Acknowledgments
Appreciation is warmly expressed to the many people who contributed knowingly and otherwise to the Fourth Edition of this book. The editor most heartily thanks the contributors, who revised chapters or prepared new chapters, for keeping in mind that thoughtfully worded information is greatly appreciated by the reader. I am also indebted to the contributors for their combined expertise making a volume of this breadth possible. I thank Colleen Pritchard, Sandra Smith, Judith Curran, Mary Beth Gannon and Dana Pedersen for their skillful editing of the manuscript. Appreciation also is expressed to the staff of Taylor & Francis both in Philadelphia and London.

Foreword to the Third Edition

Until 1982 when the First Edition of this book was published, there was no specific source to which a student or an investigator could turn for a comprehensive presentation of the methods used in modern toxicology. For anyone who was trying to teach the subject, the book filled a great void for both the teacher and the student. The book appeared at a time when technical achievements in the field related to toxicology were undergoing tremendous refinements. Techniques and the tools of experimental biology, pathology, mathematics, engineering, physics, and analytical/biological chemistry, which had been barely conceived 20 years earlier, were in common use. The rapid growth of toxicology at that same time created a need for scientists from all of the above fields to apply their expertise to the science of toxicology. Toxicology borrowed freely from these related sciences so that a developing, modern, scientifically acceptable body of procedures became identified as the methods of toxicology. Prior to the span of a single human life, the methods of toxicology consisted of some general, short term test for the determination of the lethal and irritant qualities of chemicals on animals. The First Edition of this book was truly the first to chronicle the overall aspects of this difficult area of toxicology. The expotential rate of growth of toxicology continues and the Third Edition of the book continues to be an authoritative and comprehensive source of the methods that are currently used in this science.

It toxicology can be appropriately defined as the study of the harmful effects of chemicals on biologic systems, it must then embody a systemized knowledge of the effects of chemicals which are introduced into the simplest, as well as the most complex, of all biologic systems and methods must be available to accomplish these experiments. The availability of methods to detect the harmful effects of chemicals allows for the creation of data, but those data become useful in toxicology only after they are suitably interpreted. An additional link toward understanding the subject to toxicology is the placing of results obtained from the available methods in their proper relation and perspective to the whole picture of the role that toxicology can play for the improvement of mankind. In order to accomplish this function, the toxicologist must develop not only an understanding of the methods used but also determine the significance or insignificance of their data in the complete picture of the toxicity of each compound. My graduate school mentor, Dr Roger Hubbard, once told me that no scientifically valid experiment creates erroneous results, but inappropriate or application of those results can create erroneous conclusions. An understanding of the principles together with the methods involved in the science of toxicology prepares the critical scientist for developing an insight in regard to proper application of experimental results. Results that are properly obtained by acceptable methodology and that are suitably weighted for the conditions under which they were obtained certainly contribute to the development of proper conclusions. In this book, very highly qualified toxicologists present the procedures in detail that are currently used and accepted in the science of toxicology. Discussions of each procedure or category of procedures enable the reader to formulate an educated opinion about the limitations of interpretation of experimental results. Proper, critical conduct of acceptable toxicologic tests creates the body of systematized knowledge essential to the science of toxicology. Properly applied, that knowledge serves to protect mankind and the biologic realm in general from sudden, as well as delayed, insidious chemical induced harm.

Preface to the Fourth Edition

The First Edition of *Principles and Methods of Toxicology* was written to deal with evaluation of toxicological data. It described many of the testing procedures available at that time. The Second Edition included a more systematic approach to toxicology without loosing its methodological origin. It described not only current testing protocols but offered useful guidance for data interpretation. The Third Edition was expanded and revised to reflect current needs in toxicology. This Edition continues the tradition of earlier editions by providing detailed testing procedures but with an expanded insight regarding evaluation of data. The Fourth Edition has new chapters on epidemiology for toxicologists, on exposure assessment, and a chapter on repeat dosing that combines chapters that previously subdivided multiple dosing into arbitrary intervals. As before, every effort to reflect the needs and issues in toxicology and to keep the book suitable for use as a textbook in graduate education has been made.

Classically, toxicology is the study of adverse effects of chemicals and physical agents on living systems. Nonetheless, it should be remembered that Paracelsus said, "It is the dose that determines what is not a poison." Based on this important observation, toxicology must look beyond such a simple definition and focus its attention on determining a safe dose from a harmful or detrimental dose. In order to determine the safe use of a chemical or physical agent, it is necessary to have a sound understanding of biologic mechanisms and the methods employed to define these mechanisms. The vastness of the field of toxicology and the rapid accumulation of data preclude the possibility of absorbing and retaining more than a fraction of these techniques and information. However, an understanding of the principles underlying these methods is not only manageable but essential.

This tome was designed for courses in general and advanced toxicology. The framework of the Fourth Edition follows that of earlier editions. The history of toxicology opens the book and is followed by a section which covers basic toxicological principles. Chapters in this section include metabolism, toxicokinetics, physiologically based pharmacokinetic modeling, statistics, exposure assessment, quantitative aspects of interspecies extrapolation, and a chapter on epidemiology for the toxicologist. Also included in this section are chapters on the regulatory process and the toxicologic assessment of pharmaceutical and biotechnology products. The next section covers agent to toxicity including food-borne toxicants, solvents and vapors, pesticides, metals, and radiation. The third section covers basic toxicological testing methods including many of the test protocols now required to meet regulatory standards. Organ systems, tissue culture, and cell systems are dealt with in this section. Each method or procedure is discussed from the standpoint of technique and interpretation of data. A state-of-the-art approach is emphasized as well as discussions involving various problems and pitfalls that may be encountered in performing each procedure. Each chapter contains information that allows one to perform an experiment or test a hypothesis and provides insight into the rationale behind the experiment. Consideration is given in a number of the chapters to the need for validated alternative methods to animal testing. The last section contains a glossary of terms important in toxicology. The organization of the book should facilitate its use both by the student of toxicology and the more advanced researcher. A number of new authors allowed us to provide a broader coverage of the ever-changing field of toxicology.

The Fourth Edition of *Principles and Methods of Toxicology* will be useful as a text for courses in toxicology and as a valuable, timely review for practicing toxicologists. Research scientists who have used earlier editions as a reference source will find updated materials in areas of their special or peripheral interests.

A.Wallace Hayes, Ph.D., D.A.B.T., FATS, FIBiol

Foreword to the Fourth Edition

Publishing a toxicology book on the entrance into the third millennium is an appropriate time to reflect on the progress that has been made in that discipline since its inception. Almost five hundred years ago Paracelsus published a treatise based on his intuitive observations; he merely argued that these observations should convince one that the dose makes the poison. Now science has advanced enough so that we can prove that Paracelsus was correct, because the law of mass action tells us that the degree of perturbation of a system is proportional to the chemical potential of a substance in that system. We still, however, must rely heavily on observational epidemiology to determine the details of exactly what dose effects what change in humans.

The fourth edition of this book is a magisterial, state of the art compilation of the principles and methods that toxicologists must use to identify whether a causal relationship exists between specific doses of a chemical and an alleged adverse effect, observed primarily in humans. Proper integration of principles and methods of toxicology is extremely important since the primary purpose of toxicology is to predict human toxicity. Previous editions of this book have delineated in a very useful detail the methods of toxicology and how these methods have been perfected steadily and rapidly in the last few decades. The necessarily heavy reliance on animal experimentation for determining causality in humans is obvious and certainly warranted.

This book was the first to chronicle the overall aspects of the use of animal experiments in toxicology. The expediential rate of growth of toxicology continued to be reflected in further editions of the book as the authoritative and comprehensive source of methods used in this science. Proper and critical conduct of acceptable toxicological tests still continue to create the body of systematized knowledge essential to the science of toxicology.

The current edition continues this tradition, but adds some very significant new chapters. These chapters are on epidemiology, exposure assessment, and a chapter on repeat dosing that combines previous chapters that subdivided multiple dosing into arbitrary intervals. It is remarkable that we have returned, almost in full circle, to emphasis on direct exposure and effects in human population after finally, firmly establishing the basic scientific foundations of toxicology. This thorough, complete compendium is a necessary addition to the library of everyone interested in this subject.

William J.Waddell, M.D.,
Professor and Chair, Emeritus
Department of Pharmacology and Toxicology
University of Louisville, Kentucky

Preface to the Second Edition

The First Edition of this textbook was designed primarily for courses dealing with an evaluation of toxicologic data with a particular emphasis on those methodologies used in toxicology. This Second Edition has been expanded to include a more systematic approach to toxicology without losing its methodological basis. This edition describes current testing procedures, offers useful guidelines on data interpretation, and highlights major areas of controversy. Every effort has been made to keep the book simple and suitable for use as a textbook for graduate teaching.

Since toxicology is the study of the harmful action of chemicals on biologic tissues, it necessitates an understanding of biologic mechanisms as well as the methods employed to examine these mechanisms. However, the vastness of the field of toxicology and the rapid accumulation of data preclude the possibility of any one individual absorbing and retaining more than a fraction of these techniques. There are, however, specific methods that are applicable to a large number of chemicals. An understanding of the principles underlying these methods is not only manageable but essential. Thus, individuals who are not directly involved with the day-to-day activity of toxicology, or who have not yet entered a specialized field in toxicology, will find this book a valuable resource in acquiring a broad understanding of toxicological approaches available.

This volume has been designed to serve as a textbook for, or adjunct to, courses in general as well as advanced toxicology. The overall framework of the Second Edition follows that of the initial volume with the exception that major sections or principles related to toxicology have been added. A number of new authors have been added to this edition to broaden input and provide coverage of the ever-changing field of toxicology. New chapters have been added on metabolism, food-borne toxins, solvents, pesticides, and on the regulatory process as it relates to toxicology.

The only true “facts” in biology are the results of individual experiments carried out under control conditions by carefully defined methodology. Although it is not the purpose of this volume to catalog or to discuss these biologic “facts,” it is the purpose of this book to present those methodologies which can generate these facts. Achievement of this goal requires the more or less arbitrary resolution to select methods and testing protocols from the current literature. The bibliography of each chapter will carry the reader beyond the techniques and methods presented in the book.

This volume has been organized to best facilitate its use. The first section covers basic toxicologic principles including the philosophies underlying testing strategies. The second section covers basic toxicologic testing methods and includes most of the testing procedures now required to meet regulatory standards. The third section deals with specific organ systems and contains chapters on kinetics and effects on cellular organelles and target organs. Each method or procedure is discussed from the standpoint of technique and interpretation of data. A state-of-the-art approach is emphasized as are the various problems and pitfalls encountered. Each chapter contains information that allows a person to perform an experiment or test a protocol, and also provides insight into the rationale behind the experiment.

Principles and Methods of Toxicology, Second Edition, will be useful as both a text for introductory courses in toxicology and as a valuable, timely review for the practicing toxicologist. Research scientists who have used the first edition as a reference source will find updated material in areas of their special or peripheral interest.

Page xvii

Preface to the Third Edition

The First Edition of *Principles and Methods of Toxicology* was designed for courses dealing with an evaluation of toxicological data with a particular emphasis on methodologies used in toxicology. The Second Edition was expanded to include a more systematic approach to toxicology without loosing its methodological basis. This Third Edition, as did the First and Second Editions, describes current testing procedures, offers useful guidelines on data interpretation, and highlights major areas of controversy. In addition, the Third Edition has been expanded and revised to reflect current needs and issues in toxicology. Every effort has been made to keep the book simple and suitable for use as a textbook for graduate teaching.

Since toxicology is the study of harmful effects of chemicals and physical agents on living systems, it necessitates an understanding of biologic mechanisms, as well as the methods employed to examine these mechanisms. However, the vastness of the field of toxicology and the rapid accumulation of data preclude the possibility of any one individual absorbing and retaining more than a fraction of these techniques. There are, however, specific methods that are applicable to a large number of chemicals. An understanding of the principles underlying these methods is not only manageable but essential. Thus, individuals who are not directly involved with the day-today activity of toxicology, or who have not yet entered a specialized field in toxicology, will find this book a valuable resource in acquiring a broad understanding of toxicological approaches available.

This volume has been designed to serve as a textbook for, or adjunct to, courses in general as well as advanced toxicology. The framework of the Third Edition follows that of earlier editions with the exception that several major sections on principles related to toxicology have been added, including chapters on environmental toxicology, pharmaceuticals and biotechnology products, metals, radiation, and risk assessment. New chapters on methods involving cellular and molecular techniques, instrumentation in toxicology, and physiologically based pharmacokinetics are included in the Third Edition. A number of new authors have been added to this edition to broaden input and provide coverage of the ever-changing field of toxicology. The history of toxicology now opens the book.

The only true "facts" in biology are the results of individual experiments carried out under controlled conditions by carefully defined methodologies. Although it is not the purpose of this volume to catalog those biologic—facts,—it is the purpose of this book to present those methodologies which can generate these facts. Achievement of the broad goal requires the more or less arbitrary resolution to select methods and testing protocols from the current literature. The bibliography of each chapter will carry the reader beyond the techniques and methods presented in this book.

This volume has been organized to best facilitate its use. As Abraham Lincoln so ably stated, "None seemed to think the injury arose from the use of a bad thing but from the abuse of a very good thing." The sixteenth century physician, Paracolsas, further pointed out that all substances can be poisonous with the difference between safe use and toxicity being the dose. Such often is the case in toxicology. The first section covers basic toxicological principles, including the history of toxicology and the philosophies underlying testing strategies. The second section covers agents of toxicity including food-borne toxicants, solvents and vapors, pesticides, metals, and radiation. The third section covers basic toxicological testing methods and includes many of the testing protocols now required to meet regulatory standards. Specific organ systems also are dealt with in this section. Each method or procedure is discussed from the standpoint of technique and interpretation of data. A state-of-the-art approach is emphasized as are various problems and pitfalls encountered with the various methodologies. Each chapter contains information that allows a person to perform an experiment or test a protocol and also provides insight into the rationale behind the experiment. Consideration is given in a number of the chapters to the need for, and yet the lack of, acceptable, validated alternative methods to animal testing.

The Third Edition of *Principles and Methods of Toxicology will* be useful as both a text for introductory courses in toxicology and as a valuable, timely review for practicing toxicologists. Research scientists who have used earlier editions as reference sources will find updated materials in areas of their special or peripheral interests.

