Current Regulatory Status of Eye Irritation Testing
As in acute oral toxicity testing, the current regulatory status of eye irritation testing is in a state of flux. Most international regulatory agencies are attempting both to reduce the number of animals necessary to assess the ocular hazard of a new substance and to harmonize classification and labeling schemes to accommodate some of the more modern testing approaches. For example, the use of the tier testing strategy (280) is a realistic approach that could minimize pain and suffering, reduce the number of animals without significantly compromising the safety of consumers and workers, and be harmonized to fit existing regulatory classification and labeling schemes.
The OECD has taken a lead role in coordinating the effort to harmonize regulatory strategies through its Program on Harmonization of Classification and Labeling Systems. Case studies are being conducted using existing rabbit eye irritation information submitted to various regulatory agencies under chemicals notification procedures. The data are then used to compare the sensitivity of various classification schemes. This ongoing project is attempting to define criteria for various degrees of eye irritation that are in the range of sensitivity of existing classification systems, and to explore ways to subdivide the effects for those systems that require such for labeling purposes (280).

For specific information on regulatory agency requirements for eye irritation testing, the reader is encouraged to check the most recent regulatory guidelines that apply.

VALIDATION AND REGULATORY ACCEPTANCE OF ALTERNATIVE METHODS

The typical path for the emergence of new methods has historically comprised development and intra-laboratory assessment, peer review and publication, and, ultimately, peer acceptance of the method. Although this process has served us well, continued advancements in basic science, biotechnology, and engineering will undoubtedly result in a plethora of new methods intended as replacements for traditional animal tests such as acute toxicity and eye irritancy. The implementation of new and revised toxicological test methods should occur only if such methods have the capability to provide improved assessment of the potential toxic effects of chemicals and other agents on human and animal health and the environment. One way to assure that new methods represent an improvement over existing tests is through the process of formal validation followed by regulatory acceptance.

Validation has been described as *the process whereby the reliability and relevance of a procedure are established for a particular purpose* (15, 141). In this context, validation encompasses a number of inherent criteria and features that are necessary preliminaries to regulatory acceptance of an alternative method. In contrast

Page 900

Table 18.12 Criteria for a valid test

Necessary criteria	OECD Required	ECVAM Required	ICCVAM Required
Scientific and regulatory rationale including clear statement of proposed use	X	X	X
Relationship of test endpoint to biological effect of interest	X	X	X
Detailed protocol describing: materials needed; what is measured and how; acceptable performance criteria; how data will be analyzed; species to which results apply; classes of materials that can and cannot be assessed	X	X	X
Description of variability and reproducibility (also how biological variability may impact test results)	X	X	X
Demonstrated performance using coded reference chemicals; should include positives and negatives	X	X	X
Sufficient toxicity data to compare existing test with new test (data should be of acceptable quality and from relevant species)	X	X	X
Description of limitations	X		X
Data obtained using good laboratory practices (describe if not and indicate potential impact)	X	X	X
Supporting data available for review: protocols in public domain; methods and results published in peer-review journals; independent scientific review of methods and results	X	X	X

to the traditional path for methods development, the new paradigm supplements development, publication, and peer acceptance with several additional elements. These include pre-validation (optimization and protocol transfer), formal validation conducted in several laboratories (a blind trial), an independent review of the results, submission of the method and validation results to regulatory authorities, and regulatory review and approval.

Development of new and revised test methods to replace existing animal toxicology and safety tests has resulted in the formulation of a number of specific guidelines to be used when preparing a new method for validation and regulatory acceptance (11–13, 15, 56, 134, 141, 142–145, 166, 167). There has been recent movement by the OECD, ECVAM, and ICCVAM to formalize these guidelines and to put them into a harmonized, international regulatory context (16, 269, 274). A discussion of the guidelines follows.

Criteria for a Valid Test

Compliance with comprehensive criteria designed to assure that alternative test methods will meet the standards established for a proper validation study is the first and, unquestionably, the most important step in gaining regulatory acceptance for a new test. In recognizing the importance of such criteria, the OECD, ECVAM, and ICCVAM have each published a set of validation guidelines that are fairly consistent among the groups. A valid test can be defined as including a number of specific elements as summarized in Table 18.12.

For the most part, the criteria for a valid test simply represent good science. They require an appropriate rationale for the new method and an explanation as to how the test endpoint is related to the effect of interest, and they make sure that the methodology is adequately described in a protocol that includes information on the applicability and limitations of the test. Performance criteria must be established to allow an assessment of the inherent variability of the test and its performance in evaluating the chemical class of interest. Relevant in vivo data of sufficient quantity and quality must also be available to permit a comparison of the existing method to the new test. All data generation, collection, and reporting associated with the new test should be performed with adherence to GLP. Scientific credibility can be ensured through peer review of the test methodology, testing results, and subsequent published reports that place details of the new test and the attendant validation activities in the public domain.

If proper attention is given to these criteria and to their utilization in validation programs, appropriate recognition of new test methods by the scientific community will be facilitated. Having accomplished that, the poten

VALIDATION PROCESS

I. Test Development
II. Prevalidation/Test Optimization
   A. Preliminary planning
      1. Define basis and purpose of test
      2. Develop protocol
      3. Develop control values
      4. Develop data/outcome prediction model
   B. Activities
      1. Qualify and train laboratories
      2. Measure intra- and inter-laboratory reproducibility
      3. Identify limitations of test
III. Determine Readiness for Validation.
   A. Analyze test development and prevalidation data
   B. Standardize protocol
IV. Test Validation
   A. Form steering committee/management team
      1. Define purpose of validation study
      2. Design study
      3. Select participating laboratories
      4. Establish management evaluation and oversight procedures
   B. Pretest Procedures
      1. Implement data record keeping procedures
      2. Select reference chemicals
      3. Code and distribute reference chemicals
   C. Test Coded Chemicals
      1. Measure inter-laboratory performance
      2. Compile and evaluate data
   D. Evaluate Test
      1. Analyze and summarize test results
      2. Challenge data with prediction model
      3. Peer review of protocol and data
      4. Accept, revise, or reject model
V. Submission of Test for Regulatory Approval
   A. Prepare report
   B. Make supporting data available
   C. Prepare results for publication

tial for assuring international regulatory acceptance as later described will be greatly enhanced.

Validation Process

The OECD and ICCVAM have also made recommendations on what fundamental elements should be contained within the validation process. Figure 18.8 summarizes the validation process as described by ICCVAM.

The validation process starts with the development of a new test method for a relevant biological endpoint and proceeds through a step called prevalidation. The role of prevalidation in the development, validation, and acceptance of alternative methods has been described by Curren et al. (88). It is during the prevalidation phase that information is developed that defines the basis and purpose of the test, establishes its capabilities, limitations, and transferability between laboratories, and provides sufficient data to confirm whether the method correctly predicts the toxic endpoint of interest.

The tool used to predict the toxic endpoint of interest is called the prediction model. The requirements for an adequate prediction model have been described by Bruner et al. (55, 56) as containing:

1. A definition of the specific purpose for which the alternative method is to be used.
2. A definition of all the possible results that may be obtained from the alternative method.
3. An algorithm that defines how to convert results from the alternative method into a prediction of the in vivo toxicity.
4. An indication of the accuracy and precision of the in vivo toxicity endpoint obtained from the model.

Essentially, a prediction model converts the results from an alternative method into a prediction of in

vivo toxicity. For an alternative method to be considered reliable and relevant, it is important that the prediction model has high predictive power and is relatively insensitive to sources of variability. If these criteria are not met, the alternative method should not be pursued through the validation process because it will have little or no value to the toxicologist in making safety assessment decisions. Once the reliability and relevance of the new test method have been established, and the appropriate prediction model developed, a standardized protocol can be prepared and the test validation study initiated. For additional information on prediction models see Archer et al. (1).

The success of any validation study can be directly linked to the incorporation of several key elements into the study design. A number of these have been listed by Balls et al. (19) including:

1. A clear and unequivocal statement of what the validation study is designed to accomplish.
2. A well-defined plan for the study.
3. A sufficiently large set of test substances covering the relevant chemical classes, and the range of toxic endpoints to be evaluated.
4. Comparative in vivo data of high quality on all test substances to be used.
5. A clear description of how the alternative method can be used to predict an in vivo endpoint (the prediction model).

6. Agreed statistical procedures for testing whether the method can predict the in vivo endpoint of interest.
7. Agreed criteria to be met in order to show that an alternative method could successfully and safely replace the animal test.

Perhaps the most important of the listed elements are those which address sufficiency of test samples, quality of the in vivo data, and adequacy of the prediction model and subsequent statistical analysis of the resultant data. Without appropriate attention to these critical elements, a validation study can be doomed to failure.

Once a validation study has been completed, the results are put into the form of a report with supporting data and submitted for regulatory approval. Test method submissions must contain sufficient information for an independent peer-review panel to determine the validation status of the method, that is, its reproducibility, relevance, and limitations, and for agencies to assess the acceptability of the method for providing useful information for hazard or risk assessment.

Criteria for Regulatory Acceptance

Completion of a validation study does not automatically imply that a new test method is ready for regulatory acceptance. It is extremely important that the test fit into an existent regulatory structure and that it has a suitable regulatory rationale. The best way to ensure this is to involve regulatory agencies as early as possible in the design of any validation program. The importance of early liaison with regulators cannot be overemphasized.

The OECD and ICCVAM also provide guidance on the criteria and considerations for regulatory acceptance (Table 18.13). Once again, peer review is considered a significant element, along with adequately detailed information on the test method protocol and supporting documentation.

Demonstrating linkage between the new test and the existing method is critical, and must be put into the context of specific regulatory programs and agency authorities. Technical transfer of the new test method should be relatively straightforward and at a reasonable cost, and the test should be amenable to regulatory harmonization and international acceptance. The new test also should provide some advantage in the reduction, refinement, or replacement of animal usage.

Because regulatory acceptance is an integral part of the successful implementation of new test method development, all reasonable efforts should be made to accommodate dialogue with the appropriate regulatory authorities and to take whatever measures are necessary to ensure that new methods can be harmonized into current regulatory testing strategies.

Table 18.13 Criteria for regulatory acceptance

Necessary criteria	OECD Required	ICCVAM Required
Independent scientific review (by experts with knowledge of method and no financial interest)		X
Detailed protocol with SOPs and criteria to judge performance and results		X
Data adequately measures desired endpoint; links new test to existing test or effects in target species	X	X
Data adequately represents products or chemicals of interest to agency or regulatory program	X	X
Method generates data useful for risk assessment purposes	X	X
Data is as useful (or better) than that from existing methods	X	
Method is robust and able to transfer between properly staffed and equipped labs	X	X
Method is time- and cost-effective	X	X
Method can be harmonized with requirements of other agencies or international groups		X
Method is suitable for international acceptance		X
Method provides consideration for reduction, refinement, and replacement of animal use	X	X

Regulatory Approaches to Alternatives Acceptance

International health regulatory agencies often have unique responsibilities in their mission to protect human and animal health and the environment. Because an agency usually carries out its responsibility through activities that are specific to the nature of its regulatory authority, the information requirements for data to make hazard or risk assessments are primarily driven by regulatory mandate, and many times directly linked to the regulated entity, that is, industrial chemicals, pesticides, biologics, human or

veterinary drugs, cosmetics, consumer products, or chemicals in transport.

Most U.S. agencies have unique regulatory considerations that often result in different approaches to the way in which they request and use information to make hazard or risk assessments. These unique considerations will ultimately have an effect on the criteria used by an agency to approve new test methods. Moreover, other

international organizations that require toxicological testing have their own special considerations regarding test method acceptance and use. Because of these differences, cooperation among all health regulatory agencies is a critical link to the development and acceptance of new alternative methods. There is no agreed upon international process for health regulatory agencies to coordinate the review and acceptance of new alternative test methods. Further complicating the issue, in certain OECD member countries there is neither an understanding nor even a legal obligation that once an alternative test has been considered as sufficiently validated, it must be adopted for use.

ICCVAM recognizes that regulatory agency harmonization of approaches to test method acceptance is a critical aspect of the entire alternatives development process, and includes recommendations to enhance and facilitate the regulatory acceptance and use of new methods in its guidelines (269). Recommendations are provided in five areas: development and validation, regulatory review of new methods, intra- and interagency coordination and harmonization, communication, and international harmonization. The significant aspects of these recommendations are summarized below.

Development and Validation

As previously indicated, criteria for validation and regulatory acceptance must be taken into account in the planning and design stages of validation studies, and in so doing there should be continuing communication with the relevant regulatory agencies that will be asked to review and accept the methods. Likewise, regulatory agencies should be expected to evaluate new test methods using consistent, though flexible, validation criteria and should be involved in encouraging the development of new and innovative methods. Although both correlative and mechanistic tests can be validated and accepted, mechanistically based methods relevant to the biological effects of concern should be encouraged.

Regulatory Review of New Methods

An efficient and effective process that involves communicating with regulators at all stages prior to regulatory acceptance of alternative methods needs to be set up. As part of this process, agencies should establish internal central clearing systems for the evaluation of new or revised methods and for the periodic review of methods recommended by an agency to ensure their continued relevance. If agency personnel are not familiar with new methods, training should be instituted so that current efforts to incorporate validated alternatives into regulatory testing strategies can be continued and expanded. When questions arise about the acceptability of new or revised test methods, input from the relevant scientific community should be solicited. Many times, concurrent submission of data from new and existing methods will help facilitate regulatory acceptance and preclude these kinds of questions from being raised. If not, an agency-sponsored workshop is the best venue to exchange information.

Intra- and Interagency Coordination and Harmonization

Various regulatory agencies should be consistent in their processes and criteria for acceptance of new and revised toxicological test procedures. Interagency coordination is especially important for those test methods used by more than one agency. This coordination could be ensured by the formation of an interagency committee on test methods which would be a forum for information exchange and the vehicle for consistency in the review, evaluation, and acceptance of alternative test methods. When modifying existing test guidelines, each regulatory agency should solicit input from other agencies in an effort to harmonize testing guidelines to the extent possible. Such harmonization of testing guidelines may first require the harmonization of disparate hazard classification schemes.

Communication

Agency regulations and guidelines should be available to the public to facilitate a consistent and coordinated process of involvement and communication among researchers, method users, regulators, and the public. Exchange of information among these stakeholders will encourage the validation and acceptance of new alternative methods. Scientific journals, workshops, government publications (e.g., the *Federal Register*), and other means should be used to communicate the acceptance of new and revised test methods by regulatory agencies.

International Harmonization

Regulatory agencies in the United States should encourage international harmonization and make attempts to harmonize testing guidelines through international organizations. Where appropriate, this could be done by working with the OECD, the United Nations Committee of Experts on the Transport of Dangerous Goods organization, and other international groups.

From a regulatory perspective, the pieces are in place to foster the development of new and innovative methods that can be used to generate information to support the protection of human and animal health and the

environment. Through the continued efforts of researchers working with informed regulators the future of alternative methods development is encouraging; there now exists a recognized pathway for moving appropriately validated new methods from their inception stage to regulatory acceptance.

QUESTIONS

1. What is the importance of acute toxicity testing and is a precise LD50 value necessary to adequately define acute toxicity?

Answer: Acute toxicity testing is the way in which we define the intrinsic toxicity of a chemical, identify target organs, provide information for risk assessment of acute exposure, provide information for the design and selection of dose levels for more prolonged studies (i.e., subchronic, chronic), and, most importantly, provide information to clinicians for use in treatment of acute chemical poisoning. Information from acute toxicity testing is also used to provide insight into the mechanism of action of a chemical, to formulate safety measures during the early stages in the development of a new chemical, and for categorization and labeling purposes for handling and shipping chemicals. One should not confuse the concept of acute toxicity with the term, LD50. The LD50 is a statistically defined measure of acute toxicity but is only one of many ways to define it. Indeed, a precise LD50 is seldom required in acute toxicity testing, and its use is being de-emphasized to reduce the total number of animals and pain and suffering involved in their use. The LD50 is being replaced by more modern methods. The Up-and-Down Procedure and the Acute Toxic Class Method are alternatives to the LD50 test that can be used to estimate the median lethal dose and to provide hazard classification for labeling, respectively.

2. The following mortality data were obtained from an acute oral toxicity study:

Dose (mg/kg)	1	2	4	8	16	32
Mortality	0/10	1/10	3/10	4/10	7/10	10/10

Calculate the LD50, the SE of the LD50, the fiducial limits, and the slope of the dose-response curve.

		Probits		Probabilities expected *(P)*	Responses		
Log dose *(x)*	*n*	Observed	Expected		Observed	Expected	$\chi 2$
0.30	10	3.72	3.82	11.9	1	1.19	0.0344
0.60	10	4.48	4.36	26.1	3	2.61	0.0344
0.90	10	4.75	4.75	46.4	4	4.64	0.0789
1.20	10	5.52	4.45	67.4	7	6.74	0.1646
1.50	10	–	–	–	10	–	0.0307
							$\Sigma\chi 2=0.386$
							$df=2$

Answer: Procedure

1.	Log dose	0	0.3	0.6	0.9	1.2	1.5
2.	Probits	–	3.72	4.48	4.75	5.52	–

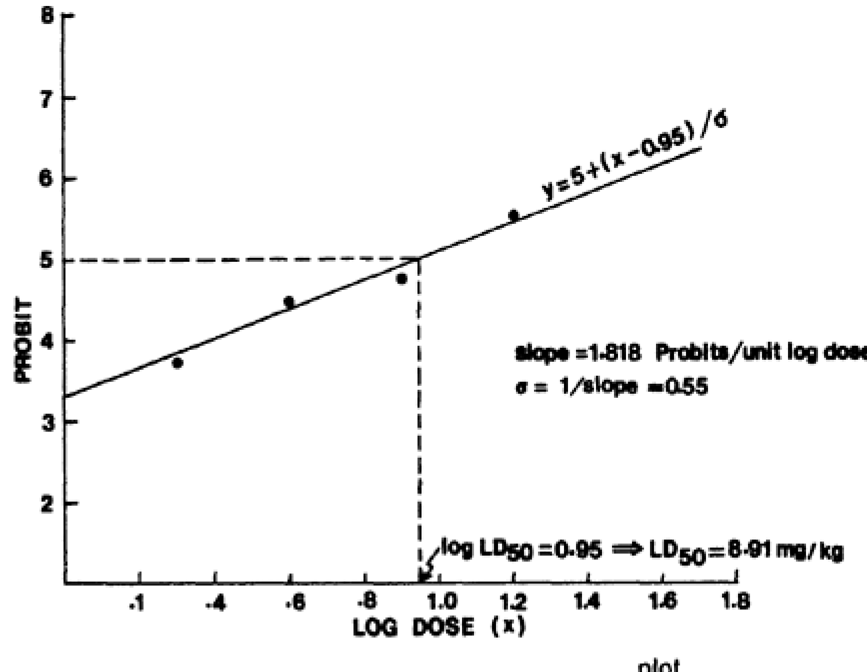
3.,4. Plot log dose versus probits (Figure 18.9) and fit the best point(s) to a straight line.

5. From the log-dose probit line, extrapolate the log LD50=0.95; then LD50=antilog 0.95=8.91 mg/kg body weight.

6. From the same line, calculate the slope as: (numbers of probit units)/unit log dose=2/11=1.818.

   Thus, $\sigma = \frac{1}{\text{slope}} = 0.55$ (Figure 18.9)

7. $\chi 2$ *test of goodness-of-fit.* Expected probability is converted from the expected probits. The test is conducted by converting each expected probit *(y)* back to the expected probability *(P)* and then to the number of expected responses *(E)* (i.e., multiply the expected probability *P* by *n*). The difference between expect



plot.

FIG. 18.9. Example of probit versus log-dose plot.

ed and observed number of responses will be used to calculate the $\chi 2$ statistic, but instead of using $\Sigma[(E-0)2/E]$, **the weighted value will be used, i.e.,** $\Sigma[(E-0)2/E(1-P)]$. The degrees of freedom *(df)* are $N-2$, where N is the number of dose levels used in the calculation of $\chi 2$. The critical $\chi 2$ for (4–2)=2 degrees of freedom is 6.0 at a $p=0.05$, and the calculated $\chi 2=0.386$, which is less than the critical value, indicating that the fitted line is adequate.

8. *Determination of precision of LD50 by weighting.* The SE of log $\mathrm{LD}_{50}=S_m=\sigma/\sqrt{\Sigma mW}=0.55/\sqrt{18.5}=0.129.$ The approx-imation of SE (LD50)=(10m) · *(Sm)*=8.91× 2.302×0.129=2.646. The precision of LD50=8.91±2.646 mg/kg.

Dose (mg/kg)	2	4	6	16
W	0.277	0.423	0.541	0.564
nW	2.77	4.23	5.41	5.64
nW			18.05	

9. *Fiducial limits.* Using the approximation formula, the fiducial limit calculated at the *F*=95% level is given by log LD50±1.96 *(Sm)*. Thus the lower log LD50 **limit=0.5−1.96× 0.129–0.697, and the** antilog 0.697=4.977. The upper log LD50 limit=0.95+1.96× 0.129=1.20=15.849. Antilogs of 0.697 and 1.2 give the fiducial LD50 limit 4.98 to 15.85 mg/kg.

3. Describe the basic elements needed to perform Quantitative Structure-Activity Relationship (QSAR) analysis and list the limitations of this method.

Answer: Basic elements needed to perform QSAR analysis include a reliable bioassay database for the predicted endpoint, a set of physical-chemical parameters that describe the chemical, structures of interest so the bioassay endpoint can be modeled in terms of these parameters, appropriate statistical methods to weigh these parameters in terms of the explanation of the endpoint, and associated computer technology to carry out the computations. Limitations of QSAR analysis in acute toxicity testing and eye irritancy include a limited database on which to base a QSAR model, uncertainties associated with extrapolating beyond the confines of the model, and biological variability (noise) in the bioassays on which the models are based.

4. Compare and contrast eye irritation and eye corrosion including in the discussion a description of the observation endpoints usually associated with irritancy in the three major tissues of the eye.

Answer: Eye irritation can be defined as reversible inflammatory changes in the eye and its surrounding mucous membranes following exposure to a material on the surface of the anterior portion of the eye. In contrast, corrosion represents irreversible tissue damage to the eye following exposure to a material. The amount of damage to each of the three major eye tissues, the cornea, the conjunctiva, and the iris, is what differentiates irritancy from corrosion. Gross tissue destruction that follows rapidly after exposure and persists for an extended period in any or all of these tissues is usually an indication of eye corrosion. Irritancy, however, can occur to various degrees. Assessment of injury is based on the presence and severity of: cloudiness (opacity) and swelling of the cornea; redness, edema (chemosis) and discharge in the conjunctiva; and increased vascularity, edema, absence of reaction to light, and cloudiness (aqueous flair) in the iris.

5. What are the Three Rs and how have they been implemented in acute toxicity and eye irritancy testing?

Answer: Three Rs refers to the reduction in the number of animals used, the refinement of testing methods to reduce the pain and suffering of animals, and the replacement of animals by other methods in testing procedures. Varying degrees of progress in the Three Rs have been made for acute toxicity and eye irritancy testing. Protocols requiring as few as six rats for acute toxicity or three rabbits for eye irritancy are being used in hazard assessment, although larger group sizes are usually required in regulatory requirements for labeling and classification of chemicals. At least one acute toxicity method, the fixed dose procedure, is based on classifying toxicity hazard using a pre-selected dose that is intended to be non-lethal, non-painful, and non-stressful, but toxicity-evident. Many company guidelines specify that materials with extremely high or low pH, e.g., <2 or >11.5, or which are severely irritating or corrosive to skin, do not need to be tested for eye irritancy, and the use of topical eye anesthetics before testing is also common practice. Quantitative StructureActivity Relationship (QSAR) analysis and various in vitro tests are being researched as replacement methods, but at the present, none appears able to replace in vivo testing in animals for acute toxicity and eye irritancy.

6. What are the basic requirements for the development, validation, and regulatory acceptance of new alternative methods?

Answer: An understanding of the nature and use of the animal or other test intended for replacement is a prerequisite to the development of a new method. The new method is built around this knowledge, which must include supporting information that explains how the new test endpoint is related to the effect of interest. If the new method is intended for regulatory approval, there should be early dialog with the appropriate regulators to assure the method fits the existing regulatory scheme. Once a new test has been developed for a specific use it undergoes a prevalidation (optimization) phase. During prevalidation, the purpose and basis of the test are defined, a test protocol is standardized, a database is developed, inter- and intra-laboratory reproducibility is assessed, and a prediction model is generated from the database. The prediction model must explain the toxic endpoint of interest in terms of the new test output(s). Next, a validation study is designed to test the new method with a sufficiently large set of coded substances covering a relevant chemical class and a range of toxic endpoints. High-quality in vivo data should be available on these substances for comparative purposes. The validation study should be conducted among a sufficient number of laboratories to further assess inter- and intra-laboratory variability of the standardized protocol. Testing results should be analyzed using appropriate statistical methods that challenge the data with the prediction model. All methods, results, and supporting data should be peer reviewed, prepared for publication, and submitted for regulatory approval.

REPEATED DOSE STUDIES AND HAZARD (SAFETY) ASSESSMENT

Repeated dose toxicity studies are conducted to screen for potential adverse effects of a chemical, using labora-tory animals as surrogates for a target species, most often the human. Repeated dose studies may be of varying duration, generally 1 to 4 weeks for short-term studies, 3 months for subchronic studies, and 6–12 months for chronic studies. Many variables associated with the health of the test species are monitored in short-term, subchronic, and chronic toxicity studies, resulting in the ability to detect a variety of adverse effects. Sometime during their career, most toxicologists are involved in the design, performance, or review of data from these toxicology studies. This results from the central role played by these studies in the safety assessment of Pharmaceuticals, pesticides, food additives, and other chemicals. It has been suggested that subchronic data alone may be sufficient to predict the hazard of long-term, low-dose exposure to a compound (50). Even though this may be true for compounds where adequate structure-activity relationships exist, it generally is not true when compounds have completely unknown toxicity or when structure-activity relationships predict a poten-tial adverse effect. For certain chemicals or mixtures, results from a short-term or a subchronic toxicity study may represent the most sophisticated toxicology data available. With many chemicals, a subchronic study is critical to the design of longer-term hazard assessment studies.

It is essential that toxicologists become familiar with the scientific principles upon which repeated dose toxicology studies are based and understand the method-ology used to perform these studies. This chapter provides an introduction to these studies and some of the principles upon which they are based. A typical hazard assessment program is illustrated in Figure 19.1. However, in the practice of toxicology, there is no such thing as a "typical" hazard assessment

FIG. 19.1. Schematic representation of a typical hazard assessment program illustrating a step-by-step, tiered approach and the interactions between the various elements. The approach presented here is not the only approach that could be used.

program. Each program is unique, based upon the indi-vidual material being tested and its intended use.

The first step in any hazard assessment is determination of the material to be studied and the purpose of the assessment. Both these factors will influence the final design of the program. At the time of selection of the material to be tested, its intended use in the marketplace will have been defined, dictating, in most cases, factors such as exposure route and the types of studies required.

The next step is the chemical and physical characteriza-tion of the material or mixture to be investigated. Knowl-edge of the major component(s) and any associated contaminants is required for almost every phase of the hazard assessment program. The more detailed the chemical and physical characterization, the greater the assurance that there will not be unexpected interferences from impurities.

Once the toxicologist has information concerning the chemical nature of the *test material*, the scientific litera-ture is searched to determine what, if anything, is known about its biological activity. If no information is available, then the potential biological activity of

Table 19.1 Objectives of short-term repeated dose studies

- Determine adverse effects of the test compound at doses low enough to allow survival of most animals, as opposed to acutely toxic doses
- Determine adverse effects over a longer exposure (dosing) period than used in acute studies
- Determine dose response for adverse effects following repeated dosing and identify no observable adverse effect level (NOAEL)
- Identify target organs
- Provide data concerning species differences, if any, in sensitivity to potential adverse effects
- Provide initial data for comparative risk assessment
- Determine need for specialized endpoints to be assessed in longer-term studies

chemicals with similar chemical structure should be ascertained. Based upon the chemical characterization data and any toxicology information available in the scientific literature, the toxicologist can then perform a structure-activity assessment. This will aid in developing the hazard assessment program and the specific designs for each of the toxicology studies.

In most cases, the first series of studies will be short-term toxicity studies. The initial short-term toxicity study is generally a single dose, *acute* toxicity study. Results from acute toxicity studies are used to estimate dosages to be used in short-term repeated dose studies and obtain initial data useful in assessing relative toxicity. A number of regulatory agencies have made recommendations concerning designs for acute studies as discussed in the acute toxicity chapter of this text. Additional variables may be added to these recommended designs based upon the structure-activity assessment and litera-ture review, if warranted.

Data obtained from short-term repeated dose studies are generally required for the successful design of subchronic toxicity studies. Similarly, data from subchronic studies are essential for design of chronic studies. Table 19.1 lists objectives for short-term repeated dose toxicity studies. Table 19.2 lists examples of data obtained from these studies that are useful in the design of subsequent toxicity studies. As is discussed later, one of the difficult decisions for a toxicologist designing a toxicology study is selection of the dose range to be used. Dose response relationships for toxicological endpoints evaluated in short-term toxicology studies are critical to the successful design of subsequent toxicity studies.

Although not always available, data from genetic toxicology and metabolism studies are useful adjuncts to data from short-term repeated dose studies. For

Table 19.2 Data obtained from short-term repeated dose studies that are useful in the design of subsequent studies

- Clinical pathology
- Gross necropsy
- Histopathology
- Identification of target organs
- Dose responses

instance, if the in vitro phase of the genetic toxicology program has indicated that the test material has genotoxic potential, it may be dropped from consideration for further development and further testing may be unnecessary. On the other hand, in vivo genetic toxicology studies can be added to the design of subchronic or chronic toxicology studies. This can, in many cases, reduce the number of animals used in the overall safety assessment and conserve other resources. If infor-mation concerning the metabolism and pharmacokinetics of the test material is known, it should be used in the design of repeated dose toxicity studies. For example, if pharmacokinetic studies indicate a potential for accumulation of the test material from multiple dosing, this is an important consideration in deciding the most appropriate dose range. Also, because different species may metabolize the test material differently, this infor-mation is important in selection of appropriate animal species and strains for subsequent testing. The major objectives of subchronic toxicity studies are presented in Table 19.3.

In some cases, subchronic toxicity testing may com-plete the data required for a hazard assessment. In other cases, as illustrated in Figure 19.1, data from subchronic studies are used in the design of additional studies, includ-ing chronic toxicity studies. Data from subchronic toxicity studies are useful in the design of oncogenicity and reproduction studies as well as any “special” studies that may be either

warranted by the results of other studies or requested by a regulatory agency.

As noted above, data from a short-term repeated dose study should be available before initiation of subchronic toxicity testing and, generally, data should be available from a subchronic study before proceeding with chronic testing. The major utility in progression from shorter-term to longer-term studies is to insure, to the extent possible, that proper dose ranges are selected. Requirements for a scientifically valid short-term repeated dose study are similar to those of subchronic

Table 19.3 Objectives of subchronic toxicology studies

- Identify adverse effects not detected in shorter-term acute or repeated dose studies
- Provide additional information on adverse effects identified in short-term studies
- Identify observable effect level and the NOAEL
- Provide data for dose selection and other study design features for chronic toxicity and other longer-term studies
- Confirm and/or identify target organs or sites of action
- Provide data to determine if specialized endpoints are required
- Provide a basis for species selection for additional studies, if required, and for data extrapolation to humans
- Provide information for regulatory agencies in support of the safety of the test material
- Provide risk assessment data

toxicity studies. Therefore, the general aspects of short-term studies will not be discussed separately. However, three aspects of short-term repeated dose studies need to be mentioned.

First, as implied by the description "short-term repeated dose study," these studies are of shorter duration than subchronic toxicity studies. Generally, the duration of these studies is either 14 or 28 days with compound administered daily. A 28-day study can pro-duce more valuable information than a 14-day study because the longer-term exposure increases the probabil-ity of detecting more slowly developing adverse effects-assuming the dose-range tested is similar.

Second, dose selection is somewhat dependent upon the purpose of the study. If the short-term dosing is designed to produce information to be used in the design of a subchronic study, then dosing should be high enough to ensure any potential adverse effect is observed. Higher doses are generally used in short-term studies to deter-mine target organs and it may not be as critical to ascer-tain a no observable adverse effect level (NOAEL). However, it is always useful to have a NOAEL in a toxicology study. If no further studies are anticipated with the compound, a dose range that includes a NOAEL becomes more important. Because little information other than acute toxicity data is generally available, it may be necessary to run a more comprehensive range of dose levels in short-term repeated dose studies. Four, five, or more dose groups are generally used in short-term studies. This increases the chances of defining the dose response and should increase the confidence of dose range selection for subsequent studies.

A third aspect of short-term studies that is different from subchronic studies is the number of animals per group. Although fewer animals may be used, 10 animals of each gender in each dose group is the recommendation for short-term rodent studies. Additional animals may be required for non-routine endpoints, such as a group added to ascertain the reversibility of an adverse effect upon cessation of dosing. Additional animals also may be added to the high-dose group if potential com-pound-related mortality is expected.

Many other factors influence the design of all repeated dose toxicity studies. Before initiation of a study, it must be decided if the specific chemical or chemical mixture—that is, the test material—to be used in the study is appropriate based on its purity and other chemi-cal characteristics. Appropriate animal models must be chosen, the correct route of exposure must be selected, and the study duration must be decided. Control and treatment groups and their doses have to be selected. Variables to be evaluated must be selected to maximize the probability of detecting potential adverse effects.

Regulatory Requirements

National and international regulatory bodies have issued guidelines for the design and conduct of repeated dose toxicity studies. Even though study designs pro-scribed by these various guidelines have similar characteristics, some differences between the require-ments have existed within and between regulatory agencies. This has resulted, in some cases, in the duplication of studies to ensure guidelines of different agencies are satisfied. The agencies themselves and the regulated community have considered this duplication of the use of animals and other resources undesirable. As a result, regulatory authorities worldwide are attempting to harmonize their guidelines to ensure toxicity studies conducted under a single set of regu-lations will be universally acceptable. In the United States, the Environmental Protection Agency (EPA) issued a single set of harmonized toxicity testing guide-lines in 1997 (17) to blend the requirements of the separate guidelines previously promulgated through the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), the Toxic Substances Control Act (TSCA), and the Organization for Economic Cooperation and Develop-ment (OECD).

OECD, an international organization of 29 countries including the United States, has issued its own toxicity testing guidelines (54). Each member country has agreed to accept studies conducted according

to these guidelines. In 1991, regulatory authorities and trade organizations from the United States, Japan, and the European Union initiated a cooperative effort through the International Conference on Harmonization (ICH) to produce

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_920.html[2010/10/28 18:49:16]

guidance documents concerning requirements for safety studies with pharmaceutical products. ICH guidance documents generally address specific issues related to toxicity testing, for example, the duration of chronic toxicity testing (43), and are not detailed guidelines for protocol design.

Each regulatory harmonization effort discussed above has been useful. However, a well-planned, scientifically valid, adequately conducted, repeated dose study should satisfy the requirements of any regulatory agency. The scientific foundation for toxicological hazard assessment is continually expanding and to compromise this foun-dation by pursuing standard checklist protocols is irrational, wasteful, and unscientific. Today, regulations generally recognize the importance of scientific judgment and encourage discussions between the regulated com-munity and the regulator about alternative study designs. Investigator and regulator each share in the obligation to do a scientifically sound study.

This chapter focuses on hazard assessment for chemicals that are small molecules. Today, biotechnology is a rapidly developing field. Hazard assessments for biologicals—for example, recombinant proteins—are a special case that will not be discussed in detail in this chapter. Suffice it to say that guidelines for testing such materials are under development. The hazard assessment for a biological is tailored specifically to the compound and may be more or less comprehensive than a classical assessment with a small-molecule compound. However, many of the principles and methods of individual studies with small molecules are applicable to testing with biotechnology products. The toxicologist responsible for investigating the safety of these materials should become familiar with the current guidelines and suggestions for their testing.

The balance of this chapter relates to the typical design and conduct of subchronic and chronic repeated dose toxicity studies. The information provided should suffice to satisfy most regulatory guidelines. Variables deter-mined in subchronic and chronic toxicity studies are essentially identical, the major difference being the sched-ule for data collection. Table 19.4 compares the minimum requirements for subchronic and chronic toxicity studies using rodents as described in the EPA (17), U.S. Food and Drug Administration (FDA) (23), and OECD (54) testing guidelines. For repeated dose study designs intended to satisfy guidelines of a particular regulatory authority, it is recommended that the reader:

(1) use the testing guidelines of that authority as a starting point during the design of a study,
(2) refine the design based upon the compound of interest,
(3) document the design in a detailed, written protocol, and
(4) discuss the protocol with a representative of the regulatory authority prior to initiating a study.

Good Laboratory Practice Regulations

In addition to regulations and guidelines concerning the design of repeated dose studies, U.S. and international regulatory authorities have issued good laboratory prac-tice (GLP) regulations or principles concerning the manner in which all nonclinical hazard assessment studies (e.g., animals studies) are to be conducted, documented, and reported (11, 19, 36, 46–48, 56, 60). Thes e G designed to ensure the quality of the study data and report. Requirements from each of the regulatory agencies are similar. GLPs set standards for the *test system,* laboratory organization, personnel, facilities, equipment, operations, and record keeping. They require that studies be conducted according to written protocols (see Table 19.5) and validated, written standard operating procedures (SOPs). Chemical analyses are required to characterize the *test article* and control article adminis-tered during the studies, and study procedures and data must be clearly and completely documented and reported. Regulatory agencies inspect testing laboratories to assure GLP compliance. Safety studies not conducted according to GLPs will not be accepted by regulatory agencies, and some versions of GLPs, including those of the U.S. regu-latory agencies, provide for disqualification of labora-tories that are in major noncompliance with GLP requirements. For these reasons, laboratories conducting studies for regulatory submission generally take great care to comply with GLPs.

STUDY DESIGN

Chemical and Physical Characterization of the Test Material

It may seem that selection of the test material for repeated dose toxicity testing should require little involve-ment by the toxicologist because it is usually provided by a chemist or product manager. However, several import-ant factors must be considered by the toxicologist to insure that a study will adequately assess the potential toxicity of the chemical and be accepted by regulatory agencies. Obviously, one of these factors is that the batch or lot of test material should be representative of the chemical intended to be tested. Adequate chemical and physical characterization is essential for this deter-mination. Several regulatory agencies and organizations have issued guidelines to describe the information needed and some of the methodology to be used to characterize a chemical (16, 24, 42, 55).

a If a test at one dose level of at least 1000 mg/kg body weight/day produces no observed adverse effects and if toxicity would not be expected based upon data from structurally related compounds, then a full study using three dose levels may not be considered necessary.

b Contingent upon the route of exposure in the test article treated groups.

c Extra animals must be added for interim sacrifices.

d Not required if similar data are available from other studies or if other clinical signs are noted to an extent that would interfere with evaluation.

e Animals in intermediate groups are to be evaluated if treatment related findings are noted in the high-dose group.

f As soon as possible after weaning and acclimation, e.g. ≤6–8 weeks of age.

g No clinical chemistry at three months.

Table 19.5 Protocol contents required by FDA good laboratory practices regulations

- Title and study objective
- Identification of test and control articles
- Identification of sponsor and testing facility
- Justification of test system (animal model)
- Test system information (number, body weight, gender, source, species/strain, age, method of identification, etc.)
- Description of study design and methods for control of bias, such as random assignment of animals to treatment groups, processing of clinical pathology samples in replicates, etc.
- Animal husbandry information
- Dosing information, including dose form preparation and route of administration
- Methods by which degree of absorption of the test and control articles by the test system will be determined, if necessary
- Types and frequencies of assays, analyses, and measurements to be made
- Description of statistical methods
- Records to be maintained

A safety assessment should include a partnership between the toxicologist and a chemist who understands the chemical characteristics of the test material. An adequate chemical characterization of the test material should be provided to the toxicologist, including methods of synthesis, precursors used in the synthesis and any solvents and manufacturing aids used in the manufacturing process. In addition, the methods of purification should be provided, to allow the toxicologist to determine the potential for occurrence of residues and impurities that could produce adverse effects. This provides the toxicologist with information needed to determine if any specific residues or impurities should be specifically targeted for additional analytical determinations.

The specific information required by the toxicologist may vary with each test material, and the required data may be different from that used to establish manufactur-ing and quality control specifications. It is essential, however, that the manufacturing and quality control specifications and procedures meet the specific regulatory requirements for toxicity testing. For instance, good manufacturing practices (GMP), which are somewhat similar to GLPs, are required for some chemicals (21, 30, 32, 33, 40). The chemist should insure that GMP records exist, if they are required.

Prior to initiation of a repeated dose study, the toxicologist should carefully review the chemical and physical characterization data. Chemical characteriza-tion should include a quantitative assessment of the major components, with associated accuracy and precision information, and at least a qualitative analysis of minor components. Ideally, the toxicologist should be provided with a mass balance for the test material.

Before initiation of a repeated dose toxicity study, chemical analyses should be conducted to ensure that the test material, in bulk form and after mixing with any carrier, is stable over the range of anticipated con-centrations and for the maximum period of use during the study. According to GLPs, this evaluation can be con-ducted concurrently with the study, but detection of insta-bility during the study could invalidate the results. If the material is stable only under certain conditions—for example, frozen storage—special arrangements for its storage should be made to eliminate instability problems with the test material, resulting in lower than expected doses and exposure of the animals to degradation pro-ducts. The products of degradation may either have their own unique toxicity or alter the toxicity of the test material. This may make it impossible to correctly inter-pret data from the study.

The toxicologist will have assessed the chemical characterization of the test material at the initial stages of the hazard assessment. More complete information may become available before initiation of repeated dose toxicity studies. Sometimes the chemical synthesis or other production methods may change between the initial assessment and the start of subchronic or chronic studies, and, it may be necessary to reassess the chemical characterization before initiation of these studies. Unanticipated changes in the chemistry of the test material or mixture may necessitate changes in the toxicity study design.

The test material should be as similar as possible to the chemical to which humans will be exposed, with every attempt made to ensure the test material is either identical to the final commercial product or represen-tative of the anticipated final product. This may not always be possible with commercial products because large-scale production facilities are usually not avail-able during this phase of a safety assessment. When such facilities become available, it may be possible to bridge between the final commercial product and the test material by chemical analysis. "Bridge chemistry" should identify any

differences between the chemical that was tested and the commercial pro-duct, allowing a determination of the toxicological bioequivalence of the test material and final commer-cial product.

If a "new" impurity of unknown toxicity is detected in a drug product after chronic animal studies have been con-ducted, the second International Conference on Harmon-ization (42) has proposed the following:

Page 925
1. If intended human use is short term:
• Single-dose toxicology comparison of old and new test substance
• Repeated dose, four-week comparison of old and new test substance
• Mutagenicity tests
2. If intended use is long term, with a high dose of the active compound:
• Single-dose toxicology comparison of old and new test substance
• Repeated dose, three-month subchronic com-parison of old and new test substance
• Mutagenicity tests (if results of the mutagenicity test are positive, carcinogenicity testing of the impurity may be considered)
3. If the product is to be given to women of childbearing age:
• Consider the need for a comparative embryotoxicity and teratogenicity (segment II) study in one suitable species

The test material should have not only the same chemical characteristics as the material of commerce, but should also have the same physical characteristics. If the test material is a solid intended to be used as a powder, it should be administered to the test animals in powder form. Particle size of the powder should be similar for the test material and the material to which humans will be exposed. If humans will be exposed to the material in solution, a solution of the material should be used in the repeated dose study. Analyses should be conducted to ensure that the composition of the test material falls within the limits of anticipated or known product specifications. Physical specifications will allow the toxicologist, often in consultation with the chemist, to determine the most appropriate method of adding the test material to the dosing matrix, such as the diet or drinking water (see Route of Exposure discussion).

It is important for the toxicologist to ensure an adequate supply of test material is available before initiating a toxicity study. A single lot of the test material should be used throughout the subchronic or chronic study, whenever possible. If the repeated dose study is part of a series of studies in a safety assessment program, it is desirable to use a single lot of test material for the entire program. This reduces the probability of encountering inconsistent results in different studies with the same test material, resulting from inter-lot differences in chemical/physical characteristics. If a single lot of test material is not available in sufficient quantity to complete a study or studies, multiple lots may be used, with chemi-cal characterization of each new lot required to insure it meets all specifications and reasonably duplicates pre-vious lots.

The FDA has issued guidelines addressing the chemis-try data requirements for direct food additives and gen-erally recognized as safe (GRAS) petitions (24). ICH has issued guidelines for chemistry requirements for drug candidates during preclinical *hazard* assessment (42). Although the toxicologist may not have as complete a data package as described above before the initiation of a repeated dose study, sufficient data must be available to meet GLP regulations.

FDA GLPs state that, "The identity, strength, purity, and composition or other characteristics which will appropriately define the test or control article shall be determined for each batch and shall be documented. Methods of synthesis, fabrication, or derivation of the test and control articles shall be documented…." (35).

EPA GLP statements concerning the requirements for chemical characterization of the test material are essentially identical to those of FDA (12). The OECD GLP guidelines for chemical characterization state, "For each study, the identity, including batch number, purity, composition, concentrations, or other characterizations to appropriately define each batch of the test or reference items should be known" (56).

Further information on the chemical characterization of the test material is provided by the FDA in its proposed revision to the guidelines for toxicity studies, "The com-position of the test substance should be known: Infor-mation should include the name and quantities of all major components, known contaminants and impurities, and the percentage of unidentifiable materials. The test substance in toxicology studies should be the same sub-stance that the petitioner intends to market"(25).

Route of Exposure and Method of Test Material Administration

The anticipated human route of exposure to the test material dictates the route of exposure for most subchronic and chronic toxicity studies. Unintended routes of human exposure also should be considered during selection of exposure route. The most common routes of exposure in these studies are dietary, oral (gavage or capsule), dermal, and inhalation. Less frequently, test materials are administered in the drinking water or parenterally by intravenous, subcutaneous, intraperitoneal or other types of injection. Other types of administration include direct implant and *parenteral* infusion using implanted or external pumps.

Frequently, there are several potential routes of human exposure to a single chemical. For example, consumer exposure to a pesticide may occur by dietary consumption of food crops containing residues of the chemical. Farm

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_925.html[2010/10/28 18:49:19]

worker exposure to the same pesticide may occur by either inhalation or dermal routes during application and harvesting. In such cases, subchronic testing may be required to assess the effects of exposure by all three routes. Emphasis is generally placed upon the route by which the most widespread human exposure would occur, with chronic testing usually conducted using only that route of exposure. Several of the more common routes of exposure are discussed in detail below.

Capsule Administration

If expected human exposure is by the oral route, a solid test material (e.g., a dry powder) can be administered by capsule. Unformulated bulk test material can be given to some large animals, such as dogs and cats, in gelatin capsules inserted into the esophagus manually or with the aid of a mechanical device designed to prevent the animal from biting the individual administering the capsule. Capsules are available in a wide range of sizes and can hold, depending on the density of the test material, as much as 1.5 g. The amount of test material that can be administered is limited by the capacity of each capsule and the practical number of capsules that can be administered at one time. For smaller species, such as rodents, this method is impractical and the test material must be administered orally as a solution or suspension in an appropriate vehicle.

Oral Gavage

Another common route of oral administration is oral *gavage* by *intubation*. This technique may be used for rodent and nonrodent species. For oral gavage, a solution or suspension of the test material is deposited into the stomach via the esophagus using an intubation tube attached to a graduated syringe or other device. A test material is added to an appropriate vehicle, usually aqueous. If the material is not readily soluble, a suspension may be prepared. For suspensions, a thickener such as methylcellulose, carboxymethylcellulose, or gum tragacanth is added to water to increase the viscosity, and the test material is homogeneously suspended in the vehicle. A wetting agent such as Tween 80 can be used to increase the suspendability of the material. Although aqueous vehicles are preferred, it is possible to use an oil vehicle for lipid-soluble materials. Food oils, such as corn oil, may be used but mineral oils must be avoided. It should be remembered that food oils add to normal dietary caloric intake and, at high volumes, oils may inter-fere with absorption of fat-soluble nutrients, such as fat-soluble vitamins. Also, absorption of the test material may be quite different with an oil vehicle compared to an aqueous vehicle and this may be highly volumedependent.

The volume of test solution or suspension administered can influence gastric emptying time. Because gastric emptying time may affect gastrointestinal uptake and bioavailability, it generally is preferred that the dose levels of the test substance be administered on a con-stant-volume (ml/kg), variable-concentration (mg/ml) basis. For dosing using a constant volume, 10 ml/kg body weight is most commonly used as the upper limit. At 10 ml/kg, a 260 g rat would receive a dose volume of 2.6 ml, a 35 g mouse would receive 0.35 ml, and a 10 kg dog would receive 100 ml. Dosing usually is conducted once daily but may be performed more frequently to mimic the intended human dosing regimen or if concen-tration and/or pharmacokinetics considerations limit the achievable single-dose exposure to less than the amount desired.