"We can never be fully in possession of a science until we know the history of its development." (Charles Greene Cumston)

"Continuity with the past is a necessity, not a duty." (Oliver Wendell Holmes, Jr.)

"History is bunk." (Henry Ford)

Toxicology! What an exciting word with interesting connotations. It initially evoked thoughts of poisons, poisoners, intrigue, cloak-and-dagger, villains, victims and perpetrators, and plants and chemicals as instruments of ill. What does the word conjure up today? Polluted water, air laden with noxious gases and particulates, foods contaminated with pesticides, soil loaded with heavy metals permanently handicapping children. There are still victims and perpetrators. In earlier times, the act of poisoning was deliberate and usually involved one or several people. Today, exposure to agents/chemicals is often unintentional (e.g., a spill), although it may be deliberate (e.g., suicide attempts) and may involve one or several individuals (e.g., in the workplace) or larger numbers of people (e.g., a community as a result of a spill). It is unfortunate that the same term, ***poisoning,*** is used whether exposure is deliberate or not. Poisonings in earlier times were probably not well reported for several reasons, including the inability to identify the poisoners or even that the cause of death was due to a poison, and to limited means of communication. Today, due to the significant advances in analytical chemistry and to better and faster means of communication, there is a faster and greater dissemination of information. Unfortunately, there is also a profusion of misinformation, and this is unnecessarily creating problems for the public. Industry is usually portrayed as the villain (by the media), and the unsuspecting public as the victim. Industry is also portrayed as profiting at the expense of the public health. If only the truth could be presented to the public in an unbiased manner! This is a challenge for modern toxicologists. Let those of us capable (by training and/or experience) of interpreting relevant data do so objectively and fairly. We must accept this challenge lest the public perish in a cesspool of media-fabricated hype. Will toxicologists rise to the occasion? The dedicated and concerned ones will.

How did we arrive at the present situation? What has happened as humans evolved from nomadic huntergatherers and cave dwellers to a relatively stable society of workers involved in many and varied activities? How can we explain the change from the direct use of poisons by individuals to kill one or several to the insidi-

ous exposure to presumed poisons to large groups by industry or other groups? An appreciation of the evolution of toxicology may be helpful.

Without definitions, meaningful discourse and science are impossible. "In the right definition of names lies the first use of speech, which is the acquisition of science; and in the wrong, or no definitions, lies the first abuse, from which proceed all false or senseless tenets" (Thomas Hobbes).

What is toxicology and how has it evolved to the eminent position it now enjoys? ***Toxicology*** is the study of the adverse effects of chemical or physical agents on biological systems; it is the science of poisons. A poison is any substance (chemical, physical, or biological) that is harmful or destructive to a biological (living) system. A poison derived from a biological source is a ***toxin,*** and the study of toxins is ***toxinology***.

"Toxin" was originally ***tekw,*** a word meaning to run or flee, later becoming ***toxsa*** in Persian and ***toxon*** in Greek, meaning bow and arrow; the toxin meaning may have come from the poison used to tip the arrows, or, as Robert Graves suggested, from the yew tree ***taxus,*** from which arrows were best made and whose berries were long known to be poisonous. The word for poison came by a devious route, like a long-delayed afterthought. It derives from ***poi,*** to drink, becoming ***potare*** in Latin, whence "potion" (and also "symposium" from ***sym,*** together, plus ***posis,*** to drink). The venomous meaning did not come until the notion of love potions evolved, and the idea of poison came to consciousness. There is the same strange history behind the word "venom." This began as the simple word ***wen*** meaning to wish or will, leading more or less directly to "win." Along the way, a fork led to "venus," "venery" and "venerate," all indicating varieties of love. The love potion was called venin, and somehow this gradually acquired today's sense of venom. Nobody can explain why "poison" and "venom" come from love potions. Perhaps it was because the pharmacology of the day was primitive and chancy, a very fine line from toxicology. Or maybe there was a commonsense consensus that any sort of chemical additive intended to induce false love, is by nature, a fundamental poison. It tells something important about the good taste of earlier human beings that venom and poison were taken resentfully out of the hands of artificial lovers and transferred to the stings of insects and the fangs of serpents.

"Noxious," incidentally, came from ***nek*** meaning death, by way of ***necare*** and ***nocere*** in Latin, providing "necropsy" and cognate words for us; nectar was the drink of the gods because it prevented death (***tar,*** meaning to overcome). Chance (origin is cadence). "Cadence" comes from ***kad,*** meaning to fall. Kad led to ***cadere*** in Latin and ***cad*** in Sanskrit, also meaning to fall, sometimes to die. Incidentally, "hazard" also came from ***dice,*** by way of Old French ***hasard*** and Spanish ***azar,*** from the Arabic ***yasara,*** to play at dice (55).

The development of toxicology reflects the history of the development of society; that is, a progression from simplicity to sophistication, from crude to cultured, from elemental to elegant. Consider killing. Killing animals for sustenance and survival predates recorded history. The biblical directive to Adam is clear. "Then God said: 'Let us make man in our image, after our likeness. Let them have dominion over the fish of the sea, the birds of the air, and the cattle, and over all the wild animals and all the creatures that crawl on the ground'" (Genesis 1:26). "God blessed them saying: 'Have dominion over the fish of the sea, the birds of the air, and all living things that move on the earth.'" God also said: "See, I give you every seed-bearing plant all over the earth and every tree that has seed-bearing fruit on it to be your food; and to all the animals of the land, all the birds of the air, and all the living creatures that crawl on the ground, I give all the green plants for food. And so it happened" (Genesis 1:28–30). Animals, including humans, were, and still are, born with a strong basic instinct for survival (and control) that involves eating and drinking. It became (and still is) necessary to kill plants and animals in order to survive. Humans also have an instinct to control their own destinies. Occasions arose when it became necessary to remove (i.e., to kill) other humans (for control, not nutritional survival). The methods used to kill humans were the same as those used to kill animals. The usual instruments of kill were clumsy physical weapons that required strength for effectiveness. Small and less powerful humans were at a great disadvantage. Even though later developments, such as the bow and arrow, required more skill and less physical strength, something more (an equalizer) was needed for the less physically endowed. Early humans probably learned through experience about the harmful properties of insects and animals (including venoms). The women studied plants and determined which were beneficial and which were poisonous. The poisonous ones were then used by the men as aids in hunting (e.g., arrow poisons). Poisons proved to be very useful in killing animals. Could they be the equalizer needed by the less powerful to solve other problems? Could humans be dispatched as readily as animals with the use of poisons? It was worth testing. Killings were sometimes performed for reasons other than for survival, such as control, frustration, anger, or convenience. For example, to satisfy their lust for power, wealth,

pleasure, and new excitements, the "power class" (wealthy landowners, rulers) found it necessary to kill other humans, but killing other humans was not limited to the "power class." In general, genteel, subtle, and undetectable means of killing were desirable (such as dispensing with a spouse to be able to enjoy a new lover), but these were not available until professional poisoners appeared on the scene. When used properly, poisons could be (and often were) the perfect solution to difficult problems and detection was impossible.

Once the value of poisons was recognized, they became very attractive as "fit instruments of ill." Humans then and now are seduced by things attractive (and useful). Poisoning as a solution to difficult problems was very appealing and had a great deal to recommend it; it could

be fast or slow, painful or painless, poisons were inexpensive and readily available; and, as noted earlier, defied detection. The seduction of toxicology had begun! Once the need had been established, suppliers and practitioners were needed for proper implementation. The amateur or do-it-yourself poisoners were soon replaced by professional poisoners (early applied toxicologists), who offered advice and/or performed the required services. The agents used were initially naturally occurring; these were supplemented by new agents developed by alchemists/chemists. Thus, toxicology evolved into an art and then into a science.

The popularity of poisoning grew until it reached epidemic proportions in some countries. This popularity was enhanced by the inability to detect poisons and to prove that poisoning had occurred. However, once the chemists turned their skills from developing new poisons to detecting poisons, the popularity of poisons as killer agents began to wane. Poisoners could now be identified. Although poisons are still used today, more subtle and ingenious means of killing are available. Today, poisoning conjures up images of large groups of individuals unintentionally exposed to chemicals; however, detection and source/cause identification of the exposure are possible and responsible party (parties) identified. In earlier times, the poisoner was usually an individual; today, poisoning/pollution may involve a corporation.

A man without a sense of history, without memory of the past, who is forced to reconsider his place in the world, a man deprived of the historic experience of his own and other peoples lacks any perspective and can only live in the present. (Chingiz Aitmatou, 1983)

POISONS ARE IN!

With respect to the art of poisoning, de Quincey wrote:

The bowl needs for its effective management a scientific precision of plan and a subtlety of execution that place it in a different category from the vulgar methods of the knife, the bullet, or the bludgeon. The process can be almost indefinitely prolonged, giving large opportunities for the exercise of skill, resourcefulness, craft, and daring; and with allowing time for the enjoyment of the full passion of deliberate crime, which finds imperfect gratification in the hasty thrust of the knife. There have been persons who poisoned, not out of covetousness or hatred or wanton cruelty, but for the pleasure of the thing. They were true artists, practicing their art for its own sake, with a proper scorn for the limitations which an irrelevant morality would impose in its exercise.

Do poisons have any redeeming value; in other words, are there uses for poisons beyond killing? Very definitely! Poisons have contributed to the health and safety of humankind and to the advancement of biological sciences (including medicine) in a number of ways. In 1878, Claude Bernard, an outstanding early physiologist and probably the first and foremost mechanistic toxicologist wrote:

Poisons can be used as agents for the destruction of life or as means to cure disease; but in addition to these uses—there is a third which particularly interests the physiologist. For him the poison becomes an instrument which dissociates and analyses the most delicate phenomena of the living machine and by careful study of the mechanism of death in different poisonings, he can gain knowledge, indirectly, of the physiological mechanism of life. (i.e. poisons can be used to explain physiological events).
(translation of P.N.Mage, 1865)

For interesting discussions of these artist-poisoners, including Locusta, Toffana, the Marquise de Brinvilliers, Ezra Wharton, Florence Maybrick, the Borgias, Catherine de Medici, Sainte Croix, and Catherine Deshayes (La Voisine), the reader is referred to articles by Gallo and Doull, Decker, Thompson, and Osius.

Claude Bernard used curare to study the physiology of the neuromuscular junction. Radiation, a "physical poison," has been an invaluable tool in elaborating some of the basic events in mutagenesis and carcinogenesis. Identifying the role of mixed-function oxidases (MFOs) and cytochrome P450 (P450) and exploring hepatic mechanisms at the molecular level would have been delayed had it not been for hepatotoxins. Low doses of certain toxins may be useful in therapeutics: for example, botulinum toxin in the management of strabismus, blepharospasm, and spasmodic torticollis. Poisons are not all bad!

Farming (food production) has evolved from a very primitive but necessary human activity to feed a few people to a very sophisticated process that feeds multitudes. In earliest times, it involved the use of simple tools, few crops, and primitive methods. With the introduction of power (animal, then mechanical), larger areas could be cultivated. More crops were developed. Efficiency improved but there was considerable room for improvement. Enriching the soil resulted in increased yields, but pests competed with humans for crops thereby reducing effective availability. Pesticides are chemicals (usually) that are used to kill unwanted subhuman organisms. The judicious use of these materials has resulted in increased food production and storage and subsequently in better health and prolonged life

expectancy. The introduction of genetically modified plants that are diseaseand pest-resistant and have a better nutrient profile and improved organoleptic properties has resulted in diminished exposure to chemical agents. There is every reason to believe that this trend will continue.

With the introduction of chemical power to enrich the soil, treat the seeds, and eliminate pests, unprecedented yields were realized. Humans began to manipulate, to control, part of their environment; they worked with Nature to their benefit. But there were occasions when the interaction with Nature was not symbiotic—when air,

water and/or soil were abused, often due to ignorance but sometimes to greed.
Food preparation and storage evolved in a similar manner. Prior to the introduction of heat (fire power), food was eaten raw. Cooking provided an opportunity to broaden one's choices and to improve the bioavailability of certain nutrients. Heat (sun, fire) was also used to preserve food by drying. Chemical power (e.g., salt) was also used to preserve food. Add to drying and chemical preservation the power of radiation and food could be maintained safe for human consumption for unbelievably long periods of time. In addition, chemicals (e.g., flavors and colors) could be used to enhance the organoleptic properties of foods. Again, humans were controlling the immediate environment to their benefit. The preparation of food (a renewable resource) for consumption was/is usually less destructive of nature.
And the need for safe drinking water! It took a long time to associate contaminated water with disease. Or did it? The Egyptians used a physical method (sand bag) to purify water, a technique used today (sand banks). But it was not until chemical power was introduced in the form of chlorine gas that waterborne diseases were finally eliminated.
Other natural products have played a role in the cultural/sociological/hedonistic aspects of human activities. These include sugar, salt, coffee, tea, rosemary, garlic, pepper, opium, digitalis, alcohol, and tobacco.
Toxicology is an evolving discipline: from art to science, from using chemicals that hurt to chemicals that help, or at least prevent hurting, and from taking lives to saving lives. It is not precisely known when the first human used a plant toxin, a phytotoxin (plant poison), to kill another human, but it probably did not require too great a leap of faith to extrapolate from effects in animals to humans. The age of poisoning, of practical toxicology, had begun. As poisoning developed into an art, its practitioners became famous/infamous. Identification of the culprit was extremely difficult since determination of the cause of death (proof of poisoning) required yet-to-be-developed analytical techniques.
Natural products were used (and are still used) to prevent and/or to treat disease. Women were the original naturopaths; they learned the biological properties (effects) of plants and used plants and/or their constituents with appropriate activity in the management of disease (to heal), while those with poisonous properties were used by the men in hunting (to kill). (The adverse effects of venomous insect stings and animal bites were probably also noted, but the practical utility of these venoms was limited.)
Interest in plant poisons (phytotoxins) and animal poisons (venoms), as nuisances to health and as tools for vindication, continued to grow. Lists (catalogs) of poisons and their effects in humans began to appear. Each culture/civilization appears to have had a list or lists of these. The use of plants, including herbs, for medicinal purposes also continued to evolve. The cures (healing or killing) for the problems of humankind were to be found in nature (a concept that has again found favor with many)! With time, the lists began to include detailed descriptions of preparation, use, and effects of biologically active plant materials. Understandably, concerns about prevention and treatment of poisoning began to emerge.
Prevention of poisoning was accomplished by the use of appropriate bioassays (e.g., official tasters of prepared food and drink) and by the development of tolerance/adaptation through the repeated ingestion of small doses of toxins. Initially, treatment (antidotes) was shrouded in folklore and mysticism. Only when mechanisms of toxicity were understood and toxicology became a recognized science did treatment have a rational, scientific basis.
Advances in chemistry led to the development of analytical chemistry. The application of analytical techniques to the detection of poisons was the beginning of the science of forensic toxicology. This had a chilling effect on the use of poisons. Now poisoning could be proved. Practitioners became more sophisticated in attempts to avoid detection, but they were no match for the dedicated chemists who continued to develop exquisitely sensitive and specific analytical methods. Perpetrators/villains could now be identified and appropriate action taken. The development of ultrasensitive analytical methods has continued into the present. Contaminants in soil, air, and water are now easily identified and quantified. The origins and the originators can be identified and appropriate action taken. Ultrasensitive analyses continue to challenge toxicologists to assess the biological/health significance of the presence of chemicals at parts per billion or parts per trillion in body fluids or tissues. Dose-response relationships were established as correlations between the level of the chemical in blood and/or in tissues and biological activity were made. Concomitant with advances in analytical/forensic toxicology were efforts to elucidate the mechanisms of action of chemical agents. This was followed by the development of rational therapy for poisonings, including the development of specific antidotes.

POISONS ARE OUT!

In light of this scientific onslaught, the deliberate use of poisons to kill declined rapidly. The practitioners of the art of poisoning disappeared to be replaced by a new breed of toxicologist, the scientist who

understood the basis of toxicity from the whole animal to the molecular level, could appreciate all of its ramifications, and could

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_4.html[2010/10/28 18:28:41]

extrapolate to the human situation. Quantification of the responses to toxic agents and the relationship of structure to biological activity became, and still is, the basis for a great deal of scientific activity.
When it became known that nondeliberate exposure to chemicals could produce adverse health effects (e.g., in the workplace), efforts were directed to the prevention of the adverse effects of chemicals by defining safe conditions of exposure to protect humans and other life forms from chemical and physical injury. This was followed by the identification and quantification of the risk of adversity following exposure (risk identification, assessment, and management). Quantifying a risk, assigning a number to it, tends to decrease the uncertainty of extrapolation and to provide a comfort factor.
In maturing to a scientific discipline, toxicology passed through a number of phases, including observation/ phenomenology (lists of poisons and antidotes), experimentation/deduction/mechanisms/analytical (including dose-response), and application (TLV, ADI, safety/ uncertainty factor) and quantification (quantitative risk assessment)/prognostication). A transition from using chemicals to kill to finding uses for chemicals/poisons that would benefit humankind (e.g., pesticides and therapeutic agents) to identifying, quantifying, and preventing adverse effects of chemicals (e.g., establishing safe exposure conditions in the workplace and safe levels of chemicals in foods and water) occurred. Toxicology had evolved to another stage wherein it became a respected member of the scientific biomedical community.
The toxicologist was needed when poisons were in and continues to be needed now that poisoning is out. From supplying poisons to studying their mechanisms of action to developing analytical methods to identifying and quantifying poisons in body fluids and tissues to developing rational antidotes to establishing safe limits of exposure from carefully designed and executed studies to quantifying and predicting adverse effects—the toxicologist continues to play a critical role in the advancement of humankind.

AGE OF OBSERVATION/RECORDING OF PHENOMENA

Biblical

Although most of the references to poisons in the Bible appear to be limited to venoms, chemicals and food regulations are also mentioned. In the Book of Genesis, God is portrayed as the Supreme Regulator and protector; God proscribed certain foods. The regulated were Adam and Eve. Had they blindly accepted the regulations imposed upon them (had they had more faith in their Regulator), there would have been no dire consequences. Is there a lesson here for us today? The bitter water to test the fidelity of a wife suspected of unfaithfulness is described in Numbers 5:11. Venoms and plant poisons appear in Deuteronomy 32:24, "with the venom of reptiles gliding in the dust," and 32:31, "poisonous are their grapes and bitter their clusters." Arrow poisons are mentioned in Job 6:4, "for the arrows of the Almighty pierce me, and my spirit drinks in their poison," and in 20:16, "The poison of asps he shall drink in; the viper's fangs shall slay him." "The venom of asps lies behind their lips" appears in Romans 3:13. In Psalms 58:5, "theirs is poison like a serpent's, like that of a stubborn snake that stops its ears," and Psalms 140:4 "they make their tongues sharp as those of serpents; the venom of asps is under their lips." Jeremiah mentions chemical and biological poisons, "he has given us poison to drink" (8:14) and "I will send against you poisonous snakes against which no charm will work when they bite you" (8:17). In James 3:8, we find "the tongue no man can tame. It is restless evil, full of deadly poison." There appears to be an awareness of the natural occurrence of poisons and the effects produced, but no mention of the deliberate use of them. Antidotes are not mentioned, only charms. There is no list of poisons in the Bible, although there are proscriptions about foods and food practices (e.g., Deuteronomy 14, Leviticus 11, 17, 19), apparently based on potential adverse health effects.

Egyptian

The first list of poisons and antidotes appears in Egyptian writings. This is not unusual since the Egyptians were the intellectual leaders of the world and Egyptian medicine was reputed to be the most advanced. Menes (Mena, Meni, Min), the first king of unified Egypt and the founder of Memphis, the capital, was reported in the Egyptian papyri to have had an interest in poisons. He cultivated and studied the effects of poisonous and medicinal plants somewhere between 3500 and 3000 BC. Unfortunately, there is no detailed written history of these activities. His son Athothis, a physician, wrote a textbook on medicine in which sanitation was stressed.
A papyrus discovered in Thebes (Luxor) in 1872 by the German egyptologist Georg Moritz Ebers (1837–1898), named appropriately in his honor the Ebers Papyrus, was written between 1553 and 1500 BC. It is more than 20 m long and contains 110 columns of hieratic (priestly) script (about 110 pages). More than 700 drugs (medicinal substances) are identified in about 875 to 900 formulas (quantitative recipes). The formulas also contain specific indications and dosages, together with appropriate spells

and/or incantations. Forty-seven case histories are pre-

sented. Modes of administration include snuffs, inhalations, gargles, pills, troches, suppositories, enemas, fumigations, lotions, ointments, and plasters. Drugs were identified on the basis of origin as plant (e.g., acacia, castor bean, wormwood, fennel, garlic), animal (e.g., milk, excrement) or mineral (e.g., alum, iron oxide, limestone, sodium bicarbonate, salt, sulfur). Vehicles used included beer, wine, milk, and honey. There is also a great deal of information on the toxicity of opium, hellebore, aconite, hyoscyamus, hemlock, lead, antimony, and copper. Insect and animal venoms were described. Antidotes, including incantations, were also mentioned. To assure recovery, Egyptian physicians used combination therapy: chemical and or biological materials (rational therapy) plus mysticism (requests for assistance from the gods; irrational therapy?). Today, some pray for assistance only after conventional therapy has been unsuccessful. Perhaps simultaneous is more effective than sequential!

There are other papyri detailing medical practices in early Egypt. The Edwin Smith Papyrus was discovered at the same time and place as the Ebers Papyrus, but it was probably written earlier. The Hearst Papyrus was written about 1400 BC and was discovered in upper Egypt in 1899. The Kahun Papyrus was written between 2000 and 1800 BC and was discovered by Sir Flinders Petrie in the Faiyum. It deals primarily with gynecology. The Berlin Papyri (two, the same period as Ebers Papyrus) and the Brugsch Papyrus were the latest to be discovered.

For example, the Egyptians used chemicals in the administration of justice. The Penalty of the Peach involved having the accused ingest the distillate from crushed pits of peaches (high in hydrocyanic acid); if the accused died, it was a presumption of guilt; if the accused lived, it was a presumption of innocence. This practice of using chemicals in the administration of justice was used by other cultures (e.g., Greek) and persists to the present; lethal injections of chemicals are used for executions in the United States.

Egyptian practitioners of medicine believed that respiration was the most important function of the body followed by circulation (blood and heart); that most diseases were caused by parasites (which is not surprising considering conditions in Egypt); that personal and social hygiene were very important in maintaining good health; and that therapeutics should be both rational and mystical. They covered all bases! The Egyptian contribution to toxicology includes lists of poisons and antidotes.

Chinese

On the other side of the world, the Chinese were also developing a culture that was advanced for the period. The second of China's mythical emperors, Shen Nung, is considered the father (founder) of Chinese medicine, materia medica, and agriculture. He is credited with inventing the cart, the plow, and the yoking of horses. He taught the Chinese how to clear land with fire to increase farmland. Shen Nung wrote a 40-volume herbal entitled ***Pen Ts'ao or Pun Tsao*** (the Great Herbal or Chinese Materia Medica) around 2735 BC. It contained lists of poisonous plants, plants with medicinal value (365), and drugs (265, 240 of which are vegetable in origin). The effects of plants and drugs and appropriate antidotes were described. Included among the drugs were iodine, aconite (also used as an arrow poison), opium, cannabis, rhubarb, alum, camphor, iron, sulfur, and mercury. He was also reputed to have discovered a number of drugs and experimented upon himself. Phytotoxicology appeared to be well developed. Here is the second list of poisons and antidotes. Like the Egyptians, drugs and poisons were presented together. (Pharmacology and toxicology joined together at this early age! Did this presage the development of toxicology?) Another emperor, Hwang Ti (2650 BC), wrote ***Nei Ching,*** the Book of Medicine, the basis for most Chinese medical writings.

In addition to the lists of drugs and poisons and their effects (the early Chinese contribution to toxicology and pharmacology), the Chinese made other significant contributions to medicine. These include discovering the circulation of blood; the yang and yin principles (two opposing forces that control everything including ebb and flow, male and female, life and death, moon and sun, heat and cold, strength and weakness (parasympathetic and sympathetic, cholinergic and adrenergic nervous systems?); the five elements of the human body (earth, fire, water, wood, metal); the five organs of the body (heart, liver, spleen, lung, kidney); five colors, and five heavenly bodies—five appeared to be a magic number in this culture. Other cultures had magical numbers; for the Greeks, it was four or seven. Health was the result of balance between the forces and elements, a concept that still has its adherents.

Hindu

The most significant contribution of the Hindus to medicine was in the field of surgery. Like the Chinese and the Egyptians, they also had their list of poisons and antidotes. The Rig-Veda, a Sanskrit document written between 1500 and 1200 BC, is the earliest written account of Hindu medicine. It contains many references to alchemy and science and magic in the treatment of disease. Included are discussions of many diseases including cough, fever, diarrhea, seizures, tumors, and skin diseases. There are

treatments for specific diseases. These

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_6.html[2010/10/28 18:28:42]

Page 7

treatments, like the Egyptian, include spells and incantations, again the combination of rational and mystical therapies! Medicinal and poisonous plants and antidotes (e.g. for snake bites) are listed. The influence of gold as a therapeutic agent and on longevity is discussed. A later work, the Ayur-Veda, the Veda of long life, a Sanskrit document written about 700 BC, discussed medicine and all its branches in eight parts; drugs and poisons were also mentioned.

"He who knows only one branch of his art is like a bird with one wing". (Susruta)

Susruta, a Hindu surgeon, authored a medical/surgical text called Susruta-Samhita, in the last centuries of the pre-Christian period. The text was divided into six sections. He identified 1120 diseases and gave fever great importance. He stressed the importance of hygiene and presented many surgical procedures in great detail. The section on drugs listed 760 indigenous medicinal plants, of which many were used externally as ointments, baths, sneezing powders, inhalations; it also listed animal and mineral remedies. The fifth section, the Kalpa Sthana, was the section on toxicology and contained mostly antidotes. The Hindus were keenly interested in poisons and antidotes, especially for bites and stings and aphrodisiacs (interesting; any message here?). Other topics discussed included malaria and the role of the mosquito and plague and the influence of rats.

Greek

There are many Greek legends and myths involving gods and goddesses concerned with poisons and poisoning. For example, Hecate used aconite; Medes, colchicine; and Hercules was poisoned with cantharidin applied to his shirt. Like other cultures, the Greeks also had their lists of poisons, lists that were consulted by citizens and by the government. Other and more significant contributions to the advancement of toxicology were made, including detailed descriptions of the effects of various agents in humans, antidotes, and principles for the management of poisonings.

The Greeks made many significant contributions to the advancement of humankind. For example, they developed a system of philosophy (***philos,*** friend; ***sophia,*** wisdom) that defined the place of humans in nature; they attempted a rational explanation for nature and natural phenomena including medicine and the healing arts; and they believed that there exists a single fundamental principle, a prime force, from which everything in nature developed. The Greeks perceived medicine as both an art, the careful examination and accurate observation of the patient, and a science, part of the science of humans and their place/role in nature. The Greeks had a great deal of knowledge about poisons (especially plant poisons), metals (especially arsenic, antimony, mercury, gold, copper, and lead), and antidotes (e.g., hot Oil and vomiting). The Greeks also executed criminals with poisons (e.g., hemlock, which was the state poison), which presaged the use of lethal injections in the United States today. Suicide by poisoning was not uncommon since poisons were readily available.

The father of the Pythagorean theorem (proposition), Pythagoras (580–489 BC), was born in Samos, and lived in southern Italy (Crotona) for many years. He was a mathematician who developed the theory of numbers and became known as the father (founder) of arithmetic, a physician and scientist who was especially interested in procreation and animal physiology, an astronomer, a philosophical-religious leader who tried to reform the political, social, and moral ills of the time, and a numerologist who considered the number seven highly significant. He believed the earth was a sphere, that animals possessed souls, and that both animal and human souls were immortal and transmigrated. His doctrine of numbers was probably the basis for the four elements and four humors and the four critical days in illness described by Hippocrates (this is surprising since he valued the number seven). His theory of harmony may be the basis for the theory that health is the result of a balance among the various elements and humors. He believed that health is perfect harmony and disease is a disruption of this harmony. His most significant contribution to medicine and to toxicology was the importance of causality and the need for critical thinking. His other contributions to toxicology include his studies of the effects of metals (e.g., tin, iron, mercury, silver, lead, gold, copper) in the body. Since he left few, if any, writings, all of his teachings have come through his disciples.