Daily exposure by oral gavage results in a *bolus dose*. Administration via the diet or drinking water results in a more constant exposure throughout the duration of the study that is more dependent on feeding patterns than dosing schedule. Because rodents are nocturnal, the peak periods for activity and feeding behavior are the end of the light and dark periods (i.e., just before lights-on or just after lights-off). If high volumes of dosing solution (i.e., 20–50 ml/kg) are to be administered to rodents and/or if the presence of feed may interfere with the absorption of the test substance, consideration should be given to dosing animals during late morning or in the afternoon. For nonrodents, timing of dosing relative to feeding (i.e., before or at a certain time after daily feeding) accomplishes the same purpose. In any case, the timing of gavage dose(s) in relation to feeding should be stated clearly in the study protocol.

Administration of a test chemical as an undiluted liquid, as a diluted liquid, as a dissolved solid, or as a solid in suspension generally results in accurate delivery of the intended dose to each of the animals in a repeated dose study when exposure is by oral gavage. To deliver an accurate dose of test chemical in solution or suspension, the chemical must be mixed with solvent or suspending agent at the proper concentration which can be calculated using the intended dose level and the dose volume of the solution/suspension to be adminis-tered to the animals. This calculation is illustrated in Figure 19.2. Obviously, this same calculation applies to solutions or suspensions for other exposure routes, for example, administration by capsule, dermally, or parenterally.

Use of a vehicle to carry the test material into the ani-mal has been mentioned several times in the

preceding discussion. Choice of vehicle is a critical decision for toxicology studies. Obviously, the vehicle should be nontoxic at the dose (volume) administered, and should not act in an additive or synergistic manner to enhance the toxicity of the test material, nor should it interfere with the expression of any potential toxicity. Because such interactions are not always predictable, it is

Page 927

• Formula

CONCENTRATION (mg test material/ml solution or suspension)=

$$\frac{\text{INTENDED DOSE LEVEL (mg test material/kg body weight/interval)}}{\text{DOSE VOLUME (ml solution or suspension/kg body weight/interval)}}$$

• Example

The concentration of a solution intended to deliver a daily 1500 mg/kg dose level of test material A to rats at a dose volume of 5 ml/kg body weight (BW) is calculated as follows:

$$\text{Concentration (mg A/ml)} = \frac{\text{1500 mg A/kg BW/day}}{\text{5 ml solution/kg BW/day}}$$

$$= \text{300 mg A/ml solution}$$

As indicated in the following, a 300 gram rat would receive 1.5 ml of this solution each day and, therefore, would receive the intended daily dose level. First, calculating the volume of solution administered to the rat:

0.3 kg body weight x 5 ml solution/kg BW/day=1.5 ml/day

Then, calculating the amount of test material A in that volume:

1.5 ml of solution/day x 300 mg A/ml solution=450 mg A/day

Finally, calculating the dose level resulting from administration of that amount of test material:

450 mg A/day÷0.3 kg BW=1500 mg A/kg BW/day

FIG. 19.2. Calculation of test material concentration in a solution or suspension.

imperative that vehicle controls be used in all oral gavage toxicology studies (and in virtually every other type of administration). However, even use of a vehicle control may not always compensate for the administration of vehicle in the groups receiving the test material. Interac-tions between vehicle and test materials can be encountered and must be considered during the design of studies because vehicles may produce physiological/ nutritional alterations that may affect the toxicity of the test material, especially in longer-term studies. For instance, an oil vehicle may result in poor absorption of fat-soluble nutrients; food oil vehicles add to the caloric intake of the animal and may produce effects in longer-term studies; absorption of fat-soluble materials from oil vehicles can be slower than when the same material is administered in an aqueous matrix. The result-ing change in the toxicokinetics of the test material can produce profound differences in toxicity. Because toxicity testing generally uses exaggerated doses compared to human exposure, it is sometimes difficult to obtain solutions. In such cases, suspensions are sometimes used, which, again, can affect toxicokinetics and influence toxicity. For these reasons, among others, great care must be utilized in selecting an appropriate vehicle for admin-istration of test materials to animals.

Dermal Application

For a drug, cosmetic, industrial chemical, or pesticide with dermal exposure potential for humans, dermal appli-cation is the most appropriate exposure route for repeated dose studies. The test material is applied to a defined area of skin from which the hair has been removed. Removal of hair by both shaving and depilatories can alter skin permeability to applied materials. Because the test animal can ingest some of a dermal dose during grooming, it is common practice to cover the test material application site by wrapping the trunk of the animal with a semi-occlusive material (e.g., gauze strips) during the exposure period. Occasionally, if exaggerated dermal absorption is desired, the application site is covered with an occlusive material (e.g., rubber dam). Either method of wrapping, occlusion or semi-occlusion, maintains the test material in contact with the skin. Wrapping also increases the accuracy of the administered dose because

on unoccluded animals, dry test materials may fall off the application site and liquid materials may run off or evap-orate from the site. Restraint and/or "Elizabethan" collars are also sometimes used to prevent tampering with the wrap or to prevent oral ingestion if the application site is unoccluded. However, use of restraint or collars stresses the animals and, therefore, may alter the outcome of a study. To avoid unnecessary stress, the animals should be trained to accept such procedures before actual dosing is initiated.

Parenteral Administration

A pharmaceutical intended for administration to humans by injection should be administered to the test animals by the same parenteral route. A common type of parenteral exposure is subcutaneous injection. To avoid irritation and other potential effects, such as fibrotic reactions, the specific site of injection should be changed daily. It is recommended that the dosing vehicle be aqueous since oil vehicles may track back along the needle path and be deposited in the lipophilic skin and hair. As with oral gavage exposure, absorption from an oil vehicle may differ compared with an aqueous vehicle. For subcutaneous administration, care must be taken to ensure the material is deposited subcutaneously rather than intradermally or intramuscularly. This can be accomplished by lifting the skin of the animal to form a pocket and injecting the dosage into the subcutaneous pocket.

Other common routes of parenteral exposure include intravenous (iv), intramuscular (im), and intraperitoneal (ip) injection. Special considerations are required for each of these routes. For iv administration, the test material must be soluble in an aqueous vehicle since physiological saline is the usual vehicle. Air bubbles must be cleared from the delivery system—the needle, catheter and/or syringe, before injecting the material intravenously. The dosing solution for iv administration must be at a physiological pH and must not be extremely irritating or corrosive. Repeated use of the same injection site must be avoided. To prevent inadvertent delivery of the test material into the muscle or other surrounding tissue, care must be taken to insure that the needle tip is in the lumen of the vein before injecting the test material. Proper place-ment of the needle can be assessed by drawing a small amount of blood back into the delivery device. If no blood is observed, the needle is not located in the lumen of the vein. For im and ip routes of exposure, proper placement of the needle tip also must be assessed before adminis-tering the dose material. In contrast to iv exposure, draw-ing back on the delivery device without obtaining blood is required prior to administering material by the im route. Similarly, drawing back on the device without obtaining blood or intestinal contents prior to injecting test material is necessary for correct ip adminstration. Most other con-siderations for im and ip exposure are similar to those for iv administration for example, the material must not be corrosive or irritating, repeated injections at the same site should be avoided, and so on.

Continuous infusion may be used to simulate a con-stant human exposure or, for intravenous infusion of poorly soluble test substances, to deliver a sufficiently large daily dose for safety assessment. Infusions may be administered using either implanted or external pumps. Implanted pumps may be battery-operated mech-anical pumps (nonrodents) or osmotic pumps (rodents and nonrodents); both of which permit unrestricted movement of the animal. Practical considerations of vol-ume and weight of implanted pumps restrict their use to very soluble and/or potent test substances that can be administered slowly over a long period. External pumps may be connected to rodents and nonrodents using tethers and swivels or affixed to nonrodents as "back packs." External pumps allow for infusion of larger vol-umes of test substance but also require more waste sub-stance because of the larger "dead space" of the tether catheter. Their use may be problematic for subchronic or chronic studies because of their relatively long duration. The patency of the catheter for implanted and external pumps must be confirmed. The dose received by each animal can be determined by measuring the weight of the pump and solution prior to initiation and following completion of exposure, or by direct meas-urement of the infused volume by syringe markings or by using calibrated pumps displaying the infusion rate. Study designs often incorporate measurement of blood concentrations of the test material and its metabolytes.

Implantation

Subcutaneous or intramuscular implantation is often used for evaluating biopolymers for medical devices or prostheses. In addition, test materials have been embedded in special matrices that allow continuous, sus-tained release for weeks or months after subcutaneous implantation. Demonstration of the stability of the test substance in the matrix, both during preparation of the pellet and after implantation, is required when using this technology. Determination of plasma concentrations of the test material and/or its metabolites can be used to confirm proper dosing. Because of size limitations, these pellets are useful only for delivery of very potent substances, such as hormones and biological proteins.

Dietary Administration

Dietary administration would be appropriate for a food additive or a pesticide that has potential to become a residue in or on food crops. This type of administration, although frequently used in subchronic and chronic toxicity studies, is less accurate than most other routes of dose delivery primarily because of differences between

body weight and feed consumption of individual animals, which result in variable compound consumption. A further complication in rodent studies is that these ani-mals tend to add body fat and not lean body mass as they age. Therefore, lipophilic compounds have a larger mass of fat into which they can partition. This may actually decrease the effective dose. In addition, fat does not have significant detoxication enzymes. Therefore, as dose is increased to account for increased body weight in older rodents, detoxication capacity may be stressed resulting in unanticipated toxicity. This complication is not unique to dietary exposure studies and will affect the effective dose of a test material in rodents exposed by most other routes. Although potential variability in effective dose is important to interpretation of the results of a study, no attempt is generally made to compensate for this varia-bility during preparation of the test diet or calculation of the administered dose in repeated dose toxicity studies. Spillage or soiling of feed, which occurs fairly frequently with some test animals, is a factor that contributes varia-bility to the calculation of dietary dose. Significant spill-age or soiling must be considered when measuring feed consumption to be used in calculation of dietary concen-tration or compound consumption. Dietary adminis-tration can be conducted by either of two methods:
(1) adjusting the dietary concentration of the test material to account for changing body weight and feed consumption, or
(2) feeding a constant concentration in the diet.
Routinely adjusting the dietary concentration of a test material based upon the changing body weight and feed consumption of the animal provides reason-ably good control over the delivered dose during a repeated dose study. Dietary concentration is usually adjusted weekly during a subchronic study. In a chronic study, diet concentration is usually adjusted weekly during the first 13-14 weeks (especially for rodents because of the rapid growth of the animals during this period) and biweekly or sometimes monthly thereafter. Using this method, the mean feed consumption and body weight of a dose group during a given study interval are used to calculate the dietary concentration to be fed to that group during the following interval. There are several ways to calculate the concentration. One formula for this calculation and an example of its use are presented in Figure 19.3. A caution in using this approach in quickly growing, young rats is that the concentration may increase dramatically during the study. Sometimes the target concentrations become too high to formulate the mix homogeneously or they reach a level that becomes unpalatable to the animals.
Feeding a constant concentration of the test material in the diet throughout the study is the second form of dietary administration. This method provides less control over the administered dose level because it is a function of the amount of feed (and, therefore, test material) con-sumed and body weight gained by each animal. The con-sumed dose, or compound consumption, of each individual animal can be calculated using its feed con-sumption and body weight. The mean of the individual animal compound consumptions represents the com-pound consumption for each dose group. A commonly used formula for the calculation of individual compound consumption is illustrated in Figure 19.4.
When feeding a constant concentration in a rodent study, the toxicologist must be aware that the compound consumption may vary significantly for an individual ani-mal or group of animals during the course of the study. For example, compound consumption during the first week of a 13-week rat study in which the test compound is fed at a constant dietary concentration is frequently more than twice the compound consumption during the last week of the study. This variation results from the rapid decrease in feed consumption relative to body weight (g feed/kg body weight/day) by young rats during the first several months of life. This variability in com-pound consumption is illustrated in the example given in Figure 19.4.
Drinking Water
Water-soluble test substances can be offered as a mixture in the drinking water, providing adequate dosage can be achieved. This route may be preferred when it mimics human exposure conditions of constant exposure, compared with event-oriented exposure such as pill taking. Spillage can be a significant problem when admin-istering material in drinking water and recovery of spilled water is usually not feasible. Another complication with drinking water administration is that evaporation of water and/or volatilization of the test material can occur from the tip of the drinking (sipper) tube, resulting in alteration of the concentration of the material in the water. Use of a sipper tube containing a ball bearing tip minimizes this problem.
Assessment of the Adequacy of Test Material Preparations
Whatever the route of exposure, it is critical to deter-mine if the test material is delivered to the animals at the intended doses. For dietary studies, test diets should be prepared before initiation of a repeated

dose study, using the intended diet preparation method. It must be shown that this preparation method yields diets con-taining the appropriate amounts of homogeneously mixed test material. Chemical analysis of samples taken from several locations in each test diet preparation should be conducted to determine if the proper concentrations of test material have been achieved and to assess the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_929.html[2010/10/28 18:49:21]

Formula

- CONCENTRATION (mg test material/kg diet)=

$$\frac{\text{INTENDED DOSE LEVEL (mg test material/kg body weight/day)}}{\text{PROJECTED FEED CONSUMPTION (kg feed /kg body weight/day)}}$$

where projected feed consumption (PFC) for a study week is based on body weight (BW) and absolute feed consumption (AFC) data from the previous week and is calculated as follows:

PFC (kg/kg/day) for weekn=

$$\frac{\text{AFC week}_{n-1}\text{ (kg)}}{7\text{ days}} \div \left[\text{BW end of week}_{n-1}\text{ (kg)} + \frac{\text{BW gain during week}_{n-1}\text{ (kg)}}{2}\right]$$

- Example

In a subchronic rat study, the mean body weight of the males in the 15 mg/kg/day dose group at the beginning of week 11 is 520 g. At the end of week 11, the mean weight for these males is 540 g. Mean feed consumption of these animals is 154 g during the 7 days of week 11. The dietary concentration intended to deliver a 15 mg/kg/day dose level of compound A to this group of rats during week 12 of the study is calculated as follows:

PFC (week 12)

$$= \frac{0.154\text{ kg feed}}{7\text{ days}} \div \left[0.540\text{ kg BW} + \frac{0.020\text{ kg BW gain}}{2}\right]$$

= 0.04 kg feed/kg BW/day

and, therefore

Concentration (week 12)

$$= \frac{15\text{ mg A/kg BW/day}}{0.04\text{ kg feed/kg BW/day}}$$

= 375 mg A/kg feed

Note that, because their body weight and feed consumption differ, the diet concentrations for males and females in the same dose group will generally differ throughout the study.

FIG. 19.3. Calculation of adjusted diet concentration to yield constant dose level.

homogeneity of the dietary admixtures. If the results of these analyses indicate the anticipated concentrations were not achieved or the distribution of test material in the diet was not homogenous, the diet preparation method should be revised and retested. Diet preparation must be validated before the study can be initiated.

During the pre-study homogeneity determinations, additional diet samples should be collected and analyzed to show that, within the range of concentrations to be used in the study, the test material is stable in the diet. These samples should be stored under animal room conditions and under frozen conditions for the maximum period of time during which the diet will be used or stored. For a study in which dietary admixtures will be prepared and fed once per week, stability of the test material in the diet would commonly be assessed for samples stored under animal room conditions for at least seven and fourteen days. This allows estimation of the degradation rate at room temperature. Analysis of frozen diet samples stored for several intervals is also advisable. Demonstration of stability under frozen storage conditions makes chemical analysis of diet samples immediately after collection during the toxicity study unnecessary and also validates the possibility of confirming analytical results by reanalysis of stored frozen samples, if needed. Adequate stability of the test material in the diet should be demonstrated prior to initiation of the study.

Even though the adequacy of the diet preparation method and stability of the test material in the diet have been demonstrated, it is important to monitor diet preparation during the study. For each diet preparation

Formula

$$\text{COMPOUND CONSUMPTION (mg test material/kg body weight/day)} =$$

$$\underset{\text{(mg test material/kg feed)}}{\text{CONCENTRATION}} \times \underset{\text{(kg feed/kg body weight/day)}}{\text{RELATIVE FEED CONSUMPTION}}$$

where relative feed consumption (RFC) for a study week is based on body weight (BW) and absolute feed consumption (AFC) during mat week and is calculated as follows:

$$\text{RFC (kg/kg/day)} = \frac{\text{AFC (kg)}}{\text{7 days}} \div \left[\text{BW start of week (kg)} + \frac{\text{BW gain during week (kg)}}{2}\right]$$

Example

In a subchronic rat study, a group of males is fed test material A at a constant dietary concentration of 2% (w/w). The body weight of one animal in this group is 175 g at the start of week 1 and 225 g at the end of week 1. Its feed consumption during the 7 days of week 1 is 168 g. Subsequently, this rat weighs 490 g at the start and 510 g at the end of week 13; and its feed consumption during that week is 1% g. The compound consumption of mis rat for each week is calculated as follows:

$$\text{RFC (week 1)} = \frac{\text{0.168 kg feed}}{\text{7 days}} \div \left[\text{0.175 kg BW} + \frac{\text{0.050 kg BW gain}}{2}\right]$$

$$= \text{0.120 kg feed/kg BW/day}$$

$$\text{RFC (week 13)} = \frac{\text{0.196 kg feed}}{\text{7 days}} \div \left[\text{0.490 kg BW} + \frac{\text{0.020 kg BW gain}}{2}\right]$$

$$= \text{0.056 kg feed/kg BW/day}$$

and, therefore:

Compound Consumption (week 1) = 2% test material A x RFC (week 1)
= 2 g A7100 g feed x 0.120 kg feed/kg BW/day
= 20,000 mg A/kg feed x 0.120 kg feed/kg BW/day
= 2400 mg A/kg BW/day

Compound Consumption (week 13) = 2% test material A x RFC (week 13)
= 20,000 mg A/kg feed x 0.056 kg feed/kg BW/day
= 1120 mg A/kg BW/day

FIG. 19.4. Calculation of compound consumption resulting from constant diet concentration.

during the first several weeks of the study, concentrations of the test material in the diets should be assessed. Subsequent analysis of diet preparations every two to four weeks will add assurance that diets were prepared properly. More frequent analysis, for example, weekly throughout the study, is even more desirable.

For routes of exposure other than dietary, the principles cited above also apply. Concentration, homogeneity and stability of the test material in solvents or suspending agents must be determined for studies using oral, dermal, inhalation, or other routes of exposure when the test material is to be administered in solution, suspension, or as an aerosol. Suspensions represent a special case because care must be taken to ensure that the suspensions do not settle and become nonhomogenous during administration to the test species. For inhalation studies, the concentration of gas, aerosol, or particulates to which the animals are exposed should also be assessed using appropriate analytical methods.

Duration of Exposure

As stated previously, the duration of subchronic toxicity studies involves exposure of the test species to a chemical during a significant portion of its lifetime. Classically, these studies are conducted for 90 consecutive days or approximately 13 weeks. Chronic toxicity studies in rodents most commonly involve exposure for a major portion of their life span, generally 12 months, although studies of shorter duration (i.e., 6-9 months) are considered acceptable by some groups (43). Rodent chronic toxicity studies are sometimes combined with lifetime oncogenicity studies to achieve efficiencies during some

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_931.html[2010/10/28 18:49:23]

of the study procedures, for example, diet preparation. During these combination studies, the animals in the chronic toxicity segment are generally studied during the first 6–12 months, and then are terminated. Those in the oncogenicity segment continue on study generally for at least 24 months. In nonrodents—for example, dogs and non-human primates, which are longer lived than rodents—6–12 months represent a significantly smaller portion of their life span but is currently considered an adequate duration of exposure to detect chronic effects.

Daily test material administration during a repeated dose toxicity study can be continuous, intermittent, or repeated. In most dietary and drinking water studies, the animals have free access to diets or water containing the test material throughout the study and exposure is essentially continuous, although influenced by diurnal variation. In dermal or inhalation studies, exposure to the test material is intermittent, generally four to six hours per day. When the route of administration is intravenous infusion, exposure may be either continuous or intermittent. With bolus dose parenteral administration or oral gavage, test material administration is generally once or, at most, a few times each day. Labor-intensive methods of administration, such as oral gavage, are sometimes done only during the standard work week, that is, five days per week. This is not recommended because two days of non-exposure each week during the study may be sufficient to allow modification or reversal of toxic responses.

Dose Groups

The minimum number of groups receiving test material in a repeated dose toxicity study is generally three (low, mid-, and high dose). The high-dose level should produce evidence of toxicity, but should not result in more than 10 percent mortality. The mid-dose level should produce no more than slight toxicity and the low-dose level should produce no toxicity yielding a NOAEL. As previously stated, a short-term (two to four weeks) repeated dose study should be conducted to aid in the selection of doses for subchronic testing. For test materials where a dose response has not been well defined during a short-term repeated dose study, additional dose groups may be required in the subchronic study to insure the range of desired responses—that is, no toxicity to significant toxicity—is achieved. However, it is sometimes difficult to completely satisfy these criteria. Before selecting doses for a chronic toxicity study, a subchronic study that defines no-effect and effect levels should be completed.

Limit Studies

For test materials that possess very low potential for toxicity, the inclusion of only one test material dose group in a repeated dose study is sometimes acceptable. A study with this design is termed a *limit study*. Limit testing is inappropriate for materials with anticipated high human exposure. The dose level for the test material group in dietary and dermal limit studies is normally at least 1000 mg/kg/day. Another type of limit study involves utilization of the maximal exposure level under the conditions of the study. For example, suppose the majority of toxicology data concerning a lipophilic drinking water contaminant has been collected using oral administration in a corn oil vehicle and additional data are desired using a water vehicle. The limited water solubility of the test material may result in the maximal dose being significantly lower than the dose used in the corn oil gavage studies. However, the test material can be tested as a saturated water solution and such a study may reveal the test material to be either more or less toxic in water than in the oil vehicle. The data are relevant to the assessment of hazard associated with exposure in the drinking water because the maximal possible exposure by this route of administration was tested. Thus, while a limit study may not define the "complete" toxicology of a test material, it can define the "practical" toxicology of the material.

Control Groups

Adequate controls are essential to successful toxicity studies of all types, including repeated dose studies. Studies should contain at least one control group for comparison with the groups receiving the test material. The control group should be treated identically to the treated groups except the control group should receive no test material. Control groups can be either negative or positive controls.

Negative control groups are intended to demonstrate the normal state of the animal for comparison to data from the groups treated with the test material. They also provide an opportunity to compare baseline data for the current study to baseline data from previous studies. There are several types of negative controls. If the test material is dissolved or suspended in a vehicle for administration, a vehicle control group should receive, by the same route of exposure, the maximum amount of solvent or suspending agent administered to any of the test material groups. If the test material is administered in the diet, an untreated control group should receive the same diet without test material. For test materials administered undiluted, a sham control group should receive the same physical treatment as the treated groups, for example, insertion of an intubation tube with or without delivery of an innocuous substance like water, administration of empty capsules, or injection of physiological saline.

Positive control groups are intended either to demonstrate susceptibility of the animal to a specific toxicity or to compare the response of test material-treated animals to that of animals treated with a chemical that produces a known toxicity similar to the test material. If a positive control group is included in a study design, at least one negative control group should also be included. Positive control groups are infrequently used in repeated dose toxicity testing. However, if the chemical structure of a test material suggests that it may possess a specific toxicity—for example, neurotoxicity—it may be important to demonstrate that the species and strain selected for testing is susceptible to that toxicity.
A positive control that is sometimes useful in repeated dose studies is the reference control. This control consists of a material that is chemically or physically similar to the test material but has either a comprehensive toxicology database associated with it or a history of use without adverse effects. Inclusion of a reference control group allows a comparison between reference and test material within the same study. This can assist in identifying any effects related to the general characteristics of the reference material. For instance, oral administration of a poorly absorbed oil can decrease the absorption of fat-soluble vitamins. If the test material is known or suspected to produce this effect, use of a reference material, such as mineral oil, can be useful. This would distinguish effects related to vitamin depletion from effects produced directly by the test material. Additionally, if the test material were to add substantially to the caloric intake, a reference control diet isocaloric to the test diet would be useful, especially in longer-term studies. A reference control group also may be useful to compare the degree of anticipated toxicity of the test material to a reference material of known toxicity. For example, it could be important to demonstrate that the hepatotoxicity of a test material intended for use as an anesthetic is significantly less severe than that produced by an anesthetic already in use.

Animal Models

To increase the probability of testing in a species that may respond to the test material in a manner similar to humans, two species are generally used. Routinely, one rodent species and one nonrodent species are utilized. Rats and dogs are the generally preferred species for most routes of exposure. The rabbit is preferred for dermal exposure. Mice, hamsters, miniature swine, guinea pigs, non-human primates, and a few other species are used on occasion in these studies. Many factors should be carefully considered during the selection of the most appropriate species and strain for testing with a specific

Table 19.6 Selection criteria for species and strain in repeated dose studies

- Requirements by regulatory agencies
- Metabolism of test material in a manner similar to humans
- Availability of historical control data
- Most sensitive species and strain
- Responsiveness of particular organs and tissues to specific toxicities
- Availability of the species and strain
- Availability of appropriate animal housing and husbandry
- Experience of the laboratory in the use of the species and strain

chemical. Some of these factors are summarized in Table 19.6.

Toxicokinetics

Ideally, selection of an animal model for repeated dose toxicity studies should be based upon the similarity between toxicokinetics of the test chemical in that species and strain to its toxicokinetics in humans. This selection criterion assumes that these factors are known in potential test animals and in humans, though often, these data are unavailable during the initial phase of a hazard assessment. Although the metabolism of a chemical may be understood in one strain of one species of laboratory animal before initiation of repeated dose testing, it is seldom known in several species and strains. With the exception of Pharmaceuticals, the metabolism of a chemical in humans is almost never known before initiation of a subchronic or chronic study. Consequently, similarity in metabolism between humans and animal models is seldom the initial basis for selection of test species and strain. This may change, however. Currently, human microsomes and systems that express specific human detoxification enzymes are commercially available. This opens the possibility of having in vitro data concerning human metabolism before initiating a hazard assessment.

Sensitivity to Test Material

Another commonly used criterion for selection of the animal species and strain for repeated dose testing is sensitivity to the test material. As a conservative approach to the extrapolation of toxic effects seen in animals to humans, the animal model selected should be the most sensitive to the effects of the chemical. Data required for this decision are often not available until

a significant portion of the total hazard assessment program for the chemical has been completed. Acute and short-term repeated dose studies may reveal information concerning species sensitivity. However, relative sensitivity of different species and strains frequently only can be determined following completion of longer-term studies with their more comprehensive endpoints. Nevertheless, sensitivity to the chemical should be considered during selection of the test animal. For example, differences in the sensitivity of particular organs and tissues to toxic compounds among different species should be considered, and strains that have aberrant metabolic pathways, especially those associated with detoxification, should not be used except in special cases. For instance, the Gunn rat does not produce certain glucuronides (63) and would not be an appropriate animal model for a hazard assessment. Cats are deficient in their ability to produce glucuronides but can produce sulfate conjugates.

Although the concurrent control is the most important source of data for comparison, availability of historical control data for the variables evaluated during repeated dose toxicity testing is an important consideration in selecting the test species and strain. These data are frequently useful in determining the significance of a finding when comparison of data from treated and concurrent control groups suggests a potential treatment-related effect. Historical data concerning growth, feed consumption, clinical pathology, and other variables are often useful in interpreting findings from a subchronic or chronic study. Historical histopathology data are of particular importance due to their subjective nature. Although published data can be useful, historical data from the laboratory at which the study is being conducted are more applicable. Most laboratories have historical databases for commonly used species and strains. If less common species are being considered, the availability of historical data should be assessed before final selection.

Other Animal Model Considerations Involved in Study Design

After consideration of the above criteria, pragmatic considerations are necessary during selection of a species and strain. The animals should be obtained from a reputable, reliable supplier who will guarantee their health and will arrange expeditious and controlled shipment of the animals to the laboratory. The supplier should maintain careful records concerning the animal colony and maintain a healthy colony, providing disease-free animals because it is often not possible to treat for disease once a study has begun. The quantity of available test material may influence the selection of the animal model. For example, it may be necessary to select a rodent species if the amount of test material available is insufficient for long-term administration to a larger species such as the dog or non-human primate. Capabilities of the testing laboratory should be considered during test animal selection. The laboratory must have appropriate caging and other equipment and must be able to maintain the proper environmental conditions in the animal room. In addition, the laboratory conducting the study should have experience with use of the chosen species in toxicology studies. This can avoid problems associated with species specific physiology and anatomy.

Age of Animals

Age of animals used in subchronic and chronic toxicity studies is relatively standard. For rodents, initiation of test material administration at six weeks of age will satisfy virtually all guidelines for testing. Dogs should be approximately four to six months of age at initiation of exposure to the chemical. Precise age of non-human primates is frequently not known; however, age can be approximated by experienced suppliers. For non-human primates and other less commonly used species, young animals generally should be used.

Pre-study Health Assessment

To the extent possible, it should be ensured that each animal included in a repeated dose study is in good health. The animals must not have been previously used for any other type of experimental procedures. An exception is sometimes made for non-human primates, which may occasionally be used for more than one study, with a reasonable period between studies to ensure any residual test material is absent. These animals should undergo extensive health screening, including clinical pathology, between studies.

For rodent studies, enough animals of each gender should be obtained to allow culling of those with conditions that could either interfere with completing the study or be interpreted as treatment related at completion of the study. It is good practice to obtain at least 10% more animals than will be required to fill the study groups. Minimally, pre-test physical examination and body weight measurement should be conducted to assess the health of each animal before study initiation. Pre-test ophthalmological examination and clinical pathology evaluations are advisable. Animals in poor health or exhibiting ocular or other defects should be eliminated from consideration for the study.

To insure the toxicologist is aware of any infection that the animals may be exposed to during the

study, a sentinel group is often maintained in the room with the study animals. For rodents, this group normally contains five to ten animals of each gender. Serum antibody titers are assessed at the initiation of the study and at the termination of the in-life phase of the study. If necessary, antibody titers and/or other evidence of infection can also be obtained from these animals during the study without

disturbing the animals on test. A relatively complete list of antibody analyses used in rodent species is presented in Table 19.7.

Health assessment of nonrodent species by the supplier is generally more comprehensive than rodents. This reduces the need to obtain many extra nonrodents. However, it is good practice to conduct procedures after receipt of nonrodents to make sure their health has not changed before use in a subchronic or chronic toxicity study.

Number of Animals

To satisfy most regulatory guidelines, a minimum of 10–20 rodents of each gender should be included in each control and test material dosed group in a repeated dose study. For nonrodents, the minimum number of animals of each gender in each group is four. However, the minimum number of animals is frequently exceeded in an attempt to allow for unexpected mortality or to increase the sensitivity of the study. Twenty rodents or four-to-six nonrodents of each gender per group are often used as the base number of animals for the study. Some study designs include an interim necropsy at one or more intervals for detection and evaluation of the progression of potential effects during the study. Other designs may contain treated animals that will be maintained without exposure after the termination of the main study groups to determine the reversibility of any adverse effects. Still other designs include satellite groups for special purposes, for example, toxicokinetic determinations or untreated sentinel animals used to monitor the health of the study animals. The base number of animals placed on study at its initiation should be increased by the number of animals to be used for these enhanced study designs.

Individual Animal Identification

Before assignment to the repeated dose toxicity study, each animal must be provided a unique identification number. This number will be associated with the animal throughout the study and will be used to identify specimens, tissues, and data from the animal after the in-life portion of the study is completed. Therefore, this number must stay with the animal continuously during the study so that there is no chance of misidentification. It is not adequate to simply attach the animal identification to each cage because animals may escape from their cages or may be placed in the wrong one during cage-changing operations. Unique identification numbers can be placed on the animals by a number of methods. Whatever the identification method, it should remain permanent and readable for the duration of the study. Older methods used for rodents included toe clipping, where a small portion of the toe was removed in a specified coded manner, and ear punching, where holes were punched through the ears in a specified coded manner. These methods are less acceptable today because more precise and humane methods have become widely available. Currently, the use of a numbered tag attached to an ear or tattoos placed on the tail or ear are commonly used methods for large and small animal identification. A newer method that has gained considerable acceptance in recent years involves subcutaneous implantation of a miniature electronic device that can be read by a hand held scanner.

Randomization of Animals

After culling all animals that do not meet the study criteria, such as those that do not pass physical examination or are not within specified body weight boundaries, and assigning unique identification numbers to the remaining animals, the next step is to randomize them into the various study groups. This is a critical step in the study to ensure the greatest ability to detect statistical differences between the groups in the study without bias. Although a number of randomization methods have been devised, some more appropriate than others, one of the most popular is the utilization of random number tables. After randomization into the various study groups, some method should be employed to determine if the animals are truly randomized based upon a variable critical to the study. The most commonly used variable is body weight. Statistical analysis of mean body weight data is conducted to show that there are no statistically signifi

cant intergroup differences in mean body weight, and, hopefully, other variables, at the initiation of the study. It is not uncommon to find that the mean body weight of the animals in one of the study groups is significantly different from one or more of the other groups. In cases where there may be a significant difference between the mean body weights of any of the study groups, the animals are again randomized into study groups and the process repeated. Randomization must be conducted independently for each gender because of body weight differences between males and females.

Animal Husbandry

Proper care and maintenance of animals in a repeated dose toxicity study is essential not only for ethical reasons but also to minimize mistakenly attributing adverse findings to the test material. The Animal Welfare Act (AWA), enforced by the Animal, Plant and Health Inspection Service (APHIS) of the U.S. Department of Agriculture, mandates standards for acceptable handling, care, treatment, and transportation of many species, including most laboratory species except mice, rats, and birds (61). In its *Guide for the Care and Use of Laboratory Animals,* the Institute of Laboratory Animal Resources (ILAR) of the National Research Council has published guidelines that are widely accepted as standards for laboratory animal husbandry (44). From their arrival at the laboratory, animals must be maintained in an appropriately controlled environment and provided an adequate quantity and quality of feed and water and housed in clean cages of appropriate design. They should be acclimated to the study room conditions for at least one week before study initiation (see Chapter 16).

Environmental Factors

Temperature and humidity should be controlled within limits specified in the documents referenced above. Table 19.8 is taken from the ILAR document and contains the recommended temperature ranges for various laboratory animal species (44). Low humidity can result in drying of the mucous membranes and eyes of laboratory animals, and high humidity can result in growth of bacterial and fungal populations that result in respiratory distress and dermal involvement, such as ringworm. In addition, urine and excreta may not dry as readily, thereby increasing room odor. Relative humidity of 30–70% is considered acceptable by ILAR for most laboratory species (44).

Adequate ventilation is a key factor in maintaining good animal health during a toxicology study. Establishing a positive room air pressure reduces possible exposure of animals to test materials being used in other animal rooms. When more air is forced into a room than can be completely cleared by exhaust systems, it flows through the cracks, around the door, and the partial pressure of air in the room becomes positive with respect to the hallway or area outside the room. Ventilation should be homogeneous throughout the room; this generally is controlled by adjustable diffusers and the ventilation of all rooms in a facility must be "balanced" periodically to provide the same relative airflow and positive pressure with regard to hallways. In general, 10–15 fresh air changes per h is considered acceptable but this range is highly dependent on a number of factors, for example, the number of animals in the room.

Common lighting schedules used are 12 h of continuous light and 12 h of darkness for rats, mice, dogs, and monkeys, and 14 h of light and 10 h of dark for hamsters. This schedule allows the animals to become acclimated to a light cycle. This stimulates a constant pattern of secretion of thyroid hormones, ACTH, and growth hormone. Regulated lighting cycles are necessary in reproduction studies because rodents enter continuous estrus under conditions of constant light without darkness. Because high-intensity fluorescent light can cause blindness in albino rodents, current practice is to limit their exposure to high-intensity light to times when observations are collected by providing dual-intensity (high-low) lighting systems.

Animal Caging

In the United States, rodents are commonly housed one per cage during subchronic and chronic toxicity studies. In other countries, rodents are frequently multiply housed during these studies because it is believed that multiple housing increases survival and decreases background pathology. Multiple caging of animals can produce problems associated with unique identification and trauma to the animals from fighting, and multiply housed rodents are more susceptible to transmitted disease and other health concerns. Furthermore, a multiply caged rodent that dies on study may sustain tissue destruction from cannibalism. It also is not possible to determine individual feed consumption when multiple animals are housed in a single cage, resulting in the loss of important data

Table 19.8 ILAR recommended dry-bulb temperatures for common laboratory species

	Dry-Bulb Temperature	
	°C	°F
• Mouse, rat, hamster, gerbil, guinea pig	18–26	64–79

• Rabbit	16–22	61–72
• Cat, dog, non-human primate	18–29	64–84
• Farm animals and poultry	16–27	61–81

because it is not possible to correlate body weight with individual feed intake. In addition, if the test material is fed as part of the diet, it is not possible to calculate actual exposure doses for individual rodents in the absence of individual feed consumption data. Although some of the same problems exist for nonrodents, multiple housing of some species (e.g., non-human primates and dogs) on a regular or continuous basis during the study is accepted practice to permit the social interaction and exercise considered necessary for these species.

Rodents generally are housed in metal (stainless or galvanized steel) or plastic (polyethylene, polypropylene, or polycarbonate) cages. Metal caging or floor pens are used for dogs. Minimum cage sizes for all species are stipulated in the ILAR publication (44) and, for nonrodents, in the AWA (61). Compliance is monitored by federal and state health agencies. Because minimum sizes for cages are stipulated, only caging type remains to be decided between solid floor cages or pens and suspended-floor cages.

Solid floor caging requires bedding to be added to the cage to absorb and contain waste materials; this may introduce dust. Sawdust and chips of some conifers induce hepatic cytochrome P450 monooxygenase activity, which may affect the outcome of the study. In addition, this type of caging allows animals to have access to their waste. Shoebox-style cages used for rodents may clear the atmosphere at a slower rate than suspended wire cages.

Cages with suspended wire floors also have disadvantages. Traumatic foot and leg injuries can occur, particularly with smaller animals. Plantar foot pad lesions are common in long-term studies of rats housed in wire bottom cages, especially in heavy males. This type of cage also exposes the animal to room drafts.

Most gradients in light, temperature, or airborne products in an animal room will occur vertically. Animals within groups should be distributed in cage racks so that members of each study group are present equally at all vertical caging levels. This practice, and the practice of periodically changing the relative position of each cage rack within the room, avoids confounding treatment group with cage position. Documentation of environmental conditions and of cage/rack rotation is essential.

Cleaning cages at frequent intervals is essential. Poor husbandry may result in skin lesions, alopecia, or the appearance of signs and behavior that may be interpreted as a possible effect of the test article.

Diets

The influence of diet and nutrition on the toxicity of xenobiotics is another important aspect of the design of toxicology studies. Because the diet fed the animals during toxicology studies can influence the results, the decision made by the toxicologist concerning what diet to feed the animals may have a profound impact upon the outcome of the studies. The diet fed during a study should have been designed for the study species. Although diets can be custom-made, they are generally obtained from commercial suppliers who should be reputable and capable of supplying information concerning basic diet composition and nutritional information. Although not feasible for a long-term study (e.g., 12 months), the same lot of diet should be used for the entire study whenever possible, and used before its expiration date. It should be stored under appropriate conditions to maintain nutritional value, minimize insect and rodent infestations, and ensure it is not contaminated by environmental chemicals.

Commercial diets are available in either ground “powder” or pelleted form. When the test material is to be incorporated into the feed, a powdered diet is generally used. Use of powdered diet also facilitates the determination of feed consumption. Pelleted diets are most frequently used when test material administration is by routes other than dietary. A powdered diet can be pelleted after a test material has been added, which reduces the dust from the diets. Pelleted diets also decrease the potential exposure of animal room personnel to the test material. However, the heat and pressure involved during the pelleting process may cause degradation of test materials sensitive to these conditions.

Diets used in toxicology studies are of two basic compositions. Currently, diets made from natural ingredients are most commonly used, but semi-purified diets made from refined macronutrients, such as protein and carbohydrate, and micronutrients, such as vitamin and mineral mixes, are sometimes used. Each has particular advantages and disadvantages that must be carefully considered by the toxicologist.

Natural diets are formulated from unrefined plant and animal products to meet the nutritional requirements of a particular species. In closed formula diets, the manufacturer does not provide the exact proportions of the constituents. The diets are formulated based upon nutritional specifications without emphasis on consistency of specific ingredients between lots. Plant materials contain a number of “non-nutritive” components that can effect various physiological and biochemical functions, including detoxification and metabolic activation, in the test animal. Because these components may vary with plant species, strain, growing conditions, and site, individual lots of closed-formula diets may differ in

these constituents. Open-formula diets are formulated with constant quantities of specified ingredients, resulting in a more consistent composition than closed-formula diets. An example is the NIH-07 rodent diet, which has been relatively well characterized (59). Open-formula diets have advantages for long-term studies because of their consistent formulation. An additional consideration -

concerning both open- and closed-formula natural diets is their potential to contain contaminants, such as pesticides, heavy metals, and mycotoxins. To overcome this problem, some manufacturers provide diets that have been assayed for certain potential contaminants to insure they are below stated specifications. It is highly recommended that these "certified" diets be used in toxicology studies. A disadvantage of natural commercial diets is that their nutritional composition cannot be readily altered. It is possible to supplement these diets but not to remove constituents. An important advantage of natural diets is their long history of use and the resulting large quantities of historical control data.

Semi-purified diets are made from refined macroconstituents such as protein, carbohydrate and fiber, and micronutrient mixes containing individual minerals and vitamins and a defined fat source such as corn oil. Their constituents can be varied to design diets for specific nutritional purposes and allow for the inclusion of test materials that may provide nutrient activity or result in nutritional deficits. Nutrient composition can be reproduced exactly from lot to lot of semi-purified diet. As opposed to natural ingredient diets, semi-purified diets do not contain pesticides, mycotoxins, and other constituents that may alter the animal's response to the test material. However, a major problem with semi-purified diets is a lack of historical data from their use in long-term studies. A large number of different dietary compositions are currently in use and data obtained from one semi-purified diet may not extrapolate to another. Even with the most commonly used semi-purified diet, the AIN-76A (1), there are insufficient data to determine its impact on long-term toxicology studies, especially carcinogenicity studies (26). Although these diets can be utilized in subchronic toxicity studies, the data obtained may not be as useful as that from studies with natural diets, especially when these data are used to design longer-term studies with natural diets. While it may be necessary to use semi-purified diets with specific test materials, care must be taken if they are to be used in a safety assessment.

Dietary restriction has been shown to prolong the life of rats and mice. There is some interest in employing restricted food intake (~20%) in chronic toxicity and carcinogenicity studies to prolong the lifespan, and therefore the exposure period, of the animals. If feed restriction is planned, it may be appropriate to employ this regimen in the shorter-term studies also. Utilization of feed restriction in toxicity studies should be discussed with the appropriate regulatory agency before it is included in a safety assessement program.

Drinking Water

Drinking water free of contaminants that could interfere with the objectives of the study should be available to the animals during repeated dose toxicity studies. Water is frequently provided to the rodent and nonrodent animals through automatic watering systems in which a common water supply is piped to the animal cages and each cage contains a valve that allows the animal ad libitum access to the water. Water bottles are another, more labor-intensive method of providing water to the rodents and some nonrodents. For this method, each bottle is fitted with a stopper containing a sipper tube through which the animal can drink and, which, is suspended on the cage. A third method, generally only used with nonrodents, is to provide the animals with water in a drinking bowl. Any of these is acceptable as long as procedures are in place to insure that the animals are provided an adequate supply of potable water.

In-Life Evaluations

Physical Examination

Several variables are routinely evaluated during the treatment phase of subchronic toxicity studies. Each animal should be observed twice daily at least four hours apart (A.M. and P.M.) for overt signs of toxicity, moribundity, and mortality. During these A.M. and P.M. observations, the cage of each animal should be opened to permit unobstructed observation. In addition, each animal should be removed from its cage for a complete physical examination at least once a week. These examinations should include detailed observations for approximate time of onset of any changes, degree and duration of changes involving the skin, fur, eyes, mucous membranes, respiratory function, circulatory system, autonomic and central nervous systems, somatomotor function, and general behavior. A study-specific or SOP-specific glossary of clinical terms and descriptive criteria for each finding is recommended, with simple and descriptive terms, and using a minimum of medical or diagnostic terminology.

Body Weight Measurement

It is recommended that body weight be measured at least once a week, even though biweekly or monthly measurement after the first three months of a chronic toxicity study is acceptable to most regulatory agencies. Weekly measurement is recommended because body weight is one of the most sensitive indicators of the condition of an animal if it is monitored frequently and carefully during a study. Rapid and/or marked body weight loss is usually a harbinger of ill health or death. Rapid body weight loss can be due to either decreased feed or water consumption, disease, or specific toxic effects.

Feed Consumption

In rodents, feed consumption generally is measured once a week during subchronic studies and the first three

months of chronic studies. After the third month of a rodent chronic study, feed consumption may be measured less frequently, that is, biweekly or monthly. For nonrodents, in which the quantity of feed required usually does not allow weekly feeding, feed consumption is evaluated for shorter intervals, often once or twice per day. Accurate measurement of feed consumption is essential for studies in which the test material is administered in the diet. As discussed earlier in this chapter, feed consumption and the dietary concentration of the test material are used to calculate the dose of test material consumed by the animals in such studies. Some species, especially the mouse and the non-human primate, frequently soil or waste feed; which makes accurate measurement of consumption difficult. In these species, feed consumption measurement can be attempted using either a feed container designed to minimize wastage or by attempting to estimate feed wastage. Limitations of such data should be considered in evaluating test material consumption and the significance of any apparent differences between feed consumption in test material-treated and control animals. Feed consumption measurement is another means of monitoring animal well-being. Animals that are ill or suffering adverse effects from exposure to the test material frequently will exhibit significantly decreased feed intake.

Ophthalmological Examination

Ophthalmological examination of all test animals should be conducted before initiation and at the completion of the test material administration period. This evaluation should be conducted by a veterinary ophthalmologist experienced in the observation of the species used for the study.

Clinical Pathology

Clinical pathology variables such as hematology, clinical chemistry, and urinalysis are important indicators of general health and toxicity and are assessed at termination of a subchronic or chronic study. In addition, pretest and interim (typically at 4 weeks in subchronic studies and at 13 weeks in chronic studies) clinical pathology may be conducted to allow evaluation of progression of any treatment-related effects noted at termination of the study. In rodents, clinical pathology determinations are usually conducted for 10 animals of each gender in each group. For nonrodents, clinical pathology should be done for all animals.

Sample collection. Proper sample collection and handling are critical to completion of a meaningful clinical pathology evaluation. Whenever possible, the method of sample collection should be the same throughout the study and should be one that distributes variance—such as run-to-run variation in an enzyme assay—equally across groups. Samples generally are collected according to either a totally random design or a stratified random design. A stratified random design ensures that approximately the same number of animals of each gender and from each group are sampled within any block of time or during any set of assays.

Repeated blood sampling of rodents can be accomplished by serial collection from the same animals by non-terminal procedures (such as puncture of the orbital sinus or jugular vein), or by collection from the abdominal aorta or vena cava at termination of subgroups of animals. Because of practical restraints on the frequency and volume of blood collection in rodents, pretest studies often are not performed. Repeated collection of adequate volumes of blood usually is not a problem for nonrodents and pretest clinical pathology is often included in studies using these animals.

The effect of repeated blood sampling on the animals and on the sample volume that can be reliably obtained at each sampling interval should be considered. Sample volumes should be sufficient both to conduct the assays indicated in the protocol and, if possible, to provide a reserve sample for any necessary repeat test. However, significant reduction of blood volume (more than 10%) by blood collection should be avoided.

Plasma or serum to be used for clinical evaluation should be clear and straw-colored. Red or pink plasma suggests that some hemolysis has occurred either as a result of pathology or as an artifact of the sample collection/preparation procedures. Severe artifactual hemolysis may alter the results for some of the clinical variables to be evaluated. Slight hemolysis, commonly observed in serum and plasma collected from rodents by orbital sinus or jugular venipuncture, generally is acceptable for clinical pathology studies as long as historical laboratory ranges have been established for blood collected by these methods. If unusual or unexpected results are obtained, aliquots of serum or plasma can be "spiked" with ascending amounts of test material to determine if it interferes with the assay.

Clinical chemistry, hematology, and urinalysis. Clinical pathology should include determination of a number of serum or plasma chemistry and hematology variables which should assess electrolyte balance, protein and carbohydrate metabolism, and organ function. An acceptable list of clinical chemistry variables is shown in Table 19.9. Additional variables should be assessed, as appropriate, to address other anticipated effects of the test material, for example, serum cholinesterase levels in the

case of carbamate or organophosphate insecticides. Assays designed for assessment of clinical chemistry in humans must be validated for use with the species used in the toxicology studies. Typical hematological variables assessed during repeated dose testing are shown in Table 19.10. The reader is referred to the chapter concerning clinical pathology in

Table 19.9 Clinical chemistry variables normally obtained in repeated dose studies*a.b*

this text for a more detailed discussion of these clinical chemistry and hematology determinations, and two excellent veterinary texts available for further reference (45, 49).