Empedocles of Agrigentum (490–430 BC) was the son of Meto, an activist politician; he was born in Sicily and died in Peloponnese, Greece. He was of the Pythagorean school, a physiologist, physician, philosopher, religious teacher, poet, and politician who believed in the unity of things. He also believed that all matter consisted of four elements (the Chinese believed in five), earth, fire, air, water; that nothing is destroyed (accord/ love holds things together, discord/strife [stress?] tends to dissociate things). These two forces, one internal (accord) and one external (discord), are antagonistic (yang and yin?). His teachings became the basis for the four body humors—blood, phlegm, yellow bile (choler), black bile (melancholy)—and for the theory that health was the result of harmony among these humors and among the four elements (cf. Pythagoras). He was a strong advocate of hygiene, personal and

social, and of public health measures to prevent epidemics (e.g., draining of swamps). Although Aristotle is often credited with identifying the four elements, he was merely a strong proponent of the four elements and not the first to identify them.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_7.html[2010/10/28 18:28:43]

Empedocles believed the heart was the most important organ since it distributed the "pneuma" throughout the body. (Egyptians considered respiration most important.) He established the basis for sense perception. He was considered a wonder worker due to his great healing skills and to his abilities to prophesy. According to tradition, he cast himself into the crater of Mt. Etna to prove something or other.

"There is only one good, knowledge; there is only one evil, ignorance." (Socrates)

Socrates (470–399 BC), son of Sophroniscus, a sculptor who was dispatched with hemlock, the state poison, is probably the most famous victim of poisoning in history. He developed the Socratic method of inquiry, a series of questions designed to elicit clear expressions or answers. He had a strong contempt for conventional ideas and life-styles that ultimately led to his demise. His idealistic philosophy was passed on through the writings of Plato, his most famous student; Socrates left no writings of his own.

"Life is short, and the Art long; opportunity fleeting; experiment dangerous, and judgment difficult." (Hippocrates; was he thinking of toxicologists when he wrote this?)

Hippocrates (460–355 BC), the father of medicine, was born on the island of Cos, the son of Heraclides, a physician, and Phenarete. It is said that he was a member of the family of Asclepiadae. He was well educated and traveled extensively. He was a contemporary of Sophocles, Euripedes, Aristophanes, Pindar, Socrates, Plato, Herodotus, Thucydides, Phidias, and Polygnotus. He had two sons, Thessalus and Dracon, and many pupils. His contributions to the advancement of medicine are legendary, due in great measure to his belief that the causes of diseases were natural and not supernatural. In addition, he stressed the importance of nutrition/diet and believed that too little or too much food was equally harmful. What he lacked in instrumentation was more than compensated for by his use of the scientific method, sound observation, and logical reasoning. He is the presumed author of a number of significant texts and treatises characterized by advanced scientific and practical thinking and skillful clinical observation. Like other Greek physicians, he believed that health was the result of an equilibrium or balance in the body among the humors (blood, black bile, yellow bile, and mucus) and that disequilibrium resulted in ill health.

He apparently was the first physician of record (a clinical ecologist?) who believed that environmental factors should be considered as probable causes of disease. For example, in his book ***Airs, Waters and Places,*** he argued that environmental factors (overall weather, local weather conditions, and drinking water) can influence health. "Every disease has its own nature and arises from external causes, from cold, from the sun, or from changing winds." According to Hippocrates, the first step in treating disease, including poisonings, should be to purify the body of disease-producing humors by purgation (catharsis, purification) by diet or by drugs. This cleansing is the first step in restoring equilibrium (including the management of poisoning). Hippocrates probably foreshadowed the current practice of the clinical ecologists, who espouse thorough cleansing of xenobiotics from the body as the first step in restoring health.

Hippocrates taught that the body is maintained by air and nutriments, that it is nature that heals, and that the role of the physician is to assist nature in the healing process by increasing nature's healing forces ("help nature to help herself'; was he portending the current "back-to-nature" movement?). This can best be done by diet and modifying one's life-style, usually to get more rest and appropriate exercise. The key to good health is proper diet, sufficient exercise, and adequate rest (makes a great deal of sense even today!). Drugs may be used to assist the dietetic cure.

Hippocrates identified about 400 drugs, mostly of plant origin, that included narcotics (e.g., poppy, henbane, mandragora), purgatives, and sudorifics. He also advocated the use of emetics and enemas (as part of the cleansing process). The patient is a unit and must be treated as such (that is, as an individual), there must be very careful observation (good case history and physical examination?), and the approach to treatment should be appropriate, simple, and rational. Mysticism was not a part of his therapeutic regimen. His advice to physicians is summarized in his ***Aphorisms,*** which include being prepared "to do the right thing at the right time." He also established a code of medical ethics, the Hippocratic oath, which has survived to the present. His contributions to toxicology include the use of the scientific method, sound observation, logical reasoning ("the scientific method"), and basic approaches to the management of intoxication (decrease absorption; if ingested, induce vomiting) and the use of proper antidotes. He died in Thessaly in 355 BC.

"For where there is the love of man [humans], there is also love of the art." (Hippocrates)

The second most famous Greek physician, Diocles of Carystus (375–300 BC), was loved for his kindness toward his fellow humans and greatly admired for his oratorical skills. He wrote a number of famous texts including ***Anatomy*** (the first systematic textbook on animal anatomy), ***Dietetics, Physiology,***

Embryology, and ***Rhizotomikon*** (considered to be the first work on botany that included the names of the plants, their habitat, means of collection, and medical uses). His second book on plants described those used for food and his third book

< previous page page_8 next page >

Page 9

dealt with poisonous plants. His works indicate that serious studies on the pharmacology and toxicology of plants had begun. Another famous book by Diocles was one that dealt with personal and social hygiene.

Diocles' recommendations for good health included cleaning teeth, massaging gums, walking and exercising before breakfast (which was a light meal), drinking water before meals, napping in the afternoon, exercising before dinner (just before sunset and followed by white wine diluted with water and honey), walking, and early retiring. Good advice!

Hippocrates and Diocles extended toxicology beyond merely listing poisons and antidotes. Rational methods for the study of the effects of poisons and the treatment of poisoning were proposed. Experimental studies to assess the biological effects of plants had begun.

"Nature does nothing without a purpose." (Aristotle)

Aristotle (384–322 BC) was the son of the court physician to Amyntas II, a student of Plato, a teacher of Alexander the Great, and a philosopher and scientist (though not a physician) who stressed the importance of biology as a science (pre-med curriculum?) and thereby influenced medicine. A scientific genius, he established the foundations for comparative anatomy and embryology. His "Ladder of Nature" was the beginning of the concept of evolution (presaging Darwin). Like other Greek scientists and physicians of his day, he believed that the human body possessed four qualities—hot, cold, dry, and moist; that it was composed of four humors—blood, phlegm, yellow bile, and black bile; and that disease resulted from an imbalance of these. His contributions to toxicology are related to his contributions to science, especially biology.

Theophrastus (372–287 BC), one of Aristotle's most famous pupils, was a philosopher and scientist (probably the most famous Greek botanist/herbalist) who wrote ***Theoretical Botany*** and ***De Historia Plantarum*** in 300 BC (two volumes, inquiry into plants and growth of plants). They included the natural history and descriptions of medicinal and poisonous plants and are considered the beginning of modern botany and an excellent medical botany text. Indications for the use of medicinal plants were presented. He was also the first to record adulteration of food. He was interested in food preservation and found that certain soils preserved wheat but in so doing it became adulterated. Others adulterated wheat with soil to increase its weight. His contributions to toxicology include a list of poisonous plants and the recognition of adulteration of food (might he be considered the founder of food toxicology?).

Cato (234–149 BC) was interested in food preservation (salting) and in detecting adulterations, expecially of wine.

Nicander of Colophon (185–135 BC) was a Greek physician, poet, and grammarian who wrote, among other things, two hexameter poems, ***Alexipharmaca*** (properties of poisonous substances and antidotes) and ***Theriaca*** (bites and stings of venomous animals and antidotes). Although there were some fanciful parts, much was accurate and reflected upon his powers of observation and his experiences. Theriac has come to mean antidote against poisons. It survived into the 19th century and was considered by some to be a tonic and a means of maintaining good health. His contribution to toxicology is his list of poisons and antidotes.

King Mithridates VI Eupator the Great, king of Pontus, polyglot king (120–63 BC), was considered a military genius and a dabbler in poisons. He evaluated poisons and potential antidotes in slaves and in prisoners (without implied consent or institutional review boards and to eliminate the need for extrapolation!). He was a student of toxicology but was obsessively possessed with a fear of poisons. To provide protection, he took daily doses of poisons (beginning with very small doses and increasing the amounts ingested) to develop polyvalent tolerance (the first recorded successful case); he drank the blood of ducks fed toxic chemicals and took mixtures of antidotes. Mithridatium, his universal antidote, which was presumably invented by one of his physicians, Zopyrus, consisted of 20 leaves of rue, one walnut, a grain of salt, and two dried figs and was to be taken each morning before breakfast to effectively prevent poisoning. The Mithridaticum of Celsus consisted of 36 ingredients, Pliny's 54, and Galen's 73; each pill was the size of a grape and 10 had to be taken before and after food. Mithridates was captured and tried to commit suicide by selfpoisoning but proved immune to the actions of the various poisons. He was eventually killed with a sword (a throwback). The term ***mithridatics,*** antidotes or preventives for poisoning containing many ingredients, immortalizes his contribution to toxicology. He was probably the first to systematically study poisons in humans and thus became the first clinical toxicologist (could be considered the founder of clinical toxicology except for the nature of his clinical studies).

Heraclides Pontius of Tarentum (240 BC), a philosopher and student of Plato, was reported to have spent a great deal of time studying poisons and antidotes, but little remains of his contributions. He

used opium to induce sleep and was concerned with cosmetology. His greatest contribution to science was probably his contention that the earth rotated on its own axis.

Andromachus the Elder (ca. 60 AD) was an archiater, the public physician who treated the poor, and the royal physician to Nero. He added squills, viper's flesh, and opium to the mithridatium and administered it, in honey, to Nero. This became known as the Theriaca of Andromachus, Theriaca Andromachi, or Venice Treacle; it contained 70 substances and was used until the 18th

century. Interestingly, he wrote 175 Greek iambic verses describing it.

Dioscorides (Pedanius Dioscorides) (40–90 AD), was born in Anazarbia in Cilicia. He was a Greek physician and pharmacologist, physician and surgeon to Nero's army, and the originator of materia medica. He is the author of many texts, including one of the greatest works (if not the greatest) on materia medica of ancient times (77–78 AD). He took advantage of his military travels to study medicinal properties of plants and minerals, which he described in a five-volume series, *De Materia Medica*, *De Universa Medica*, the leading text in pharmacology for 16 centuries. Included are descriptions of about 600 plants and 1000 simple drugs. His approach differed from that in Eber's Papyrus, in which each disease had listed all the remedies for that disease. Dioscorides described a plant and then listed all the diseases it might cure. Also discussed are the dietetic and therapeutic value of animal products (e.g., milk, honey) and mineral drugs (e.g., mercury, arsenic, lead acetate, calcium hydrate, copper oxide). He also described a surgical anesthetic made from opium and mandragora and one made from an alcoholic extract of mandrake. He was the first to recognize the toxicity of mercury. His contributions to toxicology include classifying poisons into three major classes (animal, plant, mineral), identifying antidotes, and recommending decreasing absorption to control intoxication (for example, by inducing vomiting or purgation; cf. Hippocrates).

Galen of Pergamum (129–199 AD), considered by some to be the greatest Greek physician and surgeon, was the son of an engineer (Nicon) and was very well educated. He traveled widely to increase his knowledge of medicine (as did many others), studied philosophy, and began to write. He eventually became the most celebrated ancient medical writer and influenced medicine for 1500 years. His fame as an outstanding healer in Rome began with the successful treatment of the Aristotelian philosopher Eudemus, an influential Roman, who was dying despite the care of the best physicians in the city. Galen's practice flourished and his patients included the most influential Romans of the period. At this time, he was given a dissecting room in which to study comparative anatomy (using the bodies of slain gladiators). His benefactor, Flavius Boethus, also provided him with secretarial assistance, and several anatomy books followed. Galen is considered the founder of experimental physiology. He was the first to prove that the arteries carried blood and not air and conducted other experiments involving the nervous system, heart, and liver. He taught and practiced that it is essential to select the right drug for the right condition for the right patient; he introduced rationality into drug therapy.

Galen argued that although apothecaries knew drugs, only the physician understood both the drug and the patient, and further, that drugs are tools only for physicians (hence, few experimental nonphysician pharmacologists in Greece). He recommended mixtures of drugs for treating disease, which is the basis for the term *galenicals.* The foundation of his writings was the teachings of Hippocrates. Galen tried to amalgamate the various doctrines espoused by Hippocrates, including qualities, four humors, pneuma, and physis. Galen also believed, as did many early physicians, that health depended upon a balance of the various bodily humors (phlegm, blood, yellow bile, black bile). He identified four personality types (phlegmatic, sanguine, choleric, melancholic) based on these four humors. He tried to establish a composite system of medicine, one that would include formulas/principles that would remove uncertainty from the decisions of practicing physicians. He further developed the theriac, the universal antidote, to include 100 substances, which was to be administered in honey and wine. His advice to physicians (also valid for toxicologists): "If anyone wishes to gain fame through these, and not through clever talk, all that he needs is, without more ado, to accept what I have been able to establish by zealous research."

Paul of Aegina (625–690 AD), celebrated Byzantine physician, authored a seven-volume medical encyclopedia, *Epitome.* It is based on the 70 books by Oribasius and other writings. Book 5 deals with toxicology, specifically bites and wounds of venomous animals. Paul was probably the "last Greek compiler."

The contributions of the Greeks to the advancement of toxicology include comprehensive lists of poisons and antidotes, experimental studies of the biological effects of plants (plant constituents) and metals, and rational methods for the management of poisonings.

Roman

The Romans also had an intense interest in poisons. They derived a great deal of their knowledge of medicine from the Greeks and from other cultures. Aurelius Cornelius Celsus (30 BC-AD 50), the "Cicero of physicians," "Hippocrates of the Romans," the greatest Roman medical writer and an armchair physician, was a Roman nobleman of the Cornelii family, a man of letters, and an encyclopedist who authored the outstanding encyclopedia of his day and a number of books on medical subjects. He provided a systematic survey of medicine, presented sound principles of good surgery, and stressed the

application of common sense to medical issues. Only eight volumes of his classic *De Medicina* survived. It was a medical classic and included discussions of many diseases. The importance of dietetics in treatment was stressed. He was the first to identify the four signs of inflammation: calor, rubor, tumor, and dolor.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_10.html[2010/10/28 18:30:33]

He also stressed cleanliness, the use of vinegar (currently experiencing a renaissance) and thyme oil to cleanse wounds, the use of ligatures to stop bleeding, and the use of skin from other parts of the body for facial plastic surgery. He believed that "the best medicament is food opportunely given." He also introduced the nutrient enema. *De Medicina* is considered basically Hippocratic with some methodism. Book 5, *Toxicology and Rabies,* included the works of Nicander and Dioscorides and poisons and antidotes. Celsus was not interested in mechanisms or theories of poisoning. He cited others who believed that poisons and animal venoms depressed the vital factor resulting in the loss of innate heat and chilling. Incidentally, *De Medicina* was one of the first medical works to be published after the introduction of the printing press (1478).

Consistent with Hippocratic teaching, Celsus also advocated getting rid of the poison as quickly as possible. He proposed free bleeding, sucking the wound, amputation, promoting evacuation, eliciting heating action (by administering hot, peppery materials or by the application of the warm flesh of a freshly killed fowl or small animal to a wound), and "poisoning the poison" (acrid materials applied to wounds, cupping severe wounds, suction with palms of the hand, and the use of hypertonic salt solutions). In addition, he recommended the use of appropriate antidotes (including the antidote of Mithridates, 37 ingredients in honey). His contributions to toxicology include his list of poisons and antidotes and the management of poisoning.

Pliny the Elder, Gaius Plinius Secundus (23–79 AD), was born in Como. He was a famous Roman naturalist, historian, military tactician, philosopher, and one of the most learned men of his time. He wrote 160 books. Although he was not trained in medicine, he chronicled medical history. His quest for knowledge was insatiable (it is said that he died while trying to observe an eruption of Vesuvius). He collected data about all living things. He was skeptical of the value of mithridatics. He described poisonous plants and animals and the types of injury they cause in his famous *Historia Naturalis* (Natural History), a compendium of information that consisted of 37 books. He advocated the doctrine of signatures, which stated that the therapeutic usefulness of a plant, mineral, or animal was based on its resemblance to the signs of a disease. This doctrine persisted for many centuries and still has a few proponents. He was also interested in adulteration of foods and developed methods for the detection of adulteration (e.g., chalk in flour, herbs, and spices). Like Hippocrates and others, he believed the "the greatest aid to health is moderation in food." His contributions to toxicology include lists of poisons and their biological effects and his questioning of the value of nonspecific antidotes like mithridatics.

Arab

The Arabs made significant contributions to the health professions. For example, their pharmacies are considered to be the forerunners of modern pharmacies. Since Avicenna believed in the importance of keeping patients happy, he instructed pharmacists to make medicines pleasant. To this end, the pharmacists developed sugar-coated pills, mixed rose water or perfumes with medicines, and were the first to wrap medicines (pellets) in silver foil. To make the physician's job easier and to promote more effective healing, Arabian pharmacists are credited with developing or perfecting tinctures, confections, syrups, pomades, plasters, and ointments.

Avicenna (Abu Ali Husain ibn Abdullah ibn Sina, 980–1037), the "Prince of Physicians," was born in Bokhara, Persia. He was a child prodigy who knew the Koran by heart at the age of 10. He studied philosophy, jurisprudence, and mathematics; at the age of 16 he turned to the study of medicine. By 18, his fame as a physician was so great that he was appointed physician to the prince and became physician-in-chief to the hospital in Baghdad. Avicenna was given access to the library of the prince as a token of gratitude and appreciation for healing the prince of a serious ailment. He was also the personal physician to other caliphs. By the age of 21, he had written a 20-volume encyclopedia. He developed a philosophy (avicennism) that was partly Aristotelian and partly new platonic. His most significant medical works were his *Book of Heal-ing* and *Canon of Medicine,* a five-volume treatise that included *The Theory of Medicine, Simpler Drugs, Special Pathology and Therapeutics, General Diseases,* and *Pharmacopoeia*. He also discussed oral and parenteral poisons, bites and stings and their treatment, and classified and discussed poisons as plant, animal, or mineral (cf. Ebers Papyrus). He was also the first to describe the fetid odor exhaled by those poisoned by mercury (Ecobichon, personal communication). In addition, he developed his own psychiatry and believed that psychic alterations were the result of changes in the brain (pathology due to humors [neurotransmitters?]).

His books were logically arranged (an example of "Aristotelian dialectic and Arabian scholasticism"). He was a logical thinker and an astute observer. Some have referred to him as a second Aristotle. Avicenna wanted to develop a system of medicine, to make medicine "a quasi-mathematical discipline." This would remove uncertainty from medical decisions (cf. Galen). His contributions to toxicology include

mechanisms of action of poisons including neurotoxicity and metabolic effects. He also recommended the bezoar stone as an antidote for venoms and preventive of disease. Despite his many accomplishments, Avicenna was not "a dryasdust;" he was "a man of the world, he loved wine, women, and

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_11.html[2010/10/28 18:30:34]

song—more ardently, perhaps, than was good for his health.... But before he reached the age of fifty-eight his bodily powers were exhausted, and he died" (some believe of an overdose of opium). His work was the authoritative text on poisons and antidotes for 500 years.
Note that the Arabs translated most of the important Greek works. The Arabs excelled in chemistry and invented distillation, sublimation, and crystallization. They introduced camphor, benzoin, saffron, laudanum, and naphtha.
Arabian doctors as a rule watched each other jealously. Disagreements were at times settled by duel-by-poison. In such duels each doctor was expected to take his opponent's poison, then find a quick antidote. Two court physicians once tried it: The first doctor's draught was fierce enough to "melt black stone," but his rival parried with an antidote. Then the second doctor picked a rose, mumbled an incantation, and asked his antagonist to sniff the flower. The first doctor complied, and promptly fell dead. Fright had killed him, for the rose was only a rose.
The Persians also believed in the "Poison Maiden." An attractive young girl was fed poisons (increasing doses of a number of poisons) so she became very "venomous" (double seduction). A kiss or sexual intercourse with her would prove fatal to her lover. Avicenna mentions such a girl; she was so venomous that insects that bit her were poisoned and died.
"Man should believe nothing that is not attested to (1) by rational proof as in mathematical science, (2) by evidence of the senses or (3) by authority of prophets and saints." (Maimonides)
Rabbi Moses ben Maimon (Moses Maimonides, 1135–1204), was a famous Jewish philosopher and physician, court physician to Saladin, and rabbi of Cairo. His book on poisons, *Poisons and Antidotes/Upon Poisoning and Its Treatment,* was translated into Latin by Armend and Blasii in 1305, into French in 1865, and into German in 1873 by Steinschneider. He described poisonous insects and animals and noted that the most dangerous bite was that of a fasting human. His treatment of poisons included "ligature of the bite, sucking out the poison by means of cupping glasses or with the oiled lips, again extending Hippocratic teaching to decrease absorption, and the use of external (e.g., salt, onions, asafetida) and internal remedies (e.g., emetics)." It was a much-cited text. His books on health were very advanced and are considered modern. He believed in the importance of preventive medicine and stressed the importance of hygiene; he wrote a four-volume treatise upon hygiene and diet *(Sepher Rephuoth)*. His aphorisms are as pertinent today as when they were written.

Others

Pietro de Abano (1250–1316) was born in Abano near Padua. He was a teacher of science and medicine at the University of Padua and one of the most famous teachers and skillful physicians of his time, and the author of *De Venemis,* a book of poisons. Like others before him, he classified poisons as mineral, vegetable, and animal, and he was the first to identify sound as a potential poison. He further noted that poisons can be absorbed from air and through the skin ("poisoning by touch"). The book was very popular and went through 14 editions. He also wrote *Conciliator Differentiarium,* an attempt to reconcile Greek and Arabic medicine. This tradition in toxicology has been maintained even until today, when Marcello Lotti directs an internationally recognized institute of occupational/medicine and toxicology.
The age of observations (recording phenomena) and categorizing and listing poisons gave way to the period of challenge and active investigation—experimental toxicology—through the efforts of one of the most controversial yet influential figures in medicine, Paracelsus. Although others made observations in humans (often after deliberately administering a poison), Paracelsus encouraged the use of animals to study poisons. He also developed and promulgated certain basic principles of the action of chemicals (e.g., dose-response) that still form the scientific underpinnings of modern experimental toxicology.

THE AGE OF EXPERIMENTAL TOXICOLOGY

"The universities do not teach all things." (Paracelsus)
Philippus Theophrastus Aureolus Bombastus von Hohenheim (Paracelsus, 1492–1541) was born near the village of Einsiedeln near Zurich, Switzerland, on November 10 (or 14), the son of Wilhelm Bombast von Hohenheim, a German physician/alchemist. Following the death of his mother when he was still very young, Paracelsus with his father moved to Villach in southern Austria, where his father taught chemistry, practiced medicine, and became interested in the health problems of the local miners, eventually becoming an expert in occupational medicine. Paracelsus attended the universities of Basel, Tubingen, Wittenberg, Leipzig, Heidelberg, Cologne, and Vienna, from which he received a baccalaureate in medicine in 1510, at the age of 17. He received his doctorate from the University of Ferrara in 1516. Since it was the custom of the humanists at that time to Latinize their names after they received their degree, he began using the name Paracelsus (*para* Celsus, above Celsus), since he considered himself greater than Celsus. Deichmann et al. (1986) claimed that Paracelsus "is a Greco-Roman translation of

Hohenheim and says 'next to heaven.'" He traveled throughout Europe, England, Scotland, Egypt, the Holy Land, and Constantinople, attempting to learn the most effective means of medical treatment and the latest findings in alchemy.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_12.html[2010/10/28 18:30:35]

He wanted to discover "the latent forces of nature" and wrote, "He who is born in imagination discovers the latent forces of Nature…besides the stars that are established, there is yet another—Imagination—that begets a new star and a new heaven." He returned to Villach in 1524 and became town physician and lecturer in medicine at the University of Basel in 1527. His fame had spread, and students flocked to his lectures.

Paracelsus believed all physicians who preceded him were incompetent, liars, or fakers. "I am to be the monarch, and the monarchy will belong to me." He defied tradition (a young Turk!). Paracelsus drastically and permanently changed the course of medicine. Although a theosophist and an iconoclast, he was a keen student of human behavior, a forerunner of Freud, a chemical anatomist, the founder of medicinal chemistry, and the "godfather of modern chemotherapy," who believed that practicing physicians needed to use common sense, gain experience, travel, and practice humility (good advice that is relevant and sound today). He was a peripatetic physician and was always trying to learn more medicine. His approach to medicine and the body was chemical. For example, he taught that it was more important to learn about the chemical composition of the body than about the muscles. Since God created (caused) diseases, God (Nature) also provided cures. It was the role of the alchemist (chemist) to find these and convert them to effective remedies. Paracelsus began with simple materials, the metals. When the "conservative physicians" warned that metals would poison patients, Paracelsus replied, "This poison, as you call it, has a far better effect than the wagon grease…with which you are so fond of smearing your patients."

His disdain for established authorities, for everything that had been said by his predecessors, reached its climax on 24 June 1527 when he publicly burned the books of Avicenna and Galen in front of the university. He discarded the old ways, including humoral pathology, but upheld Hippocrates; he attacked medical principles of his time, trusted only his own observations, ideas, and works, and tried to bring chemistry into therapeutics by encouraging the use of mineral salts, acids, and chemically prepared therapeutic agents ("better living through chemistry"), since he believed that the body was a chemical laboratory.

Paracelsus was a free thinker. He developed his own system of medicine and boasted about his contempt for science. One of his methods of learning was theosophical intuition; that is, all knowledge is the result of mystical insight, all wisdom comes directly from God, and one should be in intimate contact with God and God's creation. Submit to the will of God and all knowledge will flow. This intuitive process of learning was also part of gnosticism. He appeared to be contemptuous of the established way of thinking and believed that man was a little world (microcosm) that contained all knowledge. This was based on man's direct descendancy from Adam, who had within himself all sciences since he contained the germs of all creatures. In his book *Paramirum,* Paracelsus described his system of medicine. Health, disease, and human destiny depend upon five entia (cf. Shen Nung); disease is caused by the five entities: ens astrale (influence of the stars), ens venini (influence of nutrition/poisons in food), ens naturale (nature and functions of the body), ens spirituale (spirits, demons), and ens Dei (acts of God directly upon us to restore order and health). His theory of humors included three elementary principles: salt (representing stability), sulfur (representing combustibility), and mercury (representing liquidity). Disease is a separation of one principle from the other two (disequilibrium among humors/ principles?). He also believed, according to Cole, that there are five phlegms, five hydropathies, five jaundices, five fevers, five cancers, and so forth. Diseases tend to be localized in a particular "target" organ. Although he tried to bring more chemistry into medicine (e.g., by the use of inorganic salts), he also believed that God will provide cures for us since God is benevolent.

Paracelsus wrote that "nature hints at cures." This is the basis for the doctrine of signatures (cf. Pliny the Elder, "that an agent of nature shows by its external forms its unique qualities"). For example, since turmeric is yellow, use it to treat jaundice, foxglove for heart, figwort for scrofula, and hepatica for liver disease. Cope (1957) described Paracelsus as arrogant and conceited "almost to the point of insanity…extremely effective in [his] criticisms of the then accepted doctrines…reveled in the wildest speculations and taught [his] mad conjectures as unassailable truths…bitter and unscrupulous controversialist…mystic…his writings…so confused and obscure as to be often quite unintelligible… braggart, scorner of authority…that Paracelsus scarcely ever lectured except when he was half drunk, or attended a patient until he was wholly drunk." Paracelsus defended himself in his *Seven Arguments, Answering to Several of the Detractions of His Envious Critics,* written in 1537.