Urinalysis is often included in the clinical pathology evaluation and may be important, especially for test materials that are nephrotoxins. Urinalysis variables typically evaluated are listed in Table 19.10. Urinalysis however, is frequently of limited value because collection of satisfactory urine samples is fraught with technical difficulties. Urine generally is collected in containers or tubes from troughs or trays placed below the cages in which the animals are housed and, therefore, steps must be taken to minimize fecal contamination. Because urine is frequently collected during an extended period, for example, overnight, bacterial growth in the sample is a concern. Collection of the sample on ice can reduce bacterial growth but presents its own technical challenges. Care should be taken that water be either freely available to the animals throughout the urine collection period or withdrawn at the appropriate time before collection, and the sample must not be inadvertently contaminated by feed or drinking water spilled by the animal. Because of these difficulties, the utility of urinalysis should be discussed with an experienced veterinary clinical pathologist prior to its inclusion in the design of a repeated dose toxicity study. If urinalysis is conducted, its limitations must be kept in mind when the data are reviewed.

Post-Mortem Evaluations

One of the more definitive assessments of toxicological effects conducted during a repeated dose study is the macroscopic and microscopic examination of tissues and organs from treated and control animals. In typical subchronic and chronic studies, samples of approximately 50 tissues and organs are collected during the necropsy of each animal. Table 19.11 presents a list of tissues that are commonly collected for potential histopathological examination.

Necropsy

Necropsy of an animal is conducted when it dies during the study, when it is killed during the study for humane reasons (e.g., in cases of moribundity), or when it is killed at a scheduled interval (interim sacrifice or termination of the study). Necropsy should be completed as quickly as possible after the death of an animal to avoid *autolysis* that can interfere with the subsequent microscopic examination of its tissues. Autolysis is defined as the enzymatic self-digestion of cells or tissues that occurs after death.

It is an especially important consideration for animals that die during the study because their death may not be discovered for a significant period of time. Animals found to be moribund (i.e., about to die) during the study should be terminated for humane reasons and to avoid tissue autolysis.

During necropsy, tissues and organs are systematically removed and macroscopically visible abnormalities are noted, including changes in color, shape, size, or consistency of a tissue. The documentation of an abnormality in the necropsy records should include its location and a clear description of the change, using nondiagnostic terminology. Completeness of the examination during necropsy and the quality of the description of abnormalities are critical to the determination of pathological effects. An abnormality in a tissue can only be prepared for microscopic examination if it was collected and accurately described during necropsy. Because of the central role that the necropsy plays in detecting effects in a repeated dose toxicity study, it is extremely important

that necropsy technicians are highly trained and experienced in the necessary techniques.

After collection, tissue samples are usually preserved by immersion in an appropriate fixative, commonly 10% neutral buffered formalin. In some cases, particularly for organs such as testes or eyes, special fixatives may be used (62). To ensure adequate fixation, the volume of fixative should be at least 10 times the volume of tissues. Certain organs, for example, the lung and urinary bladder, are frequently filled with fixative prior to immersion to improve fixation. During collection of large numbers of tissues from many animals, it is possible to inadvertently miss a tissue. Therefore, it is highly advisable to inventory and document the samples as they are placed into the fixative containers. This inventory will be invaluable during subsequent preparation of the tissues for microscopic examination and in reconstructing the study during post-study auditing of the data. In addition, it must be ensured that the identity of each tissue is clearly maintained while in fixative. This is not a problem for tissues that are large or have distinctive morphology. To ensure subsequent identification of extremely small tissues and those with indistinct morphology, they are frequently placed in labeled plastic cassettes or cloth bags prior to being placed in the fixative container.

Organ Weights

Collection of terminal body weight and organ weights for all animals during necropsy is normal practice in repeated dose toxicity studies. Minimally, weights should be recorded for the brain, liver, kidneys, testes, and adrenal glands. Frequently, other organs such as the thyroid/parathyroid, ovaries, spleen, thymus, uterus, epididymis, heart, or lungs are also weighed. Consideration should be given to the residual blood that may remain in organs such as the spleen, heart, and lungs, which may be variable between animals due to the method of sacrifice and blood collection. Organs should be weighed as soon as possible after removal from the animal and trimmed free of fat and connective tissue prior to weighing and placed into fixative immediately thereafter.

It is common practice to normalize organ weights by expressing them relative to body weight and brain weight. Relative organ weights are used to eliminate the influence of normal variation in animal growth on the interpretation of organ weight data. However, normalized organ weight data should be reviewed with the knowledge that they have some limitations. Expressing organ weights relative to body weight can yield apparent, but artificial, treatment-related effects on organ weights in studies where the test material affects body weight gain, although organ weights normalized to brain weights help overcome this problem because test materials that alter body weight generally do not alter brain weight. The best practice is to consider all three types of data, that is, actual organ weight and organ weight relative to body and brain weight. Histopathological data are often used to help assess the significance of apparent differences between organ weights of test material-treated and control animals.

Microscopic Pathology

Microscopic examination of the tissues and organs of treated and control animals is one of the most time-consuming laboratory functions in toxicity studies. In nonrodent studies, sections of all tissues and organs from all animals should be prepared for microscopic examination. Generally, in rodent studies, only tissues and organs from the controls and high-dose group animals and animals that were killed or died during the study are examined microscopically. For the other treatment groups, only a few major organs (e.g., liver and kidney, and any other organs in which macroscopic abnormalities were noted at necropsy or in which test material-related effects are detected in high-dose animals) are examined. Although initial histopathological examination of control and high-dose tissues followed by examination of other doses is typical in rodent studies, simultaneous histopathological examination of all tissues from all animals is not uncommon. This practice yields the most expeditious completion of the histopathological evaluation phase of a study because sequential examinations are not required. Simultaneous examination also reduces the inter-group variability in diagnoses that might occur when tissues from intermediate groups are examined considerably after completion of the evaluation of the control and high-dose groups. Such variability can lead to incorrect conclusions concerning treatment relationship of lesions noted in the intermediate dose groups. In a draft of its guidelines for safety studies, the FDA has proposed that tissues from all dose groups, not just the high-dose and controls, be subjected to histopathological examination (27).

Routinely, tissues are prepared for light microscopic examination by embedding in paraffin, sectioning at 5–7 microns, and staining with hematoxylin and eosin (H&E) stain (Figure 19.5). Special stains, such as stains for the presence of fat (Oil Red O) or connective tissue (trichrome stain) may be used for some tissues. Use of a protein-specific stain (Mallory-Heidenhain) is illustrated in Figure 19.6. If desired, representative samples of selected tissues may be frozen at necropsy and stored for biochemical or immunohistochemical analyses or specially prepared for electron microscopy. In the histology laboratory,

it is important that tissues be prepared according to standardized procedures especially with respect to type of section (i.e., cross, longitudinal), location, and orientation on the microscope slide. The his-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_941.html[2010/10/28 18:49:29]

tology technician must review the observations recorded during necropsy of the animals to ensure that all grossly observed lesions are properly sectioned and mounted on the slide for subsequent microscopic examination. Whenever possible, samples of lesions prepared for examination should include the lesion and portions of surrounding "normal" tissue.

Histopathological examination of the tissues requires specialized training and is performed by a pathologist trained and experienced in the evaluation of toxicologic pathology. The pathologist must be familiar with the normal features and naturally occurring lesions that can be observed microscopically in tissues from laboratory animals. The pathologist's responsibility, however, is more than evaluation of the tissues and accounting for all the lesions reported at necropsy. The pathologist should be an integral part of the protocol design team to provide input into many factors, for example, selection of the species/strain to be used, clinical pathology variables to be evaluated, and others. The pathologist should also provide guidance concerning the list of tissues to be collected to ensure that they are processed, stained, and evaluated in a manner that satisfies the study objective.

It is critical that the pathologist review the data generated during the in-life and necropsy phases of the study before proceeding with the histopathological evaluation. Results of clinical observations, clinical chemistry and hematology determinations, organ weight measurements, and necropsy examinations can lead the pathologist to focus on particular organs as potential targets for toxicity during the microscopic examination. For example, increased liver weight should lead to a more careful examination for hepatocellular hyperplasia or hypertrophy, and elevated serum creatinine along with a necropsy description of the surface of the kidneys as "rough" should result in a more thorough examination for nephropathy.

Some have suggested that knowledge of in-life and necropsy findings will bias the pathologist, causing a more stringent examination of the potentially affected tissue. Similarly, some are concerned that knowledge of the dose level administered to the animal during the study will bias the pathologist, resulting in a more thorough examination of the tissues from animals that received the test material. The second situation, in particular, could result in a higher incidence and/or severity of microscopic findings in treated animals compared with controls, a higher incidence that is simply an artifact of the thoroughness of the microscopic examination. One way to prevent potential bias is to keep the pathologist ignorant of other study findings and of the identity of the animal until histopathological examination of the tissues has been completed. Because this so-called "blinded reading" does prevent bias but may also prevent the pathologist from identifying certain subtle, dose-related changes, blinded reading is not recommended for routine histopathological evaluations and should only be conducted in special situations.

Pathological changes in cellular or subcellular structure can occur either spontaneously, such as with aging, or as a result of exposure to a chemical. Deciding which changes are significant and what severity should be assigned to a change during histopathological examination is quite subjective. Because of this, it is possible that different pathologists looking at the same tissues will produce different diagnoses. It is even possible that, during histopathological evaluation of a large number of tissues that extends over a number of months, the criteria for diagnosis of the same finding by a single pathologist will change somewhat. The variability that results from the subjective nature of histopathological evaluation is unavoidable. To minimize its effect on the results of toxicity studies, several procedures can be useful. First, during each "reading period," the pathologist should examine tissues from a small subset of the study animals. Each subset should contain approximately equal numbers from each control and treated group to be examined. Second, if a potential target organ is identified over an extended period of time, the pathologist should re-examine that organ from all animals during a compressed reading period of a few days or less to assess to what extent, if any, "diagnostic drift" occurred over time. Third, informal peer consultation concerning unusual or subtle tissue changes observed during examination of the tissues can be conducted to arrive at a consensus diagnosis. In addition, a formal peer review process involving

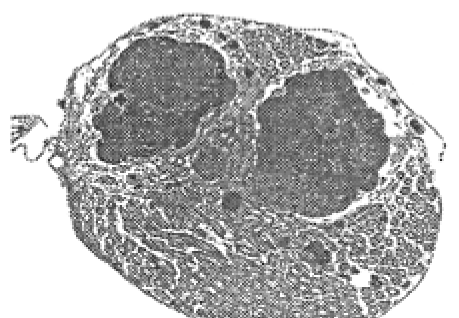
(1) re-examination of target organs,

(2) reexamination of a representative percentage of other tissues from the study, and

(3) review of interpretation of the pathology findings can be conducted by a second pathologist to ensure consistency in diagnosis and grading of tissue changes and accuracy of the pathology conclusions (37).

The objective of the histopathological evaluation is the same as the objective of all other determinations during a repeated dose toxicity study—to detect adverse effects that could be relevant to humans or any other target species exposed to the test compound. Because of certain idiosyncrasies, some animals

and strains are not useful for this purpose. In some cases, the animal exhibits a high spontaneous rate of pathology in a particular organ that prevents detection of any compound-induced increase in that rate. For example, severe testicular pathology occurs spontaneously in a very high percentage of old



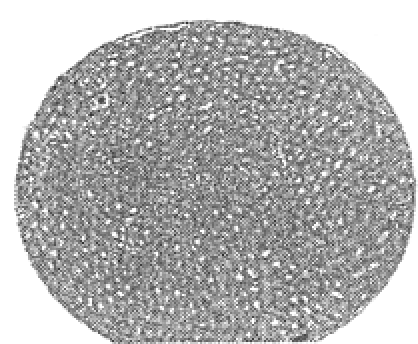


FIG. 19.5. Photomicrographs of Hematoxylin & Eosin stained testes from Fischer 344 rats (2.5 x magnification). The testis on the left exhibits an interstitial cell tumor. The testis on the right is without pathological changes.

male Fischer 344 rats (see Figure 19.5). Therefore, this strain of rat is generally not useful for the detection of testicular effects. In other cases, a pathological change occurs in the laboratory animal only in response to test-compound exposure, but that pathology would not be expected to occur in the target species. An example of this is light hydrocarbon nephropathy that occurs only in male rats. Many hydrocarbons produce this nephropathy, for example, d-Limonene and unleaded gasoline. It is caused by accumulation of a male rat-specific protein, alpha-2-microglobulin, in the renal tubule following exposure to these chemicals. This nephropathy is characterized by hyaline droplets in the cytoplasm (Figure 19.6), granular casts in the lumen (Figure 19.7) and cellular regeneration in the tubules. Because humans do not produce alpha-2-microglobulin, this gender- and species-specific pathological finding has no relevance to human hazard assessment and the male rat is not a suitable model for human renal effects related to light hydrocarbon exposure. For both examples cited, however, the test animal is perfectly acceptable for use as a human surrogate in toxicity testing as long as the limitations imposed by its idiosyncrasies are taken into account.

Even though the idiosyncratic situations discussed above do occur occasionally, the pathology that occurs in most laboratory animals and most tissues is considered relevant to the assessment of hazard in humans. The histopathological examination of tissues in a subchronic or chronic toxicity study can yield a vast array of diagnoses. A detailed discussion of possible chemicalrelated pathological findings is beyond the scope of this chapter. For detailed descriptions of methods for and diagnosis of veterinary toxicological pathology, the reader is referred to a review by Hardisty (37) and two comprehensive texts on the subject (2, 38).

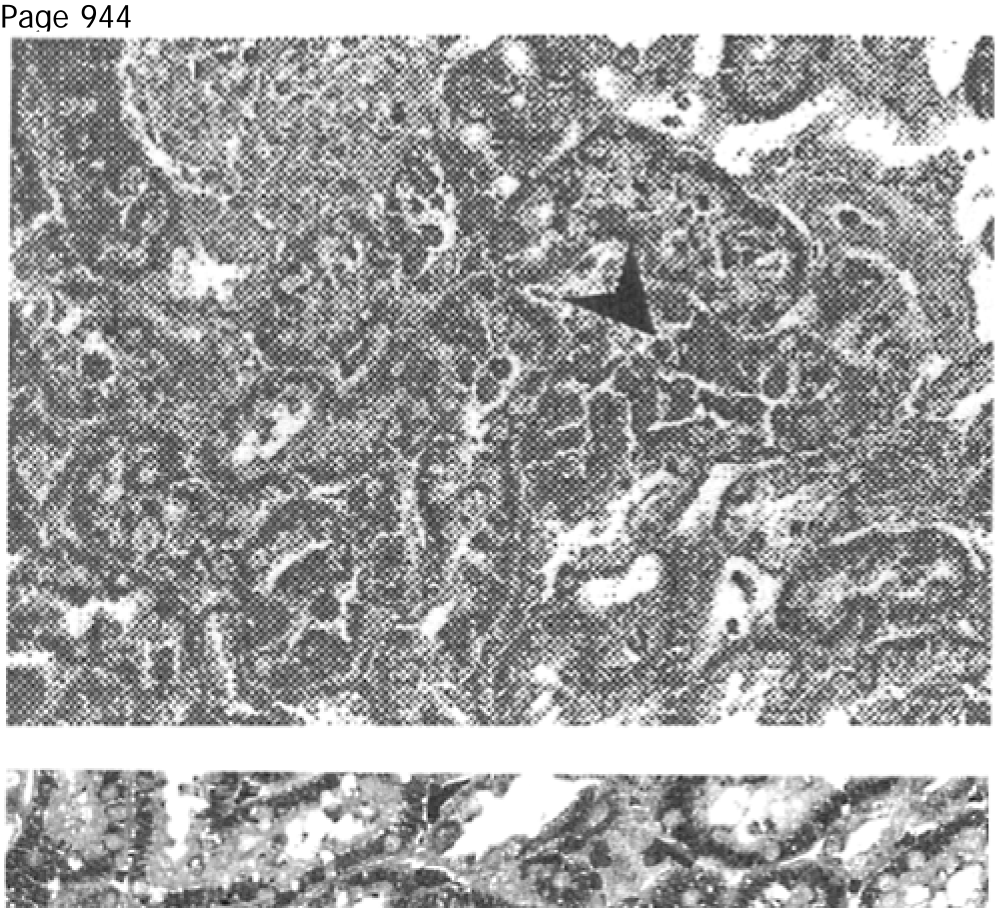
Additional Endpoints for Repeated Dose Toxicology Studies

Evaluation of special endpoints can be added to repeated dose toxicology studies to maximize the utilization of animal resources, minimize the time and cost of a hazard assessment, and obtain additional data. Care should be used in selecting these endpoints to ensure valid methodology is used and that the data will be accepted by regulatory agencies. Draft guidelines for safety assessment of direct food additives and color additives suggest data concerning the immunotoxic and neurotoxic potential of the test material should be generated during subchronic toxicity studies (27). To insure the methodology and data presentation is acceptable to the regulatory agencies, meetings should be held with the appropriate agency during design of the study.

It is possible, through the addition of special determinations, to make a subchronic or chronic toxicity study so complicated that the main objectives are jeopardized. All the ramifications of the addition of special endpoints to a study design, including practical considerations such as daily workload, should be considered to ensure that basic study endpoints are not compromised. Rather than overwhelming the capabilities of the testing laboratory, conduct of a separate study designed to evaluate the special endpoints may be preferable. This is not to say that special evaluations should never be added to subchronic or chronic studies; with appropriate consideration of the possible complications, they can be and often are.

If a question still remains whether additional endpoints should be added to short-term repeated dose study or to longer-term studies, the following should be considered. If these endpoints were added to short-term studies, then the data would be available to aid in design of longer-term

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_943.html[2010/10/28 18:49:30]



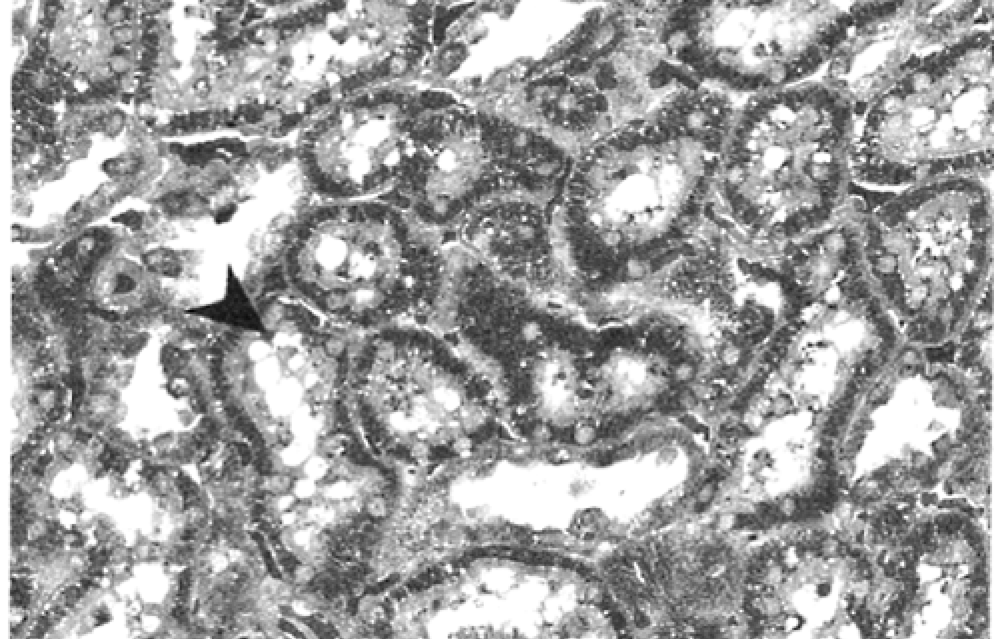


FIG. 19.6. Photomicrographs of kidneys from Fischer 344 male rats stained for protein using Mallory-Heidenhain stain (100 x magnification). The kidney tubules on the top are stained heavily and contain many hyaline droplets (arrow). The kidney tubules on the bottom exhibit normal levels of protein staining (arrow).

< previous page page_944 next page >

studies. However, if the particular variable to be evaluated appears only after longer exposure periods, any change might not occur in short-term studies. The most conservative approach is to add the endpoints to each study type. The following paragraphs provide examples of how data concerning non-standard toxicological endpoints may be obtained from classical repeated dose toxicity study designs.

Genetic Toxicology

Certain in vivo and in vivo/in vitro genetic toxicology data may be obtained during or at the termination of a repeated dose toxicity study. Addition of these endpoints to a study could decrease the number of animals used in a hazard assessment and shorten its duration. In vivo genetic toxicology studies increase the value of a hazard assessment. Because they use the route of administration by which humans are exposed to the test material and all processes of absorption, distribution, metabolism, excretion, and DNA repair are intact, these in vivo studies provide important information that cannot be obtained from in vitro studies using cellular systems.

A number of in vivo genetic toxicology assays are in use, some of which are suitable for incorporation into repeated dose toxicity assays. For example, the authors have incorporated the bone marrow micronucleus assay into a classic subchronic study design. During most repeated dose toxicity studies, bone marrow smears are made (see Table 19.11), in essentially the same manner as those used for the in vivo micronucleus assay (39). These slides can be stained with acridine orange and the polychromatic erythrocytes analyzed for micronuclei. Use of bone marrow slides from the repeated dose study has several advantages:

(1) it incurs no additional time and cost for collecting the samples,
(2) it allows the assay to be conducted on animals exposed to the test material for long periods of time,
(3) it eliminates the need for resources to conduct an independent study, and
(4) it does not interfere with the histopathological assessment of the tissues.

It may be possible to use bone marrow slides from repeated dose toxicity studies for the bone marrow chromosomal aberration assay (4). This is another in vivo genetic toxicology assay that could provide additional data without an independent study being conducted. Another such genetic toxicology assay is the in vivo/in vitro unscheduled DNA synthesis assay (51), in which freshly isolated hepatocytes are used to determine unscheduled DNA synthesis. Although this assay is

Table 19.11 Tissues collected for histopathology in repeated dose studies

Adrenals	Mammary gland (females)
Aorta	Muscle (thigh)
Bone marrow smear	Nose
Brain	Ovaries
Cecum	Pancreas
Colon	Pharynx

Epididymides	Prostate
Esophagus	Rectum
Eyes	Salivary gland (submandibular)
Femur and bone marrow	Sciatic nerve
Gallbladder (when present)	Seminal vesicles
Heart	Skin
Ileum	Spinal cord (cervical, thoracic, lumbar)
Jejunum	Spleen
Kidneys	Sternum and bone marrow
Lacrimal gland	Stomach
Larynx	Testes
Lesions	Thymus
Liver	Thyroid with parathyroid
Lungs	Trachea
Lymph nodes	Urinary bladder
(mandibular and mesenteric)	Uterus

not compatible with histopathological use of the liver, as few as two to three extra animals per group are all that are required. One problem associated with incorporation of additional endpoints, such as genetic toxicology, into a repeated dose study design is that the laboratory conducting the study must have valid assay methodology. This is not always the case.

Not all in vivo genetic toxicology assays are completely suitable for incorporation into repeated dose

studies. For instance, the in vivo sister chromatid exchange assay requires the administration of deoxybromouridine to the animals. This compound can compromise the classical endpoints used in toxicity studies, including histopathology. It is possible, however, to incorporate extra animals to assess specific endpoints while not compromising the main study animals.

Neurotoxicity

It is possible to incorporate neurotoxicity screening into repeated dose toxicity study designs. In fact, in its draft version of its food additive toxicology testing recommendations, the FDA has suggested that neurotoxicity screening be incorporated into these study designs (27). EPA has similar recommendations (14, 15).

Neurotoxicity screening is designed to determine if the test material has the potential to produce adverse effects on the nervous system. Screening is conducted to determine if additional, more sophisticated, neurotoxicity

testing is required. The first indication of a requirement for neurotoxicity testing may come from the structureactivity assessments. However, the database for neurotoxicity structure activity assessments is not as extensive as for certain other types of toxicity and may not provide useful insight into the need for neurotoxicity testing. Drugs and pesticides that target the nervous system are a well-known exception. For instance, there is no question that a new organophosphate insecticide will require neurotoxicity testing. For most compounds, it will be necessary to develop data through empirical testing.

Most classical repeated dose study designs contain elements that may provide some information on neurotoxicity potential. These include cage-side observations of the animals, physical examinations, and measurement of variables, such as food consumption, that may relate to behavior modifications during the in-life phase of the study. Additional information is obtained during histopathological examination of the structures of the nervous system collected at necropsy, such as the brain and spinal cord. The FDA believes, however, that these procedures, as well as others, should be specifically included into the design of repeated dose toxicity protocols (27). Table 19.12 lists the design elements recommended by the FDA for a neurotoxicity screen. Specific behavioral and neurotoxicity tests exist to provide most of the requested data, and the particular test designs should be chosen based upon their validity, history of use, lack of undue stress to the animal, and the

Table 19.12 FDA draft criteria for a neurotoxicity screen as a component of short-term and subchronic studies

- Histopathological examination of tissues representative of the nervous system, including the brain, spinal cord, and peripheral nervous system
- Quantitative observations and manipulative test to detect neurological, behavioral, and physiological dysfunctions. These may include:
  - general appearance
  - body posture
  - incidence and severity of seizure
  - incidence and severity of tremor, paralysis, or other dysfunction
  - level of motor activity and arousal
  - level of reactivity to stimuli
  - motor coordination
  - strength
  - gait
  - sensorimotor response to primary sensory stimuli
  - excessive lacrimation or salivation
  - piloerection
  - diarrhea
  - polyuria
  - ptosis
  - other signs of neurotoxicity deemed appropriate

experience of the laboratory with the specific test. Care should be taken to perform these procedures on all the treatment groups and controls in the study. A concern is that some of these tests may stress the animals and produce changes in the traditional variables measured during a toxicity study. If this were to happen, it is assumed that the control group would also demonstrate these changes, which may or may not be true. Therefore, a conservative approach would be the addition of extra animals to the study that would be subjected to the manipulative procedures for neurotoxicity screening and not be used in the traditional phases of the study. For a more complete discussion of the FDA recommendations, the reader is referred to the draft guidelines for safety of direct food additives (27).

Immunotoxicity

Rapid advances have been made during the last 20 years in respect to detection of immunotoxicity. The two major forms of immunotoxicity are immunosuppression and hyperactivity of the immune system. Immunosuppression results in a reduction in the animal's resistance to infection and potential increase in susceptibility to tumorigenesis by a suppression of critical immunological responses. Hyperactivity of the immune system can result in autoimmune diseases and increased sensitivity to allergic disorders. Determination of the mechanisms associated with these disorders can be extremely complex because of the large number of biochemical, cellular, and physiological factors that can be effected as well as the cellular interactions required to mount an immunological defense. The detection of potential immunological changes is less complex and a number of tests exist that can provide warning of a

potentially immunotoxic compound.

The FDA has published draft recommendations for the inclusion of immunotoxicity evaluations in repeated dose toxicity studies (27). It suggests that such evaluations be conducted in rodents. Immunotoxicology testing procedures were divided into two broad categories—Type I tests are those assays that do not require the study animals to be treated with an agent that presents an immunological challenge. Type II Tests are assays that require the study animals to be challenged with an agent that elicits an immune response, such as antigens, vaccines, infectious agents, or tumor cells. Because Type I tests do not require manipulation of animals, they can be included in the routine assays done during a repeated dose toxicity study. Because Type II tests do require treatment of the animals with an immunological challenge, these animals are not suitable for evaluations conducted during toxicity studies. Therefore, additional animals must be included in the study design.

Table 19.13 lists the immunotoxicology evaluations that the FDA suggests should be included in Type I tests.

Table 19.13 FDA draft recommendation for type I immunotoxicity test that can be included in repeated dose toxicity studies

Type I Test

Hematology	Clinical Chemistry
• white blood cell counts	• total serum protein
• differential white blood cell counts	• albumin
• lymphocytosis	• albumin-to-globulin ratio
• lymphopenia	• serum transaminases
• eosinophilia	

Histopathology
- lymphoid tissues
- spleen
  - lymph nodes
  - thymus
  - Peyer's patches in gut
  - bone marrow
  - cytology (if needed)[a]
  - prevalence of activated macrophages
  - tissue prevalence and location of lymphocytes
  - evidence of B-cell germinal centers
  - evidence of T-cell germinal centers
- necrotic or proliferative changes in lymphoid tissues

a More comprehensive cytological evaluation of the tissues would not be done unless there is evidence of potential immunotoxicity from the preceding evaluations.

Generally, these evaluations are those currently recommended for repeated dose toxicity studies with the exception of a more comprehensive histopathology of lymphoid tissues. Inclusion of these evaluations into current study designs should have no impact on the validity of the study. Inclusion of the expanded Type I tests listed in Table 19.14 would require more planning during the study design phase and assurance that the laboratory performing the study would be capable of performing the assays. The expanded Type I test generally would only be conducted after consultation with the FDA. Type II immunotoxicity tests recommended by FDA could be done as a component of a repeated dose toxicity study, but they appear to be more appropriately conducted as independent studies and are beyond the scope of this discussion.

Miscellaneous Other Endpoints

There are a wide variety of additional endpoints that could be evaluated in repeated dose studies. In part, any additional endpoints would depend upon the questions to be addressed and the creativity of the toxicologist designing the studies. For instance, the increased availability of electron microscopy makes this endpoint a more viable option today than in previous decades. Development of an increased number of histochemical assays, especially those employing specific antibodies, makes

Table 19.14 FDA draft recommendation for expanded type I immunotoxicity test that can be included in repeated dose toxicity studies

Hematology	Serum Chemistry
• Flow cytometric analysis	• Serum protein electrophoresis
• B-lymphocytes	• albumin
• T-lymphocytes	• α-globulin
• T-lymphocyte subsets	• β-globulin
• TH & TS	• γ-globulin
• Immunostaining of blood or spleen fraction	• Quantification of γ-globulin
• B-lymphocytes	• IgG, IgM, IgA, IgE
• T-lymphocytes	• Complement
	• Cytokines
	• -IL-2, IL-1, γ-interferon
	• Auto-antibodies
	• Anti-parietal cell antibodies

Histopathology
- Immunostaining of B-lymphocytes in spleen and lymph nodes with polyclonal antibodies to IgG

- Immunostaining of T-lymphocytes and subsets with monoclonal or polyclonal antibodies
- Micrometric measurements of germinal centers and periarteriolar lymphocyte sheath of the spleen and follicles and germinal centers of lymph nodes

In vitro analysis of functional capacity of specific immune cells

- Activity of natural killer cells
- Mitogenic stimulation of B- and T-lymphocytes
- Macrophage phagocytic index
- Stem cell assays

the preserved wet tissues, embedded tissues, and the histopathology slides obtained from these studies valuable for future use. In many cases, the need for additional endpoints is unknown until the initial results of the study are known, at which point the preserved materials then become a valuable resource. For instance, if it is found that the liver from a study contains vacuoles and the toxicologist suspects these to be fat vacuoles, it is possible to use special lipid stains to determine if the vacuoles are lipid. Other special stains exist for a variety of purposes. An example of a protein-specific stain, MalloryHeidenhain, is illustrated in Figure 19.6.

If the toxicologist believes the histopathological data indicate a particular compound is producing cellular proliferation, there are a number of approaches to investigate this hypothesis. A standard method to determine cellular proliferation is by injecting the animal with 3H-thymidine and measuring the incorporation of the radiolabel into cellular DNA by methods such as radioautography. However, if the study has been terminated, this is not possible. Also, the toxicologist may not want to administer radiolabel to the animals for a number of reasons, even if the in-life portion of the study has not been terminated. If the evidence of increased cellular prolifer

ation occurs in tissues with a relatively high rate of normal proliferation, such as the gut mucosa, it is possible to determine the mitotic index by counting mitotic figures in cells from slides previously prepared for histopathological analysis. Alternatively, it is now possible to immunostain for specific proteins associated with cellular proliferation in preserved tissues. Again, the particular additional endpoints added to the toxicology study should address a specific issue.

DATA ANALYSIS AND INTERPRETATION

Compilation and Summarization of Study Data

Once the data have been collected from a repeated dose toxicity study, the next steps involve data analysis, interpretation, and reporting. These data are derived either from the measurement of a variable associated with the test animal—for example, body weight, feed consumption, serum enzyme activity—or from observation of the animal, for example physical examination findings, macroscopic and microscopic pathology, and so on. The frequency, number, and variety of these measurements and observations in repeated dose toxicity studies yield an extremely large volume of data that must be organized and summarized prior to analysis. Historically, individual animal data were recorded manually and then were compiled either manually or following entry into a computer. Some specialized data are still handled manually today; however, most routine data are collected, compiled, and statistically analyzed electronically using custom or commercially available computer programs.

For quantitative data such as body weights and feed consumption, individual animal data are used to calculate the mean values with a measure of statistical variation for each treated or control group. For other types of quantitative data such as the number of animals exhibiting a behavioral effect or the number of animals in which a particular finding is determined histopathologically, the incidence of the observation in each treated and control group—that is, the number of animals affected as a fraction of the total number of animals observed—is presented. Some data, like leukocyte differential counts and results of microscopic examination of urinary sediment, cannot be effectively summarized using a group mean or incidence value. Summarization of these types of data involves listing the individual animal data in their appropriate groups.

Determination of Treatment-Related Effects

Data from the treatment groups are compared with data from the control group to determine if any treatment related effects have occurred. In virtually all cases, the data from one group of animals will differ somewhat from the data for any other group. Therefore, differences between the sets of data that are potentially related to treatment must be differentiated from spurious occurrences and from normal biological variation. This is accomplished by two methods. The first is simple examination of the data and detection of differences worthy of further consideration based upon the experience of the toxicologist and comparison with historical data. The second method uses statistical tests to detect differences for which the probability that the difference occurred by chance is low. These methods should always be used in combination. Although it is an extremely powerful and useful tool, statistical analysis alone should not be used to detect treatment-related effects because, as stated by the FDA, "… statistical outliers are not always biological outliers and a "significant" statistical test ($p<0.05$) does not always indicate biological significance" (27).

Differences between the data from the control and treated animals that are detected using the methods cited above may indicate either an adverse effect associated with the test material, physiological adaptation to the test material, or normal biological variation unrelated to the test material. Determination of the significance of differences between treated and control groups is based on a number of factors that are frequently considered in combination with each other. These are listed in Table 19.15 and discussed in the following paragraphs.

Dose-related Trend

One of the best indicators of an effect related to treatment is the presence of a dose-related trend in the data, that is, the magnitude of the effect varies directly with the dose level. Such an effect is reflective of the basic principle of toxicology stated by Paracelsus in the 16th century and often paraphrased as, "The dose makes the poison" If a difference from controls is noted in two or more dose groups and the severity or incidence of the difference increases as the dose level of the test material increases, it is probably a treatment-related effect. When a difference from controls is noted only

Table 19.15 Factors considered to determine the significance of differences between treated and control groups

- Dose-related trends
- Reproducibility
- Related findings

- Magnitude and type of difference
- Occurrence in both genders

< previous page page_948 next page >

in animals receiving the highest dose level of the test material, it may or may not be treatment-related and other factors must be considered in determining its significance. Differences from control data in test material-treated animals are probably not associated with treatment if a dose-related trend is not observed. Because of this, as stated previously, selection of an appropriate range of dose levels is extremely important and facilitates data interpretation.

Reproducibility of Effect

Another reliable indicator of a treatment-related effect is its reproducibility. If a difference from controls is noted in the treated animals at multiple intervals during a study, the difference is likely related to treatment. Further weight is given to the determination of the treatment relationship if the same difference is noted in other independent studies in which the test material was administered to the same species and, even more weight is given if the difference is observed in a second species. The absence of reproducibility, especially in the same species, is an indication that the difference may have occurred by chance.

Correlated Findings

Another consideration in the assessment of significance of an intergroup difference is the presence of related findings. For example, an elevation in the activity of serum alanine aminotransferase in treated animals when compared with the control group is probably related to treatment if there is an elevation in serum aspartate aminotransferase with concomitant hepatic necrosis. If no correlation with other findings is observed, the elevation may be of no significance or, at least, its significance must be determined considering other factors.

Magnitude and Type of Inter-group Difference

The magnitude and type of difference observed between treated and control data may also give an indication of its potential association with test material administration. For example, a doubling of an organ weight in treated animals compared with controls should be considered more likely to be treatment-related than a 10% increase, even if the smaller increase is statistically significant. Furthermore, a fairly large decrease in the activity of serum alanine aminotransferase in treated animals is generally assigned limited clinical significance whereas an increase of the same magnitude in the activity of this enzyme may be considered indicative of a toxic effect. It is obvious that the assessment of the significance of a change on the basis of its magnitude or type requires knowledge of normal trends and ranges for the data.

Gender Differences

Determination of the significance of an apparently treatment-related effect is also influenced by whether or not the difference occurs in animals of both genders. Since treatment-related effects often occur in both genders, a difference from controls that is noted only in treated animals of one gender may not be associated with the test material. It must be remembered, however, that there are cases where one gender or the other is more sensitive to the toxicity of a chemical and, therefore, only the sensitive gender will exhibit the effect at a given dose. For this reason, a difference should not be considered insignificant solely on the basis of its absence in one gender. Male rats are well known for their greater capacity to detoxify certain compounds because of their higher activity of P450-dependent monooxygenases. Therefore, they may demonstrate less toxicity to these compounds than females. However, if the metabolic product is more toxic than the parent compound, they may demonstrate higher sensitivity than females (see Chapter 3). This gender difference is not seen in a number of other species, including humans (52).

STUDY REPORT

After the data from a study have been analyzed, a report is prepared. Depending upon the intended use of the report, it may contain various levels of detail. For example, reports prepared for submission to a regulatory agency in support of the safety of a chemical will generally contain much more detail (including all individual animal data) than research reports intended for publication or that will be used by an organization or individual only to give guidance for future testing. Whatever the purpose of the report, it should be written in sufficient detail to permit peer review of the conduct and conclusions of the study and to allow the study to be reproduced.

Report Content

All reports, regardless of their purpose, should contain certain common elements that are essential to adequately describe the conduct and results of a study. The report should clearly state the objective(s) of the study. It should precisely define the test material, indicate the test species used, and describe the methods and equipment employed to collect and analyze the data. Protocol deviations and an assessment of their impact upon the study should be presented. The report should present the data

pertinent to the study objective(s) in a form that facilitates its review and should discuss these data in the depth required to support the conclusion(s) of the study. The discussion

< previous page page_949 next page >

should describe any treatment-related effects observed and should explain how the various factors described above were used to determine the significance of any differences between treated and control animals in the study. Finally, the conclusion(s) drawn from the results of the study should be clearly and concisely stated.

Retrospective Report Audits

After the study has been completed and reported, retrospective audits of the study are frequently conducted. The manufacturer of the test material may audit the study prior to submitting it to a regulatory agency in support of registration or approval of the test material for its intended use. The regulatory agency to which the study report was submitted may also conduct an audit. Regulators also audit study reports to assess compliance of the testing laboratory with GLP regulations. Whatever the reason for retrospective auditing of the study, the process is essentially the same. The raw data are inventoried to ensure that they have been properly maintained. They are reviewed and compared with the study report to ensure the report accurately and completely presents the methods used and the data collected. Any deviations from laboratory standard operating procedures, the study protocol, or GLP regulations that occurred during conduct and documentation of the study should have been clearly explained in the report. Individual animal data should support summary tables and discussion of the results should be consistent with the individual and summary data.

Retrospective auditing is of great value to all parties involved. The manufacturer of the test material can feel comfortable that it will receive no surprises during a subsequent audit by the regulatory agency. The regulator will be more confident about the quality of the study if the data have been audited. If the regulator is confident about the data, his or her review will proceed more smoothly and, therefore, regulatory decisions will be expedited.

REGULATIONS CONCERNING GENERATION AND USE OF DATA FROM REPEATED DOSE TOXICITY STUDIES

Almost every industrialized country in the world has regulations governing the introduction, transportation, and use of new pesticides, food additives, human and animal drugs, and other chemicals. Many of these countries also have regulations governing medical devices, workplace exposure to chemicals, the introduction of industrial chemicals into commerce, and the disposition of chemical waste.

There is general uniformity in the objectives of these laws, that is, not to impede the beneficial use of chemicals, but at the same time to ensure their safety in use. Even though the regulatory agencies can agree, in broad terms, on one framework of toxicity testing guidelines, the toxicologist must become familiar with the details of particular guidelines to fulfill his or her role as a bridge between scientific and regulatory concerns. Several regulations governing repeated dose toxicity and other types of toxicity testing are briefly described below.

United States Laws and Regulatory Guidelines

Federal Food, Drug and Cosmetic Act (FFDCA)

FFDCA (29) as amended by the Food and Drug Administration Modernization Act of 1997 (38), controls the introduction of human and animal drugs, direct food additives, indirect food additives (such as packaging materials), and components of cosmetics. In the case of new human or animal drugs, safety and efficacy must be established for a particular therapeutic application before the FDA grants approval for marketing. The approval process is comprehensive and involves two sequential phases. For the investigational new drug (IND) phase, industry is required to file preclinical toxicity data with the FDA before investigation of the safety and potential therapeutic value of a drug in limited numbers of humans. When the efficacy and safety of the drug in the treatment of a particular disease is established through extensive clinical trials, these data together with additional animal toxicity data are provided to the agency as part of a new drug application (NDA) or new animal drug application. The NDA is reviewed by the FDA with respect to safety and claims of efficacy of the drug, and is either approved or disapproved, or deficiencies in the data cited.

The summary of a NDA must address benefit/risk relationships, clinical data, nonclinical pharmacology and toxicology, human pharmacokinetics, bioavailability, and microbiology. It must also contain information on pharmacological class, scientific rationale and clinical benefits, and chemistry and manufacturing (34).

For food additives, industry must show that a material either intended for direct addition to food, such as a preservative or flavoring agent, or having indirect contact with food, such as a packaging or can-coating material, is safe for its intended use. Results from a hazard assessment are submitted to the FDA for review as part of a food additive petition. If the data demonstrate the safety of the chemical, a

regulation is published allowing the chemical to be used for a particular purpose in food or in contact with food. In 1982, the FDA published *Toxicological Principles for the Safety Assessment of*

Direct Food Additives and Color Additives Used in Food (23). A revised version of this document has recently been released by the FDA (Toxicological Principles for the Safety of Food Ingredients, Redbook 2000) (27). This so-called "Redbook" delineates the nature of evaluations necessary to determine food additive safety and provides a basic scheme for scientifically sound decisions for the development of the safety assessment. These guidelines include a priority-setting system that increases the efficiency of the food additive safety assessment.

FFDCA also provides an alternative method by which materials can be approved for use in or on food, the generally recognized as safe (GRAS) process (31). For a material to be considered GRAS, its safety evaluation must satisfy three basic requirements. First, a group of experts qualified by scientific training and experience must conclude that the material, when used as intended, is safe for human consumption. The sponsor of the potential additive convenes this expert group and the group operates without regulatory oversight. Second, the information considered by the expert group during the GRAS review must be common knowledge, that is, available in the scientific literature. Third, within the scientific community there must be general agreement with the conclusion of the expert group. Final GRAS approval does not require regulatory review; however, many producers of such materials petition FDA to affirm their GRAS status prior to marketing them.

There are no requirements for the FDA to review cosmetic formulations for safety prior to marketing. Even though the FFDCA only requires that the cosmetics be free of any "poisonous and deleterious" substances, responsible suppliers of ingredients for use in cosmetics and manufacturers of final products conduct toxicity studies relevant to the specific cosmetic.

FFDCA also addresses the concentrations of pesticides permitted in foods in the United States. Under FFDCA Section 408, the EPA establishes maximum allowable concentrations for pesticide residues in raw agricultural commodities—food crops, eggs, raw milk, and meat. Under FFDCA Section 409, EPA also establishes a maximum allowable concentration for a pesticide in processed food, if processing concentrates the residue of the pesticide in the raw agricultural commodity. These maximum concentrations are referred to as *tolerance levels* or tolerances. Human exposure resulting from consumption of foods containing tolerance levels of a pesticide must not exceed the maximum permissible intake of the pesticide established by EPA under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). Tolerances for most foods are enforced by FDA, and those for meat, poultry, and some egg products are enforced by the Food Safety and Inspection Service (FSIS) within the U.S. Department of Agriculture (USDA).

Federal Insecticide, Fungicide and Rodenticide Act

FIFRA was administered initially by USDA and is now administered by the EPA (10). Under FIFRA, EPA is responsible for registration of pesticides for use in the United States. This act requires extensive toxicity testing to be conducted in mammalian, avian, and aquatic species to support the safety of a pesticide. Detailed guidelines for toxicity study design and reporting have been issued by EPA (17). Toxicity data submitted in an application for registration of a pesticide are reviewed by toxicologists in the Office of Pesticide Programs at EPA. Other data specifically required by FIFRA as a condition of pesticide registration include product chemistry, residue chemistry, environmental fate, reentry protection, spray drift, plant protection, non-target insects, and product performance.

Food Quality Protection Act

The Food Quality Protection Act (FQPA) was signed into law in 1996 and amends sections of both FFDCA and FIFRA (13). It is intended to establish more consistent regulation of pesticides and to protect human health using an approach that places increased emphasis on the scientific evaluation of pesticide safety data. Among other provisions affecting pesticide registration and tolerance setting, it

(1) mandates special considerations for protection of infants and children,

(2) requires determination of aggregate pesticide exposure from all sources (e.g., food, home use, drinking water, etc.),

(3) requires summation of exposures from multiple chemicals that exhibit a common mechanism of toxicity,

(4) expedites approval of pesticides considered to be most safe, and

(5) requires periodic reevaluation of tolerances for registered pesticides to be certain that the data supporting registration remain acceptable and complete by current standards.

The methods to be used for implementation of several of the provisions of the FQPA are still being developed, and some (such as the means for special protection of children) are the subject of considerable controversy within the scientific community. EPA is considering input concerning resolution of these controversial issues from pesticide manufacturers, agricultural trade organizations, academia,

consumer protection groups, and the public prior to finalizing their approach. Significant progress must be made soon, however, because FQPA mandates that EPA complete review of the tolerances for 33% of all currently registered pesticides by August 1999, of

an additional 33% by August 2002, and of the balance by August 2006.

Toxic Substances Control Act

The Toxic Substances Control Act (TSCA) is administered by the Office of Pollution Prevention and Toxics within EPA and is a complex and far-reaching law that affects industrial chemicals existing in commerce as well as new chemicals in the United States (20). One of the first requirements of TSCA was the compilation of an inventory of chemicals that were active in commerce in the years 1977–1979 and determination of the need for toxicity testing of these chemicals.

Manufacturers or importers of industrial chemicals that are considered new under the TSCA definition are required to notify the EPA at least 90 days before the manufacture or import of a new chemical. The act requires that certain information regarding the new chemical be submitted to the EPA for review in a premanufacture notification (PMN). Although the act does not require toxicity testing to be conducted on a new chemical prior to manufacture, it does require submission of all existing health and safety data for the new chemical so that its risk to health or the environment can be assessed. If the EPA determines in its review that the new chemical does present an unreasonable risk, one of several actions it may take is to require that the chemical be tested for specific toxic effects. The EPA may also issue a testing rule requiring that a specified chemical or chemical mixture be tested for certain toxic effects. The EPA has issued test standards for the conduct of toxicity studies on chemicals or chemical mixtures for which testing will be required under TSCA. These standards are the same guidelines used for pesticide testing under FIFRA (17).

Transportation Act

Regulations promulgated by the U.S. Department of Transportation (DOT) require that materials shipped in interstate commerce be labeled and contained in a manner consistent with the degree of hazard they present (5). DOT requires that acute toxicity data for chemicals be used to place them into “packing groups,” with labeling requirements for chemicals based upon this packing group.

The Coast Guard

Prior to importing a chemical into the United States, the Coast Guard requires a set of acute mammalian toxicity data for the chemical (6). This acute toxicity profile should minimally include the following: acute oral toxicity, acute dermal toxicity, and skin and eye irritation studies.

Consumer Product Safety Act

Prior to passage of the Consumer Product Safety Act (CPSA), the classification and testing for acute toxicity of household products was conducted under regulations promulgated by the FDA, which administered the Federal Hazardous Substances Act (FHSA). The function of administering FHSA now resides with the Consumer Product Safety Commission (CPSC). If results obtained in acute oral or dermal toxicity tests conducted using methods outlined in the *Code of Federal Regulations* (CFR) for hazardous substances meet prescribed criteria of toxicity, labeling and packaging as prescribed in the regulation must be used (3).

Occupational Safety and Health Act

This law, administered by the Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor, is designed to assure safety in the workplace (58). No requirements exist in this law for manufacturers to test substances for toxicity prior to their use in the workplace. The impact of the TSCA has an overlapping effect, in that occupational exposure to new chemicals is considered in premanufacture notices. As indicated previously, specific test requirements under TSCA affect new or existing chemicals that are manufactured or processed in the United States.

Resource Conservation and Recovery Act

The Resource Conservation and Recovery Act (RCRA) authorizes the EPA to institute a national program to control hazardous waste defined as “solid, liquid, semi-solid or gaseous waste that may cause increased mortality or serious illness, or may cause substantial hazard to the health or the environment when improperly managed” (18). The main purpose of these regulations is to control the generation, storage, treatment, transportation, disposal, record-keeping, and reporting of hazardous waste. RCRA places the primary responsibility of identifying and managing hazardous waste on the waste generators. Other persons or institutions involved in waste disposal and management also have an obligation to know if the waste is hazardous. The degree of toxicity, concentration, migration to the environment, persistence or degradation in the environment, bioaccumulation in the ecosystem, types of improper management, quantities of waste, past human and environmental damage records, and other factors are all taken into consideration.