But what of Paracelsus's positive contributions? He was an original but eccentric thinker. He is considered by some to be the father (founder) of chemistry and/or medicinal chemistry and the reformer of materia medica. He did not support the humoral basis for disease; he believed that diseases

were specific/discrete conditions and are cured by specific/discrete treatments. He taught that observation and experience are essential for success in medicine (and in science?). He is credited with the introduction of the following into the practice of medicine of his day: mineral baths, laudanum, mercury, lead, arsenic, copper sulfate, and iron. He forever destroyed the doctrine of the four humors. His principal works include

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_13.html[2010/10/28 18:30:35]

Chirurgia magna (1536), *De gradibus* (1568), and *A Treatise on Diseases of Miners* (1567). In one of his books, *Paragranum,* he presents the four pillars upon which medicine should be based: philosophy (knowledge of nature; disease and healing are part of nature); astronomy (heaven paternalistically deals with us); chemistry (provide drugs and insight into biological events; "nature is the ideal chemist"); and virtue (love is the foundation of medicine). In his *Third Defense,* he wrote, "What is there that is not poison? All things are poison and nothing (is) without poison. Solely, the dose determines that a thing is not a poison." (Deichmann et al., 1986). This is often misquoted as "the dose makes the poison." This concept has been expanded to include no-effect level, threshold, extrapolation, and dose-response relationship. His other contributions include target-organ toxicity, animal experimentation to study the effects of chemicals, and the use of inorganic salts in medicine. He was thoroughly seduced by the complexity of chemical-biological interactions and spent his lifetime trying to solve the mysteries of these interactions.

Paracelsus's teachings in psychiatry are often overlooked and may be as significant as his contributions in other medically related areas. For example, he believed that in man there are two antagonistic forces, animal and godly, and that man has to suppress the animal spirit if he is to be successful (yin and yang, id and superego?). He also believed that psychoses are not demonic in origin, the mind (will or spirit) can influence the state of the body (cure or cause some diseases—psychosomatic medicine?) and not the existence of a subconscious, and that women are different from men and must be treated differently ("men are from Mars and women are from Venus").

Paracelsus was a deeply religious man. "He was intensely concerned with the eternity, or soul, in man, and felt that a doctor was neither "pillmaker" nor businessman, but a legate of God, the supreme physician. Medicine was therefore a divine mission, and the doctor must raise his eyes from "excrements and salvepots to the stars." The perfect physician, he felt, was a philosopher, an astrologer, an alchemist and above all, a virtuous man. The character of such a doctor, Paracelsus proclaimed, was far more effective than mere mechanical skill (Amen!) (Bettman, 1959).

Paracelsus died prematurely at age 49. Some say he died in a brawl at the White Horse Tavern in Salzburg on 24 December 1541, presumably exhausted. Despite his early death, he made an indelible mark on medicine and especially on toxicology.

The French physician, poet, and playwright Jacques Grevin (1538–1570), "the father of modern biotoxicology," published his classical work, *Deux Livres des Venins,* in 1568 and further developed the concept of chemical-biological interactions.

Some of the concepts developed by Paracelsus were further developed by others. For example, Felice Abate Fontana (1720–1805), an abbot, physician, physiologist, naturalist, and professor of philosophy at Pisa and director of the Natural History Museum at Florence, advanced the concept of target-organ toxicity; that is, the symptoms of poisoning are the result of poisons acting on a particular organ. He is considered the first modern scientist to study venoms (*Ricerche fisiche sopra il veleno della vipera,* 1767). He is also known for the spaces of Fontana (*Dei moti dell'iride,* 1765). Although Paracelsus drew attention to the plight of miners, little attention was focused on the effects of nondeliberate exposure to chemicals, for example, in the workplace. It was the brilliant Italian physician Bernardino Ramazzini (1633–1714) who effectively and convincingly brought the workplace situation to the attention of the world, especially to the field of medicine. He was the first to describe, in a comprehensive, systematic, and detailed fashion, industrial health problems in his *De Morbis Artificium Diatriba* and his famous *Diseases of Tradesmen/Workers,* which was originally published in 1700; the English edition appeared in 1705. As an astute scientist and physician, he had remarkable powers of observation. He first described "stone mason's consumption [silicosis], potter's sciatica, gilder's ophthalmia and lead poisoning." He is the founder of occupational/industrial medicine. He also advocated the use of cinchona bark to treat malaria, which ran counter to Galen's recommendation that it be treated with purgatives.

The observations of Ramazzini concerning the relationship between workplace exposure and disease were strengthened and extended by the classical studies of Sir Percival Pott (1714–1788), the famed British physician and surgeon to St. Bartholomew's Hospital, who achieved fame in two areas, occupational medicine/ toxicology and orthopedics. He sustained an ankle fracture following a fall and described it so well that it became known as Pott's fracture (*Treatise on Fractures,* 1750/1769). Pott's disease (caries of the spine) was first described by Percival Pott. He later described the relationship between scrotal cancer and soot in chimney sweeps (1775). His contributions to toxicology include the identification of chemical carcinogenesis in humans and noting the increased sensitivity of children to chemicals (a concept currently enjoying a resurgence).

Attempts to explain the action of toxins attracted the attention of some of the intellectual giants in the

biomedical sciences (intellectual seduction). A few will be mentioned. Ambrose Pare (1510–1590) has been called "the greatest surgeon of the 16th century," the founder of modern surgery, and one of the most famous anatomists of all time. He introduced the use of ligatures of blood vessels as opposed to cauterization and authored many

books on medical topics, including anatomy, surgery, malformations, and obstetrics. He investigated CO poisoning and published a report in 1575. On the other side of the channel, Richard Mead (1673–1754), a British physician with a medical degree from Padua who worked at St. Thomas' Hospital and was also physician to the royal family, attempted to explain the action of poisons (venoms) in his book *A Mechanical Account of Poisons* (1702). He described snake poisoning and noted that the venom is only effective parenterally. To prove this, he swallowed the venom and (fortunately) nothing happened. He also authored a book on the influence of the sun and moon on human bodies. The formal beginning of mechanistic toxicology, however, was to await the experiments of Magendie and Bernard, discussed later.

Forensic toxicology, the application of analytical techniques to the detection of poisons, had its beginning with Joseph Jacob Plenck (1738–1807), who noted in his text, *Elementa Medicinae et Chirurgiae Forensis,* that "the only certain sign is the chemical identification of the poison in the organs of the body," which is still a basic principle of forensic toxicology. Unfortunately, his works were not accepted by the medical or scientific communities of his day.

The application of analytical chemistry to matters of food and drug safety formally began with Friedrich Accum (1769–1838), although earlier attempts were made by Theophrastus (370–285 BC), Cato (234–129 BC), Pliny the Elder (23–79), Dioscoridies (40–90), and Galen (131–201). Born in Buckebourg, Germany, Accum moved to London in 1797 as a pharmacist and in 1801 began working with Sir Humphrey Davy. Being entrepreneurial, he also set up his own contract laboratory and supply house. He was the first to use analytical chemistry to detect adulterants in food and published *A Treatise on Adulterations of Food and Culinary Poisons* in 1820, a very successful book that was acclaimed worldwide. He later published *An Attempt to Discover the Genuineness and Purity of Drugs and Medicinal Preparations.* He left England and returned to Germany because of the many (false) charges directed against him.

THE AGE OF MECHANISTIC AND ANALYTICAL TOXICOLOGY

When you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely in your thoughts, advanced to the stage of science. (William Thomson, Lord Kelvin)

The adverse effects of chemicals (including poisons) in humans and extensive lists of poisons and antidotes had been recorded, some poisons had been evaluated in animals, and analytical techniques were being applied to toxicological problems. Toxicology was being recognized as a scientific discipline. But little was being done to answer the basic question, "How do poisons kill?" The era of mechanistic toxicology formally began with the classical studies of the two most famous physiologists in medical history, François Magendie and his pupil Claude Bernard. Contributions had been made by others, but these were limited and not as systematic, fundamental, and far-reaching as those of Magendie and Bernard.

François Magendie (1783–1855), French physician and experimental physiologist, contributed significantly to the advancement of physiology, medicine, and toxicology. For example, he demonstrated the functioning of spinal nerves and he studied blood flow, swallowing, and vomiting. He is credited with the introduction of strychnine, iodine, and bromine compounds into medicine. His interest in the functioning of the nervous system led him to establish the mechanisms of action of emetine and strychnine and the dynamics of movement across body membranes. He was also the first, or one of the first, to observe and describe anaphylactic shock. His most famous pupil, Claude Bernard (1813–1878), the son of a Burgundian vinegrower, studied pharmacy and enjoyed science, but wanted to be a playwright; his critics told him to study medicine and fortunately for humankind, he accepted their advice. He went to Paris and was accepted as an assistant by François Magendie at the Hotel Dieu. He enthusiastically endorsed Magendie's philosophy that physiologists must discover the laws of "vital manifestations" or physiological functions and that observation and experimentation were the only methods of investigation. He received his degree in 1843; his thesis dealt with gastric juice and digestion. He and Magendie did much to advance physiology, especially of the nervous system (autonomic) and the gastrointestinal tract, including the liver. Bernard studied both normal and pathological physiology. His contributions to toxicology include furthering the concept of target organ toxicity, establishing approaches to defining the mechanism of action of drugs and other chemicals (e.g., curare, nicotine, carbon monoxide), demonstrating that the basic principles of pharmacology and toxicology are identical, and showing that drugs and other chemicals can modify the function and structure of tissues. He believed that "the physiological analysis of organic systems…can be done with

the aid of toxic agents" (a new use for poisons!). His works were published in 18 volumes. One of his most famous, *An Introduction to the Study of Experimental Medicine,* was published in

1865 and translated into English in 1949. It is a classic in the field of experimental biology and "must" reading for all students of biology and medicine.

"One must break the bonds of philosophic and scientific systems as one would break the chains of scientific slavery. Systems tend to enslave the human spirit" (Introduction to *l'Etude de la Medicine experimental,* 1865).

Bernard's work stimulated others to experimentally establish the mechanisms of action of toxic agents and to publish textbooks. For example, Francesco Rognetta (1800–1857), an Italian physician and scientist, significantly advanced our knowledge of the mechanisms of action of toxic agents, especially arsenic. The Florentine physician and scientist R.Bellini (1817–1878) authored the first experimental toxicology text, entitled *Lezioni Sperimentali de Tossicologia*. The discipline of toxicology was also advanced by the outstanding research efforts of such noted pharmacologists as Rudolph Buchheim, Oswald Schmiedeberg, and Lewis Lewin (again noting the closeness of these two disciplines).

The time had come for analytical techniques to be formally incorporated into toxicology. It had been difficult to establish poisons as the cause of death since they could not be identified in tissues, the only scientifically valid proof. Analytical (forensic) toxicology had its formal origins in the outstanding work of Orfila. His investigations were also the forerunner of modern pharmaco- and toxicokinetics and dynamics.

"Measure what can be measured; make measurable what cannot" (Galileo).

Mathieu Joseph Bonaventure Orfila (1787–1853) was born on the island of Minorca. He was educated in Valencia and Barcelona and studied chemistry and medicine in Paris, receiving his medical degree from the University of Paris in 1811. In 1813–1815, he published his classical and monumental two-volume work, *Traité de Toxicologie: Traité des poisons tirés des regnes mineral, vegétal at animal ou toxicologie générale considerée sous les rapports de la physiologie, de la pathologie et de la médecine légale* (Crochard, Paris). This is probably the first book devoted entirely to toxicology and thereby established toxicology as an experimental science different from pharmacology. Orfila classified poisons into six classes including animal, vegetable, and mineral (not unique; cf. Ebers Papyrus and others). He presented the chemical, physical, physiological, and toxic properties of each chemical, methods of treatment and chemical tests for their identification. This classic work, the first of its kind, effectively combined forensic and clinical toxicology with analytical chemistry. It was translated into English in 1817. In 1816, Orfila published *Eléments de chimie médecale* and in 1818, *Secours à donner aux personnes empoisonnées ou asphyxixés*. He provided a rational basis for some antidotes. He demonstrated the toxicity of strychnine in numerous experiments on dogs. At that time, strychnine was widely used in prescriptions and in tonics and was considered by practitioners of medicine to be a safe drug (Magendie later established the mechanism of action of strychnine). He later published *Leçons de médecine légale* (1821), in which he classified poisons as "irritants, narcotics, narcotico-acrids and putrefiants."

Orfila's books were translated into many languages and this helped him to internationalize toxicology (presaging the efforts of Coulston, Doull, Golberg, Zbinden, and others). He was appointed professor of legal medicine at the University of Paris and became dean of the faculty in 1831. He founded the Musée Orfila of Comparative Anatomy. He retired in 1848 and died in 1853. Orfila was an excellent analytical chemist and very capable physician; he was an experimentalist and administered known doses of poisons to animals, carefully observed effects produced, examined organs for evidence of toxicity (target-organ toxicity), and chemically analyzed tissues and body fluids to establish relationships between dose, response, and tissue levels. He was able to demonstrate conclusively and quantitatively that poisons are absorbed from the gastrointestinal tract and accumulate in tissues. His significant contributions to toxicology include the chemical detection of poisons in tissues and fluids, thereby permitting better diagnoses; furthering the concept of target organ toxicity by evaluating tissues grossly and histologically; relating symptoms to specific tissue injury; and extending the concept of dose-response.