International Laws and Regulatory Guidelines

The United States has not been alone in developing laws to protect humans and their environment from

possibly dangerous effects of new industrial chemicals in the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_952.html[2010/10/28 18:49:36]

marketplace. In the European Union, the Council of Ministers of the European Economic Community (EEC) has issued a directive concerning laws, regulations, and administrative procedures which relate to the classification, packaging, and labeling of dangerous substances (7). An amendment to this directive was adopted later to protect humans and their environment from potential risks that might arise through the marketing of new chemicals (8). It requires that a new chemical be subjected to a base set of tests to define its physical and chemical properties, mammalian toxicity, and ecotoxicological effects. The base set of mammalian studies consists of the following: acute oral LDso, acute dermal LDso, acute inhalation LCso (if applicable), skin and eye irritation, and dermal sensitization. A manufacturer or importer is required to furnish the appropriate authorities in his or her EEC member state with a notification containing, in part, the results of these tests with the new chemical. Such notification must be filed 45 days before marketing in the member state in which it is to occur.

The amendment to the EEC directive is the counterpart of the U.S. TSCA. There are, however, some differences, not the least of which is in the approach to toxicity testing. The EEC requires only notification of a new chemical prior to marketing whereas TSCA demands that the notification, in the case of a domestic manufacturer, be given to the EPA at least 90 days before manufacture.

The EEC has also provided guidance on the evaluation of safety and efficacy of drugs. It has now adopted guidance notes for efficacy, testing of pharmacokinetics in humans, and bioavailability of drugs for long-term use, as well as a number of more specific activity groups including cardiac glycosides, oral contraceptives, topical corticosteroids, nonsteroidal anti-inflammatories, antimicrobials, anticonvulsants, antianginals, and chronic peripheral arterial disease agents. Safety guidance notes also were adopted for single-dose and repeated dose toxicity, pharmacokinetic metabolism, mutagenic potential, carcinogenic potential, and reproduction studies (9).

As discussed earlier in this chapter, with many countries establishing their own regulations for safety assessment, it became more likely that manufacturers would have to perform several different versions of the same tests to satisfy the requirements of different countries. In an attempt to avoid unnecessary and wasteful duplication of work, the Organization for Economic Cooperation and Development (OECD) produced a set of toxicity testing guidelines that allow tests to be carried out in a similar manner in different countries (54). The OECD package, which has been revised 10 times to implement improvements to individual study designs, includes guidelines on acute oral, dermal, and inhalation studies; eye and skin irritation and skin sensitization studies; subchronic oral, dermal, and inhalation studies; and teratogenicity, carcinogenicity, and chronic and combined chronic/carcinogenicity studies. Results from studies conducted according to OECD guidelines are generally fully acceptable to the various regulatory bodies throughout the world.

To facilitate more universal acceptance of data generated to support approval and use of pharmaceutical products, the International Conference on Harmonization (ICH) has developed guidance documents concerning the efficacy, quality, and safety of these drugs. The ICH is made up of regulatory authorities and trade organizations from the United States, Japan, and the European Union. Instead of providing detailed instructions for study design or conduct, the ICH guidances address specific issues related to testing, for example, the duration of chronic toxicity testing, definition of an acceptable battery of genotoxicity studies, required elements of chemical stability testing of new drug products, and so on (41). Because of ICH efforts, many hindrances to the approval and use of valuable Pharmaceuticals around the world have been removed.

Regulatory Internet Sites

Many of the regulatory agencies and organizations worldwide that have responsibility for protection of humans from the hazardous effects of chemicals maintain Internet websites. These websites usually include information concerning the history, structure, and specific responsibilities of these organizations. The sites also generally contain or reference the statutes and guidelines under which the organizations operate. Internet addresses for a number of informative regulatory sites are listed in Table 19.16.

ACKNOWLEDGMENTS

The third edition of this text contained one chapter concerning short-term and subchronic toxicity studies and a second concerning chronic toxicity studies. Because many elements of short-term, subchronic, and chronic toxicity testing are similar, the decision was made to combine these subjects into a single chapter in the fourth edition. Some information in this chapter is derived entirely or only with slight modification from the chronic toxicity chapter in the third edition. This note is written to acknowledge the efforts of the authors of that chapter, Drs. Kent R.Stevens and Louis Mylecraine.

QUESTIONS

1. *Better Belly* is a new drug entity intended to mitigate the irritating properties of aspirin in the human

gut. Because of its intended use, human exposure to this

compound will range from a few days to a few months. The intended treatment population includes males and females from 4 to 90+years of age. You are designated to be the toxicologist responsible for generating the toxicity data necessary to get *BetterBelly* to the marketplace. What steps/studies would you include in the hazard assessment program for this compound? When you propose your plan to FDA, what questions would you ask them concerning approval of this compound?

2. It has been determined that the hazard assessment program for *BetterBelly* should include subchronic toxicity testing. In a short-term, repeated dose study with this compound in rats at 500 mg/kg/day, oral gavage administration resulted in mortality in 40% of the animals. These rats also exhibited marked body weight loss, convulsions followed by prostration, urinary incontinence, and enlarged and discolored kidneys. At 100 mg/kg/day, no mortality occurred in the study and the only adverse signs observed were mild and reversible body weight loss, lethargy, urinary incontinence, and twitching of the extremities. At 20 mg/kg/day, neither mortality nor adverse signs were noted. Efficacy testing revealed that *BetterBelly* is effective for its intended use at 2 mg/kg/day. Pharmacokinetic determinations indicate that *BetterBelly* is excreted almost entirely in the urine and its serum half-life is 120 minutes. What dose levels would you select for the subchronic toxicity study? Why? What concentrations of dosing solutions would be required to accurately deliver these dose levels to the rats? In addition to the standard variables, what special endpoints would you include for investigation during the subchronic study?

Page 955

Table 19.17 Selected results from the subchronic toxicity study of *Better Belly* in rats

Variable/Finding/Interval	Treatment Group—Males				Treatment Group—Females			
	Control	Low	Mid	High	Control	Low	Mid	High
Body weight (g)								
Week 4	200±7	205±11	192±10	173±9a	112±8	105±8	110±5	98±6a
Week 13	403±13	410±15	371±11a	350±17a	201±12	202±10	198±13	175±10a

a Statistically significantly different from controls ($p<0.05$).

3. The results in Table 19.17 were obtained during the subchronic study with *BetterBelly.* In what dose groups is there a treatment-related effect on body weight? Are liver and kidney target organs for *BetterBelly* toxicity? If so, in which dose groups is there a treatment-related effect? Based on the data in the table, what is the NOAEL for this study?

CHEMICALS WITH CARCINOGENIC ACTIVITY

Cancer is one of the leading causes of death, and it can result from exposure to exogenous chemicals (275). Thus, in the toxicological assessment of chemicals, testing for Carcinogenicity constitutes one of the most important evaluations (Table 20.1).

A large database on the carcinogenic activities of chemicals in rodents has accrued (87, 177) as a consequence of over 80 years of basic research and the output from national testing programs in several countries, particularly the United States and Japan. Under the aegis first of the U.S. National Cancer Institute (NCI), and subsequently of the U.S. National Toxicology Program

Table 20.1 Regulations or agreements under which carcinogenicity testing may be required

Legislation/guidance	Agency	Agents of concern
Commission Directive 414 EEC (1991)	EU	Plant protection products
Commission Directive 67 EEC (1993)	EU	Risk assessment for new notified substances
Commission Regulation 1488 EEC (1994)	EU	Risk assessment for existing substances
Dangerous Substances Directive (1967; amended 1992)	EU	Industrial chemicals
Food, Drug and Cosmetics Act (1906, 1938, amended 1992)/FDA Red Book II	US FDA	Food, medicines, cosmetics, food additives, color additives, animal and feed additives, medical devices
Federal Hazardous Substances Act (1960; amended 1988)	US CPSC	Toxic household products
Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) (1948, amended 1978)	US EPA	Pesticides
Guidance on Toxicology Study Data for Application of Agriculture Chemical Registration (1985)	MAFF, Japan	Agricultural chemicals
Guideline for Toxicity Testing of Chemicals (1990)	MHW, Japan	Chemicals
Pharmaceutical Affairs Law (1980)/Guidelines for Toxicity Studies of Drugs Manual (1990)	MHW, Japan	Medicines
Guidelines for Toxicity Studies of New Animal Drugs (1988)	MHW, Japan	Animal medicines
Pesticide Registration Directive (1991)	EU	Pesticides
Technical Requirements for the Registration of Pharmaceuticals for Human Use (1995)	ICH	Medicines
Toxic Substances Control Act (TCSA) (1976, amended 1992)	US EPA	Hazardous chemicals not covered by other laws, includes premarket review

(NTP), routine rodent cancer bioassays (RGBs), mainly in mice and rats, have been conducted on about 300 chemicals (106).

The definitive test for animal carcinogenic activity is the RGB, which in its various forms is detailed here and elsewhere (115, 168, 207, 260, 261, 274). The present method for the RGB is exemplified by that currently in use by the NTP (16). This method was refined from basic procedures developed in the 1960s largely by the pharmaceutical industry under guidance from the U.S. Food and Drug Administration (U.S. FDA) and by the NCI Bioassay Program (33, 34, 48, 273). The extensive use of the RGB has led to the recognition that its results cannot be unquestioningly extrapolated to humans (172, 274), for which, of course, carcinogenic activity is established by epidemiological studies. Available mechanistic procedures to be discussed assist in assessment of potential human hazard.

Carcinogenic Activity

A committee of the International Federation of Societies of Toxicologic Pathologists has adopted the definition of a chemical carcinogen as a "substance that causes a cell or group of normal cells, which would not otherwise have shown this property, to change its biological behavior and demonstrate progressive growth of a malignant character" (66). Thus, the carcinogenic or oncogenic activity of chemicals is best defined by the finding of unequivocal evidence in a strain of animal of either gender that a test substance (TS) causes types of malignant neoplasms not seen in controls, clearly indicating ab initio induction of neoplasia. A marginal increase of a very rare malignancy of a certain type and site under some circumstances may incriminate a chemical substance. Another generally used criterion is an increase in the incidence of the types of malignant

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_960.html[2010/10/28 18:49:40]

Page 961

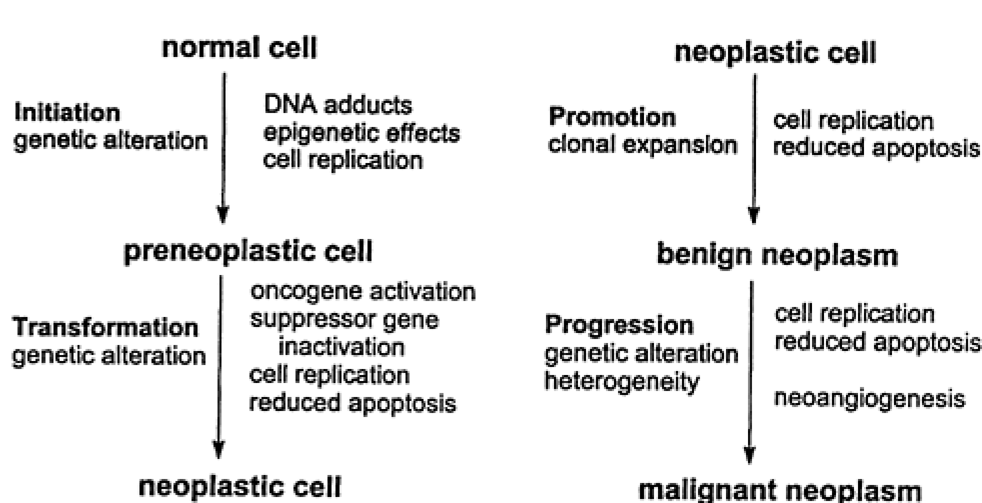

FIG. 20.1. Sequences of oncogenesis.

neoplasms that occur in controls. The malignant neoplasms can be of any histological type, epithelial or mesenchymal, and while a clear increase in malignant neoplasms is most persuasive, a combination of malignant and benign neoplasms of the same cell type of origin is generally accepted as reflecting carcinogenic activity (114, 164). The evidence of malignancy is best established by the presence of invasion or metastasis, but for most rodent neoplasms, the diagnosis of malignancy is made histologically on evidence of cellular atypia; thus some diagnoses are controversial, as discussed in the sections on anatomic pathology and on cancer hazard evaluation. The finding of an increase in only benign neoplasms, especially if the type of neoplasm is not established to be premalignant, does not constitute sufficient evidence for carcinogenicity, but does provide limited evidence. In addition to these criteria, an increase in the multiplicity of neoplasms above that in controls or a reduction in the latency period for development of neoplasms has also been considered. While these may indicate an influence of the chemical on tumor development, they are less definitive evidence of carcinogenic activity. Rarely, an increase in the overall incidence of neoplasms without increase in any specific type of neoplasm has been proposed as evidence of carcinogenic activity, but this is highly questionable (115). These criteria apply to findings in any species/strain/gender. A strong effect in one gender of one species may be sufficient to implicate a chemical as a carcinogen, but obviously findings in more than one gender or species strengthen the evidence.

Of course, each expert body applies criteria as it sees fit, often influenced by a concern for hazard identification in the interests of public health protection. Ultimately, in assessing human risk, the reason for which animal tests are done, scientific judgment must be used in evaluating all the information available, including importantly mechanism (or mode) of action.

Types of Carcinogens

Widely varied chemical structures have exhibited carcinogenic activity in rodents (87, 116, 121, 122). This reflects the fact that the multistep process of oncogenesis (Figure 20.1) can be influenced by chemicals in various ways, mainly involving either chemical reactivity in producing neoplastic transformation or epigenetic modulation of cell growth facilitating neoplastic development. Thus, chemicals can give rise to increases in neoplasms through a variety of mechanisms, which have been broadly characterized as DNA reactive or epigenetic (283, 288). The types of chemicals that can be assigned to these categories are given in Tables 20.2 and 20.3 and have been discussed in detail elsewhere (288). Carcinogens are, of course, both naturally occurring and man-made.

Page 962

Table 20.2 Classification of chemicals with carcinogenic activity

A DNA-Reactive	
1. Activation-independent	Alkylating agents Nitrogen mustards, chlorambucil Epoxides: ethylene oxide
2. Activation-dependent	Alphatic halides: vinyl chloride Aromatic amines, heterocyclic amines, aminoazo dyes and nitro-aromatic compounds: Monocyclic *o*-toluidine, 2-amino-l-methyl-6-phenyl-imidazo[4,5-b]pyridine(PhIP), polycyclic 4-aminobiphenyl, benzidine, dimethylaminoazobenzene, 1-nitropropane Polycyclic aromatic hydrocarbons: benzo[a]pyrene *N*-Nitroso compounds: dialkyl, dimethylnitrosamine; cyclic-N-nitrosonornicotine Triazines, hydrazines, azoxymethane, methyl-azoxymethamol Mycotoxins: aflatoxin B1 Pharmaceuticals: cyclophosphanide, pheacetin, tamoxipen
3. Inorganica	Metals: beryllium, cadmium, chromium, nickel, silica Minerals: asbestos
B. Epigenetic	
1. Promoter	Liver enzyme-inducer type hepatocarcinogens; chlordane, DDT, pentachlorophenol, phenobarbital, polybrominated biphenyls, polychlorinated biphenyls Saccharin
2. Endocrine modifier	Hormones: estrogens, diethylstilbestrol, atrazine, cholor-S-triazines Estrogens Atrazine Diethylstilbestrol Antiandrogens: finasteride, vinclozolin Antithyroid thyroid tumor enhancers Thyroperoxidase inhibitors: amitrole, sulfamethazine Thyroid hormone conjugation enhancers: phenobarbital, spironolactone Gastrin-elevating inducers of gastric neuroendocrine tumors: omeprazole, lansoprazole, pantoprazole
3. Immunosuppressor	Purine analogs Cyclosporin
4. Cytotoxin	Mouse forestomach toxicants: butylated hydroxyanisole, propionic acid, diallyl phthalate, ethyl acrylate Rat Nasal toxicants: chloracetanilide herbicides Rat renal toxicants: potassium bromate, nitrilotriacetic acid $\alpha 2\mu$-Globulin nephropathy inducers: *d*-limonene, *p*-dichlorobenzene
5. Peroxisome proliferator	Hypolipidemic fibrates: ciprofibrate, clofibrate, gemfibrozil Phthalates: di(2-ethylhexyl)phthalate(DEHP), di(isononyl)phthalate(DINP) Lactofen
C. Unclassified	Acrylamide, acrylonitrile, dioxane, furfural, methapyrilene, sugar alcohols

a Some are categorized as genotoxic because of evidence for damage of DNA; others may operate through epigenetic mechanisms such as alterations in fidelity of DNA polymerase.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_962.html[2010/10/28 18:49:42]

DNA-Reactive	
Aflatoxins	Cyclophosphamide
4-Aminobiphenyl	Ethylene oxide[a]
2-Aminonaphthalene	Melphalan
5-Azacytidine	MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone)
Benzidine	
Betel quid with tobacco	
N,N-Bis(2-chloroethyl)-2naphthylamine (chlornaphazine)	Nickel and nickel compounds
	Phenacetin-containing analgesic mixtures
Bis(chloromethyl) ether	
1,4-Butanediol dimethanesulfonate (myleran)	Soot
	Sulfur mustard
Chlorambucil	Tamoxifen
I-(2-Chloroethyl)-3-(4-methylcyclo hexyl)-1-nitrosourea (methyl-CCNU)	Thiotepa
	Tobacco smoke and products
Chromium compounds, hexavalent	Triethylenethiophosphoramide (treosulphan)
Coal tars	Vinyl chloride
Epigenetic	
Azathioprine	Oral contraceptives, combined
Cyclosporin A	2,3,7,8-Tetrachloro-dibenzo*p*-dioxin (TCDD)
Postmenopausal therapy	
Unclassified	
Alcoholic beverages	Diethylstilbestrol
Arsenic and arsenic compounds	Mineral oils
Benzene	Nickel and nickel compounds
	Shale oils

a Based on evidence for a relevant mechanism in humans.

Of the many chemicals with carcinogenic activity in RGBs, few are associated with cancer in humans (Table 20.3). Most of these are of the DNA-reactive type, indicating the importance of this mechanism in human hazard. In support of this, several DNA-reactive carcinogens have been active in primates (237), including transplacentally (203). Apart from cigarette smoke and mycotoxins, virtually all DNA-reactive carcinogens occur as occupational or therapeutic exposures, which are substantial compared to general environmental exposures. The few human epigenetic carcinogens are mainly Pharmaceuticals, and these are associated with cancer increase only at therapeutic exposures that produce the cellular effect that underlies their carcinogenicity in rodents, mainly immunosuppression or hormonal effects. Thus, a primary objective of cancer hazard assessment is to identify chemicals with DNA reactivity (289).

Because of the significance of DNA reactivity and the reliability with which it is identified, few agents of this type are proposed for uses in which there is any appreciable human exposure, apart from chemotherapeutic alkylating agents. In contrast, agents that elicit rodent tumor increases by epigenetic mechanisms are widely used; for example, more than 80 medicines in current use are tumorigenic in the RGB (46). Importantly, no epigenetic carcinogen has been active in primates (224, 237). Accordingly, an important aspect of carcinogen testing is to elucidate any mode of action that might lead to a tumor increase in an RCB in order to guide mechanistic research for informed hazard evaluation (289).

Potency

The magnitude of the carcinogenic activity in rodents of chemicals with respect to dose varies more than 10-million-fold (87). The most extensive system for expressing numerical indices of carcinogenic potency is the Carcinogenic Potency Data Base (87), which uses TD50 values, defined as the daily dose rate required to halve the probability of an experimental animal of remaining tumor free at the end of its standard life span (196). A simplified method proposed for use in the regulatory setting is the T25, defined as the chronic dose rate in milligrams per kilogram body weight per day that will give 25% of the animals tumors at a specific site, after correction for the spontaneous incidence, within the standard lifetime of that species (55). Also, for DNA-reactive carcinogens, there is a general relationship between carcinogenicity and DNA binding, which can be expressed as the chemical binding index (CBI) (157).

REQUIREMENTS FOR TESTING

Testing of chemicals in experimental animals for carcinogenic activity is done to assess potential human

cancer hazard under conditions to which humans might be exposed. The U.S. federal government has enacted numerous laws covering requirements for carcinogenicity testing of substances for which there is human or environmental exposure (Table 20.1). Other countries have similar provisions (Table 20.1). For Pharmaceuticals and food additives, both direct and indirect, circumstances requiring carcinogenicity studies have been agreed upon by the International Conference on Harmonization (available on FDA/Center for Drug Evaluation and Research web site, http://www.fda.gov/cder), which applies in the United States, European Union, and Japan. Cosmetics, as with foods, usually do not require carcinogenicity testing.

The requirements for testing of biopharmaceuticals present specific issues (223), for which FDA/Center for Biologies Evaluation and Research has provided guidance (http://www.fda.gov/cber). Growth factors and immunosuppressive antibodies are noted as raising concern for carcinogenic potential. Normal hormones or growth factors that are intended to correct deficiency states, such as insulin, may not need to be tested, unless they are administered by a route that results in substantial exposure of tissues that would not be exposed to the endogenous protein. Modified proteins with new biologic properties may require testing, since, for example, it is known that a modified insulin with affinity for the insulin-like growth factor-1 receptor produced mammary tumors in rats (51). Also, a fragment of parathyroid hormone with bone-trophic activity is widely rumored to have produced bone neoplasms in rats. Certain modifications of proteins to improve bioavailability, such as with conjugation to polyethylene glycol, have not raised carcinogenicity issues. As yet, carcinogenicity testing of transgenes used in gene therapy is not required.

An emerging aspect of regulatory concern is photochemicalcarcinogenicity (129). Indications for the possible need for photochemicalcarcinogenicity testing are (a) long-term exposure of the skin to chemicals that can undergo photoactivation, (b) alteration of the structure of the epidermis, (c) sensitization of the skin to ultraviolet radiation (UVR), and (d) exacerbation of suspected UVR-induced carcinogenesis (75).

Thus, for the use of many types of chemicals, proscribed RGBs are required. Nevertheless, expedited approaches to assessment of potential carcinogenic activity are valuable to obtain data quickly and cheaply with minimal use of experimental animals in order to appreciate potential hazard before extensive development or exposures of humans.

SYSTEMATIC APPROACH TO TESTING

The goal of a systematic approach to testing is to obtain reliable data for hazard assessment and evaluation of the TS at the earliest possible stage. An approach that incorporates the mechanistic concepts described above is the decision-point approach (DPA) (274), which is presented here as a general framework for the concept (Table 20.4). An expedited approach to testing is needed not only for the large reservoir of existing untested chemicals, but also for the host of new molecular (or chemical) entities (NMEs), both small and large (e.g., protein) molecules, that are being synthesized, particularly in the pharmaceutical industry, using combinatorial chemical synthesis.

Table 20.4 Decision point approach in carcinogen testing

Stage A. *Structure of chemical*

1. Possible electrophiles
2. Relation to known carcinogens

Stage B. *Short-term genotoxicity assays*

1. Bacterial mutagenesis hepatocyte, DNA repair
2. Other

Decision point 1: Evaluation of findings in stages A and B.

Stage C. *Assays for epigenetic effects*

1. Cultured cells
   - Mitogenesis
   - Induction of cytochrome P450
   - Peroxisome proliferation
   - Gap junction protein downregulation
   - Inhibition of cell-cell communication
   - Altered gene expression
2. In vivo
   - Increased cell proliferation
   - Induction of cytochrome P450
   - Peroxisome proliferation
   - Hormone perturbation
   - Gap junction protein downregulation
   - Enhancement of preneoplastic lesions
   - Immunosuppression

Decision point 2: Evaluation of results from stages A through C.

Stage D. *In vivo assays*

1. Genotoxicity
   - DNA binding

2. Limited bioassays: Preneoplastic lesions—rat liver, mouse skin, mouse lung, rat breast; transgenic mice

Decision point 3: Evaluation of results from stages A-C and selected tests in stage D.

Stage E. *Carcinogenicity bioassays*

1. Accelerated bioassays
2. Long-term bioassays

Decision point 4: Final evaluation of all results and cancer hazard assessment.

Implications of Chemical Structure

From the classes of DNA-reactive carcinogens given in Table 20.2, the types of electrophiles that are involved in chemical reactivity and hence DNA binding are well known (Figure 20.2). Such molecular features also have

Page 965

Electrophiles

carbonium ion **1** nitrenium ion **2** diazonium ion **3** aziridinium ion **4** episulphonium ion **5**

Precursors

alkyl esters of phosphonic acid; alkyl esters of sulphonic acid; N-(hydroxymethy) derivatives; monohaloalkenes; aromatic and aliphatic substituted primary alkyl halides; aromatic nitro groups; aliphatic nitro groups; N- and S-mustards; urethane derivatives (carbamates); N-chloramines; alkyl N-nitrosamines; aromatic azo groups; β-propiolactones; β-propiosultones; arene oxides; aromatic, mono, and dialkyl amino groups; alkene oxides; alkyl hydrazines; aromatic and aliphatic aziridinyl derivatives; $C(X)_4$ X=H, F, Cl, Br, or I halogenated methanes; 1,2-dibromoalkanes

FIG. 20.2. Structure of reactive electrophiles and precursors.

been referred to as structural alerts (8). In general, there is a relationship between DNA binding and carcinogenicity (157).

Among both DNA-reactive and epigenetic carcinogens, numerous classes have structural features in common within the class. The presence of one of these features in an NME of unknown carcinogenicity suggests potential activity. The U.S. Food and Drug Administration has grouped food additives into classes by chemical structure, estimating their potential toxicity. These structural classes are used for assignment to levels of concern. Additives with functional groups of high probable toxicity are assigned to category C. Additives of intermediate or unknown probable toxicity are assigned to category B, and compounds of low probable toxicity are assigned to category A (260). Artificial intelligence systems for assessing potential toxicities related to structures have been developed (141, 161).

Genotoxicity Assays

In Vitro

A large number of assays for various genetic endpoints are available (280, see Chapter 17), and all regulatory agencies have specific recommendations or requirements, which may extend beyond the intent to predict potential carcinogenicity. For pharmaceuticals, a core battery including both in vitro and in vivo assays has been agreed upon by the International Conference on Harmonization (ICH) (44).

The results of genotoxicity assays are usually interpreted in terms of potential carcinogenicity of the TS. However, the predictivity of most assays (i.e., the percentage of positives that prove to be carcinogens) is generally limited to DNA-reactive carcinogens as a consequence of the fact that DNA alteration is a molecular basis of mutagenicity. Exceptions are assays designed specifically for epigenetic effects (see Assays for Epigenetic Effects section), including cell transformation, which appears to respond to both DNA-reactive and epigenetic agents (150). The *Salmonella* microsome mutagenesis assay (87) is required in all testing batteries and has perhaps the highest predictivity, about 80% (298). Nevertheless, about 20% of bacterial mutagens are noncarcinogens. The ability of *Salmonella* mutagenicity to differentiate carcinogens from noncarcinogens is not increased by certain other standard in vitro assays, such as mammalian cell mutagenicity and chromosome aberrations often included in testing batteries (298). To reinforce assurance of the predictiveness of a positive *Salmonella* mutagenicity finding, in the DPA (Table 20.4, stage B), another well-established assay with a defined protocol, the hepatocyte/DNA repair assay (287), is recommended in addition to *Salmonella* mutagenesis because positive results in the two combined provide essentially perfect predictivity for detection of DNA-reactive carcinogens (286). The latter assay affords the valuable feature that it can be conducted with human cells. Clear positive results in both of these assays, therefore, raise serious concerns for many uses of such a chemical. If testing at this level, however, yields equivocal findings, in vivo assays for DNA reactivity are available.

In Vivo

In vivo assays are undertaken, as indicated in Table 20.4, stage D, if there is a suspicion of DNA reactivity for the NME that is not resolved by in vitro assays. The availability of radiolabeled chemical allows measurement of DNA binding (157). Otherwise, assays for DNA damage that can be applied include the in vivo/in vitro hepatocyte/DNA repair assay (21), 32P postlabeling (199), and the alkaline single-cell gel electrophoresis (COMET) assay (67). Positive results in these assays, if considered insufficient, direct the need for a radiolabeled chemical binding assay, which should include demonstration of an adducted DNA base.

Since the only agents that represent human cancer hazards apart from hormones and immunosuppressants are DNA reactive chemicals (see Cancer Hazard and Risk Assessment), a 4 week study for DNA adduct formation, if negative, could obviate the need for an RCB.

In vivo mutagenicity assays such as the mouse (rat) bone marrow micronucleus assay and rat bone marrow chromosome aberration assay are usually done as part of standard batteries. Newer models for in vivo mutagenicity include transgenics such as the Muta mouse and Big Blue transgenic mouse (175). The latter allow for detection of mutations in other tissues in addition to bone marrow and can provide information on the molecular nature of induced mutations. These assays, if negative, provide further evidence of lack of in vivo DNA reactivity of a chemical and combined with a negative adduct study, further preclude the need for an RCB.

Assays for Epigenetic Effects

The assays in Table 20.4, stage C are applied selectively depending on the properties of the NME, that is, chemical structure, biologic or pharmacologic action and toxicity. They provide evidence for an epigenetic mechanism that may result in an increase in neoplasms in chronically exposed rodents. Many can be conducted in cultured cells, particularly hepatocytes, although even when applied in vivo, the

experiments are of short duration, except for assays for promoting activity, which are described further in the section on limited carcinogenicity bioassays. Positive results for the TS indicate a potential tumorigenic

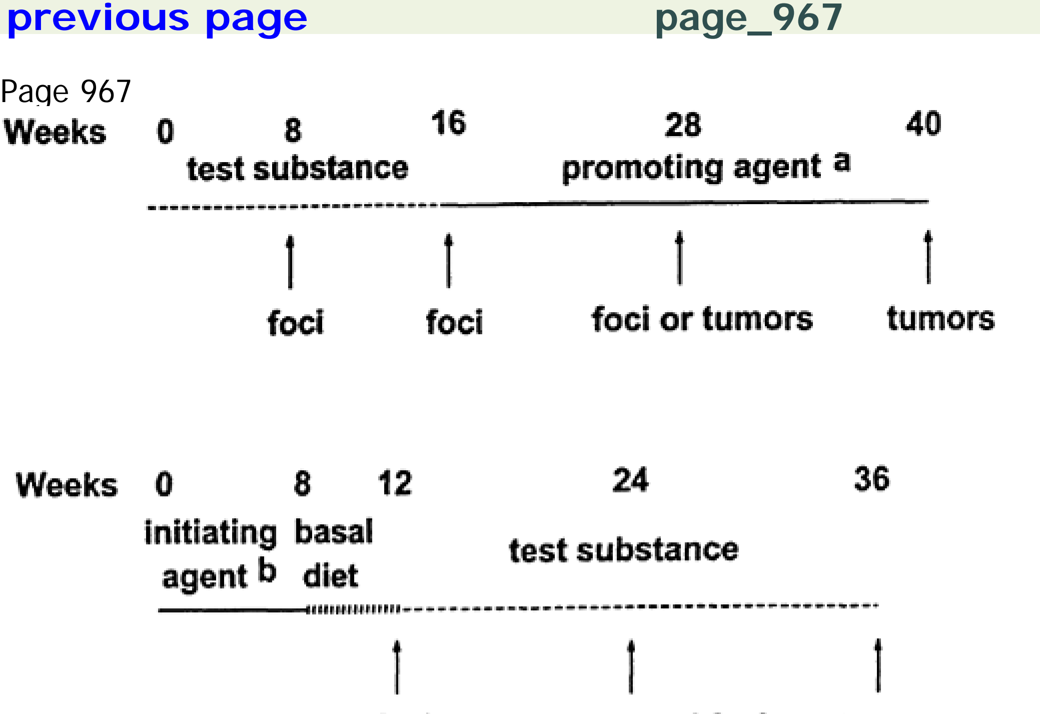

FIG. 20.3. Limited bioassays for initiation and promotion in rodent liver.

effect, in which case the carcinogenic potency of established tumorigens with a similar mechanism and organotropism provides a guide to whether a favorable risk assessment can be made for the NME.

Genomic technologies are becoming available for screening for effects on gene expression and function, including microarray hybridization methods ("DNA Chips") and proteomics. If expression of specific genes, such as acyl coenzyme A (CoA) oxidase (peroxisome proliferators) or cytochrome P450s (liver promoters), can be linked to epigenetic carcinogenesis, then these methods will have utility for screening.

Limited Carcinogenicity Bioassays

Limited carcinogenicity bioassays (LCB) are based on either neoplasms or established pre-neoplastic lesions as their endpoint (60, 61, 284). These can be applied as initiation assays, in which the TS is tested for its ability to induce the endpoint lesion, or as promotion assays, in which the TS is administered after an agent known to induce the endpoint lesion to determine the ability of the TS to enhance development of the lesion (240).

Initiation/Promotion

In early experimental studies of initiation of skin carcinogenesis, initiation was achieved with a single exposure (11). Although this is possible with potent DNA-reactive agents, repeated exposure is required for an adequate assay for initiation. Since promotion requires an even longer time for expression, more extensive exposure, up to 6 months, is required for an adequate bioassay. Essentially, an assay for initiating activity is directed largely toward assessing potential in vivo genetic activity of the TS, whereas the assay for promoting activity assesses an epigenetic mechanism. Accordingly, assays for promoting activity are also appropriate in the DPA at stage C in vivo assays for epigenetic effects (Table 20.4).

The most extensively validated and used model for an LCB is rat liver (53, 60, 61, 226). This is a consequence of the extensive capability of chemical biotransformation in the liver and the availability of sensitive and reliable markers for preneoplastic lesions. A typical study design for initiation and promotion is shown in Figure 20.3.

Other commonly used LCBs are the mouse skin papilloma, the mouse lung adenoma, and the rat mammary-gland tumor assays (274). These have advantages for specific types of agents; for example, mouse skin is very responsive to polycyclic aromatic hydrocarbons.

Positive findings for initiation are highly indicative of potential carcinogenic activity (123). In fact, Williams et al. (294) calculated that initiation/promotion can be

as sensitive as chronic bioassay in detecting carcinogenic activity. Promoting activity also suggests a likelihood of carcinogenic activity (123). In either case, it is possible to establish dose-response data and no-effect levels for design of chronic bioassays or risk assessment.

Transgenic Mice

Another type of LCB, the use of which is expanding rapidly, is the transgenic mouse model (56), in which the principal genetic targets are specific oncogenes (H-ras model) or tumor suppressor genes (p53 model), or the entire genome in DNA-repair-deficient animals (XPA-deficient model). Four models are receiving the greatest attention: the p53 heterozygous mouse (p53+/−), the Tg-AC mouse, the CB6FI-Tg-H-ras2 mouse and the XPA−/− mouse (234). Other models, such as Min, Eμ-pim-1, ARF-deficient, and double mutant p53/XPC, have shown responsiveness to carcinogens but are being used mainly for mechanistic research. The studied transgenic models have responded appropriately to a number of carcinogenic and noncarcinogenic agents and have been introduced as alternatives to the RGB in mice and accepted as providing evidence of carcinogenicity (35, 234).

Three of the commonly used models are based upon alterations in genes that are relevant to many human and rodent neoplasms—the p53 tumor suppressor gene and the H-ras oncogene—while the XPA−/− model provides an enhanced response to DNA damage as a consequence of the absence of nucleotide excision repair. Each model has specific features. Mice heterozygous for p53 differ in response depending upon the strains used as parents. For example, the C57BL, which is most widely used (52), is resistant to hepatocarcinogenesis, whereas the C3H is highly susceptible. The Tg-AC model carries a v-Ha-ras oncogene fused to the promoter of C-globin gene in the FVB/N mouse strain (151), a strain not commonly used in toxicology and that is susceptible to audiogenic seizure. The Tg-H-ras2 mouse carries five to six copies of human c-Ha-ras gene integrated in tandem array in the genome of Fj mice of transgenic male C57BL/6J mice and normal female BALB/cByJ mice (212), which again are strains not very susceptible to hepatocarcinogenesis. Currently, the p53+/− and Tg-AC mice are widely available, whereas the Tg-H-ras2 is available only in Japan where it was developed. Although any route of exposure can be used with these models, most data have been obtained by the oral route for the p53+/− and Tg-H-ras2, whereas skin painting is the preferred route for the Tg-AC. In these models, tumors can be elicited within 6 months with few or no tumors in controls. Beyond 6 months, these animals begin to develop genetically determined tumors in high incidence as follows: the p53+/− with a C57BL parent develops lymphomas and sarcomas (159); the Tg-AC, odontogenic tumors, erythrocytic leukemia, and salivary-gland and ovarian tumors (158, 159); and the H-ras2, benign and malignant lung tumors, splenic hemangiosarcomas, and forestomach papillomas (212). Therefore, evaluation of increases in any of these tumor types must consider whether the increase is attributable to induction of neoplasia as opposed to acceleration of development. The XPA-deficient mice do not show appreciably increased incidences of spontaneous neoplasms (only some liver neoplasms in C3H-derived strain) (50, 268).

All the models respond primarily to DNA-reactive carcinogens, although the Tg-AC model has the potential to identify epigenetic skin carcinogens (230), and the Tg-H-ras-2 has also responded to epigenetic carcinogens (297). A mouse model engineered to contain the human growth hormone gene under the control of the human heat-shock protein 70 (Hsp 70) promoter has been demonstrated to respond to toxicants of which some act as epigenetic carcinogens (210).

The p53+/− mouse in the few studies available so far clearly responds with accelerated development of thymic lymphomas (e.g., phenolphthalein), but compared to the wild-type background has not exhibited an accelerated response to DNA-reactive carcinogens targeting liver (e.g., diethylnitrosamine) (139), mammary gland (e.g., 7,12-dimethylbenz[a]anthracene) (131a), or colon (e.g., 1,2-dimethylhydrazine). This may reflect the fact that p53 mutation is not an early event in murine carcinogenesis for some tissues. If established, this situation strongly diminishes the usefulness of the p53 model for chemical screening.

For all these models, evaluation may be enhanced by measurement of cell proliferation in critical target organs.

Other Models

The newborn mouse is also used as an LCB (70). In this model, newborn mice of any strain are administered intraperitoneal injections or oral intubations of TS at days 8 and 15 after birth and then held for observation for up to 1 year of age. The model exhibits high sensitivity to DNA-reactive carcinogens, but is unlikely to respond to epigenetic agents because of the limited exposure that is provided.

An interesting new approach is the use of avian eggs for an in ovo carcinogenicity assay (IOCA) (61).

TS is injected into the egg white of fertilized turkey or quail eggs prior to incubation. The embryonic liver is removed 3–4 days before hatching for the evaluation of preneoplastic lesions. This assay has the advantage of being defined as an in vitro method for carcinogenicity testing.

Table 20.5 Accelerated carcinogenicity bioassay

Initiation segment (IS)		Promotion segment (PS)	
Control, 16 weeks		Control, 24 weeks	
TS, 16 weeks		Promoter, 24 weeks

Accelerated Cancer Bioassay

The accelerated cancer bioassay (ACB) model can be used to develop data on carcinogenicity when (a) there is not a requirement for a RGB, (b) there is an urgent need to obtain data, or (c) as an alternative RGB for one species.

The ACB is essentially a composite of six or more LCBs for rodent organs in which carcinogenicity has been found for known human carcinogens: the liver, lung, kidney, urinary bladder, stomach, and mammary gland. The protocol involves two segments, a first in which the TS is administered for 16 weeks in an initiating segment followed by promoters for the target organs and a second part in which the TS is administered in a promotion segment for 24 weeks after exposure to initiating agents for the target organs (Table 20.5). The TS is also given alone for 40 weeks, to assess carcinogenicity.

The ACB has a number of advantages as follows: (a) It takes less time than the RCB, as the name implies; (b) it provides mechanistic data on initiation/ promotion; and (c) the animals exhibit much less age-related pathology at termination because they are less than 1 year of age. Of course, the chief limitation is that the ACB is not as comprehensive as the RCB, although it has been calculated that because of the promoting stimulus, initiation is as sensitive as a chronic bioassay (294).

RODENT CANCER BIOASSAY

Historically, the RCB has been conducted in rats and mice, although other species may be used, as discussed in the section on animals and their environment. For Pharmaceuticals, experts in Europe question the value of a mouse RCB (267). Alternatives to the mouse RCB that are now being evaluated are the transgenic or neonatal mouse bioassays and the ACB in mice, as discussed in the section on limited bioassays.

The RCB was developed for testing of small molecules, but also is being used for testing of large biological molecules. Such biomolecules were introduced into medicine beginning with the hormone insulin and now include oligodeoxynucleotides, genes, recombinant human proteins, humanized monoclonal antibodies, blood products, vaccines, and cellular therapies. Each of these presents specific issues in application of the RCB. The International Conference on Harmonization has produced a framework for preclinical safety evaluation of biotechnology-derived Pharmaceuticals (223, 265). In the systematic approach discussed here, genetic toxicology studies unfortunately are not particularly informative for biopharmaceuticals because the large molecules may not enter the cells used in assays, particularly bacteria. Moreover, it is exceedingly unlikely that such macromolecules would be genotoxic. Customized approaches are usually required for chronic preclinical safety assessment of biotechnology-derived Pharmaceuticals and genetically engineered food products (265). Some of these products are intended for intravenous administration, which is a difficult route of administration for an RCB. Immunogenicity presents an additional complication with proteins, since with the development of neutralizing antibodies the biological activity of the protein can be abrogated, and the chronic antigenic

stimulation can compromise carcinogenicity testing. Guidances concerning the design of chronic/carcinogenicity studies are generally based on the clinical indication or in-use exposure. Exceptional with these products is the possibility of using relevant but nontraditional species or the use of animal models of disease (223). Any testing should, of course, be done in a species in which the molecule has biological activity. For an immunogenic protein, one solution to this problem is to test a homologous rodent molecule in the corresponding species.

Design

Most RCBs are done to meet regulatory requirements, as listed in Table 20.1; otherwise, there are more efficient approaches to carcinogen identification, as discussed in the section on systematic approach to testing. An RCB

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_969.html[2010/10/28 18:49:46]

performed for regulatory requirements must follow guidelines (63, 66, 261, 265), and, in particular, the regulations for Good Laboratory Practices (described below), although those conducted by the NTP do not strictly meet this criterion. Detailed descriptions of standard procedures for an RGB with chemicals have been published (168, 207, 274). Aspects of the design, conduct, analysis, evaluation, reporting, and interpretation are given next.

Feeding Procedures

During the past 20 years, increased variability in body weights, survival and incidences of spontaneous tumors in Sprague-Dawley and Fischer 344 strain rats and CD-I and B6C3Fi mice have been noted (3, 29, 137). Specifically, increased body weights, decreased survival, and increased spontaneous tumor incidence can confound and even jeopardize the interpretation of an RGB (19, 135, 137, 183, 200, 222, 238).

Thus far, most RGBs have been conducted using ad libitum (AL) feeding. To overcome the problem of overeating with AL feeding, two solutions have been proposed (29, 137, 183, 238); one is referred to as caloric optimization diet (COD) and consists of limiting caloric intakes to 50–80% of AL consumption (29, 94, 95), while the other is called the diet-restricted (DR) model, in which animals are given diets limited in offered quantity of feed sufficient to produce a 15% reduction in body weight compared to the AL controls (1, 183). In addition to these procedures, the use of weight-matched groups that are fed in such a way that their mean body weight is matched with that of the high exposure AL group has been evaluated (1, 183) but is not currently being used. The COD and DR procedures clearly improve the health and survival of animals, reducing the occurrence of age-related pathology, such as chronic progressive nephropathy and myocardiopathy in rats (113) and incidence of certain spontaneous neoplasms (113). Another approach to over-coming the overeating problem is simply to use a strain that does not present this difficulty (see the section on species and strain).

In the past, dietary control was routinely used in testing of oral contraceptives (132). Recently, an emphasis has been placed on the use of dietary control for all medicinal and chemical products (3). Differences in the incidence of neoplasia between AL-fed and DR rodents are shown in Table 20.6 for the two commonly used rat strains, Sprague-Dawley and Fischer 344, and the B6C3F] hybrid mouse. In both rats and mice, and especially the latter, hepatocellular neoplasia in both genders is reduced in DR groups. Similarly, pancreatic (both acinar and islet) neoplasia (especially in male rats), pituitary (especially in female rats) neoplasia, and adrenomedullary (especially in male Sprague-Dawley rats) neoplasia reduction with DR was present in both species. In general, these decreases in DR groups are due to changes in metabolism and hormonal homeostasis induced by DR. In addition, certain decreases in the DR groups are only present in one species (thyroid C-cell, mammary gland, pulmonary, ovarian, uterine, and hematopoietic), one strain (thyroid C-cell neoplasia in male F344 rats), or one gender (pulmonary adenoma in male mice). The mechanism of these decreases cannot be explained currently. Available information, however, on the impact of either COD or DR on response to well-studied carcinogens generally reveals a reduced response. Accordingly, detection of carcinogenic effects may be masked at sites sensitive to tumor reduction by body weight gain inhibition. Analyzing tumor incidence within body weight strata can reduce bias introduced by weight differences (see the section on statistical analyses).

Groups

Animals must be assigned to groups using randomization procedures. Randomization eliminates bias, but if there is another source of variation, such as gender, cage position, and order of euthanasia at termination, then a stratified randomization is more appropriate. This involves separate randomization within each level of stratifying variable, such as body weight or cage position (152). For further information, see the section on statistics.

The use of two independent control groups helps to control for biological variability in incidences of commonly occurring cryptogenic neoplasms that may occur in only one group. The usual group size is 50–60, which permits detection of neoplasms with incidences in the range of 5–10%. Groups of 75 can be used to allow for an interim kill, as described later in the statistical analyses section. An interim kill of control and exposed animals is useful in that it provides information on time to tumor. This information is not otherwise available when the neoplasia is not life-threatening and there are no resultant unscheduled deaths with neoplasms (80, 152). Finally, since the diagnosis of proliferative lesions can be controversial, a short recovery segment (1–3 months) is desirable, because induced neoplastic lesions should progress while nonneoplastic proliferative lesions may regress. To monitor for intercurrent diseases (see the section on animals and their environment), a satellite group of six or nine is used.

The groups typically consist of a high-dose group (see the section on dose selection) and one or two

lower doses. Many laboratories, including the NTP, favor a second group at half the high dose to provide sufficiently exposed animals in the event that the high dose impairs adequate long-term survival. Other laboratories space doses by

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_970.html[2010/10/28 18:49:47]

one-third or one-fourth. Since generally only TSs that are not DNA reactive should advance to an RGB, a valuable third group is one at the no-effect level (NEL) for any epigenetic effect identified at higher doses that may lead to tumorigenesis. This NEL should yield a cancer NEL, which is valuable for risk assessment. If quantitative risk assessment is envisioned, even more dose levels may be needed.

Duration

With the commonly used strains of rats the anticipated life span is 24–30 months, and 18–24 months for mice. The usual duration for both a rat and mouse RGB is 24 months, although for a mouse RGB, 18 months is acceptable, especially if survival is compromised (33). Exposure should be daily (7 days/week) and should start shortly after weaning. Exposure groups are not allowed to live longer than control groups. If a high-dose group experiences high mortality (greater than 50%) due to exposure, it should be terminated; the other exposure groups and controls should continue until 24 months are completed. In general, survival should not be less than 50% for mice at 15 months and rats at 18 months, or 25% for mice at 18 months and rats at 24 months (33).

GOOD LABORATORY PRACTICE

As regards the RGB, the main intent of Good Laboratory Practice (GLP) is the maintenance of integrity of a complex system of data management. This presupposes that the study is designed, conducted, evaluated, and reported according to standard operating procedures and that records are maintained in a manner that ensures a comprehensive and independent review (251, 259). GLP must be conducted in such a way that all data can be validated.

GLP is a global process, which is internationally harmonized, with de facto reciprocal recognition of national GLP programs. This occurs through planned publications of the International Conference on Harmonization (ICH) since 1990 (43, 231). The purpose of ICH is to make continuous recommendations on ways to achieve harmonization of technical guidelines and requirements for medicinal product approval. In addition, the U.S. Food and Drug Administration (FDA) and the U.S. Environmental Protection Agency (EPA) have relied in the past on bilateral memoranda of understanding (MOU). Currently, both agencies are negotiating a mutual recognition agreement (MRA) with the European Union. It is conceivable that all MOUs will be replaced by MRAs. At the time of this writing, MRAs exist between Germany, Netherlands, and the United Kingdom. In a GLP study, the study director plays the critical roles of moderator, catalyst, and gatekeeper, responsible for the integrity of study data. As with any process, the management of the GLP process has three components; these are planning (organizing, goal setting, prioritizing, and scheduling), operating (implementing, conducting), and controlling (monitoring, evaluating, and taking of remedial action). Here the importance of the test facility manager is crucial. The test facility manager has the ultimate responsibility for ensuring that all work from all studies is carried out in accordance with GLP principles. The specific responsibilities of the test facility manager include appointment and, if needed, replacement of the study director, the commitment of adequate and trained human resources to each study, the appropriateness of housing for the experimental animals, and scientists and equipment dedicated to the conduct of a study and the assurance of the integrity of the TS.

At the core of the GLP process are information transfer and data acquisition systems and programs. Documented and validated performances (using a standard data set) of these systems and programs are requirements in GLP. Manual systems are subject to standard operating procedures (SOP) review and approval. Computer-based systems (both hardware and software) are subject to validation. The validation methods must address common features relating to system definition, documentation and management. These methods must be clear, specific, operational, and must be periodically reviewed. Validation is the responsibility of the end user. The validation control system includes (a) system definition, (b) test protocol, (c) validation testing, (d) performance evaluation, (e) operational procedures, and (f) validation report. The basic objectives of the test protocol should include determination of accuracy, reliability, performance, and reporting of activities and errors. There are systems such as statistical analysis system (SAS), vendor-supplied graphics, word processor, spreadsheet applications, and calculator programs, which ordinarily have a validation control system provided by the vendor. For these, documentation is needed of the source of codes and formulas. For other programs requiring a control system, validation of hardware, the manufacturer's name, model, serial number, configuration options, peripheral devices, memory boards sensors, interface boards, controlling devices, communication links, and references to system documentation are needed. For other software, development resources (e.g., compilers), function libraries, source-code management tools, and debugging utilities are needed.

All raw data must be properly identified and stored, eventually in study notebooks that ensure the

integrity of the data. All data must be entered in a permanent and legible manner. Any changes to data must be dated and identified as changes, with reasons noted for any change, as well as the identification of the scientist making

the change. Further, the professionals responsible for data entry, verification, and review should also be identified. Finally, the documentation of the data so described must be maintained at all times, and secure audit trails must be created for authorized changes in the database and also in the study notebook (251). In histopathology, raw data are by definition the tissues on glass slides and their respective blocks, requiring a specific trail leading from sampling records during necropsy and trimming records after necropsy (15, 259). To achieve proper material, tissues are prepared according to standardized procedures with respect to location, type of section (e.g., cross), and orientation on the slide. In addition, slides of lesions should include both lesion and surrounding "normal tissue." Any failure to adhere to this regimen is a form of censorship and results in noncompliance. It is the duty of the study pathologist to integrate clinical (cage-side observation), structural (gross and microscopic), and functional (cellular and biochemical) data. Failure to integrate the three types of data will result in compromise of data and loss of data integrity. The pathologist must keep the study director apprised of events as they occur. The responsibilities of the study pathologist include keeping account of all the lesions reported at necropsy and performing microscopic evaluation of the normal and abnormal tissue changes. Thus, the pathologist ensures that appropriate tissues are collected, processed, and evaluated in a manner that satisfies the objective of the study. The pathologist also functions in a quality control capacity for the morphologic aspects of a carcinogenicity study (e.g., if a compound discolors adipose tissue, the pathologist ascertains whether all adipose tissues of exposed animals are discolored or whether the intensity is more pronounced in the high-dose group, etc.). Finally, the pathologist ensures consistency in diagnosis, integration of data, and grading of pertinent lesions, avoiding diagnostic drifts and censorship, as discussed in the section on pathology.

For a facility to be GLP compliant, specified environmental conditions (see the section on animals and their environment) must be maintained and monitored through a program applied at appropriate intervals.

The final regulatory end-product for every study is the compliance statement of the final report, which is signed by the study director. In this section of the report, all modifications, deviations, and amendments to the protocol should be listed. A second page with a quality assurance (QA) statement is signed by the QA auditor. During the last 20 years of GLP implementation, several common findings of importance (listing deficiencies in form FD-483) have been compiled by various agencies. The deficiencies noted were in all subparts of the FDA regulations (subparts A-J, 21 Code of Federal Regulation (CFR) 58.10–58.190). Those pertaining to pathology are detailed in the section on anatomic pathology.

Clearly, implementation of GLPs has benefited the conduct of chronic toxicity and carcinogenicity studies in many ways. These include (a) improved documentation, (b) refinement in bioavailability/bioequivalance information, (c) crystallization of the thinking process in safety assessment, and (d) strong, science-based regulated professionalism.

HEALTH AND SAFETY PROCEDURES

A comprehensive, rigorously followed health and safety plan is necessary for the proper conduct of an RCB. The fact that the substance is being tested for such activity makes it, in effect, a suspect carcinogen, although information in the Material Safety Data Sheet (MSDS) (e.g., genotoxicity, reproductive toxicity) influences the stringency of the handling procedures instituted, from receipt of the chemical through disposal of animal waste and processing of tissues for histopathological examination. All measures are subject to quality control.

The safety plan (178, 190) must address the responsibility within management for development and adherence of the plan; medical surveillance for employees; employee training; safe handling practices for the chemical; animal handling; general laboratory safety; safe personnel practices; safe work-area practices (e.g., spill control and decontamination); handling of air, liquid, and solid wastes; monitoring of workers and physical equipment; emergency control; record keeping; the design of facilities; and the pollution potential. Applicable regulations of the Occupational Safety and Health Administration (OSHA) provide only a minimum structure from which to work, and lessening of the hazard within the particular facility must be addressed individually and with ingenuity. Laboratory directors must appreciate that chemicals may penetrate protective clothing and travel a considerable distance from their point of use (189, 214, 215, 216, 254, 257).

No safety measure is unique to an RCB; it is the degree of adherence to such procedures that distinguishes the conduct of these studies from all others. It is beyond the scope of this section to address each individually. A few examples of aspects that are often inadequately addressed include the following: (a) use of a properly ventilated cage dumping area or an enclosed animal bedding disposal cabinet to prevent inhalation of contaminated dust and aerosols by employees; (b) an air-handling

system that provides decreasing gradations of air pressure from clean corridor to the animal rooms to the dirty corridor and that is periodically tested under such stress as several doors being opened at one time or with all possible chemical hoods in operation; (c) main

tenance personnel as well as scientific supervisors that follow the same rules as technicians for personal protection; (d) storage facilities that protect the integrity of the chemicals over an extended period of time during which unused material may be held and the immediate containers checked for deterioration; (e) a "breathable air" line available for use with an air-supplied respirator in the TS preparation areas; and (f) workers, including weekend staff, who are familiar with emergency safety instructions within the laboratory and know whom to notify in the event of various types of potential emergency situations.

ANIMALS AND THEIR ENVIRONMENT

The use of animals in research is subject to national regulations. In the United States, the use of rats, mice, and birds is not regulated. Guidelines for other animal use have been provided by the U.S. Department of Health and Welfare for Care and Use of Laboratory Animals (178, 179, 249), the latest amendment of the U.S. Congress Animal Welfare Act (245), the U.S. Public Health Service Policy of Humane Care and Use of Laboratory Animals (179), the U.S. Department of Agriculture Animal Welfare Rules (248), the Animal Welfare Act of the National Research Council (182), and the U.S. EPA Health Effects Test Guidelines (258). Institutional responsibilities include making available all protocols for review by a committee and providing veterinary care. More extensive coverage is provided in Chapter 16.

Species and Strain (Genotype)

For the rat RGB, several strains have been widely used. The NTP generally uses the inbred Fischer F344, while the pharmaceutical and chemical industries have favored the outbred Sprague-Dawley or Wistar. For the mouse RCB, industry generally favors the CD-I strain, whereas the NTP uses the B6C3Fi hybrid, which is the first-generation cross between male C3H and female C57BL/6 strains.

Both rat and mouse strains differ substantially in their background of tumors and their susceptibility to induction of tumors (30). For example, the F344 has very high incidence of several neoplasms (Table 20.7). Among mouse strains, those derived from the C3H, that is, B6C3F1, have a high incidence of liver tumors. Thus, male C3H/HeJ mice are highly susceptible to induction of liver cancer whereas those of the C57BL strain (6J or 10J sublines) are resistant; the B6C3F] hybrid is intermediate. Furthermore, when A/J mice (high lung tumor susceptibility) were crossed with C3HeB/FeJ (C3H) mice (high liver tumor susceptibility), the relative frequency of lung tumors was A/J>Hybrid>C3H and of liver tumors was C3H>Hybrid>A/J. For both tumor types, the incidences were higher in males than in females. The comparative percent incidence of the principal spontaneous neoplasms from five different strains of rats and mice is given in Table 20.7.

Several factors that influence response to carcinogens differ among genotypes. Notably, biotransformation activities differ considerably for certain chemicals. In addition, gender-dependent differences in xenobiotic metabolism are most pronounced in rats. The differences involve mainly cytochrome P450s (CYP), sulfotransferases, glutathione transferases, and glucuronyltransferases (176, 184).

A troublesome feature of the F344 rat and B6C3F1 mouse is that their average survival has progressively decreased and increases have occurred in the incidences of liver tumors in female and male mice, pituitary tumors in female mice and thyroid tumors, adrenal pheochromocytomas and leukemias in male rats, and mammary tumors in female rats (201, 243). Some of these tumor increases are positively correlated with excessive body weight (243), due to overeating. A detailed discussion of this issue is presented earlier in this chapter, in the feeding procedures section. Likewise, in Charles River Sprague-Dawley rats decreases in survival have been reported (136, 137). These problems may be due to breeding practices. Currently, the Wistar strain does not appear to present this problem (197).

Feed and Water

Four major types of diets are available, as follows: (a) natural-product, unrefined, largely cereal-based formulations unusually referred to as "chow-type" diets, such as NIH-07 (Purina 5018 or Purina 5001); (b) semipurified diets, formulated from refined nutrient ingredients, such as AIN76A (with sucrose) or modified AIN 76A (with dextrose); (c) open-formula diets, such as NIH-31 (Purina 7017), which are formulated to contain researcher-specified quantities of nonproprietary ingredients; and (d) chemical-defined diets, which are individually specialized (142, 182). Industry generally favors the open formula diet. The NTP has introduced a new diet, NTP-2000, designed to reduce certain spontaneous pathologies in the F344 rat.

Details about various regimens of feed availability are given earlier, in the discussion of Feeding Procedures.

Caging and Stratification

Following randomization (see section on groups), animals can be caged individually or with more than

one animal in each cage, each having advantages and disadvantages. Individually caged animals tend to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_974.html[2010/10/28 18:49:49]

overeat. Multiple-animal caging leads to a conflict for hierarchy in the cage and consequent cage differences. Group-caged female mice develop pseudopregnancy, which results in uterine decidual reactions. Also, group caging of mice produces almost a doubling of the lymphoma incidence in both males and females (236). In general, group-caged rodents demonstrate higher survival rates and lower background pathology (206). For inhalation and dermal administration studies, single housing is required.

All cages used should be either metallic (stainless or galvanized steel) or plastic (polycarbonate, polyethylene, or polypropylene), with a minimum stipulated cage size (249). The floor of the cages can either be solid or suspended. Solid-floor cages require bedding, that should not possess enzyme induction properties, such as hardwood bedding (269).

Rotation of cages and racks periodically should be used to balance known confounding sources of variability such as proximity to dual-intensity fluorescent light (148, 202). Consequently, rodents within groups should be distributed in cage racks in such a way as to be present equally at all vertical levels of caging. A thorough documentation of such cage and rack rotation is mandated.

Ventilation, Temperature, Humidity, and Emergency Power

Environmental stress to test animals must be minimized, particularly with mice, which are easily stressed even when maintained under conventional housing conditions and handled in the usual manner. The incidence of tumors in mice infected with viruses can be increased by chronic stress (205, 221). Standards for care are detailed in the *Guide for the Care and Use of Laboratory Animals* (182). These include (a) 10–15 fresh air changes per hour in each animal room; (b) air pressure adjusted so that the animal rooms are slightly positive to the "dirty" corridor and negative to the "clean" one, with minimal crossovers between the corridors; (c) all air adequately filtered before it enters the animal facility, and diluted or filtered after it leaves to prevent possibly toxic concentrations of the test chemical from entering the outside air (a process that is particularly important with inhalation studies because of the large amounts of chemical used); (d) temperature and humidity maintained within those ranges reported to be optimal, that is, 23.3±1.1°C (74±2°F) and a relative humidity of 40±5% in rat and mouse rooms; and (e) automatic control systems that record both temperature and humidity at least three or four times per day. Control of lighting is essential. Usually, a 12-h continuous light interval per day is used for both rats and mice (14-h light day for hamsters). Moreover, high (only during cage-side observation time of approximately 4 h)-low (20 h) intensity of fluorescent light is recommended in order to avoid blindness caused by high-intensity light. In addition, because the light and temperature gradients occur vertically, a cage-rack rotation is mandated (182). An emergency power source is essential to maintain operation of storage freezers and refrigerators, lighting, tissue processors, and some degree of air-conditioning, as well as air handling, during power failure or when personnel are unable to reach the facility. The emergency power and alarm systems should be tested on a regular schedule. In a GLP-compliant facility, all these conditions must be monitored.

Also important is control of pests by adequate facility design and sanitary procedures. Pesticides must not be allowed to contaminate the animal rooms, feed rooms, or cage washing areas and accordingly should be dispensed only in closed traps in limited areas. Detergents and cleaning agents for use on floors, cage washers, and other equipment must be nonvolatile and must not leave a residue.

DOSE SELECTION STUDIES FOR DIOASSAY

Dose Selection: The Maximum Tolerated Dose

Dose setting can be based upon a number of end-points, including toxicity, toxicokinetics, saturation of absorption, and maximum feasible dose (73). Generally, it has been expected that the high dose level in an RCB should be a toxicity-based dose, the maximum tolerated dose (MTD) (229), which is also referred to as the minimum toxic dose (or the minimally toxic dose used by NTP) (100). The various methods for selection of the high-dose level have been reviewed by a working group on dose selection convened by the International Life Sciences Institute (73). Testing at the MTD has the virtue that a negative outcome is compelling, but creates problems in the interpretation of positive findings, because of specific high-dose effects, as discussed with rodent cancer bioassay evaluation.

The first widely used definition of the MTD was formulated by the National Cancer Institute (229) as follows: "The MTD is defined as the highest dose of the test agent during the chronic study that can be predicted not to alter the animals' normal longevity from effects other than carcinogenicity." This definition does not stipulate that any toxicity be produced, and hence a slight, but significant, reformulation was introduced by the U.S. Interagency Staff Group on Carcinogens (181, 262) as follows: The MTD is "the highest dose which when given for the duration of the chronic study is just high enough to elicit signs of minimal toxicity without

significantly altering animals' normal lifespan due to effects other than carcinogenicity." The MTD so defined is a dose used in the chronic study (7), which, of necessity, is selected from subchronic studies (normally 90-day). The ICH defines the MTD as the dose predicted from a range finding study to produce minimum toxicity over the course of the carcinogenicity study (262). Such toxicity may be predicted from alterations in physiological function that would be expected to alter survival, toxicity to target organs, significant alterations in clinical pathological parameters or suppression of weight gain of no more than 10% relative to controls calculated as the difference between the starting weights and those at the end of the study (181, 262). A fortuitously selected target MTD should in the RGB study suppress weight gain by 10% or slightly greater and produce only minimal other toxicities. This, however, infrequently happens, and issues arise when the high dose is either below or above what is considered by a regulatory agency to be an MTD.

Toxicokinetic endpoints have gained acceptance for dose setting for Pharmaceuticals (42, 76). A dose that produces saturation of absorption is considered an MTD, and a dose that produces a plasma concentration that is 25 times greater than human exposure is considered pragmatic (124). The endpoints are easier to establish.

Toxicodynamic endpoints can be used to establish a high dose that will produce a cellular effect beyond which the validity of the study would be compromised. An example is induced toxicity, which would be expected to become more severe with aging in rats as they develop chronic progressive nephropathy.

To identify the target MTD or high dose, subchronic studies are performed, as described next. If the target MTD (or the high dose) cannot be established on the criteria discussed, it is usually recommended that the high dose level or limit dose not exceed 5% in the feed (115, 169, 191), which translates into approximately 3–4 g/kg/day for rats and 7–8 g/kg/day for mice. This limit appears to be based upon concern for the nutritional impact of high proportions of TS. Certainly, some TSs at high exposure interfere with nutritional elements, such as impairment of vitamin K function by butylated hydroxytoluene (37, 127), but such problems can be overcome by nutritional supplements. Nevertheless, reduced feed intake, and hence caloric intake, will affect the outcome of the RGB, usually reducing tumor incidence (1, 29, 183).

In the United States, for Pharmaceuticals, the dose selection should be submitted to the FDA Center for Drug Evaluation and Research Carcinogenicity Assessment Committee, which strongly favors a toxicity-based endpoint. Such consultation is not yet practiced in Europe.

The selection of other dose levels is discussed in the section on rodent cancer bioassay groups.

Subchronic Study

The MTD is usually identified from results of a 90-day study, using the route of administration to be used in the RGB. It is unusual that a tested dose would qualify as the predicted MTD, and therefore interpolation is usually made. When genders show different MTDs, then based on kinetic study results, different sets of doses are administered.

Kinetic Studies

Before starting an RGB, it is helpful, and in the case of medicinal products, it is a requirement (76, 124), to determine the time course of exposure and the relationship between the concentration of exposure and effect. For this purpose, multiple-dose toxicokinetic studies are conducted (23, 42, 124). Plasma protein binding of the TS in rodents and humans should be determined before initiation of the carcinogenicity studies. Should binding exceed 80%, it is advisable to express exposure (plasma TS concentration) in terms of the free fraction (26, 276). In addition, tissue distribution and accumulation data can be valuable (25, 198, 225), but this is more difficult and requires other techniques.

Furthermore, accurate and useful extrapolation from rodents to humans presupposes understanding of histokinetic and xenodynamic considerations. For example, smaller species (e.g., rodents) have a higher xenobiotic metabolic rate per kilogram of body weight, faster rate of tissue distribution, and shorter tissue half-life (111). Tissue volume directly affects the volume of distribution of xenobiotics, bioavailability, half-life, and systemic clearance (13, 130, 140). In general, with increasing age, as will occur over the course of a carcinogenicity study, body weight increases, as does the proportion of adipose tissue, which has a lower metabolic rate than skeletal muscle mass (82). Both influence the outcome of kinetic studies. In dose-proportional linear kinetics, half-life and clearance are independent of xenobiotic concentration. In contrast, in nonlinear kinetics, these parameters are dependent, because the various processes (e.g., absorption, distribution, metabolism, and excretion) can become saturated (153).

The toxicokinetic component of a carcinogenicity study often entails satellite groups run in parallel and consists of at least three rodents per group per gender per time interval, with interim kills at least every

6 months. The time-course factor is very important in explaining how the various concentrations accumulate and relate to different exposures (76). The animals are maintained and exposed under identical conditions with the main study. Approximately 4 blood samples are taken from each animal over the duration of the RGB, with the blood removed not exceeding 15% of the total blood volume.

The parameters examined may include (a) the maximum achieved concentration (Cmax), the minimum concentration (Cmin), the time to Cmax (rmax), and the area under the flood concentration versus time curve (AUC) for TS and all metabolites (109). Only the AUC is required to establish exposure (124). In an RGB, together with measuring the systemic concentration of exposure (AUC), determination of the total (cumulative) amount of exposure over time is also essential so that exposure can be related to induced effects (124, 198). In addition, if indicated from chronic toxicity data, target site (tissue) compound levels (or major metabolites) can be measured, but, as noted, this requires separate assay validation and a more extensive study design to acquire appropriate tissues. Target site compound levels potentially connect the target site of both chronic toxicity and carcinogenicity. For accurate extrapolation of exposure over time, human time equivalent (HTE) values are employed. These values amount at 12 months of exposure to a HTE of 38 years for the mouse and 34 years for the rat, and at 24 months to a HTE of 76 and 64 years for the mouse and rat, respectively (109, 111).

Pharmacokinetic data are critical, not only for delineating blood levels, but also for understanding the effects of exposure—that is, if the parent or a metabolite is the main active moiety, or even if the plasma concentration reflects the cellular site of action, and which is the interspecies concentration (blood)-response (site) relationship (109, 171, 193). Furthermore, metabolism can also distort concentration-response homeostasis. Here, at high exposures, together with absorption and elimination being saturable (i.e., capacity limited), intermediary metabolism can also significantly target tissue bioavailability through transformation, which is especially important in interspecies extrapolation (27, 86, 225, 296). Moreover, metabolic saturation and activation of secondary routes of metabolism should also be taken into consideration (25, 47, 85, 93). Knowledge of metabolic behavior (e.g., species differences in biotransformation enzymes) of the xenobiotic under test is the best foundation for interpreting the mechanism(s) of neoplasia and for extrapolating to humans.

QUALITY CONTROL OF THE TEST SUBSTANCE

The test substance should be of a high quality and stability, and should be manufactured in the same way and contain the same concentration of impurities as the final product. Impurities in excess of 0.1% should be individually identified. For Pharmaceuticals, the preclinical and clinical final product tested should be preferably the same. The product should have a well-defined and described scale-up process (125).

Most medicines will be formulated with excipients and, accordingly, the noncarcinogenicity of these must be established. In other situations, as with agricultural chemicals and cosmetics, the technical-grade product or a representative technical grade of active ingredients is tested. In some instances, complex mixtures are tested, as with polychlorinated biphenyls. This aspect is discussed further with complex mixtures.

Test Substance

Chemicals or Small Molecules

In some situations, it is desirable or necessary to test pure chemicals, as with candidate medicines or food additives. With isomeric compounds, if the two enantiomers exhibit inversion in vivo or have the same biological activity, they are considered one entity and carcinogenicity of the racemate is appropriate. If the biological activity is not the same, then carcinogenicity testing of the active enantiomer is indicated.

Biopharmaceuticals

Biopharmaceuticals include recombinant human proteins, humanized monoclonal antibodies, oligodeoxynucleotides, and genes. Recombinant human proteins are being produced by a variety of techniques, often in bacteria where glycosylation does not occur. Quality control of biopharmaceuticals, as with small molecules, is necessary to establish that they are actually what they are expected to be at all times during the study. For this purpose, all relevant information, such as synonyms, trade names, and structural and molecular formulas and weights, as well as methods of analysis and chemical and physical properties of the pure substance, should be provided.

Impurities or Contaminants

It is highly recommended that all TS should be pure chemicals of analytical grade, since even traces of impurities of <1% can have confounding effects resulting in neoplasms. An example of this would be o-toluenesulfonamide (OTS), an impurity of saccharin, present in the early carcinogenicity studies (173). Impurities can occur in the starting materials to be used in the formulation, or in materials used in the manufacturing process of the TS (69, 131, 266). Impurities in excess of 0.1% should be thoroughly identified. If the TS with the identified impurity is intended for long-term use, such as with a high dose of active compound, then multiple-dose toxicity (up to 3 months) and mutagenicity studies should be

performed. If the results of the mutagenicity assays are positive, carcinogenicity testing of the impurity may be considered (125).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_978.html[2010/10/28 18:49:52]

Preparation of Dose
The most essential aspects in preparing a TS for dosing are identity of all ingredients, homogeneity of the product, particle size, stability of all active ingredients, and vehicle (carrier) to be used (69, 131). All batches of dosage preparations must be analyzed for concentration to confirm accurate preparation prior to use.

Homogeneity of the TS-diet mixture and stability of the TS in diet under the intended in-study conditions should be established prior to the start of RGB. During the conduct of the RGB, samples of the TS-diet mixture are taken approximately every 6 months for analysis and correction if necessary. It is recommended that the same batch be used for the entire RGB. This presupposes that there is a complete method of analysis for the active ingredients at hand. Quality control data as described earlier should be provided, and monitoring should continue throughout the duration of the study.

TEST SUBSTANCE OF ADMINISTRATION
The route of administration should be appropriate to potential human exposure and reflect knowledge about comparative bioavailability. Thus, comparative absorptive, dispositional, metabolic, and excretion data are essential and should be used in designing the 2-year RGB.

The most common route is the oral, followed by parenteral exposure and inhalation. The selection of a delivery system is crucial for all routes, as it has the potential to significantly affect bioavailability. Second, producing uniform and homogenous TS exposure throughout the bioassay is equally important. This requires the availability of a validated analytical methodology (124, 225).

For some TS there is a rationale for prenatal exposure, but generally exposure is begun postweaning at 4–6 weeks of age.

Oral
The oral route of administration is most frequently used, especially for medicines and food additives for which ingestion is the usual route of exposure of humans. For oral administration, the TS can be admixed in the feed or given by intragastric (ig) instillation (gavage). Comparable systemic exposures can be achieved with either, but with the ig route, the bolus dose results in a higher blood Cmax (143). The concentration of TS in diet is adjusted to compensate for changes in body weight. During the rapid growth phase the concentrations are adjusted biweekly at first, then weekly, and later monthly after the growth plateau has been reached. Here TS stability and homogeneity data are essential. Periodically during the study, samples of TS-diet mixtures should be analyzed to confirm desirable concentrations and enable corrective action to be implemented. In general, this is the most cost-efficient mode of exposure with most TS.

Intragastric (ig) administration affords the most precise oral delivery of TS. For this route of administration, a vehicle is required, such as corn or olive oil. For a TS that cannot be dissolved in water or oils, a suspension in Tween 80 or carboxymethylcellulose can be used. For a TS that is unstable or volatile in diet, microencapsulation can be used. Oils as vehicle will prolong residence time in the stomach compared to water (23). Corn oil given ig is reported to increase the body weights of male rats, but to have an opposite effect on females (99). Also, the incidence of some background tumors, such as mononuclear-cell leukemia and pancreatic acinar-cell tumors, can be affected. For this reason, a second control group (without gavage) is strongly recommended. For more details, see the section on feeding procedures. In general, the TS volume in rats is 3–5 ml/kg body weight. In mice a volume of up to 10 ml/kg has been shown to be desirable, as this enables more accurate measurement of the dose. In addition, dilution enhances absorption and decreases local irritation, especially with weak bases or acids, which comprise the majority of TS (17). Unscheduled deaths should be closely monitored at necropsy by inspection of the lungs and trachea for TS. If deaths are due to gavage accidents, then a monitoring program should be implemented. In general, the baseline rate for accidents per technician should not exceed 1 per 10,000 gavages.

Dermal
Under certain circumstances of dermal human exposure, TS are delivered via this route either by topical application or injection. The sensitivity of this route of exposure depends on the fact that the skin is also capable of biotransformation, albeit not to the same degree as that of the liver or intestinal tract (23). Dermal application is usually to the superior dorsal area of the back (interscapular), where the skin is clipped at least weekly, 24 h prior to application (149). In dermal studies, animals are routinely housed singly to minimized ingestion by other cage mates. TS (0.25–1 ml) is applied topically over the clipped area at intervals (e.g., 2 times or 3 times weekly) to allow for recovery (especially when the TS is irritating). Skin penetration varies with species, chemistry of TS, and vehicle (219), Thus, one should consider, in dermal dosing by weight or surface area, to the fact that rats are large enough to vary

significantly in size, whereas mice are not. Moreover, effects at the site of dermal injection should be monitored carefully.

Inhalation (Intratracheal)

With some TS, chronic inhalation is indicated. Routinely, under these conditions, animals are exposed 6 h/day during the day (104). After exposure, the animals can either remain in the chamber or be taken to another room. Either way, constant airflow through the chamber during and after exposure prevents build up of ammonia. Single cage occupancy is recommended to avoid grooming and licking-based ingestion. The cages should be rotated within the chamber periodically. Inhalation exposure is an expensive, labor-intensive route of administration, requiring frequent monitoring of achieved air concentrations. Sampling should be done from several fixed locations in the chamber after documenting homogeneity of the test atmosphere (162).

Nose-only or head-only exposure units are available for rodents (228). Their major advantages include minimization of external contamination and effective monitoring of respiratory parameters. The major disadvantages include restraining the animals, leading to alteration of many physiological parameters and entailing excessive manpower requirements.

Intratracheal exposure can be conducted under anesthesia to permit chronic delivery (up to 2 years) directly into the bronchial passages. Here, a second control group (with the anesthetic) should be added and exposure should be limited to once or twice weekly (227).

Parenteral

In special cases, or when the TS is destroyed in the gastrointestinal tract, intraperitoneal, intramuscular, or subcutaneous routes of administration are employed. Here, new factors such as molecular size and pH have the potential to affect absorption and cause irritation (9). Again, if a carrier is used, then a second control group without carrier is needed. The exposure regimen here is limited to two or three times per week. In using these routes, the potential exists for local tumor formation due to physical factors (207).

Multigenerational/Transplacental/Perinatal

Experimental transplacental carcinogenesis has been extensively studied, mainly in rats and mice (239), but also in primates (203, 237). The design of experiments ranges from multigenerational, involving exposure of germ cells of one or both parents and subsequently the progeny, to exposure of embryonal or fetal cells (4, 239). It has frequently been discussed whether such exposures should be included in an RGB, but so far, it is accepted that a conventional RGB beginning at 4 to 6 weeks of age can identify carcinogens that might have activity in developmental stages.

CLINICAL AND PATHOLOGICAL EXAMINATION

The RGB is not an extended chronic toxicity study; standard chronic toxicity assays (i.e., 6 and 9 or 12 months, depending upon requirements) involve more clinical observations than are necessary or appropriate for the RGB. In the RGB, animals should be observed at the beginning and at the end of each work day so that unwell animals can be euthanized before they become moribund or are lost to autolysis (or cannibalization, if multiple caging is used). Real-time automated programs for carcinogenicity studies have been developed (188), allowing for monitoring, at least biweekly, the appearance, location, and growth of palpable cutaneous or subcutaneous masses.

Standard parameters measured in the RGB include body weight, health status, and mortality.

Body Weight and Survival

In RGBs using an MTD, controls frequently show greater weight gain and often poorer survival than the high-dose group, in which body weight is reduced both by toxicity as well as secondary effects resulting in reduced feed consumption or energy utilization (156).

Intercurrent Diseases

Laboratory strains of rats and mice are susceptible to a variety of diseases, both genetic and acquired. The genetically determined conditions include predisposition to development of neoplasms, as discussed with species and strain. Also, pathologies such as amyloidosis in mice and chronic progressive nephropathy in rats are common. These conditions increase with age and complicate long-term studies. Acquired diseases, such as sialoadenitis and murine hepatitis, can be minimized by proper animal husbandry. Many strains of mice harbor *Helicobacter hepaticus* in the gastrointestinal tract. Infection with this organism can lead to an increased incidence of liver neoplasms, particularly in male mice (91). Satellite sentinel animals are included in all chronic studies to effectively monitor intercurrent acquired diseases.

Clinical Pathology

Several regulatory agencies have suggested the monitoring of continuous variables, including hematology, clinical chemistry, urinalysis, and organ weights (128, 260). It must be realized that, in spite of initial randomization, aged rodents are no longer homogeneous because of nonrandom attrition

and development of diseases in the latter portion of the in-life phase. Although

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_980.html[2010/10/28 18:49:53]

such measures may be helpful at times, they need not be implemented without a specific reason; for example, hematology smears assist in the diagnosis of leukemia.

Anatomic Pathology

Pathology is not only an integral part of the protocol design, but plays a pivotal role throughout the conduct, evaluation, and interpretation of carcinogenicity studies (16), as discussed in Good Laboratory Practice. In general, emphasis is placed on routine methods, but special pathology methods may be required depending on the target organs. Whatever can be anticipated from previous subchronic and chronic studies should be utilized in the protocol for pathology. Furthermore, the pathologist must correlate clinical observations, body weight gain and survival patterns, clinical pathology data, and other data with gross and microscopic changes. The general and specific GLP and statistical considerations are given in separate sections elsewhere in this chapter.

All animals euthanized for humane reasons and those found dead should be submitted to a complete necropsy. At scheduled necropsies, the pathology team should be prepared for potential outcomes by participating in a prenecropsy briefing, where all known clinicopathological correlations are discussed. At necropsy, body weights are obtained. Examination of all recorded palpable masses constitutes an initial procedure with examination of all body orifices and skin. A ventral midline incision, with reflection of the skin so that subcutaneous tissues are exposed, initiates the opening of the abdominal cavity, followed by the thoracic and finally the cranial cavities. All gross lesions are described as to their location, size, shape, consistency, and color. In general, organs should be examined in situ as well as after removal from the animal. Any artifactual tissue damage (e.g. crushing or tearing of tissues) must be avoided, but if this is not possible, damage should be minimized and noted. Tissues should be cleaned by rinsing in physiologic saline solution (tap water is not acceptable because the low osmolarity damages cells). Alimentary-tract hollow organs (because of their rapid rate of autolysis) are opened to avoid tissue autolysis and examined (their anatomic integrity if possible should be maintained). Lungs are instilled (with 10% neutral buffered formalin, ~4 ml in rats and ~2 ml in mice) with care not to overinflate, and if indicated, also the urinary bladder (with formalin ~0.2–0.5 ml), after which the trachea and urethra, respectively, are ligated to maintain the inflated state. Lesions/neoplasms are dissected to include regional lymph nodes, if possible, and a small portion of surrounding (normal) tissue. At least 55 standard tissues and lesions are sampled, trimmed, and pro cessed for histopathological examination, including brown adipose tissue, blood and bone marrow smears (28, 79, 163, 207). Any significant deviation from any of these procedures amounts to censoring, which potentially compromises the integrity of the study (see GLP and statistical analyses sections). Organ weights are usually not taken in carcinogenicity studies because of variability of weights caused by disease, neoplasms, or body-weight fluctuations. In some cases selected organs are weighed (260, 261), usually the adrenals, brain, heart, kidneys, liver, lungs, spleen, testes (with epididymides), and uterus (including horns). Where organ weights are taken, organ-to-body-weight percentage values are recommended (79).

The preparation of routine microscopic slides should be in accordance with a standard operating procedure (SOP). Each slide should be matched with blocks and routinely taken tissues or grossly observed findings. Special methods (e.g., quantification of proliferating cell nuclear antigen [PCNA]), compatible with formalin fixation, should be either described in detail in the protocol or be part of an SOP. Recently, these methods have shown utility, since they are capable of identifying proliferation (PCNA) and preneoplasia and early neoplasia (112, 294). During microscopic examination, an "open" slide evaluation is recommended (107, 108, 186). It consists of evaluation of the concurrent control group(s) first and, subsequently, the highexposure groups. After this the rest of the exposure groups are evaluated and the presence or absence of an exposure response pattern is established. Lastly, the findings can be compared to in-house historical or published control data to minimize subjectivity and diagnostic drift. "Open" evaluation is preferably conducted by one pathologist. If the study entails more than 1000 animals, then one pathologist may read the males and a second the females, to reduce the length of time to complete the histopathologic evaluation. "Open" evaluation is also performed when quantitation is performed (e.g., PCNA). Under certain circumstances, a re-evaluation of certain tissue-specific lesions is needed. Then a "blinded" microscopic examination of selected target tissues may be performed, in which all slides are reevaluated by the pathologist in a blinded manner in a random sequence. Also, the valuable practice of peer review can be utilized. This consists of an independent examination by a second pathologist of all tissues from a representative sampling of randomly selected animals of both genders from the control and high-dose groups and a representative sampling of proliferative lesions to substantiate the data from the initial evaluation for neoplasms and other proliferative lesions. Here it is also recommended that the evaluation be "open," and that all changes

(not only microscopic) are taken into consideration.

It is vital that all pathology data are recorded in a consistent manner and are depicted as individual data in appendices. A summary of all exposure-related data should be in tables. An appendix depicting all missing tissues is highly desirable. Neoplastic diagnoses should adhere to an accepted nomenclature of histopathologic terms, according to recommendations made by the Society of Toxicologic Pathologists (Guides for Toxicologic Pathology, STP/ARP/AFIP, Washington, DC), with particular care to distinguish between proliferative non-neoplastic lesions, benign neoplasms, and malignant neoplasms (65, 66, 88, 90, 164). The pathologist must integrate all clinical, structural (gross and microscopic), and functional (cellular and biochemical) data. Moreover, the pathologist ensures proper accounting of gross and microscopic lesions and changes, as detailed in the sections covering Good Laboratory Pratice and statistical analyses. In pathology, the most common deficiencies in Good Laboratory Practice are as follows: (a) Gross observations are not fully available and the exposure related ones are not compared side-by-side with microscopic findings; (b) gross microscopic pathology data do not match and no explanation is provided; (c) organ weights in notebook and report do not match; (d) termination dates before completion of the study are not in the final report and no explanation is given; (e) differences between forms of data recording by the pathologist and the SOPs are not explained; (f) individual animal data in the notebook and data in tabular form in the report on the corresponding animal are not the same and no explanation is provided; (g) there is a lack of uniformity in pathology nomenclature and no explanation is provided; (h) there is lack of lesion accountability and important tissues are missing without any explanation being given; (i) the method of slide evaluation is not stated (e.g., open, peer-reviewed, etc.); and (j) lack of initialing and dating in various records such as gross data, tissue trimming, microscope evaluation, tissue recuts, and so on. Each of these is important and, if no explanation is provided, can compromise the RGB.

RODENT CANCER BIOASSAY EVALUATION

Tumor Increases or Decreases

If the RGB has been conducted properly, it should provide adequate evidence to assess whether exposure has lead to increases or decreases in the incidence of specific well-defined neoplasms. A conclusion of lack of carcinogenic activity requires survival of adequate numbers of animals given sufficient relevant exposures, usually the MTD, with no evidence of tumor increases according to the criteria discussed in the section on chemicals with carcinogenic activity.

A conclusion for a positive outcome is generally less rigorous. That is, in the interest of conservative hazard identification, a clear increase in tumors is often accepted as valid in spite of artifacts in the study such as excessively reduced weight gain or poor survival. Nevertheless, the possibility must be considered that the tumor increases are a consequence of the toxicity of the treatment conditions (89), and not a chemical action of the TS.

A critical aspect in the evaluation is the interpretation of pathological diagnoses. Findings of increases in malignant neoplasms are universally accepted as evidence of carcinogenic activity. Combining malignant and benign neoplasms of the same cell type of origin is also widely accepted, and guidelines have been published for the NTP procedures (164). In evaluating tumor increases, attention must be paid to pathology in the tissue that is the site of tumors because cell injury and compensatory cell proliferation can facilitate tumor development (see the section on cancer hazard and risk assessment).

The most appropriate comparison of an experimental group is with its matched control or controls, where two groups are used (83). Nevertheless, in arriving at a conclusion of tumor increase, it is important to consider historical control data (98), especially if control groups differ. Differences between controls and exposed groups can be analyzed by a variety of statistical methods, as discussed next. Whether any true increases in neoplasms have relevance for human cancer hazard is discussed in the section on cancer hazard and risk assessment.

A controversial issue is the interpretation of tumor decreases in the RGB (45), which are quite frequent (101). One consideration is that the reduction should not be attributable to nonspecific weight gain suppression, as discussed in the feeding procedures section. A variety of mechanisms for specific anticarcinogenesis have been delineated, as discussed in the section on anticarcinogenesis.

Statistical Analyses

An expert biostatistician should be involved in the RGB. The methods ultimately employed can be diverse and only some general guidance is provided here. More extensive coverage is provided in Chapter 7.

Statistics are employed in all aspects of the study, that is, design, conduct, evaluation, analysis, and interpretation. The object of statistics is to aid an investigator in the interpretation of RBC results by providing a quantitative measure (p value) of the likelihood that an increased tumor incidence is due to

random variability. Other than exposure, two other factors can underlie an increase in neoplasia: One is bias, which is a systematic difference other than what is caused by exposure, and the other is chance, a random difference. It is indeed

highly desirable to avoid bias and to minimize (and control) chance, although it cannot be completely excluded (i.e., identically exposed animals do not respond identically—the biological reality). The probability of chance can be statistically measured: the smaller the probability, the higher the confidence (152). A further complicating factor is that the multiplicity of tumor sites examined in a typical RGB increases the likelihood that an increased tumor incidence at any single given site is due to chance.

A one-sided (one-tailed) *p* value, is the probability of getting by chance an exposure effect in a specified direction as great as or greater than that observed (68). A two-sided (two-tailed) *p* value is the probability of getting by chance an exposure difference (effect) in either direction that is as great as or greater than that observed. The calculation of a *p* value of <0.05 implies that the effect could have occurred by chance less than 1 time in 20. Theoretically at least, randomization eliminates nonsystematic bias. But if there is another major source of variation (e.g., gender of the same strain, or batch of the same strain), then a stratified randomization is more appropriate. To achieve that, separate randomization within each level of the stratifying variable (e.g., cage position, order of weighting, or order of killing at termination) must be performed (152). The power of any statistical measurement refers to the probability that the subject test will correctly detect a difference, when such a difference truly exists (80).

There are three aspects that determine the nature of collected data: the biological system, the study design instrumentation, and methodologies applied. Censoring any of these must be minimized. In general, exposure variables are independent, while effect variables are dependent. (80, 152). Representative samples should be appropriately collected and be of sufficient size. In addition, samples should be accurate (of high quality) and precise (reproducible). The pattern of distribution of data in the sample is very important, because it shows their central tendency and dispersion. There is the Gaussian distribution (the most common), in which two-thirds of all values are within one standard deviation. Others include binomial and chi-square patterns of distribution. In order to successfully combine data for analysis, stratification is applied (e.g., early, late, or total deaths).

In order to enhance detection exposure effects, the exposure-related trend is employed (233). Furthermore, if there are differences in survival, there is a need for age adjustment to avoid bias. Certain statistical procedures used in the analysis of tumor data require specification of the context of observation is taken into account—that is, whether the condition (neoplasm) is assumed to have caused death, or death was an incidental finding (195). If the study pathologist concludes that it is not possible to determine the context of observation, then alternative methodology must be used (78). Because of the multiplicity of tumor sites examined it may also be necessary in certain cases to employ a statistical adjustment for multiple comparisons.

When animal weights differ across dose groups, as is usually the case with high-dose testing, such differences can contribute to differences in tumor incidence (see feeding procedures). Analyzing tumor incidence within body weight strata can reduce the bias resulting from weight differences (84).

In the past, the single most important statistical consideration in the analysis of bioassays was a simple quantal response: that is, either neoplasia did occur or it did not occur. Presently, the mechanisms underlying neoplasia induced by chemicals are more fully understood and must be given individual consideration. These mechanisms include effects on survival rate, body weight gain, age at first tumor, time-to-tumor, patterns (trends) of tumor incidence, tumor multiplicity, rates of proliferation at target sites, presence of markers of preneoplasia or early neoplasia, and exposure response. As recommended in the study design section, at least one interim kill should be included, and possibly also a short (1–3 months) recovery segment before final termination.

In an RGB, the time course of adverse effects (or risks) is of importance. Consequently, life-table methods are employed to compare survival curves and/or survival time until neoplasms develop (40, 41, 195). For continuous, normally distributed outcome measures, group means are typically compared against the control mean using a one-way analysis of variance (ANOVA) followed by Dunnett's method for multiple comparisons, which is a powerful post hoc test (54). Moreover, a square-root transformation may be necessary in some cases to stabilize the variance. To make all possible pairwise comparisons, Tukey's multiple-comparison procedure may be used (72). To assess the course of exposure response (its linearity), ordinary least-squares regression analysis can be used, fitting the outcome level versus exposure and squared exposure terms. For incidence of specific site neoplasia comparing all test groups, the Pearson chi-square test followed by pairwise comparisons of each exposure group with control, adjusted for multiple comparisons, can be applied (77). For incidence trend analysis, the Cochran-Armitage test, partitioning the chi-square statistic into the overall trend and departure from linearity (*p* nonlinear), can be tested (71). Furthermore, survival data can be used by applying log-rank test for

both homogeneity and exposure-related trend (96, 97). Neoplastic data can be analyzed using a survival-adjusted trend test discriminating fatal, incidental, and palpable neoplasms (195). For rare neoplasms, a *p* value of <0.025 and for common neoplasms

Table 20.8 Classification of carcinogens

IARC	HWC	EPA	IFSTP
Group 1	Group I	Group A	Group 1
Group 2A	Group II	Group BI	Group 2a
Group 2B	Group III	Group 82	Group 2b
—	—	Group C	—
Group 3	Group IV	Group D	Group 3 a
—	—	—	Group 3b
—	—	—	Group 3c
Group 4	Group V	Group E	—

Note: IARC=International Agency for Research on Cancer, (116). HWC=Health and Welfare Canada, (103). EPA=U.S. Environmental Protection Agency (250). IFSTP=International Federation of Societies of Toxicologic Pathologists, Faccini et al. (66).—, not applicable. Group I=Group I=Group A=Group I=The agent is carcinogenic to humans; there is sufficient evidence in man showing a positive relationship between cancer and human exposure; chance, bias, and confounding variables can be reasonably ruled out. Group 2A=Group II=Group B1=Group 2a=The agent is probably carcinogenic to humans; there is limited evidence in man showing a positive relationship between cancer and human exposure; but chance, bias, and confounding variables cannot be ruled out; there is sufficient evidence of carcinogenicity in animals, i.e., the genotoxic agent is sufficiently in strong evidence of carcinogenicity in animals, i.e., the agent has caused benign and malignant neoplasms in two independent studies or there is a positive relation between cancer and animal exposure. Group 2B=Group III=Group B2=Group 2b=The agent is possibly carcinogenic to humans; there is either limited evidence or absence of data in man; there is either sufficient or limited and weak evidence of carcinogenicity in animals, i.e. presence of other relevant data, genotoxic agents that cause only benign tumors or increases in certain spontaneous neoplasms; Group C=The agent is possibly carcinogenic to humans, there is either absence of data in man, or limited evidence of carcinogenicity in animals, i.e., agents that cause only benign tumors, or neoplasm incidence increases are marginal and not consistent; Group 3=Group IV=Group D=Group 3a=The agent is not classifiable as to its carcinogenicity in man; in Group V the data are inadequate for evaluation, or these agents cannot be classified in other groups; in IFSTP Group 3a, the experimental data of epigenetic carcinogens show threshold level within the range of human exposure. Group 3b=The experimental data of epigenetic carcinogens show threshold level beyond the range of human exposure. Group 3c=The experimental data of epigenetic carcinogens show that their mechanism of action is not applicable in humans. Group 4=Group IV=Group E=The agent is probably not carcinogenic to humans; there is evidence suggesting lack of carcinogenicity in man (even if it is inadequate) and animals (negative animals studies); in IFSTP Group 4, the suspected carcinogens have not been sufficiently tested.

a p value of <0.05 are appropriate levels of significance (Table 20.7) (96).

The interpretation of analyzed data is the final critical step of the whole process. Of importance here is the existence of extensive historical control data, both published and unpublished, for the specific species and strains used (97, 99, 147, 189). The operational concepts here involve the biological and statistical data differences between control and exposed groups. Important here is the nature of these differences and the main reason for the differences. The final interpretation should be based on both biological and statistical consideration (66, 265). If a statistical test falsely detects a significant neoplastic effect when none truly exists, a false positive outcome is the result. This constitutes a type 1 error. Conversely, if a statistical test fails to identify a true biological effect (e.g. a small increase in the incidence of a rare tumor), then a type 2 error has occurred. In both cases, by providing an explanation for the differences (causality) and demonstrating the proof for the underlying mechanism, both types of error are minimized. Statistical considerations are very important, but they should not be a substitute for sound biological judgement.

Finally, any statistical evaluation of RCB data should take into account the following eight factors: (a) exposure-effect relationship; (b) incidence of proliferation and preneoplastic and early neoplastic markers at the target site of neoplasia; (c) presence of gender and species similarities or differences at the target sites; (d) convergence in target sites of nonproliferative chronic toxicity and neoplasia; (e) combined neoplasia increases in tissues affected by chronic toxicity; (f) neoplasms of similar histogenetic target sites in other genders or species; (g) concurrent and historical control data, and (h) relative survival of control and exposed groups.

BIOASSAY REPORTING

The final critical step of the RCB is the study final report. The final report consists first of an introductory section containing the compliance statement signed by the study director, followed by the quality assurance and study identification statements. The study identification statement contains the study title and number, the test substance, the testing facility, the sponsor, the study director, and the principal investigator of all study aspects, the exact specific study timetable, and approved signatures from all final report authors. This should include the study director and the investigators of all aspects of the study (e.g., analytical, toxicokinetic, duringlife, pathologist, etc.). The first part of the final report itself consists of the summary. This is an abstract of the entire study. It contains, in this order, an introduction, a listing of the materials and methods, the results, and the conclusions. The summary is followed by a summary table that depicts all pertinent findings in tabular form.

After the summary section, there is an extensive introduction into the origin and purpose of the RGB, followed by listings of test animals, test materials, methods, results, discussion, conclusions, and references. All sections should fully describe all methods used and all data obtained. All individual data should be in appropriate appendices (e.g., analytical, body weight, necropsy, and microscopic data). All relevant summary data should be in tables (e.g., analytical, body weight, etc.). Numerical incidences should precede percent incidences. Tables and graphs presenting special issues and arguments are recommended in the text (text tables or text graphs). Appropriate statistical analysis of correlation of survival patterns, clinical observations, body weight gain pattern, and toxicokinetic data with gross and microscopic

findings should be conducted. All of these considerations have been discussed in other sections in detail. An effective way of summarizing the findings is a format used in Europe known as the tabulated study report (TSR). All relevant data are presented in standardized tabular form without narrative. This corresponds to the tables of the final report described here.

CLASSIFICATION OF EVIDENCE OF CARCINOGENICITY

Completed RGBs must be reported to the regulatory agency under whose purview they were performed (33, 48, 63, 255). The results are then subject to evaluation and classification.

In the United States, the results of RGBs on Pharmaceuticals tested under Investigational New Drug applications (INDs) approved by FDA Center for Drug Evaluation and Research (CDER) are submitted to the Reviewing Division, which then evaluates them often through the CDER Carcinogenicity Assessment Committee (CAC). The final interpretation of the results will appear in the labeling of the medicine, if approved. The FDA normally describes the RCB data without comment on human relevance, except to note multiples of exposure in the rodents compared to humans. The CAC consists of a chair, an executive secretary, and members from several divisions: The Office of Epidemiology and Biostatistics, the Office of Testing and Research, and the Office of Pharmaceutical Sciences. The Reviewing Division (of the FDA) notifies the sponsor when a CAC meeting is scheduled after all RCB studies are submitted.