His influence on modern toxicology is legendary and probably secondary only to that of Paracelsus and Bernard. His books were published in many languages and used in many countries (including the United States). He spawned other works in toxicology and brought to toxicology the recognition it deserved and needed. For example, Sir Robert Christison (1797–1882), a noted Scottish physician with a medical degree from Edinburgh, studied toxicology with Orfila and became professor of forensic medicine and materia medica at Edinburgh. He published *A Treatise on Poisons* in 1829. The fourth edition, published in 1845, became the first American edition. He also strove to provide a further scientific basis for toxicology. His works helped develop the basis for expert witnessing (and created opportunities for

consultants!). Alfred Swaine Taylor (1806–1880), famous British physician and the founder of British forensic medicine, is also the founder of modern medical jurisprudence, a natural sequel to the development of forensic toxicology. He received a diploma from the Apothecaries Society in 1828, his certificate to practice from the Royal College of Surgery in 1830, and presented the first course in medical jurisprudence in England in 1831. He taught chemistry and medical jurisprudence

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_16.html[2010/10/28 18:30:37]

at Guy's Hospital. He was probably the most famous expert witness of his time and published his *Manual of Medical Jurisprudence* in 1842. It became very popular, and the tenth edition was published in 1879. Other forensic toxicologists of note include the following: Henry Coley, New York City forensic toxicologist, published *Poisons and Asphyxia* in 1832. Included in this book were mineral acids, caustic alkalis, ammonia, nitrates, phosphorus, cyanide, metals, and alkaloids, as well as their chemistry, uses, signs and symptoms of poisoning, cause of death, postmortem findings and treatments. James M.Marsh, developed a test for arsenic (1836). Duflos, developed a test for systematically searching for mineral poisons that involved wet ashing with chlorine (1838). Hugo Reinsch, developed a test for arsenic and mercury (1842). Frensenius and von Bobo reported on a systematic scheme for detection of mineral poisons using wet ashing with chlorine (1844); Jean Servais Stas developed a method for extracting alkaloids from cadavers (1850). T.Graham and A.W.Hofman reported on the adsorbing properties of charcoal (adsorbed strychnine from beer) and proposed utilizing adsorption in toxicological analyses (1853). Theodore George Wormley published *Microchemistry of Poisons,* the first American toxicology textbook (1867). Lieben reported on an iodoform test for alcohol (1870). K.L. Dey developed a test for opium in toxicological analysis. A.W.Blyth published *Poisons: Their Effects and Detection,* an excellent analytical toxicological text (1884). Rudolph A.Witthaus and Tracy C.Becker edited a four-volume text, *Medical Jurisprudence, Forensic Medicine and Toxicology,* which became the standard reference text in the field (1894–1896). Walter S.Haines and Frederick Peterson wrote a toxicology text (1903). Alexander Gettler, who probably influenced the development of forensic toxicology in America more than anyone else, began working in the Office of the Chief Medical Examiner in New York City (1918). Rolla Harger developed the Drunkometer for testing drivers presumed to be under the influence (1937).

Advances in chemistry, physiology, pathology, and clinical medicine in the 18th and 19th centuries resulted in significant advances in toxicology. The discipline of toxicology was recognized in the scientific community as a distinct entity, separate from pharmacology and drawing upon chemical, biological, and physical sciences. Today, toxicology continues to benefit from advances in all the sciences.

The advances in forensic toxicology paralleled advances made in understanding the basic mechanisms of action of chemicals and drugs. The mechanistic studies of Claude Bernard were furthered by many scientists including the brilliant German chemist, microbiologist, and immunologist Paul Ehrlich (1854–1915) who significantly advanced mechanistic toxicology (toxicodynamics) and pharmacology (pharmacodynamics). His keen interest in chemistry and biological structure and function led him to propose the concept of a receptor as the sensitive site for chemical-biological interaction; that "chemical substances in organisms had specific points of attachment" (receptors), and once these were known, specific remedies could be developed. His most famous remedy was the use of arsenic in the management of syphilis (Compound 606, arsphenamine). He subsequently identified several receptors. His successful bout with tuberculosis stimulated his interest in immunity (as did his association with Koch), and he subsequently formulated the concepts of active and passive immunity and the side-chain theory of immunity. His contributions to toxicology and pharmacology include developing the receptor theory (the founder of the receptor theory), underscoring the importance of mechanistic studies and structure-activity relationships. He shared the Nobel prize for physiology and medicine with E.Metchnikoff in 1908.

Rudolph Kobert (1854–1918), a student of Oswald Schmiedeberg (one of the founders of modern pharmacology and toxicology and himself a student of Rudolph Buchheim, the founder of modern pharmacology), published a toxicology textbook (1893). A contemporary, Louis Lewin (1854–1929) reported on the toxicology of alcohols, chloroform, opiates, and plant-derived hallucinogens and also wrote a toxicology text (1929).

Mechanistic studies led to a better understanding of the toxic action of many chemicals and to the development of specific antidotes: for example, the use of BAL (dimercaprol) as an antidote for arsenic (based on the studies of Carl Voegtlin [1923] and Rudolph Peters [1945]), nitrite and thiosulfate for cyanide (K.K.Chen [1934], one of America's most distinguished pharmacologists), and organophosphorus compounds and the use of 2-PAM (Wilson [1951, 1955] and W.Lange and G.Schrader [1952]).

Occupational medicine and industrial toxicology were identified by Paracelsus, systematized and advanced by the pioneering efforts of Bernardo Ramazzini, and further advanced by one of America's foremost physicians, Alice Hamilton (1869–1970). Physician and pathologist, she researched occupational diseases, publicized the hazards of industrial chemicals to workers, and wrote several books on industrial toxicology. She was the foremost woman occupational physician and industrial hygienist, the first woman faculty member of the Harvard Medical School, and the only woman to serve on the Health

Committee of the League of Nations. She graphically described the history of industrial toxicology/occupational medicine in the United States in her autobiography, *Exploring the Dangerous Trades* (1943). Others who contributed significantly to this field include Cecil Drinker (1887–1919) of Harvard; R.Bohm

(who believed that toxicological information was accumulating very rapidly; mechanisms of toxicity were being elaborated and exposure to chemicals was increasing due to advances [?] in manufacturing); and Ethel Browning (1891–1979), who received her doctorate in medicine in 1927 and wrote the *Toxicity of Industrial Organic Solvents* in 1937. Interestingly, this was the first book on this subject and was written when Browning had no personal occupational medical experience. Her other publications included *Ionizing Radiations* (1959), *Toxicity of Industrial Metals* (1961), and her greatest work, *Toxicity and Metabolism of Industrial Solvents* (1965).

The stage was set for the application of toxicological principles and findings to protection of the public and especially workers from the adverse effects of chemical exposure. Consumers also needed protection from the potentially adverse effects of chemicals found in air, water, foods, and other consumer products.

AGE OF SAFETY EVALUATION, QUANTIFICATION, AND PROGNOSTICATION

"In no single thing do men approach the gods more readily than in giving of safety to mankind" (Cicero).

In the United States, Harvey Washington Wiley (1844–1930), physician and chemist, served as head of the Bureau of Chemistry of the U.S. Department of Agriculture from 1883 to 1912. His main goal was to provide effective food and drug legislation to protect the unsuspecting public. His efforts culminated in the first U.S. Food and Drug Act (1906), which has been expanded and which formed the basis for food safety legislation worldwide. He issued a number of bulletins summarizing his studies of the effects of food chemicals in human subjects, the "Poison Squad." He wrote, "Injury to public health, in my opinion, is the least important question in the subject of food adulteration, and it is the one which should be considered last of all. The real evil of food adulteration is deception of the consumer." Wiley also served as Director of Foods, Health and Sanitation for Good Housekeeping magazine from 1912 to 1930. He wrote a number of books, including *Principles and Practices of Agricultural Analysis* (three volumes, 1894–1897), *Foods and their Adulteration* (1907), and *History of a Crime Against the Food Law* (1929). Another prominent regulatory pharmacologist/ toxicologist was Arnold J.Lehman (1900–1979), who earned his PhD from the University of Washington in Seattle in 1930 and his MD from Stanford in 1936. He taught at a number of universities and joined the U.S. Food and Drug Administration as Director of the Division of Pharmacology in 1946. He and his staff published *Appraisal of the Safety of Chemicals in Foods, Drugs and Cosmetics,* in 1955, the first attempt by the agency to provide guidelines for toxicological studies (this presaged the Redbooks). He and his colleagues, most notably O.Garth Fitzhugh, developed the concept of safety factors (a number applied to the highest dose that did not elicit an adverse effect in a properly designed and executed toxicological study, the no-observed-adverse effect level, NOAEL). He is also renowned for the expression on his office wall: "You too can become a toxicologist in two easy lessons, each ten years long." He was succeeded by Leo Friedman (formerly of MIT), who advocated the use of in utero exposure in lifetime studies. Sandford Miller (also of MIT) served as successor to Friedman. To assist toxicologists concerned with the safety of food and color additives, the U.S. Food and Drug Administration issued a series of guidelines, Redbook I and II. The Organization for Economic Cooperation and Development (OECD) issued similar guidelines. Both of these guidelines are designed to encourage sound science and the conservation of resources while providing adequate data for determining safe exposure limits for consumers. The first comprehensive text to address the principles and practices of toxicology was edited by A.Wallace Hayes. At the international level, the World Health Organization (WHO), through the enlightened efforts of Frank Lu and Gaston Vettorazzi, applied sound toxicological thinking to establishing safe exposure conditions for food chemicals including pesticides. They developed the concept of an acceptable daily intake (ADI) based on sound toxicological data and the proper use of appropriate safety factors (SF). This concept is recognized and used worldwide and has been found very effective. There have been no significant problems with food chemicals evaluated in this manner. The evaluations are conducted through the auspices of the International Programme on Chemical Safety (IPCS), and implemented by the Joint Expert Committee on Food Additives (JECFA) and the Joint Meeting on Pesticide Residues (JMPR), under the chairmanship of John Herrman.

"Even while they teach, men [they] learn" (Seneca).

"Toxicology is the ultimate Renaissance science." (Gillett, 1987)

"Irrespective of its location and source of identity, toxicology as a field must studiously cross many traditional boundaries.… The science of toxicology is located somewhere between medicine and the sciences, but drawn toward law by forensic uses and the need to regulate various human activities. Societal values and needs tug the field more into the center of the tetrahedron." (Gillett, 1987).

As toxicology became a recognized scientific discipline and more were seduced by its scientific and public health

< previous page page_18 next page >

appeal, training programs began. Although it was very difficult to develop programs that could address the many facets of toxicology including chemistry and biochemistry, physiology and pharmacology, pathology, statistics, and epidemiology, excellent training programs were developed at some of the most prestigious universities. Examples included, in the United States, California, Chicago, Harvard, Iowa, Kansas, Medical College of Virginia, New York University, Rochester, and Vanderbilt; in Germany, Freiburg, Hannover, Tubingen, and Wuurzburg; in Sweden, Karolinska; in Denmark, Copenhagen; in Switzerland, Zurich; in Italy, Bologna, Milan, and Padua; in England, Guy's Hospital, London, and St. Mary's, Surrey; in Ireland, Dublin; and in Australia, Canberra. A list of current training programs in the United States appears in the Appendix following Chapter 37. The continuing (and increasing) popularity of toxicology is due to many factors including its intellectual and emotional appeal. It is multidisciplinary in nature, challenging and demanding, and its experimental findings are relevant and applicable to public health issues, including improving the quality of life and (hopefully) extending it.

"Knowledge is of two kinds. We know a subject ourselves or we can find information on it." (Samuel Johnson)

The need for a standard textbook became evident. Although several texts were available, none appeared adequate. This issue was addressed and resolved by Louis J.Casarett and John Doull. Dr. Casarett received his PhD in 1958 from the University of Rochester, where he studied respiratory toxicodynamics and morphological changes following exposures to potentially toxic materials, especially to polonium. In 1967 he moved to the University of Hawaii, where he developed a program in toxicology. His research involved drugs of abuse and pesticides. He was considered an excellent researcher and teacher. Dr. Doull received both his PhD in pharmacology and his MD from the University of Chicago. He remained at Chicago for a number of years, then moved to the University of Kansas Medical Center, where he established one of the most outstanding programs in toxicology in the world (and attracted and trained a number of internationally famous toxicologists). Casarett and Doull published *Toxicology, the Science of Poisons* in 1975. It is now in its fifth edition.

Significant contributions to the advancement of toxicology came and continue to come from many sources, academic, governmental/regulatory, and industrial. Government/regulatory toxicologists have made significant contributions especially in the area of safety evaluation, including the quantification of risk. Regulatory agencies demand adequate data of high quality to serve as the basis for establishing safe exposure levels. The extent of testing was and is often determined by the depth of the science, as well as the chemical and physical properties of the agent and the extent of exposure. For example, if absorption, distribution, metabolism, and excretion (ADME) studies were conducted properly, and it was determined that the test material was not absorbed from the gastrointestinal tract, then the need for long-term studies was not compelling. This caused toxicologists who were conducting safety studies to design programs that addressed basic issues early, often resulting in considerable saving of resources. If the agencies had not recommended or required these data, they probably would not have been conducted, or at least not early in the program. The regulators appeared to be driving the science!

Academic and industrial and governmental research laboratories continue to advance the frontiers of toxicology by seeking the molecular basis for toxic action. Contract toxicology laboratories have also made a significant contribution to toxicology by providing unique opportunities for those interested in the pragmatic (applied) aspects of toxicology, namely, the conduct of appropriate tests to establish safe conditions of exposure. These studies must consider the latest developments and advances in toxicology and related disciplines and the needs of regulators internationally. This is especially challenging today in this era of increased international trade and harmonization.

As with other recognized, independent scientific disciplines, toxicologists realized a need for a learned society to provide a forum for the exchange of scientific information. Toxicology continued to attract (to seduce) more students and practitioners, and this resulted in more research. The need for an appropriate journal in which to publish, and thus disseminate, the results of investigations was acute. The journal, *Toxicology and Applied Pharmacology* was founded by Fred Coulston; this was followed by *Fundamental and Applied Toxicology* (now *Toxicological Sciences*). Other journals included *Food and Cosmetic* (now *Chemical*) *Toxicology* (founded by Leon Golberg in 1963), *Journal of Applied Toxicology, Human and Experimental Toxicology*, and others.

The Society of Toxicology was founded in 1965. This was the first international society for and by toxicologists. Since its founding and as a result of the tremendous growth of toxicology, other societies of toxicology have been established. Almost every developed country has its own society of toxicology, a testimony of the recognition of its importance and its growth.

Toxicology continues to grow. Its uniqueness continues to attract (yes, to seduce by virtue of its

attractiveness) some of the brightest students. There is something for everyone: from the molecular to the macro to the modeler, from the gene to the whole animal to the human, from SAR to QSAR. Toxicology's uniqueness and strengths derive from the integration of many chemical and biological sciences and supporting disciplines. This

< previous page page_19 next page >

provides a strong base from which to extrapolate data to humans. Toxicology is also one of the few sciences in which academic, industrial, and regulatory scientists can effectively interact to protect the public. The importance of toxicology is recognized by governments worldwide. Toxicology has evolved from listing poisons to protecting the public from the adverse effects of chemicals; from simply identifying effects (qualitative toxicology) to identifying and quantifying human risks from exposure (quantitative toxicology); and from observing phenomena to experimenting and determining mechanisms of action of toxic agents and rational management for intoxication. As Claude Bernard noted:

Where then, you will ask is the difference between observers and experimenters? It is here: we give the name observer to the man [human] who applies methods of investigation. whether simple or complex, to the study of phenomena which he [she] does not vary and which he [she] therefore gathers as nature offers them. We give the name experimenter to the man [human] who applies methods of investigation, whether simple or complex, so as to make natural phenomena vary, or so as to alter them with some purpose or other, and to make them present themselves in circumstances or conditions in which nature does not show them. In this sense, observation is investigation of a natural phenomenon, and experiment is investigation of a phenomenon altered by the investigator. (Bernard, 1865, p.)