The U.S. Environmental Protection Agency (EPA) has been using an alphabetical/numerical classification ranging from group A, human carcinogen (based on animal data), to group E, noncarcinogen (192, 255, 258), but has proposed to convert to a narrative classification (257, 258), which allows incorporation of mechanistic data, similar to the International Federation of Societies of Toxicologic Pathologists (IFSTP) classification, described later. At the U.S. EPA, an ad hoc CAC of the EPA Science Advisory Committee evaluates the submitted dossier.

RGBs conducted by the NTP are reviewed by a peer review panel and published as technical reports, which are submitted to the National Institute of Environmental Health Sciences (NIEHS) and subsequently to the U.S. EPA, FDA, and OSHA for regulatory action (255, 256). The NTP uses a classification system of no, limited (some), or clear evidence of Carcinogenicity (183). The NTP also publishes a biennial report on carcinogenesis, the most recent of which appeared in 2000 (249a).

In Europe and Japan, similar classification schemes are used by various health boards and the Commission for Proprietary Medicinal Product of the European Medicine Evaluation Agency (48, 55, 62, 64).

The International Agency for Research on Cancer (IARC) convenes working groups several times each year to evaluate groups of chemicals with published Carcinogenicity data. The findings are published as monographs with evaluations of the experimental and human data. The grouping ranges from group 1, carcinogenic to humans, to group 4, evidence suggesting lack of Carcinogenicity.

The IFSTP (66) has proposed a classification as follows: 1, carcinogens for man based on epidemiological data; 2, genotoxic carcinogens for animals based on experimental data; 3, epigenetic carcinogens for animals based on experimental data; and 4, suspected carcinogens insufficiently tested. This is the only classification that explicitly incorporates mechanistic distinction.

Some of the classification schemes are depicted in Table 20.8. The IARC reviews are the most comprehensive, since they include all chemicals with published reports, and review all chemical and biologic data relevant to risk assessment.

CANCER HAZARD AND RISK ASSESSMENT

In cancer risk assessment, the first step is hazard identification, which involves the RCB to identify exposure-related tumors (see the section on rodent cancer bioassay evaluation). Using dose-response data from the bioassay and potential human exposure, a cancer risk is assessed (180), often involving allomorphic scaling (253). To identify a potential human cancer hazard, as for example following the IFSTP recommendations, the RCB results must be interpreted together with other mechanistic data. If the agent is clearly genotoxic, that implies a potential hazard (279), as discussed later in the section on types of cancer hazards. On the other hand, as discussed earlier, it is now recognized that epigenetic carcinogens may elicit their effects only in particular rodent species, as for $\alpha 2\mu$-globulin nephropathy inducers, or only at high toxic doses, as for nitrilotriacetic acid. Such effects are considered irrelevant to human hazard (252) or can be subjected to a margin-of-exposure (MOE) risk assessment (256, 258). The mechanism of carcinogenesis for epigenetic (nongenotoxic) agents is complex, involving a variety of secondary organ and tissue target sites, with indirect interference with the organ/tissue homeostasis. Disruption of endocrine, paracrine, nervous, and immune systems is often involved in the pathogenesis of neoplasia induced by such agents. Accordingly, the carcinogenetic effects of these agents are species, gender, and tissue specific.

Table 20.9 Examples of neoplastic effects in rodents with limited significance for human safety

Neoplastic effect	Pathogenesis (agents)
Renal tubular neoplasia in male rats	*α*2μ-Globulin nephropathy/hydrocarbons (*d*-limonene, *p*-dichlorobenzene)
Hepatocellular neoplasia in rats and mice	Peroxisome proliferation (clofibrate, phthalate esters, phenoxy agents) Phenobarbitol-like promotion
Urinary-bladder neoplasia in rats	Crystalluria, carbonic anhydrase inhibition, urine pH extremes, melamine, saccharin, carbonic anhydrase inhibitors, dietary phosphates
Hepatocellular neoplasia in mice	Enzymatic-metabolic activation (in part unknown)/phenobarbital-like promotion
Thyroid follicular-cell neoplasia in rats	Hepatic enzyme induction, thyroid enzyme inhibition/oxazepam, amobarbital, sulphonamides, thioureas
Gastric neuroendocrine-cell neoplasia mainly in rats	Gastric secretory suppression, gastric atrophy induction (cimetidine, omeprazole, butachlor)
Adenohypophysis neoplasia in rats	Feedback interference/neuroleptics (dopamine inhibitors)
Mammary-gland neoplasia in female rats	Feedback interference/neuroleptics, antiemetics, antihypertensives (calcium channel blockers), serotonin agonists, anticholinergics, exogenous estrogens
Pancreatic islet-cell neoplasia in rats	Feedback interference/neuroleptics
Harderian-gland neoplasia in mice	Feedback interference/misoprostol (PGEi), nalidixic acid, aniline dyes
Adrenal medullary neoplasia in rats	Feedback interference (lactose, sugar alcohols)
Forestomach neoplasia in rats and mice	Stimulation of proliferation/butylated hydroxyanisole, phthalate esters, proprionic acid
Lymphomas in mice	Immunosuppression/cyclosporin
Mononuclear-cell leukemia in rats (mainly F344)	Immunosuppression (in part unknown)/furan, iodinated glycerol
Splenic sarcomas in rats	Methemoglobinemia (in part unknown)/dapsone
Osteomas in mice	Feedback interference (calcineurin, in part unknown)/cyclosporin, misoprostol, proestrogens
Leydig-cell testicular neoplasia in rats	Feedback interference/lactose, sugar alcohols, H2 antagonists, carbamazepine, vidarabine, isradipine, dopaminergics, finasteride
Leydig-cell testicular neoplasia in mice	Feedback interference (proestrogens, finasteride, methoxychlor, cadmium)
Endometrial neoplasia in rats	Feedback interference (proestrogens, dopamine agonists)
Uterine leiomyoma in mice	Feedback interference (*β*1-antagonists)
Mesovarial leiomyoma in rats (occasionally in mice)	Feedback interference (*β*2-agonists)
Ovarian tubulostromal neoplasia in mice	Feedback interference (cytotoxic agents, nitrofurantoin)

Most of these secondary mechanisms involve interference with proliferation, disruption of hormonal feedback pathways, inhibition of the trophic activity in tissues including long-standing tissue ischemia, immune surveillance dysfunction, sustained exaggerated pharmacological effect, inhibition of enzymatic reaction/ activation in cells, modulation of apoptosis, and sustained accumulation of normally low occurring level of endogenous products. All these effects result in sustained cellular toxicity, leading to compensatory proliferation, which is a common pathway through which agents with diverse cellular effects ultimately induce neoplasia (31, 38, 112). The effects that lead to compensatory cellular proliferation usually require high levels of exposure and exhibit thresholds. It is perhaps for this reason that of the NCI/NTP rodent carcinogens tested, 6% had increased tumor rates that were limited to the top dose for all sites of carcinogenicity (100). Examples of neoplastic effects with limited significance for human hazard are given in Table 20.9, and some mechanisms and tumor findings are described in more detail next.

Mechanisms Not Indicative of Cancer Hazard to Humans

For several neoplastic responses in rodents, sufficient mechanistic information has accrued to support the general conclusion that the underlying mechanisms for agents that are not DNA reactive in the target tissue are species specific and do not operate in humans.

Rat Kidney **α2μ**-*Globulin Nephropathy-Mediated Increases in Kidney Neoplasms*

Various xenobiotics induce kidney tumors in male rats, mainly F344, which excrete α2μ-globulin in the urine. This protein is associated with hyaline droplet formation, atypical hyperplasia of the epithelium of the P2 segment of the proximal tubules and neoplasia. Male rats (especially F344) are very proteinuric compared to humans, and no human renal protein is similar to α2μ-globulin (252). Accordingly, the U.S. EPA (252) concluded that renal tubule tumors produced as a result

of the α2μ-globulin accumulation mechanism are not an appropriate endpoint for human hazard identification. Likewise, an IARC working group concluded that an agent that acts solely through α2μ-globulin nephropathy in the production of renal cell tumors alone in male rats is not a cancer hazard to humans (204).

Rat Stomach Acid Secretion Suppression-Mediated Neuroendocrine Neoplasm (Carcinoid)

Hyperplasia and neoplasia of gastric neuroendocrine cells (enterochromaffin-like cells) are stimulated by gastrin in rats and to a lesser degree in mice. Elevations of gastrin are elicited by reduced hydrochloric acid production, which can be caused either by gastric anti-secretory medicines such as proton pump inhibitors (lansoprazole, omeprazole, pantoprazole) or H2 antagonists (loxtidine or cimetidine) (18, 170). Agents that cause gastric atrophy—for example, alachlor and butachlor—have also elicited this neoplasm (235). Rats have a high density of gastric neuroendocrine cells (NE), achieve high levels of gastrin (over 1000 pg/ml), and are very responsive to elevation of gastrin (241). With most of the agents, female rats are more susceptible than males.

NE cell tumors have been observed in patients with multiple endocrine neoplasia syndrome (MEN-1), associated with elevated gastrin, but not with antiulcer therapy (170). Significant NE cell proliferation in humans is seen only with gastrin levels above 400 pg/ml, and this can be controlled.

Rat Urinary Bladder Luminal-Milieu-Modification-Based Increases in Transitional Cell-Neoplasms

Many studies have used rat models for urothelial neoplasia. Rats have been shown to be more sensitive than mice to urothelial damages, apparently because the rat bladder lacks tight junctions, rendering the superficial urothelial layer ineffective as an intraluminal barrier, leaving the underlying layers vulnerable to chronic stimulation (110, 144). Moreover, rats have more intraluminal proteins, silicate precipitation, crystal formation, and urolithiasis than humans. In particular, rats, unlike humans, develop calcium phosphate urinary precipitates (204). Thus rats are more prone to chronic cell damage to the bladder urothelium, which results in cell proliferation and neoplasia (31). This effect does not occur in humans (31, 57, 291). An IARC working group has concluded that production of bladder cancer in rats under conditions of formation of calcium phosphate-containing urinary precipitates is not predictive of cancer hazard to humans (204).

Rodent Liver Peroxisome Proliferator-Mediated Increases in Liver Neoplasms

Widely varied xenobiotics elicit increases in rodent liver tumors associated with increased numbers of per oxisomes (120). Rodents are more susceptible to induction of hepatic peroxisome proliferation than primates or humans (120, 290), apparently because of high expression of the peroxisome proliferator activated receptor of the class (PPARα) in rodent liver (242). Perhaps related to this, it has been reported that in rat hepatocytes, peroxisome proliferators enhance DNA synthesis and suppress apoptosis, whereas in human hepatocytes, DNA synthesis was suppressed and apoptosis enhanced (194). While the mechanisms of carcinogenicity of these agents is not fully understood, none is associated with cancer in humans, and an IARC group has recommended that a tumor response in mice or rats secondary only to peroxisome proliferation could modify the evaluation of carcinogenicity (120).

Rodent Thyroid-Pituitary Disruption-Mediated Thyroid Tumor

Few DNA-reactive carcinogens elicit thyroid tumors, probably because bioactivation is minimal in this gland. On the other hand, thyroid-pituitary disruption is a common mechanism of thyroid carcinogenesis in rodents, particularly rats (236). Reduced thyroid hormone levels, through either inhibition of synthesis by antithyroid agents (e.g., amitrole) or increased clearance as a result of enhanced conjugation (e.g., phenobarbital), can lead to feedback increase of thyroid stimulating hormone levels, which produce thyroid follicular-cell hypertrophy, hyperplasia, and eventually neoplasia. Species differ in their susceptibility to this disruption, with the rat being particularly sensitive (59). Several inducers of liver thyroid hormone conjugation (which often is associated with increased liver tumors) in rats do not affect mice (270). No nonradioactive chemical exposure is known to cause thyroid follicular neoplasms in humans (204). Accordingly, it has been concluded that chemical-specific data on thyroid effects in rodents can be applied to risk assessment (105), and that agents that cause thyroid neoplasia through an adaptive hormonal mechanism belong to a different category from those acting through genotoxic effects or involving pathological response to tissue injury (204).

Mechanisms Probably Not Indicative of Cancer Hazard to Humans

Several mechanisms of epigenetic tumorigenesis in rodents appear not to be relevant to human cancer hazard (6).

Rat Testes Hormone Disruption-Mediated Leydig-Cell Neoplasms

Leydig- or interstitial-cell neoplasms occur spontaneously in high incidence (>80%) in aged F344 rats

(102). These tumors are invariably benign. The human counterpart is extremely rare, and no agent that produces increases in rat testicular tumors (i.e., cimetidine, hydralazine, gemfibrozil, carbamazepine, vidarabine, isradipine, exogenous gonadotropins, luteinizinghormone releasing hormone [LHRH] analogs, flutamide, ergolines, and finasteride) has been associated with induction of this or any other neoplasm in humans. Therefore, the data suggest that nongenotoxic compounds that induce Leydig-cell neoplasms in rats do not indicate a human cancer hazard (36).

Rodent Hormone Disruption-Mediated Mammary and Adenohypophysis Neoplasia

The occurrence of mammary neoplasms and prolactinomas in female rats (mainly) and mice after exposure to neuroleptics, antiemetics, antihypertensives, calcium channel blockers, serotonin agonists, exogenous estrogens, or anticholinergics is species specific (185, 217, 277, 289). The triggering mechanism for this consists of sustained prolactin (PRL) elevation. PRL is controlled by dopamine. In contrast to its action in humans, PRL is luteotrophic in rats and mice, leading to progesterone elevation and sustained stimulation of proliferation of mammary epithelium (209). These neoplasms are accompanied by an increase in serum PRL, contrary to mammary neoplasia in humans (208, 220).

Tumors of Questionable Significance to Human Cancer Hazard

Tumors of questionable significance for hazard assessment (6) are those whose pathogenesis may be unique to rodents, in some cases due to their cell type of origin, and for which no association with human cancer hazard has been established. If one of these is the only tumor increased in the RGB, such a finding should not be taken as evidence of human cancer hazard.

Mouse Bladder "Mesenchymal Lesion"

This lesion occurs in the trigone area of the bladder and has been known under various names for sometime (133). Recently the lesion was called "mesenchymal tumor" (20, 92). The lesion has been found in mice given agents that bind to progesterone receptors (165). Persuasive evidence has been provided (133, 134) that the lesion represents a decidual reaction of mesenchymal cells carrying or developing progesterone receptors. No known counterpart of this lesion has ever been described in humans, and therefore its significance is questionable.

Mouse Histiocytic Sarcoma

This neoplasm of histiocytes affects mainly the liver and uterus in mice. A comparable lesion has not been reported in humans and no agent established to produce an increase in only this neoplasm is associated with cancer development in humans (244).

Mouse Ovary Tubular Adenoma

This is a benign neoplasm with tubular, stromal, or mixed components, and occurs mainly in mice (5, 24). Tubulostromal adenomas have been observed with cytotoxic agents but are not seen in other laboratory animals or humans and are considered irrelevant for human safety assessment (5, 24).

Rat Granular-Cell Tumor

A proliferative lesion of "granular" cells with granular eosinophilic cytoplasms occurs in the vaginal-cervical regions of female Sprague-Dawley, Donryu, and Wistar rats (39, 218). This lesion is probably under hormonal influence, mainly estrogen. Granular cell aggregates occur rarely in the vulva of women, but there is no evidence to suggest that the pathogenesis is similar to that of rat granular-cell tumors. Thus, this lesion is considered probably not relevant for humans.

Rat Mammary-Gland Fibroadenoma

This is a benign neoplasm with a minor glandular epithelial component and a predominant pericanalicular type of proliferation of connective tissue. It bears no resemblance to the common intracanalicular type of fibroadenoma seen in women (208, 209), which is hormonally responsive (10). Fibroadenoma is the most common breast neoplasm in all the major rat strains and does not progress to malignancy. Thus, combining fibroadenomas and carcinomas is inappropriate and the tumor by itself is of questionable significance.

Rat Mesovarial Leiomyoma

Smooth-muscle tumors of the ovarian suspensory ligament have developed in female rats after long exposures to beta2-adrenoceptor stimulant medicines (138). This neoplasm is rare in humans, and the agents that have induced it in rats (i.e., soterenol, mesuprine, zinterol, terbutaline, reproterol, salbutamol) are not associated with cancer in humans.

Rat Mononuclear-Cell Leukemia

This neoplasm occurs in high incidence (about 60% in males and 40% in females) in F344 rats (102). Mononuclear-cell leukemia (MCL), also referred to as large granular lymphocyte leukemia (LGL), is a spontaneously occurring lethal neoplasm that first develops in the spleen and then in the liver, lungs, lymph nodes, and bone marrow. It occurs at over 18 months of age. No agent

has been demonstrated to reproducibly induce this neoplasm and hence nothing is known about its pathogenesis. MCL is induced by DNA-reactive agents such as elthylene oxide. In addition, a number of chemicals that are not implicated in human cancer (furan, C.I. direct blue 15, iodinated glycerol, diisononyl phthalate, and dimethylmorpholinophosphoramidate) are known to be associated with increased incidences (58, 155).

Rodent Forestomach Squamous-Cell Carcinoma

A number of DNA-reactive agents have induced neoplasms of the forestomach in rodents (146), usually through a direct effect. The rodent forestomach is a portion of the stomach between the esophagus and glandular stomach, lined by squamous epithelium, and does not exist in humans. Nongenotoxic agents such as butylated hydroxyanisole, propionic acid, and HMG CoA-reductase inhibitors have produced increases in this neoplasm. The epigenetic mechanism appears to involve chronic irritation leading to a promoting action, which requires high exposure, as shown for butylated hydroxyanisole (291, 293). None of these epigenetic agents has been associated with cancer in humans.

Flat Scrotal Tunica Vaginalis Mesothelioma

This mesenchymal lesion, which includes hyperplasia and neoplasia (166), arises from the serous membranes of the scrotal tunica vaginalis testes. It is common (about 3%) in F344 rats, (102). Since the scrotal lesion often arises in association with testicular tumors, especially Leydig-cell tumors, which assume large size, there may be an element of physical initiation involved in the pathogenesis. Chemicals that produce increases in this tumor (e.g., acrylamide, potassium bromate, pentachlorophenol) are chemically diverse and no mode of action has been established. None of these is associated with mesothelioma in humans or with any other cancer.

Types of Cancer Hazards

Formerly, all rodent carcinogens were considered to be potential human cancer hazards. This concept was embodied in the Delaney clause to the 1958 Federal Food, Drug, and Cosmetic Act, section 409(3)(A), which provided that no chemical determined to be carcinogenic in either humans or animals could be allowed as a food or color additive, regardless of concentration. Likewise, the U.S. EPA cancer principles of 1970 stated that no level of exposure to a chemical carcinogen should be considered toxicologically insignificant for humans. Subsequently, expanded understanding of mechanisms of carcinogenesis has led to refinements of hazard assessment. Notably, in Europe, governmental agencies have not been required by legislatures to impose standards of no exposure for carcinogenic agents and have used more flexible approaches than those imposed in the United States (278). Beginning in 1992, the I ARC accepted data on mechanisms as being relevant to evaluation of the carcinogenic risk of an agent to humans (118), and this is being elaborated upon (204). Recently, the distinction between DNA-reactive and epigenetic carcinogens has been explored in detail by an international group of experts, drawing on comprehensive reviews of mechanisms of 10 prototype carcinogens (126).

Currently, in assessing potential human cancer hazard, regulatory agencies often refer to findings implicating an agent as a "genotoxic carcinogen" usually with only an operational definition (32) that the chemical produced positive results in genotoxicity tests. All chemicals that are reliably positive in a variety of tests are in fact DNA reactive and thus belong to that category of carcinogen, as discussed in the section on types of carcinogens. Most chemicals, however, are positive in some tests, like phenobarbital and DES (116, 123), sometimes because of intrinsic spurious positive results (19), and thus the issue becomes the question of which tests are to be accepted as evidence of genotoxicity. A scientifically sound approach is to define genotoxicity as a mechanism of carcinogenesis; that is, a genotoxic carcinogen is one that forms molecular lesions (such as DNA adducts) that lead to mutations or one that produces mutations in the cells that are the precursors of tumors induced by the agent. Under this definition, genotoxic carcinogens would likely be confined to DNA-reactive agents fulfilling the criterion for carcinogenic activity of an agent that induces malignant tumors not seen in controls. Such chemicals are generally multispecies carcinogens, which induce tumors in high yield with short latent periods and often in several organs. For agents of this type, assumption of human hazard is well founded (279), although evidence is accruing that even DNA-reactive carcinogens have thresholds (294). Moreover, some of the underlying mechanisms of these agents are species specific and do not operate in humans because of functional or toxicokinetic differences. Epigenetic carcinogens, in contrast, are generally not relevant to human hazard, as evidenced by the few associated with human cancer (Table 20.3), in spite of the large number to which humans are regularly exposed (87, 122). The lack of relevance stems from the fact that their effects are either rodent specific or require high and long-duration exposure in rodents in order to elicit the cellular effect leading to carcinogenicity. Epigenetic mechanisms that are either not indicative of a cancer hazard to humans or probably not indicative have

been discussed already. These should be taken into account in formulating any risk assessment.

Cancer Risk Assessment

It is becoming increasingly accepted that for epigenetic agents, even if some cancer hazard is presumed, a safety margin can be established. For plasma concentration versus time pharmaceuticals, this has been referred to as the safety factor, which is the ratio of the area under the concentration vs. time curve (AUC) in rodents for the highest noncarcinogenic dose (nontumorigenic effect level, i.e., NTEL) to the human AUC at the therapeutic dose (12, 32). In 1996, the Federal Food, Drug, and Cosmetic Act was amended by removing the zero-risk provision of the Delaney clause and replacing it with a new standard of "a reasonable certainty of no harm" (33). The new standard applies to pesticide residues in both raw and processed foods, allowing the presence of some residues that have been shown to cause cancer in animals (246, 247). In the new U.S. EPA draft cancer assessment guidelines, the safety margin is referred to as margin of exposure (MOE) (192). The FDA Center for Food Safety and Nutrition has published a "threshold of regulation" procedure for indirect food additives (263, 264). In an analysis of human risk for carcinogenic veterinary drugs present as tissue residues, Galer and Monro (81) argue that human intake of up to 100/ig/person/day presents no cancer risk, similar to the assessments of Williams (282) and Munro et al. (174). In a further refinement, Williams (285) proposed a carcinogen safe exposure level (SEL) as the no-effect level for the molecular/cellular effect that is the basis for carcinogenicity divided by a safety margin, similar to uncertainty factors. This is actually more conservative than using the NTEL, since the NEL for molecular effects is lower.

For genotoxic or DNA-reactive agents, authorities regulate such agents either by prohibiting human exposure or using a linear no-threshold model for quantitative risk assessment (250, 255, 295). In the European Union, it is proposed to incorporate potency considerations, including T25 values, and to classify all carcinogens in three potency groups (55). However, evidence is accruing that even DNA-reactive carcinogens have thresholds (294), and accordingly, the SEL concept just described can also be applied to DNA-reactive carcinogens using a NEL for DNA binding (285).

INTERACTIVE CARCINOGENESIS

Interactive carcinogenesis comprises the enhancement or inhibition of carcinogenesis by combined, concurrent, or sequential exposures to more than one carcinogen or a carcinogen and noncarcinogen (281). Various types of interaction between chemicals have been described, including syncarcinogenesis, tumor promotion, cocarc inogenesis, and anticarcinogenesis. In the testing of complex mixtures, these types of interactions can influence the outcome (Figure 20.4).

Syncarcinogenesis

Syncarcinogenesis is the enhancement of carcinogenesis produced by concurrent or sequential administration of two carcinogens, usually of the DNA-reactive type. This interaction in the case of DNA-reactive carcinogens represents a summation of the genetic effects of the agents. Usually the enhancement occurs in a target organ where both carcinogens produce a tumor effect.

Promotion

Tumor promotion is the enhancement of tumor development by a second agent given after an initiating carcinogen (11), when a sufficient interval has been allowed for acute molecular effects, such as DNA adducts, to be processed. If the second agent is administered when molecular lesions are still present, the enhancement may be due to cocarcinogenesis (discussed next). Promoting agents essentially facilitate clonal expansion of initiated cells and their evolution into neoplasms. The selective growth of preneoplastic populations can be achieved either by an enhanced rate of cell proliferation in the tissue or a decreased rate of apoptosis in incipient neoplasms.

Promoting agents are usually assumed to be noncarcinogens, but in fact, most are weak carcinogens under some circumstance, probably because they facilitate tumor development from cryptogenically initiated cells that are the source of spontaneous tumors. Thus, most, if not all, promoters are epigenetic carcinogens (Table 20.2). An essential characteristic of a promoting agent is that it is not DNA reactive and is not an initiating agent; otherwise, the enhancement is likely to be due to syncarcinogenesis.

Cocarcinogenesis

Cocarcinogenesis is the enhancement by a noncarcinogen of the carcinogenicity of a carcinogen when administered prior to or concurrently with the carcinogen or when given shortly after a carcinogen at a time when molecular damage is still present. Cocarcinogens may enhance the uptake of the carcinogen, enhance its tissue localization, increase the proportion that is bioactivated, or enhance the induced neoplastic transformation, usually by transiently increasing cell proliferation. Cocarcinogens do not act as pro

		carcinogen[1]		Tumor yield

FIG. 20.4. Types of interactive carcinogenesis.

moters, although most promoters have cocarcinogenic activity, often due to enhancement of cell proliferation.

Anticarcinogenesis

Anticarcinogenesis is the reduction of the carcinogenicity of an agent by a previously, concurrently, or subsequently administered agent, usually a noncarcinogen, although certain epigenetic carcinogens, such as phenobarbital, are effective anticarcinogens. Three operational pathways are recognized as follows: inhibitors that prevent formation of carcinogens, blocking agents that counteract effects of carcinogens, and suppressing agents that suppress tumor development (272).

Photochemical Carcinogenesis

A specific type of interactive carcinogenesis is photochemical carcinogenesis, which is the combined skin carcinogenicity of a chemical and ultraviolet light (75, 129). Photochemical carcinogenicity can result from several types of interaction between the chemical, ultravioltet radiation (UVR), and the skin. Some chemicals, such as psoralens, can be photoactivated to DNA-reactive chemical species. Others, such as fluoroquinolones, can undergo photoactivation to generate secondary reactive molecular species such as reactive oxygen (230a). Also, some chemicals can affect the structure of skin, for example, thinning of the epidermis in the case of retinoids, to sensitize the skin to effects of UVR radiation. Finally, immunosuppression can enhance skin carcinogenesis (145).

Photochemical carcinogenicity studies are often required for topically applied medicines and even for some oral medicines, as well as for topically applied cosmetics and consumer products. The test species is usually the SKH1 albino hairless mouse, which has the advantage that it does not require hair clipping and allows easy detection of UVR-induced squamous-cell papillomas and carcinomas. In a typical protocol (49, 74, 213), the test substance is applied before UVR (at 290–400 nm by a UV solar simulator) on Monday, Wednesday, and Friday and after UVR on Tuesday and Thursday for 40 weeks, followed by a 12-week observation period without exposure. This pattern of exposure allows detection of photoactivated chemicals, as well as those that may modulate photocarcinogenesis. Typically, separate groups are administered low and high UVR in addition to the TS. The endpoints of evaluation include tumor incidence (prevalence), multiplicity (yield), and latency (time to tumor).

Complex Mixtures

Most chemical exposures involve mixtures rather than single agents. Yet the scientific data for these mixtures are generated almost entirely from studies of individual

agents. Mixtures are comprised of chemicals with several isomers, chemicals with major contaminants, hazardous waste in solid or liquid form, and air pollutants. The mixtures can either have a common source (e.g., tobacco smoke, aluminum production, coal tars) or be formulated deliberately (coal gasification, footware processing work exposure). Several such mixtures are recognized as human carcinogens, such as tobacco smoke and coal tars. A daunting challenge has been to ascertain the role of individual components in the carcinogenicity of such mixtures (117). To accomplish this, complex mixtures can be fractionated and characterized into chemically defined entities, which can be individually tested. Nevertheless, in the mixture, individual chemicals can enhance or inhibit the activity of others, as discussed earlier.

The most relevant information for cancer hazard identification and risk assessment for cancer of humans involves a combination of mixture characterization/ exposure data from experimental systems and epidemiological data from humans (117). Characterization and definition of exposure, identification of the source, and distribution and occurrence of the mixture, as well as its composition and physicochemical properties, are essential. Here the most common method of fractionation is the one that partitions complex mixtures into organic and inorganic constituents. This is followed until active agents are separated from inactive ones. Chemical characterization of all biologically active ingredients is pursued. Important in experimental systems is the identification of in vitro/in vivo effects and rodent carcinogenicity data. In addition, definitions of dosimetry, toxicokinetics, bioavailability, disposition, and molecular and biochemical effects are also needed. The comparative potency method (CPM) is one that is based on data correlation from all in vitro and in vivo experimental assays, with human potency estimates (2, 22). What is being compared is a known human risk complex mixture with a CPM from a similar complex with incomplete data (154). CPM for cancer risk estimation is not validated yet, and consequently its utility is still limited.

Comparative Potency Method

The comparative potency method (CPM) has been applied to estimate human lung cancer risk from coke oven emissions, roofing tar, and cigarette smoke condensate, all combustion products of complex mixtures. Each of these complex mixtures was compared using standard protocols, which included an in vivo mouse skin initiation/promotion study, and two in vitro studies, such as mouse lymphoma and *Salmonella typhimurium* (Ames) mutagenicity assays. The result of the three mixtures showed agreement among assays (Ames activity was highest with cigarette smoke condensate), and thus it was possible to use CPM for cancer risk estimation (22, 154).

One of the major limitations of CPM is due to the chemical changes of the complex mixtures over time. Such changes come about through environmental biodegradation, photo-oxidation, volatilization, migration (to groundwater), or adsorption (to solid soil particles). Another limitation is the inappropriateness of short-term in vivo or in vitro assays to the assessment of some complex mixtures, such as diesel particulates, which may not be accessible for in vitro systems.

Toxic Equivalency Factor

The toxic equivalency factor (TEF) was first developed to assess the toxicological interactions of specific complex mixtures, that is, polychlorinated dibenzodioxins and dibenzofurans. For this purpose, a number of short-term assays were utilized, including enzyme induction, receptor binding, and cell keratinization studies. All are helpful in predicting carcinogenic responses. The reference substance was 2,3,7,8-TCDD, which was assigned the value of 1 (22).

Based on this, the TEF was determined by multiplying the substance concentration with the relative toxicity from the short-term assays for each mixture ingredient—that is, the product is the TEF. The TEF is very helpful with chemically related compounds in a mixture. The process has been applied to polycyclic aromatic hydrocarbons and polychlorinated biphenyls. However, results of several studies have also shown that for specific responses, the TEFs for some halogenated aromatic hydrocarbon mixtures are nonadditive (211).

ACKNOWLEDGMENTS

We thank Barbara Iatropoulos and Katey Bateman for preparation of the text. Also, we gratefully acknowledge the thoughtful comments by many colleagues in the chemical and pharmaceutical industries. The preparation of this chapter was made possible by support provided to the Medicine, Food, and Chemical Safety Program at New York Medical College.

QUESTIONS

1. What are the pertinent mechanisms of carcinogenesis operational in rodents and man?
2. What are the mechanisms of carcinogenesis operational only for rodents? Explain why.
3. Which neoplasms are of questionable significance to human cancer hazard? Explain why.

4. What are the types of cancer hazard?
5. What constitutes adequate exposure in a rodent cancer bioassay?

Clinical pathology is an integral component of preclinical safety assessment and toxicity studies designed to identify target organs and establish dose-response relationships. In the context of these studies, clinical pathology usually consists of relatively routine hematology, clinical chemistry, and urinalysis tests. The majority of the parameters evaluated are identical to those used in human and veterinary medicine because the fundamental physiology and pathophysiology of blood and major organ systems are similar in most mammalian species. There are, of course, species differences for reference ranges, some methodologies, the value or appropriateness of individual tests, and interpretation of findings. Selection of tests for a toxicology study is dependent upon several factors, including study objectives, test species, regulatory requirements, and characteristics of the test material.

Clinical pathology tests are best characterized as screening tools to identify general metabolic or pathologic processes and target tissues. Although specific diagnoses and precise mechanisms for a toxic effect are infrequently identified, test results narrow the possibilities and help direct further studies. Clinical pathology tests also provide one measure for determining the biological importance of effects associated with administration of a test material. Alterations in clinical pathology test results are typically not the only evidence of adverse or pathologically significant toxicologic effects. In-life clinical observations and/or anatomical pathology findings usually corroborate pathologically meaningful laboratory findings.

Interpretation of clinical pathology data from a toxicology study is considerably different from the assessment of data from an individual patient suffering from an unknown illness. The most obvious difference is that data from groups of treated subjects, receiving increasing dose levels of a test material, are compared with data from a group of age-, weight-, and sex-matched control subjects that are concurrently exposed to the same environmental and experimental conditions. For larger laboratory animals (e.g., rabbits, dogs, monkeys), pretreatment clinical pathology data for each individual are also

available for comparison with posttreatment results. Finally, clinical pathology results from a toxicology study can be correlated with carefully recorded in-life observations, necropsy observations, organ weight data, and histopathologic findings for an extensive list of tissues. Given the uniformity of the animals studied and the analytical precision of modern clinical pathology instrumentation, identification of very subtle effects on clinical pathology results, which would not be apparent for an individual

patient, is the norm. One of the most challenging aspects of data interpretation for a toxicology study is differentiating potentially harmful toxic effects from minor changes representing subtle homeostatic or metabolic responses to benign effects of the test material or to study-related procedures. Proper interpretation of clinical pathology results from a toxicology study requires not only an understanding of the tests themselves, but knowledge of species differences, study design, unique studyrelated procedures, clinical observations, anatomical pathology findings, and the test material. Interpretation of one test result is frequently dependent upon the results of another test, and pattern recognition is essential.

This chapter addresses (a) experimental design considerations including test selection, timing and frequency of testing, sources of variability in clinical pathology test results with emphasis on preanalytical factors, and quality control, (b) basic principles of clinical pathology data interpretation including the use and misuse of reference ranges, and (c) the characteristics and interpretation of routine hematology, clinical chemistry, and urinalysis tests used in toxicology studies. For in-depth descriptions of clinical pathology tests, including methods, the reader is referred to references 8, 14, 63, 68, 72, 73, and 84.

EXPERIMENTAL DESIGN CONSIDERATIONS

The value of clinical pathology in toxicology studies is heavily influenced by the experimental design. Selection and timing of appropriate tests, consideration of unique study procedures, reduction of sources of variation, proper sample collection and handling, and controlled analytical technique are all factors that ultimately determine the worth of clinical pathology test results.

Test Selection

The selection of appropriate clinical pathology tests for a toxicology study is first dependent upon the objective or purpose of that study. If the objective is simply to screen a number of similar chemical entities for potential hepatocellular toxicity, it may be sufficient to limit the laboratory evaluation to a single test such as alanine aminotransferase activity. On the other hand, if the study is part of the package of studies required to support governmental approval of a new drug or other chemical entity with potential human exposure (e.g., food additives, pesticides, chemicals used in manufacturing), there are several tests required or recommended in study guidelines published by the presiding governmental regulatory agencies (e.g., U.S. Food and Drug Administration, FDA; U.S. Environmental Protection Agency, EPA; Japanese Ministry of Health and Welfare) or professional standards organization (e.g., the European Organization for Economic Co-operation and Development, OECD) (60). Although there are many similarities between the various published guidelines with respect to recommended clinical pathology tests, there are also several differences and instances of ambiguous or inappropriate testing requirements.

In an effort to encourage global harmonization of regulatory guidelines, a Joint Scientific Committee for International Harmonization of Clinical Pathology Testing was formed in 1992 to provide recommendations for clinical pathology testing of laboratory animals used in regulated safety assessment and toxicity studies. The committee was comprised of representatives from ten different professional organizations, located throughout the world, with scientific expertise in animal clinical pathology and was independent of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use. The committee prepared a document (135) listing minimum recommendations for clinical pathology testing in regulated safety assessment and toxicity studies. These recommendations are described in the following paragraphs.

With respect to hematology, the core recommended tests are total white blood cell (WBC) count, absolute differential WBC count, red blood cell (RBC) count, hemoglobin concentration, hematocrit (or packed cell volume), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), evaluation of RBC morphology, and platelet count. The importance of calculating absolute WBC differential counts from the total WBC count and the relative (%) WBC differential counts was stressed. The method for evaluation of RBC morphology was not defined, but most laboratories prepare blood smears and examine the RBCs microscopically for morphologic characteristics such as variations in size (anisocytosis, microcytosis, or macrocytosis), color (polychromasia), shape (poikilocytosis), and hemoglobin content (hypochromasia). Other laboratories may choose to evaluate RBC morphology with the use of automated measurements such as MCV, MCH, MCHC, red cell distribution width (RDW), and hemoglobin distribution width (HDW). For those laboratories using automated measurements, it is prudent to routinely prepare blood smears in the event the data indicate a need to examine the cells microscopically.

Although not routinely recommended, absolute reticulocyte counts and bone marrow cytologic

examinations may be indicated by other hematology findings. For example, test material-induced anemia is an indication for performing absolute reticulocyte counts to assess whether the anemia is regenerative or non-regenerative. Unexplained nonregenerative anemia, leukopenia, thrombocytopenia, and pancytopenia are indications for performing bone marrow cytologic examinations. It was therefore recommended that blood

smears be prepared for possible reticulocyte counts and bone marrow smears be made at termination for possible cytologic examination. If a laboratory has the ability to perform automated reticulocyte counts, it may wish to do these routinely as an alternative to preparing reticulocyte count smears.

Prothrombin time (PT) and activated partial thromboplastin time (APTT) [or appropriate alternatives such as the Thrombotest (55)] and platelet count are the core recommended tests for assessment of hemostasis. If blood volume limitations are a concern (e.g., multiple blood collections for a rat study), it may be necessary to perform PT and APTT only at study termination.

Current regulatory guidelines recommend performing limited hematology tests on some or all animals at set intervals during a carcinogenicity/oncogenicity study (e.g., weeks 26, 52, 78, and 104). This approach to identifying leukemogenic test materials is very insensitive compared with the microscopic examination of multiple tissues from animals that died during the study, were terminated because of poor health, or survived to the terminal kill. For carcinogenicity/oncogenicity studies, the only procedure recommended by the Joint Scientific Committee is to make blood smears for all animals at unscheduled kills (e.g., moribund animals) and at the terminal kill. If necessary, the smears can be used as an adjunct to histopathology for the identification of hematopoietic neoplasia. For example, if the histopathologist is unsure whether leukocytic infiltrates in multiple tissues from an animal represent leukemia or a leukemoid response (i.e., marked leukocytosis secondary to an inflammatory stimulus), the blood smear can be examined to help differentiate between the two conditions. It may also be possible to diagnose a specific type of leukemia from the blood smear (e.g., lymphocytic leukemia versus granulocytic leukemia).

With respect to clinical chemistry, the core recommended tests are glucose, urea nitrogen, creatinine, total protein, albumin, globulin (calculated from total protein and albumin), cholesterol, calcium, sodium, potassium, and selected tests of hepatocellular and hepatobiliary health and function. Measurement of at least two scientifically appropriate tests for hepatocellular evaluation (e.g., alanine aminotransferase, aspartate aminotransferase, sorbitol dehydrogenase, glutamate dehydrogenase, or total bile acids) and at least two scientifically appropriate tests for hepatobiliary evaluation (e.g., alkaline phosphatase, gamma glutamyltransferase, 5′-nucleotidase, total bilirubin, or total bile acids) was recommended. Because there are several acceptable tests used to evaluate hepatic health and function, the Joint Scientific Committee decided it was appropriate to give each laboratory the freedom to choose those tests that best met their individual needs and with which they had the most experience. For example, glutamate dehydrogenase is commonly evaluated in Europe, but no commercial kit for this enzyme assay is available in the United States.

The core recommended urinalysis tests, performed on an overnight sample (i.e., approximately 16-h collection), are an assessment of urine appearance (color and turbidity), volume, specific gravity or osmolality, pH, and either the quantitative or semiquantitative determination of total protein and glucose.

The Joint Scientific Committee listed several tests that are specifically not recommended for routine use in animal toxicity and safety studies. These tests include ornithine decarboxylase, ornithine carbamoyltransferase, lactate dehydrogenase, creatine kinase, serum or plasma protein electrophoresis, microscopic examination of urine sediment, and urinary mineral and electrolyte excretion (e.g., urine sodium, potassium, chloride, calcium, or inorganic phosphorus excretion). Although ornithine decarboxylase appears in the test lists of several regulatory guidelines, it has no value as a diagnostic clinical chemistry test (19). This enzyme may have been included in the original FDA guidelines by mistake, and the error was repeated by other organizations. The FDA may have intended to include ornithine carbamoyltransferase, a liver-specific enzyme involved in the urea cycle that enjoyed limited popularity as a diagnostic test in the late 1970s. This enzyme never demonstrated a clear diagnostic advantage over other more common liver enzymes (e.g., alanine aminotransferase) and is rarely measured in today's laboratories. Lactate dehydrogenase is very similar to aspartate aminotransferase, and the use of another nonspecific enzyme is not considered beneficial. Creatine kinase may be helpful for evaluating test materials that cause muscle injury but is not considered necessary for the great majority of test materials, especially if aspartate aminotransferase is already part of the clinical chemistry test list. Blood collection techniques that potentially damage muscle and contaminate the blood sample (e.g., cardiac puncture and retro-orbital plexus collection) can diminish the value of measuring muscle enzyme activities by increasing variability. As a diagnostic test for patients, serum or plasma protein electrophoresis is used to evaluate large, unexplained increases or decreases in globulin concentration. With respect to increased globulin concentration, the goal of protein electrophoresis is to rule out a monoclonal gammopathy caused by some cancers of lymphoid origin (e.g., plasma cell

myeloma). Monoclonal gammopathies and large, unexplained decreases in globulin concentration are rare in toxicity and safety studies, and the routine use of protein electrophoresis is inappropriate. Microscopic examination of urine sediment may be helpful for screening test materials that are known to cause severe renal or bladder toxicity, but histopathology is a more sensitive tool for detecting lesions of the kidney and bladder. In part, this is because

the collection of high-quality urine specimens from many animals at one time is very difficult. On rare occasions, examination of urine sediment may be valuable for detecting the presence of crystals specific for a test material. Measurement of urinary mineral or electrolyte excretion may be appropriate for test materials that are known to affect renal function (e.g., diuretics) or bone metabolism (e.g., parathyroid hormone), but as routine screening tests, these are inappropriate. If serum/plasma mineral and electrolyte concentrations are greatly affected by a test material and other causes for these findings are ruled out (e.g., vomiting, diarrhea, renal failure), an assessment of the renal handling of the mineral or electrolyte in question may then be valuable.

The recommendations of the Joint Scientific Committee and the requirements listed in the various regulatory guidelines should be viewed as a minimum database for screening the potential toxicity of a test material that will undergo extensive evaluation in studies of varying duration with multiple species before regulatory approval. There are many additional tests that may be appropriate to perform, depending upon the study objectives and known characteristics of the test material. Platelet function tests (e.g., platelet aggregation and bleeding times) may be appropriate for evaluating drugs that target platelets. Analysis of methemoglobin concentration or the enumeration of erythrocyte Heinz bodies can be valuable for assessing oxidative injury caused by a compound. Activity of plasma or red blood cell cholinesterase is a measure of exposure to organophosphates or carbamates. Activity of brain cholinesterase is a measure of the toxic effect of these compounds. Determination of urinary enzyme activities and characterization of urinary protein excretion can be used for screening related compounds known or suspected to cause renal toxicity (29, 77, 117). Various hormones may be measured when endocrine dysfunction is suspected, and lipoprotein analysis may help define effects on lipid metabolism. Serum inorganic phosphorus and chloride concentrations are commonly measured as part of standard chemistry profiles in the United States and can be helpful when assessing changes in calcium and sodium concentrations, respectively. Determination of alkaline phosphatase and creatine kinase isoenzyme activities may help differentiate the origin of increases in total activity of these enzymes. The list of potentially valuable clinical pathology tests is long and growing. The key is to use the tests judiciously. That is, a nonstandard test should be used for a specific purpose and only after the test has been proven useful for the species in question.

Frequency and Timing of Testing

Frequency and timing of clinical pathology testing are dependent upon study objectives, study duration, the bio logical activity of the test material, and the species tested. The Joint Scientific Committee made minimum recommendations (135) that may be modified because of these factors.

With respect to regulated, acute, or single-dose toxicity studies, it is interesting to note that the regulatory guidelines have no clinical pathology requirements. Traditionally in these studies, the animals are dosed once and killed and necropsied following a 2-week observation period. Although the purpose of many of these studies is to determine appropriate dose levels for future repeated-dose studies, a great deal can be learned about potential toxicities of the test material because the dose levels are frequently higher than those administered in the repeated-dose studies. If clinical pathology tests are utilized, it is a mistake to wait until the end of the observation period to obtain samples. Two weeks following the administration of near-lethal doses of carbon tetrachloride or mercuric chloride to rats, standard clinical pathology tests will fail to recognize the effects of these compounds on the liver and kidney, respectively, because of the regenerative capacity and large functional reserve of these tissues. Although there is no single optimal time for all test materials, a general guideline for clinical pathology testing following an acute dose is to obtain samples between 24 and 72 h postdose. Occasionally, specific clinical pathology tests may be most appropriate within hours postdose because the test material has a very short half-life or a limited duration of action (e.g., some cytokines, peptides, and organophosphates). Following administration of acute renal toxins, urinary enzyme activities tend to be greatest in the first 24 to 48 h postdose. Alternatively, the effects of some test materials (e.g., cytotoxic chemotherapeutic agents) may take longer to reach their peak. For these test materials, it may be best to wait several days before performing clinical pathology tests or to take samples at multiple times in order to distinguish the time of greatest effect (e.g., days 4, 7, 10, and 14).

Limited blood volume in mice dictates that blood sample collection is usually practical only when the animals are killed. Because the blood volume of a 30-g mouse is less than 2 ml, it is difficult to acquire a full milliliter of blood from a single mouse, regardless of the blood collection technique. If several tests are required or desired (e.g., full hematology and clinical chemistry profiles), it may be necessary to specify certain animals for hematology tests and others for clinical chemistry tests. A preferred alternative is to limit the number of clinical chemistry tests to those that are the most relevant as

screening tools for major organ toxicity (e.g., urea nitrogen or creatinine, alanine aminotransferase or another liver-specific enzyme, total protein, and albumin). Pooling of blood samples is inappropriate for clinical pathology testing.

Page 1005
Prestudy clinical pathology testing is not recommended for rats because of the relatively large number of animals per group, the homogeneity of the population, and the risk of adversely affecting the health of young animals due to blood loss or the blood collection procedure. For repeated-dose studies in rats, testing should at least be done at study termination. Interim testing may not be necessary for long-duration studies (e.g., a 13-week study) if testing were done in short-duration studies (e.g., a 4-week study) that used dose levels not substantially lower than those of the long-duration studies. On the other hand, interim testing (e.g., a week 6 testing point during a 13-week study) can be beneficial for interpretation of subtle effects. Clinical pathology testing is not recommended for rodents after 52 weeks because naturally occurring geriatric disease conditions (e.g., ulceration and infection of mammary gland tumors, chronic progressive nephropathy, pituitary tumors disrupting normal endocrine function) obscure meaningful interpretation of laboratory data.
For repeated-dose studies in dogs and monkeys, testing should be done before initiation (i.e., prestudy or baseline), at least once during the study, and at study termination. Animals shipped from a supplier should have several days to acclimate to the new environment before baseline testing is performed. The baseline data are important for screening out animals with potential health problems or results that are notably different from those of their peers. Findings that may signal possible subclinical health problems and that are commonly cited for eliminating animals from study consideration include low values for erythrocyte parameters (e.g., red blood cell count, hemoglobin concentration, hematocrit, and mean corpuscular volume), high white blood cell and neutrophil counts, low total protein and albumin concentrations, high globulin concentration, and high liver enzyme activities. There may be a specific need to eliminate otherwise healthy animals because they have findings that might complicate interpretation of test material-related effects. For example, beagles that are heterozygotes for factor VII deficiency have slightly prolonged prothrombin times. Even though these animals are clinically normal, it may be inappropriate to include one in a study evaluating a product that targets coagulation. One might choose to exclude an animal with a normally low neutrophil count from a study of a chemotherapeutic drug because it may be more difficult to determine if, or how much, the drug is impacting neutrophil production. By the same token, if an animal has an unusually high neutrophil count at a baseline interval simply because of excitement or fear during blood collection (i.e., physiological leukocytosis), then a subsequent postdose decrease in the neutrophil count, when the animal is less fearful of various procedures, could be overinterpreted as caused by the test material.
The advantage of using test animals such as dogs and monkeys with greater blood volume enabling more frequent clinical pathology evaluations is offset by the low number of animals in each treatment group (often four or less per sex per group) and the increased variability between animals for many tests. The lower the number of animals studied, the more desirable it is to have more than one baseline interval. Because monkeys tend to exhibit greater variability than dogs, it can be helpful for data interpretation to have more than one baseline interval for studies using monkeys, regardless of the number of animals per sex per group. An additional benefit to multiple baseline intervals is that the animals become more accustomed to the blood collection procedures, and variability caused by excitement or fear is generally reduced. In some range-finding studies, it is not unusual to have only one animal per sex per group. In essence, each animal serves as its own control. Using at least two baseline intervals affords an appreciation for normal day-to-day, intra-animal variability. Finally, two baseline intervals are generally desirable for animals that have been surgically manipulated (e.g., placement of indwelling intravenous catheters) to avoid using animals with iatrogenic complications.
The timing and number of clinical pathology intervals for repeated-dose studies in dogs and monkeys are often dictated by the test material. For studies of 6 weeks duration or less, an interim testing interval is sometimes recommended within 7 days of initiation of dosing. The primary purpose for this early interval is to detect transient increases in serum enzyme activities that may be absent at later intervals (34). This information can be very important for the clinical trials. For studies with cytotoxic chemotherapeutic agents, the number and frequency of hematology intervals are often considerable because one common objective is to identify the nadir for circulating leukocyte counts and the timing of hematopoietic recovery. For example, a single-dose study of a chemotherapeutic agent in dogs might require hematology tests twice before initiation of treatment and at days 4, 7, 10, 14, 21, and 28 and clinical chemistry tests twice before initiation of treatment and at days 7 and 28.
Urinalysis testing should be conducted at least once during a repeated-dose study. It is best to conduct the urinalysis testing at the same time as other clinical pathology tests. Although not stated in the Joint Scientific Committee's document, urinalysis testing for mice is impractical and not recommended as a routine test.

Sources and Control of Preanalytical Variation

Although most toxicology studies are relatively well controlled, there are many study design and procedural

factors that affect variability of the data and impact clinical pathology evaluation and interpretation. In order to identify subtle (and in some cases, not so subtle) effects on clinical pathology test results, preanalytical sources of variation should be reduced whenever possible within the limitations of the study. Sources of variation can be loosely categorized as physiological, procedural, and artifactual. Physiological sources of variation include differences associated with age, strain, sex, diet, fasted condition, excitement or fear, stress, and time of blood collection. Procedural sources of variation include order of sample collection (i.e., group order versus randomization), blood collection site and technique, and anesthesia. Causes of artifactual or spurious results include poor-quality specimens (e.g., partially clotted hematology samples; hemolyzed serum/plasma samples), inappropriate use of an anticoagulant, improper sample storage, and iatrogenic blood loss.

Initiation of treatment for most regulated toxicology studies occurs when the animals are relatively young and still in a growth phase (e.g., rats 6–8 weeks old and beagles 4–6 months old). As the animals mature, several clinical pathology parameters are affected. Typical changes in most species include increasing red blood cell count, hemoglobin concentration, hematocrit, absolute neutrophil count, total protein and globulin concentration and decreasing reticulocyte count, mean corpuscular volume, absolute lymphocyte count, alkaline phosphatase activity, and inorganic phosphorus concentration. Although these and other age-related changes may be subtle, they are sufficient to evoke false conclusions if interpretation of posttreatment data were based solely on comparisons with pretreatment or baseline data collected more than a week or two earlier. Age-related changes are just one of many factors that make concurrent control groups an absolute necessity for most toxicology studies. As previously mentioned, the variability of a number of parameters becomes much greater for aging rodents, especially those over 1 year of age. This variability significantly reduces the likelihood of drawing meaningful conclusions from clinical pathology data collected in the latter half of chronic rodent studies.

Strain differences, especially for rodents, are important to consider when evaluating clinical pathology data. Differences for hematology parameters tend to be the most obvious. For example, Fischer 344 rats tend to have lower leukocyte counts than those of Sprague-Dawley rats but are also more predisposed to developing large, granular lymphocytic leukemia (86, 119). An important difference has recently been identified for red blood cells of cynomolgus monkeys *(Macaca fasicularis)* based on geographical origin. Cynomolgus monkeys from China and contiguous areas such as Vietnam have much larger, but fewer, red blood cells than cynomolgus monkeys from Indonesia, the Philippines, or Mauritius (16). The differences are so great that reference ranges for red blood cell count and mean corpuscular volume for these animals may not overlap. Interpretation of hematologic effects could easily be compromised if monkeys from these different geographical origins were used in the same toxicology study or perhaps different studies of the same test material. Although not yet reported, it is likely that there are other differences for clinical pathology test results between these populations of cynomolgus monkeys.

Diet clearly affects many clinical pathology parameters, and standard diets are necessary to avoid small differences that might be misinterpreted. Comparison of data from animals fed purified or unusual diets with data from animals fed standard diets (e.g., historical reference ranges) should be done with caution. Some species, such as the rabbit, are prone to the effects of atherogenic diets and exhibit very high cholesterol concentrations when fed these diets. The amount of protein in the diet is known to affect urea nitrogen concentration but likely has subtle effects on other parameters over time. Because some diets, especially for dogs, are more prone than others to cause false positive results for fecal occult blood, diet can be an important factor when assessing the potential of a test material to cause gastrointestinal ulceration or hemorrhage.

Much has been published on the effects of fasting animals prior to blood collection for clinical pathology (1, 76, 85, 87, 124), and differences of opinion exist concerning this practice, especially with respect to rodents. While most laboratories routinely fast dogs and monkeys overnight prior to blood collection, procedures for rodents differ among laboratories. Historically, fasting has been encouraged in clinical practice as a means of reducing the variability of certain parameters, most conspicuously glucose concentration, so that the physician can more readily compare the results from a single patient with reference ranges in order to formulate a differential diagnosis. In toxicology studies, because the concurrent control group is much more relevant for comparison purposes than are historical reference ranges, the key principle is to treat all of the groups the same with respect to conditions prior to blood collection.

Fasting of mice for longer than a few hours is not encouraged because mice reduce their water consumption when fasted and rapidly become dehydrated. Not only does dehydration affect many

clinical pathology parameters (e.g., erythrocyte count, serum protein concentrations, urea nitrogen concentration), it makes blood collection more difficult and reduces the volume of blood collected. Because some laboratories prefer to fast animals before killing (in part to reduce hepatocyte glycogen stores and improve histopathologic detection of hepatocellular injury or change) and because blood collection from mice is often a terminal procedure prior to

sacrifice, mice are sometimes fasted for a limited time before blood collection and kill (e.g., four h). If this is done, care must be taken to keep the period of fasting similar for all animals even though the killing of many animals may take several hours because of necropsy procedures.

Most laboratories in the United States prefer to fast rats overnight. Although one frequently cited reason for this is to reduce variability for certain parameters such as glucose, perhaps the most important reason is to "standardize" the conditions for all animals. If animals in the high-dose group are eating poorly, providing all animals with access to feed before blood collection can have the effect of comparing fed animals (i.e., the control animals) to fasted animals (i.e., the high-dose animals). Since there are several differences for clinical pathology parameters between fed and fasted animals, it is more difficult to determine if differences between the control and high-dose groups are due to an effect of the test material or simply to differences in overnight feed consumption. When compared with rats having access to feed, fasted rats tend to have lower white blood cell counts; lower urea nitrogen, cholesterol, triglyceride, calcium, and bilirubin concentrations; and lower alanine aminotransferase and alkaline phosphatase activities (76, 87).

Excitement/fear and stress can have pronounced effects on clinical pathology test results. Excitement and fear are associated with acute endogenous catecholamine release ("fight or flight" phenomenon), and stress is associated with endogenous corticosteroid release. Effects of catecholamines are immediate but short-lasting (e.g., less than 30 min). Effects of corticosteroids tend to be more gradual and long-lasting. The most obvious changes observed in very excited or frightened animals are increased leukocyte counts and glucose concentrations. These changes are observed occasionally with the overexcited beagle and with unanesthetized monkeys that are not used to handling for blood collection. Monkeys may also react to the presence of several people in the animal room performing additional study-related procedures at the same time as blood collections. Endogenous corticosteroids affect leukocyte counts, but somewhat differently than catecholamines. Whenever possible, clinical pathology testing should be delayed for at least a week following shipping or surgical procedures to avoid stress-related changes.

Blood samples should be collected in a manner that minimizes the possibility of temporal biases. Examples of time-related biases include differences between morning and afternoon results (circadian effects), differences caused by delayed separation of serum from clotted blood, and day-to-day differences (may be preanalytical or analytical). These biases can be eliminated or at least minimized by randomization of the animals for blood collection and the use of procedures that enable blood collection and sample processing over the shortest reasonable amount of time. An alternative to true randomization is a structured pattern of bleeding such that one animal from each group is bled in succession. Once samples have been collected, they should be analyzed in the same order as the blood collection. Rearranging the samples back to group order has the potential of causing false positive findings that are actually due to analytical drift. For example, a small drift in the analysis of chloride by ion-selective electrode (e.g., an increase of 2 mmol/L over 60 samples) may be sufficient to produce a statistically higher mean chloride concentration for the high-dose animals if the groups are sufficiently large (e.g., 15 animals/sex/group), the control animals are analyzed first, and the high-dose animals are analyzed last. If animals must be bled over 2 days because of laboratory or necropsy capacity issues, the problem of day-to-day variability can be reduced by collecting and analyzing samples from the males on one day and the females on the other.

Randomization of animals for blood collection is occasionally impractical (e.g., if timed collections must follow intravenous administration of the test material). When animals must be sampled by group, it is better to sample the high-dose group immediately before or after the control group than to sample the animals in consecutive group order (i.e., control, low-dose, mid-dose, high-dose). If it is necessary to sample the animals in consecutive group order, then procedures must be in place to analyze or process the samples in a similar time frame. When control animals are bled 1 h or more before the high-dose animals, analysis of the hematology samples and separation of the chemistry samples should not be delayed until all of the groups are bled. Such a delay can result in differences between the control and high-dose groups that are due solely to time-related, in vitro changes. This is most likely to occur for rodents when blood collection is one of the terminal procedures and several hours are necessary to bleed, sacrifice, and necropsy all of the animals. If hematology analysis of whole blood from the control animals is delayed, it is possible that the last group bled will appear to have increased platelet counts relative to those of the control group because platelet counts decrease over time as a result of spontaneous platelet aggregation. If clotted blood from the control group is allowed to stand 1 or 2 h longer than that from the high-dose group before separation of serum, the high-dose group will often

have statistically significant differences for several chemistry parameters, including higher glucose concentration, lower potassium and inorganic phosphorus concentrations, and lower aspartate aminotransferase and lactate dehydrogenase activities. These differences result from changes in the control animal samples—that is, the consumption of glucose by erythrocytes, and the

release of cell constituents by erythrocytes, leukocytes, and platelets. Circadian effects are another potential source of variation when blood collection is protracted. For example, rodents bled early in the morning can have slightly higher leukocyte counts than those bled in the afternoon during their normal period of inactivity.

Collection site, collection technique, and use of anesthesia are perhaps the most commonly cited procedural influences on clinical pathology test results. Many investigators have analyzed differences in data resulting from these variables (6, 33, 75, 76, 86, 88, 92, 94, 104, 112, 118, 121, 126), especially for the rat. But while differences in the results do exist (e.g., total leukocyte counts in samples from the retro-orbital venous plexus are higher than those from larger vessels such as the abdominal aorta or posterior vena cava; glucose concentrations in samples from the abdominal aorta are higher than those from other sources), the principal message from these works is that laboratories should use the technique with which they have had good success obtaining high-quality samples and with which they are most comfortable. Use of an unfamiliar or unpracticed blood collection technique introduces unnecessary variability and spurious results. With appropriate instruction and practice, any of the commonly used techniques can generate adequate results. To optimize the value of the data, however, a single method of collection should be used throughout a study or series of comparable studies. For example, anesthesia tends to decrease interanimal variability for clinical pathology results from monkeys, especially their cell counts and electrolyte concentrations. If pretreatment or baseline blood collection is performed on animals anesthetized for physical examinations or other baseline procedures, the relatively heterogeneous data obtained from unanesthetized animals during treatment may cause confusion or be misinterpreted. Similar problems can occur when interim blood samples from rodents are collected from the tail or retro-orbital venous plexus, and terminal blood samples are collected from the heart or posterior vena cava. Small differences observed between control and treated animals at one interval may be masked at another interval because of increased preanalytical variability. The cause of the variability is often related to differences in bleeding technique proficiency and not the method itself (88). Blood collection from dogs, monkeys, and rabbits is facilitated by relatively easy access to large vessels (e.g., jugular, cephalic, and saphenous veins for dogs; femoral, cubital, and saphenous veins for monkeys; ear and jugular veins for rabbits). Blood collection from mice is complicated by size and volume limitations, and terminal procedures are often used (e.g., cardiac puncture or sampling of the posterior vena cava or abdominal aorta at necropsy). There are many acceptable methods for blood collection from rats, and the choice of technique depends on a number of factors, not the least of which is frequency of opportunities to collect blood from rats. If a laboratory performs enough studies on rats to require blood collection every day or two, then it is probably worthwhile for some of the technical staff to become proficient at collecting blood from the jugular vein (105). Although every bleeding technique has procedural advantages and disadvantages, this technique offers the greatest number of advantages if mastered. Several high-quality blood samples can be collected from one animal, directly from a large vessel with needle and syringe, without anesthesia or expensive equipment, and without damaging important structures such as the eye or heart. Because there are no time-consuming ancillary procedures (e.g., warming the tail to dilate the tail vein or anesthesia), samples can be collected quickly, and it is possible to accurately collect timed samples (e.g., at 1, 5, 10, and 15 min postdose) from a single animal. As with most techniques, blood collection from the jugular vein requires regular practice to remain proficient.

Inappropriately collected or prepared samples increase variability of the data by introducing spurious or artifactual results. Fibrin or clot formation in a hematology sample always results in a spuriously low platelet count but may also cause low erythrocyte and leukocyte counts. Small clots may form because of an insufficient amount of anticoagulant (potassium ethylenediamine tetraacetic acid [K EDTA] is the anti-coagulant of choice for hematology samples), inadequate mixing of the blood with anticoagulant, or poor blood collection technique with exposure of the blood to substances from traumatized tissue. Excessive anticoagulant can cause dilutional errors for cell counts and prolonged coagulation times. In addition to the dilutional error, manual packed cell volumes are further lowered because of shrinkage of the erythrocytes. The use of an inappropriate anticoagulant can cause spurious results and must be avoided. Intentional or accidental exposure of clinical chemistry samples to K EDTA results in very high potassium concentrations, very low calcium and magnesium concentrations due to chelation, and very low activities of enzymes such as alkaline phosphatase and creatine kinase that use magnesium as a cofactor (41). Trisodium citrate, the anticoagulant of choice for the coagulation assays, also chelates divalent cations and would additionally increase sodium concentration if incorrectly used for the clinical chemistry sample.

Hemolysis can be caused by poor technique for sample collection, sample transport, or serum/plasma separation, and hemolysis can result in spuriously increased or decreased test results by two principle mechanisms: release of erythrocyte constituents, and interference with test methodology (41, 50, 53, 80, 81).

Techniques and procedures should be chosen that eliminate in vitro hemolysis to the greatest extent possible.
As previously indicated, prolonged contact between serum and clotted blood causes spurious changes that can be controlled by prompt separation of the serum (143). Although most analytes are relatively stable for a reasonable amount of time (73, 97, 125), unnecessary delay or storage of samples before analysis should be avoided. Ideally, hematology samples should be analyzed within a few hours of collection and no later than 24 h after collection. If samples for coagulation tests cannot be run on the day of collection, the plasma should be frozen at −20°C and thawed only once before analysis (38). If samples for clinical chemistry tests cannot be run on the day of collection, the serum or plasma (lithium heparin is the recommended anticoagulant when plasma is used for clinical chemistry) should be refrigerated or frozen overnight. If there will be a long delay before analysis or if a desired analyte is relatively labile, then the samples should be frozen at −70°C.
There are several other sources of variation for clinical pathology data, but the impact of each on data interpretation in toxicology studies is generally minimized by the inclusion of age and sex-matched control groups exposed to the same environmental conditions and undergoing the same experimental procedures. Occasionally overlooked are the effects of procedures that may differ between the control and treated groups. Because toxicology studies in larger animals frequently include blood collections for analyses other than clinical pathology (e-g-> toxicokinetic measurements or detection of antibody directed at a peptide test material), it is imperative that control animals be bled in a similar manner to the treated animals. The number and volume of blood samples for these tests can have a significant effect on hematology and clinical chemistry results (108), and data interpretation is seriously compromised if control animals do not undergo the same procedures. Even when control animals are bled in a like manner, iatrogenic blood loss can complicate data interpretation (67).

Analytical Variation and Quality Control

In addition to sources of variation that occur before sample analysis, the analytical procedure itself is a source of variation. Analytical variation is minimized by an active quality control system within the clinical pathology laboratory. Detailed discussions of quality control systems are available in many textbooks (14, 100, 138). At a minimum, the quality control system should include initial verification that a new method satisfies the goals of the laboratory for accuracy and precision for the analyte being measured; standard operating procedures for all laboratory functions necessary for analysis and reporting of test results; documentation of routine instrument calibration procedures; documentation of routine and nonroutine instrument maintenance; documentation of appropriate personnel training; proper labeling of all reagents, controls, standards, calibrators, and other chemicals in the laboratory; routine analysis of quality control specimens and review of quality control data for detection of systematic errors; routine review of "patient" data for detection of random errors; standard procedures for responding to and documenting "out-of-control" situations; and participation in some form of external quality control or proficiency testing with "unknown" samples for analysis.
Analytical variation is affected by the accuracy and precision of a test procedure. Accuracy is a measure of the extent to which the mean estimate of a quantity approaches its true value, and precision is a measure of the agreement among replicate measurements (i.e., the reproducibility of a test result). Accuracy is generally determined in a formal way when a new method is introduced into the laboratory, and it is continually reassessed, albeit somewhat crudely, by means of proficiency testing. Most analytical procedures exhibit a small amount of systemic bias or inaccuracy that is either constant or proportional. In other words, the mean estimate of the quantity of analyte is always in error in the same direction, either higher or lower, than the true quantity. Precision of a test can be assessed within a single run (e.g., 20 consecutive analyses of the same sample for within-run precision) or from day to day (e.g., the same sample analyzed several days in a row for between-run precision) and is reflected by a test's coefficient of variation (CV). The CV expresses the error or variability of replicate test results as a percentage of the mean value (i.e., [standard deviation/mean] x 100); the lower the CV, the greater is the test's precision or repeatability.
Although accuracy and precision are both desirable, test procedures can be accurate but imprecise or inaccurate but precise. In the context of most toxicology studies, where results from groups of treated animals are compared with results from concurrent control groups and their own pretreatment results, good precision is more valuable than good accuracy. This is in contrast to the clinical setting, where the physician or veterinarian evaluates individual patients under less controlled conditions and uses, by necessity, broad historical reference ranges for making decisions. An imprecise test, regardless of accuracy, is less able to detect small differences between the control and treated groups. If the true

mean glucose concentrations for 4 control dogs and 4 treated dogs are 100 and 115mg/dl, respectively, but the standard deviations for the groups are large because of imprecision, then it is unlikely that the observed difference between the means (i.e., 15 mg/dl) will be considered a real difference. A precise test, regardless of a systemic bias or inaccuracy,

is better able to identify small test material-related differences between the groups. In the same example, if the glucose test had a positive bias but was more precise, the means of the two groups might be 110 and 125 mg/dl with lower standard deviations. The improved precision permits a more accurate interpretation of the same 15-mg/dl difference between group means.

Clinical pathology laboratories that test animal samples frequently use tests, especially standard clinical chemistry tests found in routine chemistry panels, that are optimized for accuracy using human samples. It is likely that many of these tests have small systemic biases when used for animal specimens. In most cases, however, the excellent precision afforded by using standardized commercial reagent kits, standards, and calibrators is preferable to time-consuming, costly efforts to optimize the accuracy of a test for different animal species by using "home-brew" materials that undermine precision. Occasionally there are standard chemistry tests that do not work well for certain species, such as albumin for rabbits, and these tests require specialized methods. Immunoassays utilizing monoclonal or polyclonal antibodies raised against human substances (such as hormones) are frequently inappropriate for use on animal specimens, and hematology analyzers that enumerate and differentiate blood cells must be modified for animal blood because of differences in cell morphology.

For human hospital laboratories, federal regulations allow each laboratory to set its own policies for assaying control materials as long as at least 2 control samples of different concentrations (i.e., normal and abnormal levels) are assayed every 24 h. The data from each quality-control analysis are used to make decisions about the validity of the patients' data. In the setting of preclinical toxicology studies, it is advisable to assay at least two control samples with each study run. In other words, if a laboratory is scheduled to run samples from two or more regulated toxicology studies (e.g., studies needed to make submissions to regulatory agencies and using Good Laboratory Practices), then quality control samples should be assayed with each of the studies, and the results should be maintained with the study data. If results from a control sample are found to exceed the allowable limits for one or more analytes, then steps must be taken to resolve the problem. Actions that may be taken include, but are not limited to, the following: check for obvious problems such as reagent levels, clots, or mechanical fault; repeat the assays on control samples using fresh aliquots; repeat the assays using newly reconstituted control samples; recalibrate the instrument for the analyte(s) in question, then reassay the control samples; change the reagents, recalibrate, and reassay the control samples; and perform maintenance, recalibrate, and reassay the control samples.

PRINCIPLES OF DATA INTERPRETATION

Interpretation of data from toxicology studies begins with the identification of differences between control and treated groups and ends with an assessment of toxicological or biological relevance. Or in other words, are there real differences between the groups, and if so, are those differences bad? Interpretation of clinical pathology data requires an understanding of each test's characteristics, species differences, and principles of internal medicine. Factors that influence the interpretation of a potential effect include study design and conditions, clinical observations, other clinical pathology results, anatomical pathology findings, and the test material itself. Interpretations of many clinical pathology findings are interdependent, and pattern recognition is critical. After range-finding studies have been conducted, appropriate dose selection usually precludes large, dramatic effects on clinical pathology test results. The most common effects are relatively mild and often appear to be secondary to small alterations in metabolic or homeostatic mechanisms. However, test materials causing significant damage to liver, kidney, or hematopoietic tissue can produce marked changes in clinical pathology results. Effects on clinical pathology results are rarely the only evidence of biologically important or adverse toxic effects. Clinical observations or anatomical pathology findings usually corroborate biologically important laboratory findings.

Statistical Comparisons

Statistical analysis of clinical pathology data is commonly performed in toxicology studies, and it often results in identification of several statistically significant differences between control and treated groups. However, all effects caused by a test material need not be statistically significant, and all statistically significant differences do not necessarily represent true or lexicologically significant effects. If used, statistical tests should be viewed simply as a tool to help identify differences between groups and not as the principal justification for decisions concerning potential test material effects (20, 26). It is important to remember that the power of a statistical test is affected by the number of animals per group. Fewer test subjects increases the likelihood that statistical tests will fail to identify a true effect. Since the number of animals/per group is usually quite small for studies with dogs or monkeys (e.g., 4/sex/group, or less), it is imperative that the data for each animal at the different test intervals be examined to look

for patterns of change over time among the treated animals that are absent among the control animals. As the number of animals per group increases, the frequency of identifying statistically significant differences of very small magnitude

increases. In rat studies with 15 or more animals per sex per group, it is common to observe statistically significant differences that have little or no effect on the health of the animals and are not lexicologically relevant.

Is an Apparent Difference Real?

When faced with an apparent difference between control and treated groups, the first answer the investigator must determine is whether or not that difference represents a true effect of the test material or is an incidental finding. Many factors can influence the answer, not the least of which is the size of the difference. A large difference is obviously more likely to be real than a small one. Additional factors that favor a difference being test material-related include dose dependency, consistency over time, consistency between sexes, correlation with clinical observations (e.g., low chloride concentration and emesis), correlation with other clinical pathology findings (e.g., low hematocrit and high reticulocyte count), correlation with anatomical pathology findings (e.g., high globulin concentration and lymph-node hyperplasia), presence in a large number of animals (e.g., 15/sex/group versus 3/sex/group), and consistency with previously identified effects of the test material or related compounds. With large animals, it is necessary to make certain that an apparent difference was not present before treatment was initiated. The chronology of an apparent difference is also important for interpretation. For example, following a single administration of most test materials, it is more likely that a real difference will occur within a few days rather than only after 2 weeks. Following repeated administration of most test materials, it is more likely that a real difference will occur after a few months of treatment rather than only after several months. In other words, it is somewhat unusual that a real difference at 6 months will be completely absent at 3 months.

With regard to specific tests and test species, the amount of expected analytical, interanimal, and intra-animal variability can influence the interpretation of apparent differences. For example, because alanine aminotransferase activity has much greater interanimal and intra-animal variability for monkeys than for dogs, a relatively modest difference for this enzyme between control and treated groups is less likely to be a true effect for monkeys. Interanimal variability increases dramatically for older rodents (e.g., >52 weeks of age) because of naturally occurring disease conditions, and small differences between groups are less likely to represent true effects. Procedural factors such as the route of test material administration, blood collection technique, and randomization for blood collection also affect variability and must be considered. For example, continuous intravenous infusion increases interanimal variability for several tests (e.g., white blood cell count, hematocrit, serum proteins), and interpretation of small differences in results of these tests is difficult. Blood collection by cardiac puncture affects variability of muscle enzymes such as creatine kinase and aspartate aminotransferase. The potential for spurious findings associated with lack of randomization for blood collection was discussed previously.

Is a Real Difference Bad?

If a difference between control and treated groups is clearly real, the next answer the investigator must determine is whether or not that difference represents a bad or adverse effect. Does the finding itself (e.g., low hemoglobin concentration) or the condition that caused the finding (e.g., blood loss from gastrointestinal erosions/ulcerations) represent a toxic effect that compromises the animal's health? The answer is often ambiguous and quite subjective. Many of the factors previously considered are important, and the size of the difference is clearly a focal point. Although a large difference for a given parameter is more likely to be adverse than a small difference, it is clearly not that simple, and it is not possible to define set limits for each test that represent an adverse effect. The same magnitude of change for a given test can have completely different connotations depending upon the mechanism for that change, correlative findings, the test species, the study design and procedures, and the test material itself (e.g., a clinical pathology parameter may be the target for the pharmacological activity of a drug). Urea nitrogen may be markedly increased because of dehydration (e.g., mice that have been fasted too long before blood collection or animals that refuse to drink water containing test material), but only mildly increased in the early stages of renal toxicity. Increased alanine aminotransferase activity associated with histopathological evidence of hepatocellular degeneration and necrosis is likely to be more lexicologically important than the same level of increase for which there are no correlative findings. Because of species differences for interanimal variability, a threefold increase for alanine amino-transferase activity for dogs (i.e., treated vs. control group means) is more likely to represent an adverse condition than the same increase for monkeys. A 10% decrease in hemoglobin concentration is less likely to represent an adverse condition in animals that were bled repeatedly during a study or that received the test material by continuous intravenous infusion than in animals that were not bled repeatedly or were treated by oral gavage. Very high neutrophil counts would normally reflect an

adverse condition, but if the test material was a granulocyte

colony-stimulating factor, the high counts would be a desirable effect.

Some tests measure analytes that are critical to good health (e.g., neutrophil count, hemoglobin concentration, glucose concentration, calcium concentration, potassium concentration), and correlative in-life observations (e.g., bacterial infections, lethargy, weakness, weight loss) may help determine whether an observed effect on such a test has impacted the animals' health. Other tests measure analytes that are markers for effects best evaluated by histopathological examination (e.g., alkaline phosphatase, urea nitrogen). All routine tests can be altered by more than one process or mechanism, and some mechanisms have worse implications than others. For example, increased urea nitrogen in mice associated with poor feed and water consumption is likely of less concern than increased urea nitrogen because of proximal tubular necrosis. When determining the biological or toxicological significance of an effect on a clinical pathology test result, consideration must be given to the analyte's normal function for maintaining health, correlative findings that may better define the overall impact of the test material on health, and the mechanism that brought about the change.

Reference Intervals

Like statistical comparisons, historical reference intervals can be used as a tool when assessing apparent differences between control and treated groups. Unfortunately, the value of reference intervals for data interpretation is sometimes overestimated, and the potential for their improper use is great (61, 131, 134). It is tempting to invoke historical reference intervals when trying to decide whether apparent differences for clinical pathology results are true effects or whether they are adverse effects. While historical reference intervals can be helpful for establishing some perspective concerning what is typical or expected, the conditions of every toxicology study are unique, and it is inappropriate to use a reference interval as the primary reason for dismissing an apparent difference between control and treated animals as being incidental or biologically insignificant. It can be equally inappropriate to use a reference interval as the primary reason for determining that an apparent difference is real or adverse. As detailed in the previous sections, there are many other factors to consider when evaluating the nature of an apparent test material effect.

Reference intervals (often incorrectly referred to as reference ranges or normal ranges) are constructed with values obtained from reference individuals. In most clinical pathology laboratories used for toxicology studies, the reference individuals are control animals from previous studies and clinically healthy animals that have not received treatment (e.g., monkeys or dogs that have clinical pathology tests performed before initiation of dosing). In human medicine, the National Committee for Clinical Laboratory Standards recommends that reference intervals be estimated by the nonparametric method and that a minimum of 120 values from reference individuals be used (93). Test results from the reference individuals are subjected to statistical treatment such that rare values at both ends of the distribution are eliminated. For example, if the lowest and highest 2.5% of the values are eliminated, the resulting reference interval represents the central 95% of the distribution of values. If the distribution is gaussian, the interval corresponds to the mean±1.96 SD. By definition, when the central 95% is used as the reference interval, 5% of the results from "normal" individuals (1 of 20) are outside of the reference interval for any given test. Clearly, a value outside of the reference interval does not necessarily indicate an abnormality (36).

The suitability of a historical reference interval for data interpretation for a given study is a function of the parameters or *partitioning factors* that define the reference population used to construct the interval. There are many potential partitioning factors with respect to toxicology studies, and their importance is sometimes overlooked. The most commonly used partitioning factors are species, strain, sex, and age. In other words, a typical reference population might be defined as male Fischer 344 rats from 8 to 10 weeks of age. However, many other partitioning factors can influence the reference interval and make it broader, narrower, higher, or lower. These factors include animal supplier, site of blood collection, use of anesthetic, type of anesthetic, diet, fasting status, time of sample collection, and sample matrix (e.g., serum or plasma). If control animals are used for the reference population, additional partitioning factors include route of administration (e.g., dietary, oral gavage, or intravenous infusion), vehicle or control material administered (e.g., sterile water or corn oil in a gavage study; sterile saline or 5% dextrose in an intravenous infusion study), and whether or not the animals were bled repeatedly for toxicokinetic analyses or multiple clinical pathology intervals. Finally, there are laboratory considerations including instrumentation or technique used to analyze the specimen and sample storage conditions (e.g., storage temperature and time interval between collection and analysis). Ideally, whenever a new instrument or reagent system is introduced, a new reference interval is constructed. In practice, laboratories often rely on evidence that demonstrates relative consistency between the old and new analytical methods to

avoid complete replacement of old intervals.
The number of partitioning factors used obviously has a direct impact on the number of reference individuals

available for each reference interval. With the exceptions of reference intervals for dogs and monkeys tested before treatment is initiated (e.g., male beagles, 4 to 6 months old, XYZ supplier, jugular vein, no anesthetic, fasted), it can be very difficult obtaining enough data for meaningful reference intervals. Because of this problem, laboratories often ignore many of the partitioning factors and "lump" together the data from control animals of dissimilar types of studies or from samples that have been handled differently. The result is broader reference intervals with less relevance to data interpretation.

Even when reference intervals are appropriate for a given study (i.e., the partitioning factors match the study animals, conditions, and procedures), it is wrong to assume that a difference between control and treated groups represents a true effect or an adverse effect simply because the mean of the treated group falls outside of the reference interval. Concurrent control animal data for a given study are never a perfect reflection of the historical reference data; that is, they do not exhibit the same means and distribution. The mean for the control group may fall anywhere within the reference interval, and the distribution of results for the control group is almost always narrower than that of the reference interval. Depending on the location of the control group data within the reference interval, a very small, incidental difference for the treated group may fall outside of the reference interval and a relatively large, adverse test material-induced difference may fall within the reference interval. There are many situations when a small difference, within the reference interval, represents a very significant adverse effect. For example, anemia and hypoproteinemia can be masked by dehydration, and the loss of an entire subpopulation of lymphocytes is not necessarily enough to cause absolute lymphocyte count to fall below the reference interval. When reference intervals are broad, as occurs when few partitioning factors are used or normal interanimal variability is great (e.g., alkaline phosphatase activity for monkeys), significant toxicity can occur without test results exceeding the limits of the intervals. Investigators must understand the limitations of reference intervals with respect to data interpretation. By themselves, reference intervals do not determine whether or not an apparent difference is real or adverse. They are simply an adjunct to sound scientific judgment.

Regardless of the many pitfalls affecting their use for data interpretation, historical reference intervals do have other important functions. They serve as a nonspecific measure of quality control that can detect changes over time in assays, study conditions, or animal characteristics. For example, it may be noticed that liver enzyme activity in mice has increased over time. The cause of this finding might be traced to changes in handling practices or animal supplier. Reference intervals also serve as a nonspecific measure of analyte variability. The cause of seemingly excessive variability might be inadequate assay precision, nonstandardized preanalytical procedures, or true interanimal variability. Finally, reference intervals can be valuable when very few animals are used for small investigational studies with no concurrent control group. Although pretreatment baseline data are more relevant to interpretation of potential effects, it may be discovered that the few animals acquired for the study have preexisting problems or are atypical with respect to historical data.

HEMATOLOGY TESTS AND INTERPRETATION

The hematology tests recommended and most often performed for toxicology studies evaluate erythrocytes, leukocytes, platelets, and coagulation. Technological advances by manufacturers of hematology and coagulation analyzers, along with a growing interest in supporting customers who must evaluate samples from a variety of animal species, have increased the availability of highly sophisticated instruments to perform these tests with precision and accuracy suitable for preclinical safety assessment studies. The automated methods are a necessity. Manual methods are unacceptably imprecise, labor-intensive, and slow. Many currently marketed hematology instruments are capable of measuring or calculating all of the routinely recommended tests and more from less than 150 μl of anticoagulated whole blood. The instruments typically utilize a combination of two or more principles including electrical aperture impedance, laser light scatter, and differential staining characteristics to determine cell number (RBC, WBC, and platelet counts), cell size and size distribution (MCV, RDW, mean platelet volume [MPV], and platelet distribution width [PDW]), and cell type (WBC differential count). They measure hemoglobin concentration directly and calculate MCH and MCHC; some also calculate HDW. Because the blood cells of laboratory animal species differ morphologically from human blood cells, instruments and the instrument software used for human samples are generally inappropriate for use without modifications. Fortunately, instrument manufacturers are producing instruments with the necessary modifications to permit accurate and precise analysis of blood from a variety of laboratory animals species. Modifications have also been made for coagulation analyzers that measure the time required for fibrin clot formation in a plasma sample, to which reagent has been added, by detecting changes in conductivity, physical resistance, light scatter, or optical density. Most instruments can now be

programmed to permit detection of clot formation at times much faster (e.g., prothrombin time for dogs) or

< previous page page_1013 next page >

slower (e.g., prothrombin time for guinea pigs) than are typically observed for human samples.

Erythrocytes

Effects on erythrocyte parameters typically reflect a change in the balance between red blood cell production and red blood cell loss or destruction. In addition, changes in plasma volume (e.g., dehydration or volume expansion) can indirectly affect erythrocyte parameters. Although mechanisms for effects on erythrocyte parameters may be obvious, such as hemorrhage from gastric ulceration, they are often relatively obscure. But even when the exact mechanism is unclear, the effects can usually be described in terms of broad mechanistic categories and impact on health.

Anemia

Anemia is defined clinically as the condition characterized by a hemoglobin concentration below the lower reference limit. RBC count and hematocrit may or may not be proportionately lower, depending on the cause of the anemia and whether or not cell size and hemoglobin content are affected. Low hemoglobin concentration reduces the oxygen-carrying capacity of blood, which in turn may result in clinical signs such as pallor, weakness, exercise intolerance, tachycardia, or tachypnea. In many toxicology studies, a treated group has lower means for RBC count, hemoglobin concentration, and hematocrit than those for the control group, but the differences are less than those necessary to cause clinical signs and are not indicative of anemia. For example, reductions from control values for these parameters up to approximately 10% are relatively mild and probably do not have an adverse effect on the health of the animal. Reductions from approximately 10% to 25% may be considered a moderate effect and may or may not be clinically adverse. Reductions of more than 25% are marked and clearly represent a clinically adverse anemic condition. Keep in mind that while a 5% reduction in hemoglobin concentration may be insufficient to adversely affect health, the cause of the reduction (e.g., liver toxicity) may be very adverse. Unless the differences for RBC count, hemoglobin concentration, and hematocrit are quite large, it is preferable to simply discuss the magnitude of the differences between the control and treated groups and avoid using the term *anemia*. In this chapter, however, *anemia* is used for the purposes of discussing mechanisms.

Anemias are broadly categorized as regenerative or nonregenerative. Regenerative anemias are characterized by an appropriate erythropoietic response to reduced circulating erythrocyte mass or hemoglobin concentration, and nonregenerative anemias are characterized by the absence of an appropriate erythropoietic response.

Regenerative anemias result from two general causes: abnormal blood loss (hemorrhage), and accelerated erythrocyte destruction (hemolysis). Following acute blood loss or hemolysis, it takes approximately 3 to 4 days for new erythrocytes, called reticulocytes, to increase in number in peripheral blood. Reticulocytes are larger and slightly more basophilic than mature erythrocytes when stained with the Romanowsky-type stains (e.g., Wright or Giemsa stain) typically used for assessing red blood cell morphology and doing manual WBC differential counts. During a strong regenerative response, erythrocyte morphology is described by the terms *anisocytosis* (variable size) and *polychromasia* (variable color) because of the increased numbers of reticulocytes. Greater numbers of nucleated red blood cells, also called metarubricytes, and Howell-Jolly bodies (small pieces of nuclear material not cleared from the erythrocyte) may be observed during a regenerative response, but these may also increase with some nonregenerative conditions. Reticulocytes can be counted with an automated reticulocyte counter or counted manually by staining blood with a vital stain such as new methylene blue before making a blood film. For proper interpretation, the absolute reticulocyte count (i.e., reticulocytes/μ1) should always be determined by multiplying the relative reticulocyte count (i.e., percent of erythrocytes) by the RBC count. Relative reticulocyte counts can be increased in severely anemic animals even though the absolute reticulocyte counts are no different than for normal animals. In this case, the erythropoietic response is not appropriate for the degree of anemia and indicates inadequate RBC production is at least partially responsible for the anemic condition. During a strong regenerative response, the increased number of "young" erythrocytes will usually result in higher MCV and lower MCHC because these relatively large cells have lower hemoglobin concentration. In practice, higher MCV is more commonly observed than lower MCHC. During a strong regenerative response, erythrocyte production can increase six- to eightfold over normal levels. As long as the accelerated erythropoiesis is able to match the erythrocyte loss or destruction, the anemia will not become worse. If erythropoiesis exceeds the loss or destruction, or if their cause is eliminated, the anemia will be reversed.

In toxicology studies, mild nonregenerative anemias are more common than regenerative anemias. If normal erythrocyte production is reduced for any reason, or if erythropoiesis does not increase in

response to decreased erythrocyte survival, circulating erythrocyte mass will decrease over time. In nonregenerative anemia, erythrocyte morphology is characterized by the absence of anisocytosis and polychromasia. Most often, the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1014.html[2010/10/28 20:19:34]

erythrocytes appear normocytic (normal size) and normochromic (normal color). Absolute reticulocyte count is unchanged or decreased, depending on whether the problem is simply an inability to adequately respond to increased needs or, more significantly, failure of erythropoiesis. Mean corpuscular volume is typically unchanged or mildly decreased.

The most common hematology findings in preclinical toxicology studies are mildly decreased RBC count, hemoglobin concentration, and hematocrit without a corresponding increase in absolute reticulocyte count and without an obvious mechanism for the effect. The decreases are usually no more than about 10% from the values for the respective control group (e.g., mean control group hematocrit=44%; mean high-dose group hematocrit=40%) and less than what would be classified as anemia. Slightly lower MCV (e.g., control mean= 56 fl; high-dose mean=54 fl) may also be observed, especially in rodents. In conjunction with these minor effects, the animals may exhibit mild reductions in body weight or body weight gain and less frequently, feed consumption. They may have other clinical signs of poor health, including dull haircoat, poor grooming habits, and decreased activity. Potential concurrent effects on other clinical pathology test results include mildly decreased total protein and albumin. Although specific mechanisms for these changes are typically not identified, they suggest a generalized reduction of anabolic processes. Anything that affects the normally brisk pace of RBC production (in humans, approximately 100 billion new cells/day), will ultimately be reflected in the test results. It is possible that decreased physical activity and correspondingly decreased tissue oxygen demand may contribute to reduced erythropoiesis. These relatively mild, nonspecific findings for circulating erythrocyte mass are identified most frequently in rat studies where the number of animals per sex per group is usually high (e.g., 10 animals per sex per group), the dose levels used are typically higher than those for dog or monkey studies, and the normal interanimal variability of hematology data is relatively low. In addition, because the circulating life spans of mouse and rat erythrocytes (approximately 25 to 40 and 45 to 65 days, respectively) (68) are shorter than those for dogs (approximately 100 to 120 days) and nonhuman primates (varies with species; for rhesus monkeys, approximately 85 to 100 days) (68), similar reductions in RBC production will first become apparent for mice and rats.

Nonregenerative Anemias

There are several other causes of reduced RBC production, and they are distinguished from one another by their severity, the presence of morphologically distinct erythrocytes, and other findings that identify the etiology. Test materials may affect RBC production directly or indirectly. Direct inhibition of erythropoiesis, if sustained, will result in a gradually developing, severe anemia because senescent erythrocytes are not replaced. Indirect effects on erythropoiesis are more common in toxicology studies and result from toxic effects on other tissues or organ systems. Indirect effects on the erythron tend to be relatively mild and are not as toxicologically important as the effects on the primary target tissue.

Direct injury to pluripotent hematopoietic stem cells or their stromal microenvironment causes failure of blood cell production, resulting in the condition called *aplastic anemia* (109, 137). Aplastic anemia is characterized by varying degrees of pancytopenia (i.e., decreased erythrocytes, leukocytes [primarily neutrophils], and platelets) and hypocellular bone marrow. If the animal survives long enough, the anemia becomes severe. Typically, however, decreased resistance to bacterial infections causes severe illness or death before the anemia is life-threatening. Irradiation is a classic model of stem cell injury and is used therapeutically as part of the process for bone marrow transplantation. In addition to irradiation, several chemicals and drugs are known to cause aplastic anemia in humans. These include benzene, toluene, lindane, pentachlorophenol, chloramphenicol, phenylbutazone, penicillamine, gold salts, and acetazolamide. Chemotherapeutic drugs such as alkylating agents (e.g., busulfan and cyclophosphamide), anti-metabolites (e.g., fluorouracil and methotrexate), and cytotoxic antibiotics (e.g., doxorubicin and daunorubicin) have the potential to cause aplastic anemia because of their pharmacological activity. Normally, however, their effects are reversible following completion of each treatment cycle. In toxicology studies with test materials such as these, decreased WBC and platelet counts are typically recognized earlier in the study (generally 7–10 days after initiation of treatment) than decreased RBC counts because the circulating life spans for neutrophils (12–24 h) and platelets (7–10 days) are much shorter than that for erythrocytes. On the other hand, reticulocyte counts can be a sensitive indicator of hematopoietic injury and may be better than WBC or platelet counts for identifying the onset of toxic effect and subsequent recovery. The value of assessing reticulocyte counts when testing antineoplastic drugs is most apparent in rodent studies because the normally high reticulocyte counts for young rodents facilitate identification of decreases while their normally low neutrophil counts make neutropenia more difficult to recognize. Furthermore, reticulocyte counts are not compromised by poor blood collection technique that may cause increased interanimal variability for platelet count. The

timing of sample collection following administration of a test material that temporarily interrupts hematopoiesis will dictate the findings in peripheral blood and can impact interpretation. During the peak effect, reticulocytes, neutro

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1015.html[2010/10/28 20:19:35]

phils, monocytes, eosinophils, platelets, and often lymphocytes are decreased in number, and histopathologic examination of the bone marrow reveals hypocellularity. Once the effect ends, hematopoietic tissue usually mounts a strong recovery, sometimes called a rebound effect, that is characterized peripherally by reticulocytosis, thrombocytosis, and sometimes neutrophilia. Increased extramedullary hematopoiesis in the spleen, especially for rodents, is often apparent before the bone marrow repopulates. Because the time to peak effect and the duration of effect vary for different test materials, it is necessary to perform hematology tests at multiple intervals for proper interpretation.

Pure red cell aplasia is rarely observed in toxicology studies, even though several drugs are known to cause the disorder in humans (46). Because drug-induced pure red cell aplasia is usually an idiosyncratic condition and may be immune mediated, recognition of this toxic effect is low in animal studies using a limited number of test subjects. Furthermore, it would be very difficult to prove that uncomplicated, nonregenerative anemia in a single animal was a direct effect of the test material.

Chronic inflammatory diseases (44, 48, 49) and significant kidney (23), liver (99), and endocrine dysfunction (e.g., hypothyroidism and hypoadrenocorticism) (45) negatively affect erythropoiesis and erythrocyte survival, and all of these conditions can be associated with a mild to moderate, normochromic, normocytic anemia. With chronic inflammatory conditions, the principle cause of reduced erythropoiesis is thought to be decreased availability or transfer of iron to developing erythrocytes. True iron deficiency, most commonly associated with chronic blood loss or inadequate dietary iron, is relatively rare in toxicology studies, and, in contrast to the anemia of chronic disease, is characterized by microcytic (low MCV), hypochromic (low MCHC) erythrocytes. With renal disease, reduced erythropoiesis is attributed to decreased renal production of erythropoietin and the effects of "uremic toxins." Liver failure is sometimes associated with acanthocytosis, a morphological abnormality of erythrocytes characterized by several blunt cytoplasmic projections resembling pseudopodia. The acanthocytes are thought to result from accumulation of free, nonesterified cholesterol in the RBC membrane. Acanthocytes are relatively inflexible and are eventually removed from circulation by cells of the mononuclear phagocyte system. Small reductions in circulating erythrocyte mass are observed with hypothyroidism and may result from reduced basal metabolic rate and cellular requirements for oxygen. Changes in thyroid metabolism may play a role in the mild erythrocyte effects observed in some animals with reduced food consumption because caloric malnutrition can result in decreased TS and decreased responsiveness to TB, which may in turn lead to reduced production of erythropoietin.

Megaloblastic anemia is a nonregenerative anemia characterized by macrocytic erythrocytes, asynchronous maturation of cytoplasm and nucleus in hematopoietic precursors, and hypersegmented or "giant" neutrophils (2). In humans, it is associated with a variety of disorders that cause folate or vitamin 812 deficiency (e.g., sprue, alcoholic cirrhosis, and pernicious anemia) and drugs (e.g., methotrexate) that impair DNA synthesis. Macrocytosis results because developing erythrocytes undergo fewer divisions before maturation. Megaloblastic anemia is rarely identified in laboratory animals, perhaps due to differences in uptake and metabolism of folate and vitamin B12. On the other hand, nonhuman primates have been used frequently as animal models for folate and vitamin B12 deficiency (142).

Finally, nonregenerative anemia is usually a feature of leukemia because the proliferating neoplastic hematopoietic cells compete with normal hematopoietic cells for nutrients and space in the bone marrow and spleen. It is not unusual in carcinogenicity studies to observe severe anemia secondary to naturally occurring leukemia in a few animals.

Regenerative Anemias

Blood loss can occur secondary to a variety of conditions or study-related procedures and should always be considered when a decrease in circulating erythrocyte mass is accompanied by a similar decrease in serum protein concentration. The source of the blood loss may be identified by clinical observations (e.g., dermal ulceration, melena, epistaxis), necropsy findings (e.g., gastrointestinal ulceration, cystitis), or other laboratory tests (e.g., fecal and urine occult blood tests). Blood loss associated with serial blood collection for pharmacokinetic investigations, clinical pathology tests, or other study-specific requirements must always be accounted for when interpreting changes in erythrocyte parameters. Blood loss typically results in increased polychromasia, MCV, and reticulocyte count unless the condition is very acute (i.e., less than the 3–4 days necessary for the regenerative response to build up) or there are complicating factors affecting erythropoiesis.

There are a number of potential mechanisms for test material-induced hemolysis, but the three most common mechanisms observed in toxicology studies are direct damage to the red blood cell membrane, oxidation of hemoglobin resulting in Heinz body formation, and immune-mediated red blood cell

destruction (90). Each has specific characteristics, and they are relatively easy to differentiate.
Test materials administered intravenously are those most likely to be associated with direct damage to the red blood cell membrane. The lipid bilayer of the cell membrane is sensitive to test materials with detergent-like properties, and intravascular hemolysis can occur rapidly

during treatment when the red blood cells are exposed to high concentrations of the test material at the site of injection or infusion. If the amount of released hemoglobin exceeds the carrying capacity of circulating haptoglobin, unbound hemoglobin passes through the glomerulus and is excreted in the urine. Visible hemoglobinuria (red-tinged urine) may be observed within a few hours of treatment, and a regenerative response is detectable in the blood within 3 or 4 days of treatment. Intravenously administered test materials that cause extensive intravascular hemolysis are usually associated with local damage to endothelium. The effect of the vascular damage may be observed grossly (e.g., tail lesions in rodents treated via the tail vein) or histologically. Additional histological evidence of intravascular hemolysis is the presence of hemoglobin pigment within renal tubular epithelial cells and hemoglobinuric nephrosis. Administration of a very hypotonic solution, as might occur if sterile water is inappropriately chosen as the vehicle for a low concentration solution, is another potential cause of acute intravascular hemolysis. Water passively enters red blood cells because of the ionic concentration gradient, and the cells swell and rupture. Hypertonic solutions typically do not cause hemolysis.

Heinz bodies are particles of irreversibly denatured hemoglobin attached to the interior of the red blood cell membrane. They result when test materials with oxidative properties cause disulfide bonds to form from the sulfhydryl groups of hemoglobin. Red blood cells containing Heinz bodies may be removed from circulation by cells of the mononuclear phagocyte system (extravascular hemolysis), or they may become morphologically distinct (e.g., ghost cells and blister cells) following selective removal of the Heinz bodies. Although Heinz bodies can be difficult to detect with the Romanowskytype stains, they stain prominently with vital stains such as methylene blue, crystal violet, or brilliant cresyl blue used for manual reticulocyte counts, and the number of affected cells can be determined in the same manner as that for manual reticulocyte counts. The size and number of Heinz bodies are dependent on the causative agent, the dose, and the time after exposure. Acute exposure to a potent oxidative agent typically causes an acute anemia characterized by the observation of many affected red blood cells containing a single, large Heinz body, or, less frequently, multiple, small Heinz bodies. Ghost cells, blister cells, and other morphologic abnormalities may be present. Reticulocytosis develops after 3 to 4 days. As is true for most causes of significant, acute extravascular hemolysis, splenomegaly and extramedullary hematopoiesis are common findings. Bilirubinemia and bilirubinuria are possible but less common correlative findings. Chronic, low-level exposure to an oxidizing agent usually does not cause anemia. Although absolute reticulocyte count and MCV may be slightly increased, hematocrit and hemoglobin concentration are relatively unchanged or only slightly reduced. The number of red blood cells containing Heinz bodies is low, and they may go unrecognized if not looked for specifically. Identification of test materials that cause Heinz body formation is particularly important clinically because the most common human erythrocyte enzyme deficiency, glucose 6-phosphate dehydrogenase deficiency, makes affected individuals particularly susceptible to oxidant-induced hemolysis (7).

Test materials that cause Heinz body formation have the potential to cause methemoglobinemia and vice versa (91). Methemoglobin is hemoglobin in which the iron has been reversibly oxidized from the ferrous state (Fe^{2+}) to the ferric state (Fe^{3+}); it is incapable of carrying oxygen. The clinical signs of methemoglobinemia, therefore, are those of hypoxia. Mucous membranes become cyanotic at methemoglobin concentrations above 10%. Lethargy and weakness occur at concentrations of approximately 30% or more. At greater than 80%, methemoglobinemia may be fatal. Blood containing a high concentration of methemoglobin appears brown. Accurate and efficient measurement of methemoglobin concentration can be accomplished with dedicated instruments called hemoximeters. These multiwavelength, microprocessor-controlled photometers are designed to measure hemoglobin pigments such as carboxyhemoglobin and methemoglobin as well as the percentage of hemoglobin oxygenation. Samples collected for methemoglobin determination should be analyzed quickly (e.g., within 30 to 60 min) because methemoglobin is normally reduced by the erythrocyte enzyme methemoglobin reductase. The combination of a sensitive, precise instrument and a well-executed toxicology study allows detection of test materialinduced methemoglobin formation at concentrations well below those necessary to cause clinical signs (35). Among laboratory animals, the mouse is a poor model for studying the potential of test materials to cause methemoglobinemia because it has very high activity of methemoglobin reductase (115). Test material-induced methemoglobin in mice is quickly reduced to hemoglobin and therefore more difficult to detect.

Immune-mediated red blood cell destruction has been associated with many drugs (98) but is largely an idiosyncratic phenomenon and is therefore detected infrequently in preclinical toxicology studies. When it is observed, there are typically only one or two animals affected, and they may or may not be in the high-dose group. In contrast to hemolytic conditions that occur immediately upon exposure to the test

material, immune-mediated hemolysis is typically not observed until the test material has been administered for at least a week. There are three general mechanisms for

immune-mediated hemolysis: The test material acts as a hapten bound to the red blood cell membrane; the test material elicits an antibody response and the resulting antigen-antibody complex binds to the red blood cell; and the test material causes the immune system to mistakenly recognize normal red blood cell membrane antigens as foreign, and true autoantibodies are produced. On rare occasion, immune-mediated hemolysis is complement mediated and intravascular. More commonly, cells of the mononuclear phagocyte system, especially in the spleen, recognize antibodycoated red blood cells and either phagocytize the entire cell (extravascular hemolysis) or remove a portion of its membrane, creating morphologically distinct cells called spherocytes. In a blood film, spherocytes appear smaller and denser than other red blood cells; they are perfectly round and lack central pallor. While small numbers of spherocytes can be observed with other conditions, they are the predominant morphologic feature of immune- mediated hemolytic anemia. Autoagglutination of red blood cells will sometimes occur, especially if the antibody response is primarily immunoglobulin M (IgM), and may be observed in the blood film. Alternatively, autoagglutination may be detected in a wet mount of fresh blood diluted with saline. Direct antiglobulin tests may be used to confirm the presence of antibody or complement on red blood cells, but species-specific anti- immunoglobulin or anticomplement must be used. Animals with test material-induced immune-mediated hemolytic anemia become severely anemic with repeated administration of the test material. However, they usually exhibit a strong regenerative response and will nearly always recover if administration of the test material is stopped. Confirmation that the anemia was induced by the test material can be accomplished by rechallenging the animal following recovery. Upon rechallenge, hemolysis should be evident within a day or two. Immune-mediated hemolytic anemia, unrelated to test material administration, is a common sequela of the large granular lymphocyte leukemia observed in a high percentage of Fischer 344 rats older than 1 year of age (119).

Whenever regenerative anemia is identified in a nonhuman primate study, consideration must be given to the possibility of hemolysis associated with the hemotropic parasite *Plasmodium*. Many imported monkeys, even though they are captive bred, harbor subclinical infections with the organism that causes malaria (39). The readily identifiable intracellular organism is frequently observed in blood films from healthy animals that have no signs of anemia. Parasitemia, however, is inconsistent or cyclical, and multiple blood samples may be examined from an animal before the organism is identified. On rare occasion, administration of a test material or the stress of shipment and study-related pro cedures precipitates a hemolytic crisis. When this occurs, the parasitemia is usually quite obvious.

An infrequent cause of hemolysis in toxicology studies is mechanical fragmentation or microangiopathic hemolysis. This form of hemolysis typically occurs when red blood cells are forced to pass through small, fibrin-obstructed vessels in highly vascular tissue. The resulting fragmented red blood cells are called schizocytes (helmet cells) and are easily identified microscopically. Disseminated intravascular coagulation (DIG) is the best example of a condition causing microangiopathic hemolysis, but widespread vascular injury in tissues such as lung, liver, or intestine also causes some degree of fragmentation. These conditions, especially DIG, are generally so severe that an animal may fail to mount a significant regenerative response before it dies or is humanely killed.

Leukocytes

The differential WBC count enumerates neutrophils, lymphocytes, monocytes, eosinophils, and basophils in peripheral blood. Increased numbers of these cells in circulation are termed neutrophilia, lymphocytosis, monocytosis, eosinophilia, and basophilia, respectively. Neutropenia, lymphopenia, monocytopenia, and eosinopenia refer to decreases; normal basophil numbers are so low that decreases are not recognized. Leukocytosis and leukopenia are less specific terms that indicate increased and decreased total WBC count, respectively. When interpreting and reporting differential WBC count results, it is essential to evaluate the absolute cell counts (i.e., cells/^1). Relative or percent counts are simply a means for determining the absolute counts and have little or no inherent value for assessing an animal's condition. A 50% neutrophil count in a dog could be normal or represent neutrophilia or neutropenia, depending on the total WBC count.

Neutrophils and lymphocytes are the most numerous cell types in peripheral blood, and toxicological effects on leukocytes usually involve them. While direct effects on these two cell lines can and do occur (136), indirect effects, in response to study-related procedures or test material effects on other tissues, are much more common.

Physiological Leukocytosis

Excited or frightened animals may exhibit a physiological leukocytosis secondary to endogenous catecholamine release. Increased heart rate, blood pressure, and muscular activity shift cells from the marginal leukocyte pool (i.e., cells that adhere to the endothelium of small vessels or are sequestered in

vascular beds of tissues like the spleen) to the circulating leukocyte pool. The total WBC count may double in number. The specific cell type

< previous page page_1018 next page >

responsible for the majority of the increase varies with species because of species-dependent differences in normal distribution of leukocyte types. Neutrophilia is the most obvious change for dogs, while lymphocytosis is most conspicuous for rats. The physiological leukocytosis observed for primates is fairly evenly distributed between neutrophils and lymphocytes. Because physiological leukocytosis is most frequently observed in animals that are not accustomed to handling or blood collection, it is not unusual for a few animals to have notably high WBC counts only at the first blood collection interval for a study. Recognition of this phenomenon is critical in studies using few animals (usually dogs or monkeys) and only one pretreatment interval. Overinterpretation of the data might lead to the false conclusion that a test material has a myelosuppressive effect because posttreatment WBC counts, determined when the animal is less excited, may be much lower than pretreatment counts. By the same token, if the test material is an antineoplastic drug, and myelosuppression is a critical endpoint, strong consideration should be given to acquiring at least two pretreatment hematology samples to facilitate proper data interpretation.

Steroid- or Stress-Induced Leukocyte Response

This leukocyte pattern occurs following exogenous corticosteroid administration or when stressful conditions result in increased production of endogenous corticosteroids. It is characterized primarily by mature neutrophilia (immature neutrophils, such as bands, are absent), lymphopenia, and eosinopenia. Monocytosis may or may not be present. It is relatively unusual to observe this pattern for an entire group of animals on study, even though study-related procedures or administration of the test material appear to create conditions typically considered stressful. However, individual animals, especially those in moribund condition resulting from toxicity, often exhibit this pattern.

Neutrophilia and Neutropenia

Although their primary function is to protect the host from bacterial infections, neutrophils are a common component of many nonseptic inflammatory lesions as well. It is therefore not unusual to observe increased neutrophil counts secondary to a variety of inflammatory conditions resulting from test material toxicity or study-related procedures (e.g., chronic catheterization or repeated injections), with or without the involvement of an infectious agent. If severe enough, degeneration and necrosis of most tissues result in inflammation and a systemic neutrophil response. Hemolysis, for example, can be a potent stimulus for neutrophilia. In addition, various cytokines with therapeutic potential have been identified and produced that affect neutrophil kinetics directly and may result in mild to marked neutrophilic leukocytosis. The term *left shift* refers to an increased number of immature neutrophils (e.g., band neutrophils) in circulation, usually in response to an inflammatory lesion with a significant demand for neutrophils. Lesions that cause left shifts or marked neutrophilia are almost always easily identified, either by physical examination or at necropsy, and often involve invasion of damaged tissues by bacteria. The term *degenerative left shift* describes the combination of a normal or decreased absolute neutrophil count with more immature than mature neutrophils. It generally reflects a very severe infection as might occur with aspiration pneumonia, gastrointestinal perforation, or septicemia associated with bacterial contamination of an indwelling intravenous catheter. In conditions such as these, "toxic neutrophils" may be observed. These neutrophils have distinct morphological characteristics including cytoplasmic basophilia, vacuolation, and granulation and the presence of Dohle bodies (small, bluish-gray cytoplasmic inclusions made of aggregated rough endoplasmic reticulum).

Unless the test material is a potent cytotoxic agent (e.g., a conventional chemotherapeutic), the observation of severe neutropenia, with or without a left shift or toxic neutrophils, is generally limited to one or two individuals that have severe complications secondary to test material toxicity or study-related procedures. Leukocyte effects of cytotoxic agents, on the other hand, are typically observed in most or all of the animals in groups receiving toxic dose levels. Because mice and young rats normally have very low neutrophil counts (e.g., less than 1000//zl), recognition of neutropenia is more difficult for these species than for others. In addition, while a neutrophil count below 500/μl is generally considered an indicator of great risk for bacterial infection in humans, monkeys, and dogs, the same is not true for rodents.

Single or short-term administration of a potent cytotoxic agent is usually characterized by neutropenia within a few days to a week of treatment, followed by a recovery that may include the presence of immature neutrophils for a short time and may result in a rebound neutrophilia. Detection of these changes is dependent on the timing and frequency of hematology testing. Similarly, the appearance of the bone marrow, whether hypocellular or hypercellular, is also dependent on timing of sample collection. Hematology findings for test materials that directly injure pluripotent stem cells or rapidly dividing committed precursor cells are usually characterized by decreased numbers of reticulocytes,

platelets, neutrophils, monocytes, eosinophils, and possibly lymphocytes. Selective damage of granulocyte precursors without affecting erythropoiesis or thrombopoiesis is unusual.

Page 1020
Lymphocytosis and Lymphopenia
Lymphocytes are responsible for a wide variety of immune system functions. There are several subpopulations of lymphocytes, but they are indistinguishable by light microscopy. Lymphocytes are relatively long-lived compared with other leukocytes and have the ability to leave the vascular system through venules in lymph nodes and eventually reenter the blood via the thoracic duct. Lymphocytosis is an uncommon test material-related effect, although it may be observed in conjunction with chronic inflammatory lesions, especially in rodents, or with administration of test materials that are antigenic and elicit an immune response by the test animals. Physiological leukocytosis should be considered whenever lymphocytosis is present in only a few animals.
Lymphopenia is most frequently observed as part of the stress- or steroid-induced leukocyte response. Moribund animals are commonly lymphopenic. Cytotoxic test materials often cause decreased absolute lymphocyte count, but the magnitude of the decrease is usually less prominent than that for neutrophils. In rodents, however, it may be easier to detect the effect on lymphocytes because of the normally high number of lymphocytes compared with neutrophils. During recovery from effects of cytotoxic test materials, lymphocyte counts may remain decreased longer than neutrophils and typically do not exhibit a prominent rebound response. Because of the many subpopulations of lymphocytes, it is difficult to gauge the biological importance of small decreases in absolute lymphocyte count. Selective reduction or elimination of a subpopulation may occur (e.g., the human immunodeficiency virus effect on CD4+ lymphocytes) without greatly affecting the total lymphocyte count. Evaluation of the overall health of the animals and findings that might suggest immunosuppression are essential correlates that help to place the importance of small changes into context.
Monocytes, Eosinophils, and Basophils
Absolute counts for these cell types are generally quite low (e.g., < 1000/+l), and effects on these cells are infrequently observed in toxicology studies. As with neutrophils and lymphocytes, increases in circulating numbers of these cells are generally secondary phenomena unless the test material is a hematopoietic growth factor or other cytokine (e.g., interleukin-5 increases eosinophil count) that directly stimulates cell production. Eosinophils are part of the body's defense against helminthic parasite infections, and eosinophilia is occasionally observed in nonhuman primates with a heavy parasite load. Eosinophilia is also observed secondarily to some hypersensitivity reactions. A primary function of monocytes is phagocytosis and digestion of large particulate matter, such as senescent cells and necrotic cell debris. Monocytosis may occur secondarily to any condition with substantial tissue destruction, such as widespread inflammation, tumor-associated necrosis, or hemolytic anemia. Because of their normally low circulating numbers, decreases in these cell types are often difficult to detect. However, eosinopenia and monocytopenia are sometimes identified following administration of chemotherapeutic agents, and eosinopenia is occasionally observed as part of the stress-induced leukocyte pattern. Effects on basophil counts are extremely rare.
Leukemia
In most, if not all, 2-year carcinogenicity studies using rodents, a small percentage of the animals will develop leukemia, a neoplastic proliferation of a hematopoietic cell line. Although leukemias are often characterized by markedly elevated white blood cell counts and the presence of neoplastic cells (e.g., blasts) in circulation, some animals with leukemia exhibit neither of these prominently, and the diagnosis is best made by histopathological examination of tissues infiltrated with the neoplastic cells. The odds of correctly identifying animals with leukemia are much greater by doing routine histopathology than by doing periodic examinations of the blood at regularly scheduled intervals. Even when neoplastic cells are present in peripheral blood, it is often difficult to determine from which cell line they were derived (e.g., granulocytic, lymphocytic, myelomonocytic, etc.) because immature, anaplastic, or blast-stage cells from different cell lines can be indistinguishable by light microscopy using standard staining techniques.
The most commonly observed leukemia in laboratory animals is large granular lymphocyte leukemia of Fischer 344 rats (119). As many as 30–40% of Fischer 344 rats may develop this leukemia, also known as mononuclear cell leukemia, in the second year of a carcinogenicity study. The neoplasm appears to arise in the spleen and commonly infiltrates other tissues, particularly the liver. Affected rats consistently develop an immune-mediated hemolytic anemia and often exhibit hyperbilirubinemia and elevated liver enzyme activities in the serum. Neoplastic cells in peripheral blood appear as large, immature lymphocytes and may contain prominent azurophilic granules. Erythrophagocytosis by the neoplastic cells is occasionally observed.
Platelets
When blood vessels are damaged, platelets quickly adhere to the subendothelium, undergo a shape

change, and begin to aggregate, forming a primary platelet plug that is sufficient to control bleeding from minor injuries to small vessels. These activated platelets secrete a var-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1020.html[2010/10/28 20:19:38]

iety of substances that stimulate vasoconstriction and promote fibrin formation. Fibrin serves to cement the aggregated platelets into a stable hemostatic plug. Healthy endothelial cells in close proximity to the damaged vessel release inhibitors of platelet aggregation and fibrin formation in order to limit the size of the clot.

Thrombocytosis is typically asymptomatic, although extremely high platelet counts may increase the risk of thrombosis. Signs of thrombocytopenia include petechial and ecchymotic hemorrhages, most commonly observed in mucous membranes or at mucocutaneous sites, epistaxis, melena, menorrhagia, and prolonged bleeding from small wounds such as venipuncture sites. These signs typically do not occur spontaneously unless the platelet count is very low (e.g., less than 20,000/jul) or there is some type of hemostatic challenge (e.g., surgery) (9). Test materials that affect platelet function have the potential to cause the same clinical signs as marked thrombocytopenia, but the tendency to do so is much less because of the complexity of platelet function and the presence of alternative or redundant pathways in vivo for the various platelet functions. Platelet function tests such as bleeding time and platelet aggregation may be beneficial when evaluating safety of therapeutic agents related to coagulation and platelet function, but it is important to recognize the considerable analytical and interanimal variability for these tests. Group results may be less meaningful than assessment of results from individual animals before and after test material administration.

Thrombocytosis

Unless the test material is a hematopoietic growth factor (e.g., thrombopoietin), increased platelet count is almost never a primary effect. The terms *reactive* or *secondary thrombocytosis* have been used to describe the increased platelet count observed in conjunction with generalized bone marrow stimulation as observed with hemolytic anemia, blood loss, and many types of acute and chronic inflammation. Release of cytokines such as interleukin-6 and interleukin-11 may be at least partially responsible for the increased platelet production (141) in some of these conditions. Acute, transient thrombocytosis may occur in association with physiological leukocytosis because catecholamine-induced splenic contraction releases platelets into circulation that were sequestered within the sinusoids of the spleen. A rebound thrombocytosis typically follows significant thrombocytopenia caused by test materials such as chemotherapeutic agents that reversibly inhibit platelet production or injure megakaryocytes. The increased platelet counts observed in toxicology studies are generally small and not likely to have any biological significance.

Thrombocytopenia

Decreased platelet count is a relatively common spurious finding associated with difficult venipuncture or inadequate anticoagulation of the blood sample and subsequent in vitro platelet aggregation. When this occurs, platelet clumps can usually be observed at the feathered edge of the blood film. Although most typically a problem detected for individual mice and rats, spuriously low platelet counts can sometimes appear group related because animals receiving the test material may be more difficult to bleed as a result of poor health, dehydration, or small size relative to the control animals.

When not a spurious finding, decreased platelet count results from decreased production or increased consumption of platelets. Test materials that reduce erythroid and myeloid cell production, such as chemotherapeutic agents, frequently inhibit platelet production as well. Moderately to markedly reduced platelet counts tend to occur a few days after obvious reductions in neutrophil and reticulocyte counts because the circulating life span of platelets is about 7 to 10 days. Thrombocytopenia due to increased consumption of platelets can occur secondarily to acute lesions of highly vascular tissues such as the gastrointestinal tract or result from extensive hemorrhage, especially from multiple sites. If lesions affecting blood vessels are severe and widespread, disseminated intravascular coagulation may develop, and platelet counts will be markedly decreased. Immunemediated thrombocytopenia, like immune-mediated hemolytic anemia, has been associated with many drugs (54) but is largely an idiosyncratic phenomenon and is therefore detected infrequently in preclinical toxicology studies. When observed, there are typically only one or two animals affected, and these animals may or may not be in the high-dose group. Immune-mediated thrombocytopenia and immune-mediated hemolytic anemia may occur together. Antiplatelet antibody is very difficult to detect, and the best evidence that thrombocytopenia is immune mediated may come from a rechallenge exposure with the test material following cessation of treatment and recovery. Upon rechallenge, platelet count should drop acutely if the mechanism is immune-mediated destruction.

Bone-Marrow Smear Evaluation

The most important aspect of bone marrow smear evaluation is understanding when it is indicated. Although preparation of smears is advisable for most regulated, repeated-dose toxicology studies,

evaluation of those smears is usually unnecessary. The standard hematology tests provide considerable information con-

earning bone marrow function, and if results from these tests are unaffected, it is very unlikely that bone marrow evaluation will provide any additional knowledge concerning potential significant test material effects on the hematopoietic system. Even when results of hematology tests are affected by administration of a test material, bone marrow evaluation has no benefit if mechanisms for the hematology findings are already evident. For example, regenerative anemias indicate a normal erythropoietic response to hemorrhage or hemolysis, and bone marrow evaluation would simply confirm the presence of erythroid hyperplasia. Neutrophilic leukocytosis in response to an inflammatory condition is normal, and bone marrow evaluation would only confirm granulocytic hyperplasia. The main indications for bone marrow smear evaluation in toxicology studies are moderate to marked nonregenerative anemia, leukopenia, or thrombocytopenia (or any combination of the three) with no apparent etiology. If the effects observed in peripheral blood are relatively small, it is less likely that bone marrow smear evaluation will be beneficial. The primary objective of the bone marrow smear evaluation is to assess the relative numbers of precursor cells, their morphologic appearance, and whether they are developing or maturing normally. Miscellaneous findings such as increased iron stores, plasma cell hyperplasia, or excessive cytophagia may also be recognized.

There are multiple approaches to bone marrow smear evaluation. Regardless of the approach taken, the findings must be interpreted in conjunction with peripheral blood test results. The most simplistic and least informative bone marrow evaluation is to determine the myeloid: erythroid (M:E) ratio by counting at least 500 cells and differentiating the granulocytic cells from the erythroid cells. An increased M:E ratio may indicate granulocytic hyperplasia, erythroid hypoplasia, or both. If the animal has a high neutrophil count and its hematocrit is normal, then an increased M:E ratio likely indicates granulocytic hyperplasia. If the animal has a normal neutrophil count and a nonregenerative anemia, then an increased M:E ratio likely indicates erythroid hypoplasia. In both cases, the outcome of the M:E ratio could have been predicted from the peripheral blood results. If the animal is neutropenic and has a nonregenerative anemia, an increased M:E ratio only indicates that there are relatively more granulocytic cells than erythroid cells. It does not help to understand the underlying problem.

The most time-consuming and labor-intensive bone marrow evaluation is to perform a bone marrow cell differential count by differentiating the cell type of at least 500 cells. When completed, the M:E ratio can be calculated from the results. This evaluation yields more information but at a very high cost. Differential counts provide numerical information concerning the relative numbers of different precursor cells and whether a cell line is maturing normally. Unusual or abnormal morphological characteristics of the cells must be described separately.

The most cost-effective and informative approach to bone marrow evaluation is the subjective cytological examination. In this approach, the bone marrow smear is examined in much the same manner as a morphologic pathologist examines a histologic section of liver, and a diagnosis or interpretation is recorded. The person performing the examination, usually a veterinary pathologist or clinical pathologist, assesses the quality and cellularity of the smear, the presence and relative number of precursors for each of the three major cell lines (erythrocytes, granulocytes, and platelets), and the maturation of each of the cell lines. Abnormal morphology is noted, as well as unusual numbers or characteristics of other cell types such as lymphocytes, plasma cells, monocytes, macrophages, and mast cells. A diagnosis or interpretation is rendered based on the examination of the smear and the results of the peripheral blood tests. Because bone marrow smears are relatively poor indicators of the actual cellularity of the bone marrow, it is also prudent to consider the histopathological findings for sections of sternum, rib, or possibly femur. While these sections are inadequate for evaluating individual cell types and abnormal cell morphology, they can provide a good assessment of overall cellularity. Ultimately, the goal of the bone marrow smear evaluation is to determine if administration of the test material has negatively impacted the number and/or maturation of hematopoietic cell precursors (103). For example, the absence of megakaryocytes indicates thrombocytopenia is due to failure of platelet production rather than increased platelet consumption peripherally. Increased numbers of normal-appearing megakaryocytes indicate thrombocytopenia is due to a consumptive process.

Coagulation

The clotting mechanism or "cascade" has traditionally been divided into two pathways. In vivo, the intrinsic pathway begins with the activation of zymogen factor XII following exposure to negatively charged subendothelial components such as collagen. Factors XI, IX, and VIII are also part of the intrinsic pathway. The extrinsic pathway begins with the activation of zymogen factor VII following exposure to tissue factor (also called tissue thromboplastin) expressed by cells deep in the vessel wall. Both pathways share the same terminal sequence of events including activation of factor X, con-

version of prothrombin to thrombin, and conversion of fibrinogen to fibrin. It is thought that the extrinsic pathway is the primary initiator of coagulation in vivo (70). The intrinsic and extrinsic pathways are routinely evaluated by the activated partial thromboplastin time (APTT) and one-stage prothrombin time (OSPT or PT), respectively. The activated coagulation time (ACT) test is a simple, rapid measure of the intrinsic pathway that does not require a coagulation analyzer (17, 107, 140). These coagulation assays are relatively insensitive and nonspecific. Activity of a single clotting factor must be reduced to approximately 30% of normal before noticeably prolonged times are detected for an individual animal. When the results from groups of animals are com pared, statistically significant differences are occasionally observed that are smaller than what would generally be considered an important change for an individual animal (e.g., less than 2 s of difference between the means for the control and high-dose groups). The toxicological sig nificance of differences such as these is sometimes difficult to determine. While they clearly do not represent an effect likely to be associated with a bleeding diathesis for indi vidual animals, they may be an indication of an important change in coagulation homeostasis. It may be valuable to design a longer study or increase the dose level to see if the effect is repeatable, dose-related, and associated with clinical signs.

Under the conditions of most toxicology studies, where animals are exposed to high concentrations of a test material for a prolonged period of time, any major effect on the production of a clotting factor will likely result in a clinically obvious bleeding diathesis. The adminis tration of vitamin K antagonists such as dicumarol or the ingestion of synthetic or poorly absorbed fat substi tutes is associated with bleeding and prolonged APTT and PT because the fat-soluble vitamin K is required by the liver for production of functional forms of factors II, VII, IX, and X. In theory, PT will be affected before APTT because factor VII has the shortest half-life of the clotting factors. Although nearly all the clotting factors are synthesized by the liver, APTT and PT are insensitive measures of liver function. Because of the liver's large functional reserve, liver injury must be rela tively severe before coagulation times are noticeably affected. In addition to the previously mentioned thrombocytopenia, disseminated intravascular coagula tion is characterized by depletion of all clotting factors, including fibrinogen, and moderately to markedly pro longed coagulation times. In many cases of disseminated intravascular coagulation, the plasma samples fail to clot during the coagulation assays.

Similarly to platelet count, coagulation times can be spuriously prolonged by difficult blood collection or poor collection technique. The combination of low platelet count and prolonged coagulation times, in an otherwise healthy animal, is an indication of poor sample quality. Inherited factor VII deficiency affects a small number of laboratory beagles (38). These animals can usually be distinguished during pretreatment screening by a PT that is 2 or 3 s longer than those of the other animals acquired for the study. Although the deficiency rarely causes a clinical problem, it would be inappropriate to use these animals if the test material is known or suspected to affect coagulation. PT and APTT can both be artifactually prolonged because of excessive sodium citrate anticoagulant in the plasma sample (79, 96). This could occur if insufficient blood volume is added to standardized collection tubes or if the animal's hematocrit is elevated because of hemoconcentration (e.g., dehydration) or drug-induced polycythemia. Normal coagulation times vary from one laboratory animal species to another. Among the notable differences are the relatively fast PTs for dogs (e.g., 6 to 8 s) and slow PTs for guinea pigs (e.g., 30 to 40 s).

CLINICAL CHEMISTRY TESTS AND INTERPRETATION

Routinely performed clinical chemistry tests provide information concerning hepatocellular and biliary integrity and function, renal function, carbohydrate, lipid, and protein metabolism, and mineral and electrolyte balance. Modern clinical chemistry analyzers require very small sample volumes, and complete biochemical profiles can be obtained from rats at multiple intervals within a study without compromising the health of the animals because of excessive blood collection. Less than 250 µl of serum is needed to perform as many as 20 tests. Few of the common test methods require modification for testing animal samples.

Hepatocellular and Hepatobiliary Integrity and Function

Many routine clinical chemistry tests can be affected by liver toxicity because of the liver's critical metabolic, synthetic, and excretory functions and the abundant enzymatic machinery needed to perform these functions (110, 120). Conversely, a significant loss of liver tissue with little or no detectable change in routine tests is possible because of the liver's large functional reserve. No single test is superior for detecting all of the various types of liver toxicity, but the pattern of abnormal findings in a battery of tests may help characterize the location and severity of liver lesions (21).

Liver Enzymes

Many enzymes normally present within hepatocytes exhibit increased serum activity following hepatocellular

injury with degeneration and necrosis. The utility of a particular enzyme depends on factors such as relative specificity to liver, intrahepatic location, intracellular location, the concentration gradient between cell and serum, serum half-life, in vitro stability, and economy of measurement (12, 13, 74). The most frequently used enzymes to assess hepatocellular injury are alanine aminotransferase (ALT), aspartate aminotransferase (AST), sorbitol dehydrogenase (SDH), glutamate dehydrogenase (GDH), and lactate dehydrogenase (LDH). Each has advantages and disadvantages. The aminotransferases, ALT and AST, were formerly referred to as serum glutamic pyruvic transaminase (SGPT) and serum glutamic oxaloacetic transaminase (SGOT), respectively, and are the most commonly measured of all serum enzymes. Although sometimes included under the heading of liver function tests, serum activities of hepatic enzymes do not evaluate liver function.

In general, ALT is the most useful enzyme for detection of hepatocellular injury in the majority of laboratory animal species. Although the enzyme is present in many tissues, its greatest concentration in most species is within hepatocytes, and for practical purposes, significant elevations of serum ALT activity result only from release of ALT by hepatocytes. Species for which ALT is less useful because of relatively low hepatocyte concentrations include the guinea pig (28) and large domestic animals such as pigs, goats, sheep, cows, and horses (13, 30, 78). Because the enzyme is primarily cytosolic, and its concentration within the cell is up to 10,000 times greater than that in the serum, ALT may enter the serum in any condition that sufficiently alters cell membrane permeability. In addition to simple leakage from degenerating or necrotic cells, there may be other mechanisms for movement of the enzyme across the cell membrane because high serum activities of ALT are occasionally observed with no apparent cell death. The magnitude of serum activity elevation is proportional to the number of affected hepatocytes and is not necessarily indicative of the reversibility of the lesion. However, the greatest elevations result from severe lesions affecting a large portion of the liver. As a general guideline, activities for ALT in excess of 200 IU/L are usually accompanied by histopathologic evidence of hepatocellular injury, while activities below this level may or may not have correlative findings. Following an acute but reversible hepatotoxic event, serum ALT activity rises relatively rapidly, peaks within 1 or 2 days, and then declines over the next few days. Significant hepatotoxicity can go undetected if clinical pathology tests are delayed for 1 or 2 weeks following a single administration of test material. Prolonged elevations following a single insult may reflect increased production of ALT in regenerative liver tissue or continued loss of ALT from cells in close proximity to the primary lesion that undergo degenerative changes as a result of the altered microenvironment.

Increased serum ALT activity does not always indicate primary hepatocellular injury. Biliary disease or toxicity and bile duct obstruction may cause increased serum ALT activity at least in part due to the effect of retained bile salts on the cell membranes of neighboring hepatocytes. Muscle damage, if severe and extensive, can increase serum ALT activity in the absence of hepatic injury (123, 133). Increased intracellular activity of ALT as a result of induction will cause serum ALT activity to increase proportionately. Drugs such as corticosteroids and anticonvulsants appear to induce ALT production. Because these drugs may also have pathologic effects on hepatocytes, it may be difficult to determine whether an elevation is due to enzyme induction or drug-induced disease.

Interpretation of potential effects on serum ALT activity in monkeys may be complicated by the presence of subclinical, enzootic hepatitis A infection (111). Transiently increased serum ALT activity correlates with seroconversion to the virus and periportal inflammation. Because animals entering a facility may not have been exposed to the virus previously, it is possible to observe sporadic, high ALT activities (e.g., up to approximately 300 IU/L) for a few individual monkeys during the course of a toxicology study. Some facilities choose to bank serum collected from monkeys before a study is initiated for possible serologic testing to help clarify ambiguous study findings for ALT activity. Interpretation of serum ALT activities for mice is complicated by considerable interanimal variability, much of which is probably due to the effects of handling (122). In toxicology studies using mice, it is not unusual for a few animals, including the control animals, to have much higher serum ALT activities than those of the majority (e.g., 200 IU/L vs. 40 IU/L). The cause of these high activities is thought to be physical damage to the liver, especially when mice are handled by grasping the body. Unfortunately, if the only animals affected happen to belong to the high-dose group, it may be difficult to rule out an effect of the test material.

Serum AST and LDH activities tend to parallel serum ALT activity with respect to liver damage, but these enzymes are much less liver specific because of high concentrations in other tissues, especially muscle. Rodents tend to exhibit increased interanimal variability for these enzymes, some of which may be due to contamination with muscle tissue during blood collection procedures such as cardiac puncture and

rupture of the retroorbital plexus. There is little advantage to determining both of these enzyme activities, and AST is generally preferred. Elevations in serum AST activity caused by hepatotoxicity are usually less pronounced than concurrent elevations in serum ALT activity. Since a portion

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1024.html[2010/10/28 20:19:40]

of intracellular AST is located in mitochondria, a more severe injury may be necessary for release of like quantities of AST. As with ALT, drugs such as corticosteroids and anticonvulsants may induce production of AST.

Decreased serum activities of ALT and AST are occasionally observed in toxicology studies. Among the potential causes for these findings are decreased hepatocellular production or release of the enzymes, inhibition or reduction of the enzymes' activity, and interference with the enzyme assay. The most widely recognized of these causes involves an effect on pyridoxal 5′-phosphate (vitamin Be), a coenzyme cofactor required for full catalytic activity of the aminotransferases. If a test material negatively affects this cofactor, directly or indirectly, serum aminotransferase activities decrease (31, 37, 132). Because the aminotransferase assays can be run with or without additional pyridoxal 5′-phosphate, a test material-related effect on pyridoxal 5′-phosphate can be identified by correction of an apparent decrease in aminotransferase activity when the assay is repeated with additional cofactor. Regardless of the mechanism involved, decreased serum activities of the aminotransferases have not been shown to correlate with toxicologically significant effects on the liver.

Serum SDH and GDH activities have been recommended as good indicators of hepatic toxicity in laboratory animal species (21, 40, 135) because increased serum activities are liver specific and relatively sensitive. SDH is a cytosolic enzyme, and GDH is mitochondrial. Elevations in serum SDH activity generally return to baseline levels faster than for other liver enzymes because of a short serum half-life. The addition of either of these tests to a standard clinical chemistry profile is a good choice if potential liver toxicity is of particular interest. The major drawback for both, however, is the assay. Although GDH is commonly used in Europe and both enzymes have been used in veterinary medicine for assessing liver injury in large domestic animals, simple test kits and standard automated procedures are unavailable because these enzymes lack popularity in human medicine in the United States.

Several enzymes that originate from hepatocytes and biliary epithelial cells are increased in serum as a result of increased production following intrahepatic or extrahepatic cholestasis or in conjunction with biliary hyperplasia. These include serum alkaline phosphatase (ALP), gamma-glutamyltransferase (GGT), leucine aminopeptidase (LAP), and 5′-nucleotidase (5′-N). Of these, the most commonly measured are ALP and GGT.

Serum ALP activity results from a mixture of membrane-localized isoenzymes, the product of different genes, and isoforms, the product of posttranslational modifications. In humans, at least four genes have been identified that code for different ALP isoenzymes: tissue nonspecific (found in liver, bone, and kidney), intestinal, placental, and germ cell. In most laboratory animals, only two genes have been identified: tissue nonspecific and intestinal. Although the ALP activities originating in liver, bone, and kidney are the product of the same gene and therefore are isoforms, they can be distinguished because of differences in degree of posttranslational glycosylation and tissue of origin and have classically been referred to as isoenzymes (64, 65). Dogs have a unique isoform, known as the corticosteroid-induced ALP isoenzyme, that is a hyperglycosylated form of the intestinal ALP isoenzyme. The contribution of each isoenzyme to the total serum ALP activity is dictated by tissue production and serum half-life.

In normal dogs, serum ALP activity is a combination of the liver, bone, and corticosteroid-induced isoenzyme activities. The relative amount of corticosteroid-induced ALP activity is small compared with the others, and it is completely absent for most dogs. In young puppies, the bone isoenzyme may be responsible for up to 95% of total serum ALP activity, while in adult dogs, the liver isoenzyme is the predominant form. Intestinal and kidney ALP isoenzymes are virtually absent in dog serum because of extremely short serum half-lives, and diseases affecting these tissues do not increase serum ALP activity. In normal rats, serum ALP activity is a combination of the liver, bone, and intestinal isoenzyme activities. The intestinal isoenzyme activity increases after feeding and is reduced with fasting (130). Because toxicology studies are routinely initiated with young, growing animals, it is common for total serum alkaline phosphatase to decrease during the course of the study as a result of reduced osteoblast activity (the origin of bone ALP) in the maturing animals.

In spite of the number of ALP isoenzymes, serum ALP activity is most frequently considered a measure of cholestasis. It is a sensitive indicator of cholestasis in the dog and usually increases well before other markers such as GGT and total bilirubin. Because of cell swelling and pressure obstruction of small bile ductules, primary hepatocellular toxicities often cause enough intrahepatic cholestasis to elevate serum ALP activity. Periportal lesions result in higher activities than do centrilobular lesions. Extrahepatic cholestasis, as might occur with pancreatitis, biliary calculi, or complications of bile duct cannulation, stimulates higher serum ALP activity than intrahepatic cholestasis. The degree of elevation, however, is rarely sufficient for differentiating primary hepatocellular toxicity from primary biliary toxicity. In contrast

to the dog, the value of serum ALP activity for distinguishing cholestatic lesions in monkeys is reduced because of marked interanimal variability.

Although the lack of specificity is sometimes considered a fault of ALP, the potential for detecting increases in serum ALP activity due to effects on bone is actually

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1025.html[2010/10/28 20:19:40]

Page 1026

a benefit of this test. Elevations of serum ALP activity can be the first indication of a toxic effect on bone formation. Elevations of serum ALP activity due to increased osteoblast activity tend to be less pronounced than those due to cholestasis (e.g., no greater than two- to threefold higher than control animals). If the test material is administered for sufficient duration, the effect on ALP activity is usually accompanied by clinical or histopathological evidence of effects on bone.

Drugs such as anticonvulsants and corticosteroids can induce production of the liver ALP isoenzyme, with or without evidence of hepatobiliary disease. Following corticosteroid administration to dogs, liver ALP activity increases within a few days, while the corticosteroid-induced ALP activity does not increase noticeably for about 10 days (113). Although an increase in corticosteroid-induced ALP activity has been observed in dogs with a variety of chronic disease conditions (65) and may be related to increased endogenous corticosteroid release, this isoenzyme has not been closely evaluated in toxicology studies using dogs.

The measurement of serum GGT activity has gained popularity because it is more specific than ALP and was shown to be effective in certain models of biliary toxicity in the rat (82). Although the highest tissue concentrations of this membrane-localized enzyme are in the kidney and pancreas, serum elevations have been reported only with hepatobiliary toxicity and following induction by drugs that stimulate microsomal enzyme production (56, 110). Unlike ALP, GGT is not affected by bone growth or disease. Furthermore, its serum activity is less likely to increase secondary to primary hepatocellular toxicity or intrahepatic cholestasis due to hepatocellular swelling. In rodents, serum GGT activity is often undetectable, and even small increases may be significant.

Serum LAP and 5′-N activities have been investigated as alternatives to ALP and GGT but have not found general acceptance. In some models of liver toxicity, 5′-N appears to be more sensitive than ALP or GGT (21, 22).

The sensitivity or predictive value of any liver enzyme is largely dependent on the models of hepatotoxicity used to make those determinations. Acknowledgment of this fact is at least partially responsible for the practice of including multiple liver enzymes in the clinical chemistry test panels for toxicology studies. The absence of change in liver enzyme activities does not necessarily rule out the possibility of hepatotoxicity or hepatic dysfunction. Elevations may be missed because of poor timing for clinical pathology testing, and excessive variability within the control group (especially for mice and monkeys) may obscure an effect on treated groups. Furthermore, serum liver enzyme activities are not hepatic function tests. The liver can be dysfunctional in the absence of significant cholestasis or ongoing hepatocellular degeneration and necrosis. Animals with end-stage liver cirrhosis, for example, can exhibit normal serum enzyme activities. In contrast to the liver enzymes, serum total bilirubin concentration is primarily a liver function test. In the absence of hemolysis, hyperbilirubinemia indicates liver dysfunction.

Bilirubin

Bilirubin results from the breakdown of heme by cells of the mononuclear phagocyte system. Hemoglobin from senescent erythrocytes accounts for approximately 85% of all serum bilirubin. When macrophages release bilirubin into circulation, it is known as free, unconjugated, prehepatic, or indirect bilirubin. It is water insoluble and circulates bound to albumin. Hepatocytes efficiently remove unconjugated bilirubin from plasma and prepare it for removal from the body by a four-step process that includes uptake, conjugation, secretion, and excretion. Secretion of conjugated bilirubin across the canalicular membrane is the rate-limiting step in the process, and small amounts of conjugated or direct bilirubin escape into plasma. Conjugated bilirubin is not bound to albumin and is freely filtered through the glomerulus. In most species, conjugated bilirubin is completely reabsorbed by renal tubular epithelial cells unless the amount of filtered bilirubin is excessive. In the dog, the renal threshold is low and traces of bilirubin are normal in concentrated urine.

Even though the liver is a frequent target organ, increased total bilirubin concentration, whether due to conjugated bilirubin, unconjugated bilirubin, or both, is a relatively uncommon finding in toxicology studies because of the large functional reserve of the liver. In the dog, a 70% hepatectomy will not increase total bilirubin concentration.

Conjugated hyperbilirubinemia occurs as a result of impaired secretion of bilirubin, cholestasis, or both. Because bilirubin secretion is the rate-limiting step, any disease that damages enough hepatocytes can potentially increase serum conjugated bilirubin concentration. Periportal lesions cause higher serum bilirubin concentrations than do centrilobular lesions, and extrahepatic cholestasis causes higher serum bilirubin concentration than does intrahepatic cholestasis. When increased bilirubin concentration results from a cholestatic process, particularly in the dog, serum ALP activity is elevated.

Unconjugated hyperbilirubinemia occurs almost exclusively as a result of relatively severe, acute

hemolysis. If hepatocytes cannot process the large amount of unconjugated bilirubin produced by macrophages during a hemolytic episode, serum bilirubin concentration increases. A hemolytic event sufficient to overload a normal liver always produces other findings indicative of hemolysis. It is possible, however, for

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1026.html[2010/10/28 20:19:41]

relatively modest hemolysis to cause unconjugated hyperbilirubinemia if hepatic function is already compromised. Although a number of nonhemolytic, unconjugated hyperbilirubinemia syndromes are known, these syndromes are usually due to hereditary defects in the uptake and conjugation of free bilirubin.

Unconjugated (or indirect) bilirubin can be differentiated from conjugated (or direct) bilirubin by the Van den Bergh test. The test is used clinically to help distinguish prehepatic causes of hyperbilirubinemia, such as hemolysis, from hepatic or posthepatic causes such as hepatitis or biliary obstruction. In well-designed toxicology studies, the combination of clinical observations, other laboratory data (e.g., hematocrit or liver enzyme activities), and anatomical pathology findings (e.g., hemosiderin accumulations in splenic macrophages or periportal hepatocellular necrosis) are usually more than sufficient to determine the primary mechanism for any observed hyperbilirubinemia. Laboratory determination of direct and indirect bilirubin is rarely necessary and should not be included as part of the routine panel of tests performed in toxicology studies.

Decreased serum bilirubin concentration is occasionally associated with administration of test materials that induce microsomal enzyme production (56). Human patients receiving phenobarbital therapy have lower serum bilirubin levels than the general population as a whole (69). Enzyme induction apparently enhances the metabolism and excretion of bilirubin and could potentially mask an otherwise elevated bilirubin level.

Bile acids are synthesized from cholesterol by hepatocytes, conjugated to an amino acid, secreted into the biliary system, and excreted into the intestine where they facilitate fat absorption. There is an efficient enterohepatic circulation of bile acids with most of the reabsorption occurring at the level of the ileum. Portal blood conveys the bile acids to the liver for uptake, reconjugation, and resecretion. Any toxicity of the liver has the potential to alter one of the steps in bile acid metabolism and cause increased serum bile acid concentration. Like bilirubin concentration, bile acid concentration is a measure of a hepatic function. Although not commonly used in toxicology studies, serum bile acid concentration is considered a sensitive and specific test for hepatobiliary disease (24). Alone, however, increased serum bile acid concentration does not discriminate between different types of hepatic lesions.

Miscellaneous Parameters

The liver is wholly or partially responsible for the synthesis of many substances including glucose, cholesterol, urea nitrogen, and a variety of proteins. Severe hepatocellular dysfunction can cause decreased serum urea nitrogen concentration, hypoglycemia, hypocholesterolemia, hypoproteinemia (especially hypo albuminemia), and prolonged coagulation times. On the other hand, liver disease can also result in hypercholesterolemia and hyperglobulinemia. The patterns of change caused by different types of liver toxicity, whether primary or secondary (e.g., hypoxia-induced centrilobular necrosis), are varied, but often overlapping. Examination of the entire biochemical profile, along with other clinical pathology and anatomical pathology findings, is necessary to properly evaluate potential liver toxicity.

Renal Function

Serum urea nitrogen and creatinine concentrations, in conjunction with urine specific gravity or urine osmolality, are the most common tests used to evaluate renal function (10, 52, 83, 101, 116). Although easy and inexpensive to perform, these tests are relatively insensitive to small effects on the kidney, and there are a number of nonrenal causes for changes in their results.

Urea is synthesized by the liver from ammonia that is absorbed from the intestine or produced by endogenous protein catabolism. Urea is freely filtered through the glomerulus and excreted in urine. Some urea is reabsorbed passively with water at the level of the proximal tubule; the amount reabsorbed is inversely related to rate of urine flow through the tubule. Serum urea nitrogen concentration is therefore affected by the rate of urea production, the glomerular filtration rate (GFR), and flow rate of urine through the renal tubule. Increased serum urea nitrogen concentration, termed azotemia, is categorized as prerenal, renal, or postrenal.

Prerenal azotemia occurs as a result of increased urea synthesis or decreased renal blood flow. Increased urea synthesis results from consumption of high-protein diets or conditions that increase protein catabolism such as starvation, fever, infection, tissue necrosis, and high gastrointestinal hemorrhage. Decreased renal blood flow, which decreases GFR, results from conditions such as dehydration (the most common cause of increased urea nitrogen in toxicology studies), cardiovascular disease, or shock. Changes in serum urea nitrogen concentration caused by increased urea synthesis are typically small. Changes caused by decreased renal perfusion may also be small, but if GFR is severely affected, the increase in urea nitrogen is indistinguishable from that which would occur due to primary renal failure. The causes of prerenal azotemia typically do not affect the ability of the kidney to

concentrate urine. If dehydration is the cause of increased serum urea nitrogen concentration, urine specific gravity and urine osmolality will usually be increased, and urine volume will be decreased, because the kidneys attempt to conserve water. It is not unusual to observe very small, but statistically significant, differ

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_1027.html[2010/10/28 20:19:41]