Toxicology has come a long way! As science continues to advance, toxicology will continue to draw from these advances in its constant quest to protect the public from harm. Toxicology has come of age!

It is fitting to close with the daily prayer of Moses Maimonides (appropriate for practicing toxicologists): "May there never rise in me the notion that I know enough, but give me strength and leisure to enlarge my knowledge.... Thou hast chosen me in Thy grace to watch over the life."

"It is your work in life that is the ultimate seduction." (Pablo Picasso)

QUESTIONS

1. Define poisons and describe several functions for poisons.
2. How has toxicology evolved from an art into a science?
3. How has the receptor concept influenced the development of toxicology?
4. Discuss some of the similarities and differences between toxicology and pharmacology.
5. Should Claude Bernard or Paracelsus be credited with the title, founder of (modern) toxicology? Defend your choice.

BACKGROUND

Regulatory toxicology is that area of toxicology directed at protecting public health by regulating exposure to potentially harmful materials. Historically, regulatory toxicology has developed in a manner that has reflected humankind's ability to relate exposure to certain agents with adverse health effects. Thus, early regulatory attention generally focused on preventing the acute effects of chemical agents, because these effects were observable and could be easily associated with exposure. Once the germ theory of disease was developed and the disease potential of human and animal waste was recognized, the disposal of these materials began to be regulated. Food and drugs were also the focus of early regulation, due, no doubt, to the relative ease in associating acute health effects, such as food poisoning, with exposure to materials in the diet or in medications. Hutt (82) notes that adulteration of the food supply was a serious problem in the ancient world, and quotes Pliny the Elder. writing in the first century AD, as saying, "So many poisons are employed to force wine to suit our taste—and we are surprised that it is not wholesome!"

Occupational exposures were also an early focus of regulation, due again to the fact that the relationship between exposure and effect was often observable. Early industrial hygiene efforts were typically intended to prevent overt or frank effects of materials in the workplace. Some of the first observations of the effects of chronic human exposures to certain chemicals were also made in occupational settings. Hutt (82) notes that during the 16th century, Paracelsus wrote about diseases characteristic of miners. The fact that certain chronic occupational hazards affected the exposed

individual at the point of contact also made the connection between agent and effect easier to discern. The first epidemiological study linking human cancer to a specific cause is attributed to Sir Percival Pott, who identified occupational exposure to soot as being responsible for scrotal cancers in young British chimney sweeps (153).

The development of regulatory toxicology during the 20th century has continued to shadow the ability to detect both chemicals and effects; that is, as we have become able to detect chemicals at lower and lower levels and to detect smaller biochemical and physiological changes, we have turned regulatory attention to these "new problems." For example, small increases in airway resistance following exposure to certain air pollutants are currently used as one basis for regulating these air pollutants; historically, no one would have been aware of these subtle effects. The practice of regulatory toxicology has evolved from historical concern about overt effects at high exposure levels to current concern about subtle effects at very low exposure levels, thus paralleling our ability to detect smaller amounts of chemicals and more subtle effects. For example, guidelines for occupational exposures to benzene have decreased by two orders of magnitude from 100 ppm in 1927 to the current Occupational Safety and Health Administration (OSHA) standard of 1 ppm. Ambient criteria for nonoccupational benzene exposures are currently as low as 0.03 ppm in some states (141).

Because of the recent dramatic increase in our ability to detect smaller effects and lower concentrations, programs to regulate chemicals in the environment have increased at an astronomical rate during the last 25 years. Factors contributing to the recent increase in regulatory activity include:

- The realization of the vast number of chemicals that humans have dispersed into the environment and to which humans have been exposed. Approximately 60,000 chemicals that are used commercially have been identified and listed under the Toxic Substances Control Act (TSCA) (214). Advances in analytical chemistry have allowed parts-per-billion levels of chemicals to be detected in "pristine" areas, in wildlife, in food products, and in human body tissues. This message was delivered initially by Rachel Carson in 1962 with the publication of *Silent Spring* (34).
- The realization that historical chemical management practices might not have been protective for the health effects we are concerned with today (effects at low doses), although such practices were consistent with the state of knowledge at the time. For example, during the 1970s, residents of Love Canal realized that they had unknowingly been exposed to chemicals that had migrated from a nearby landfill into their basements. The Comprehensive Emergency Response, Compensation, and Liability Act (CERCLA), also known as Superfund, was enacted shortly after the Love Canal incident.
- The establishment of causal relationships between certain diseases and chronic chemical exposures, such as leukemia and benzene, or mesothelioma and asbestos.
- The reduction in illness and mortality due to microbial diseases and the improved standard of living, which have focused increasing attention on other causes of ill health.

The rapid increase in the number and complexity of regulatory programs to address potential health effects from chemical exposures is also a result of the increased scientific uncertainty about toxicology and risk that has evolved with our increased understanding of these subjects (i.e., the more we learn, the more we realize how much more there is to learn). As we have come to better understand the complexities of toxicology, we have developed more complex procedures for characterizing toxic responses. An example of this is provided in the sixth section of this chapter, which describes probabilistic risk assessment methods.

In 1958, when the Delaney Clause forbidding the addition to food of any substance found to induce cancer in animals or humans was passed (156), the public generally believed that the intent of the law to provide a "zero risk" food supply was achievable. No one foresaw that, 20 years later, scientists would have identified over 500 animal carcinogens, been able to detect chemical concentrations between two and five orders of magnitude lower than they could detect in the 1950s, and found that many naturally occurring chemicals in food could be considered animal carcinogens (213). These developments have forced the recognition that absolute safety is impossible to achieve, even in products regulated to assure safety. Thus, Scheuplein (167) has noted that "the vast improvement in our methods of analytical detection have [sic] exposed carcinogens in the food supply in amounts too minuscule for our carcinogen bioassays and our risk assessment procedures to evaluate with comparable precision. We are capable now, more than before, of asking scientific questions that we cannot answer." (p. 244)

CURRENT REGULATORY FRAMEWORK

At the federal level in the United States, four agencies bear most of the direct responsibility for the regulation of toxic chemicals: the Consumer Product Safety Commission (CPSC), the U.S. Environmental Protection Agency (EPA), the Food and Drug Administration (FDA), and the Occupational Safety and Health Administration (OSHA). Table 2.1 describes the acts that empower these and several other federal agencies.

It is clear from Table 2.1 that there is a broad range of chemical exposures with which federal

regulatory auth-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_24.html[2010/10/28 18:30:41]

Table 2.1 Federal laws related to exposures to toxic substances

Legislation	Agency	Area of Concern
Food, Drug and Cosmetics Act (1906, 1938, amended 1958, 1960, 1962, 1968, 1976)	FDA	Food, drugs, cosmetics, food additives, color additives,new drugs, animal and food additives, and medical devices
Federal Insecticide, Fungicide and Rodenticide Act (1948, amended 1972, 1975, 1978)	EPA	Pesticides
Dangerous Cargo Act (1952)	DOT, USCG	Water shipment of toxic materials
Atomic Energy Act (1954)	NRC	Radioactive substances
Federal Hazardous Substances Act (1960, amended 1981)	CPSC	Toxic household products
Federal Meat Inspection Act (1967); Poultry Products Inspection Act (1968); Egg Products Inspection Act (1970)	USDA	Food, Feed, color additives, and pesticide residues
National Environmental Policy Act (1970); amended 1975, 1985, 1987, 1989, 1996, 1997)	EPA	Ecosystems and natural resources
Occupational Safety and Health Act (1970; amended 1974, 1978, 1982, 1983, 1984, 1986, 1987, 1990, 1992, 1995, 1996, 1997)	OSHA, NIOSH	Workplace toxic chemicals
Poison Prevention Packaging Act (1970, amended 1981)	CPSC	Packaging of hazardous household products
Clean Air Act (1970, amended 1974, 1977, 1990)	EPA	Air Pollutants
Hazardous Materials Trasportation Act (1972)	DOT	Transport of hazardous materials
Clean Water Act (formerly Federal Water Pollution Control Act; 1972, amended 1977, 1978, 1987)	EPA	Water pollutants
Marine Protection, Research and Sanctuaries Act (1972)	EPA	Ocean dumping
Consumer Product Safety Act (1972, amended 1981)	CPSC	Hazardous consumer products
Lead-based Paint Poison Prevention Act (1973, amended 1976)	CPSC, HEW (HHS), HUD	Use of lead paint in federally assisted housing
Safe Drinking Water Act (1974, amended 1977) and subsequent amendments	EPA	Drinking Water, Contaminants
Resource Conservation and Recovery Act (1976, amended 1984)	EPA	Solid waste, including hazardous wastes
Toxic Substances Control Act (1976); Asbestos Information Act (1988)	EPA	Hazardous chemicals not covered by other laws, includes premarket review
Federal Mine Safety and Health Act (1977)	DOL, NIOSH	Toxic substances in coal and other mines
Comprehensive Environmental Response, Compensation, and Liability Act (1981); Superfund Amendments and Reauthorization Act (1986); Emergency Planning and Community Right-to-know Act (1986)	EPA	Hazardous, substances, pollutants and contaminants
Radon Gas and Indoor Air Quality Research Act of 1986	EPA	Indoor air
Oil Pollution Act (1990)	DOT	Oil pollution
Pollution Prevention Act (1990)	EPA	Toxics use reduction
Food Quality Protection Act-amendments to FDCA and FIFRA	EPA	Pesticides in food

Note. Adapted from Office of Science and Technology Policy (147)

orities are concerned. Chemicals may be regulated on the basis of environmental medium (e.g., air, water), activity (e.g., food manufacture, chemical transport, ocean dumping), and type of exposure environment (e.g., workplace, residential). While the statutes in Table 2.1 represent almost 100 years of federal legislative history, 17 of the 23 have been written since 1970, illustrating the recent increase in public concern about chemical exposures.

The language of each statute provides the implementing agency with the basis for issuing regulations under the law. Some statutes instruct the agency to limit chemical release or exposure by requiring the use of certain control technologies. Other statutes require the agency to develop and implement risk-based standards, while others require the agency to balance risks with the costs of regulating or the benefits of not regulating. The latter two types of statutes are the most likely to involve regulatory toxicology in their implementation.

Section 307 of the Clean Water Act (CWA) is an example of a statute that requires technology-based standards for pollution control. Under this portion of the CWA, industries discharging to surface water must use the best available control technology to limit their pollutant discharges; installation of the appropriate control technology is required from the discharger to obtain a National Pollutant Discharge Elimination System (NPDES) permit.

Other statutes specify the standard for safety that regulations and standards issued under the law are supposed to provide. A commonly cited example of a law that required health-based, or risk-based, standards for pollution control is Section 112 of the 1970 Clean Air Act (CAA), which required the EPA to set emission standards for hazardous air pollutants (under the National Emissions Standards for Hazardous Air Pollutants [NESHAPS] program) that would "protect public health" with an "ample" margin of safety. Implementation of this standard of safety for carcinogenic air pollutants proved to be so troublesome for the agency that between 1970 and 1990, NESHAPS were set for only seven air pollutants. The difficulty in setting the risk-based standards was that the statute provided no indication of what an "ample margin of safety" was or how such a concept might be applied to carcinogens, given that the agency considered carcinogens to act by a no-threshold mechanism. The 1990 amendments to the CAA replaced the NESHAPS health-based standards with specified technology-based standards for controlling hazardous air pollutants. The statute states that after installation of the control technology, health-based standards must be set to further control emissions where unacceptable risks remain.

The Federal Food, Drug, and Cosmetic Act (FFDCA) is another example of a law requiring health-based standards for limiting the public's exposure to chemicals. Section 409 of the FFDCA requires the sponsor of a food additive to show that no harm to consumers will result when the additive is put to its intended use, and contains the Delaney Clause (discussed earlier), a special provision that forbids the use of any food additives that have been found to induce cancer in humans or animals. The Delaney Clause essentially specifies that the acceptable risks from carcinogens as food additives is zero. This bright line has proven to be very difficult for both the FDA and (until passage of the Food Quality Protection Act in 1996) for the EPA to implement, because the law does not allow the implementing agencies to specify *de minimis*, or acceptable, levels of risk. The EPA regulates pesticides under both the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the FFDCA. Under the FIFRA, the agency was required to balance the risk from the pesticide with the benefit associated with its use. However, under the FFDCA, the EPA was bound by the Delaney Clause with regard to pesticides that may concentrate in processed foods above the level allowed on the raw agricultural commodity. This dichotomous standard (known as the "Delaney Paradox") forced the EPA to regulate to zero risk for pesticides applied to foods that may concentrate during processing, while regulating using risk-benefit analysis to regulate the same pesticides on raw agricultural commodities (134). In 1992, a Circuit Court ruled that the Delaney Clause does not allow the EPA to permit use of carcinogenic pesticides under the FFDCA, even if their use is associated with negligible risk (1). The Delaney Clause has also been difficult for the FDA to implement as more chemicals (including naturally occurring chemicals in foods) have been determined to be carcinogens, and the FDA has searched for ways to establish acceptable risk levels for food additives. In 1988, the U.S. Court of Appeals for the District of Columbia struck down an effort by the FDA to interpret the Delaney Clause as allowing the agency to set a *de minimis* risk level for two color additives for use in cosmetics and drugs (212).

Other laws require the implementing agency to balance the risks and benefits of alternative regulatory choices. Examples of balancing statutes include Section 408 of the FFDCA, which, until the Food Quality Protection Act (FQPA) of 1996, required tolerances for pesticide residues on raw agricultural commodities to be set at levels necessary to protect the public health, while considering the need for "an adequate, wholesome, and economical food supply" (134). Section 6 of the Toxic Substances

Control Act (TSCA) requires the EPA to consider the potential benefits of using a chemical and the economic consequences of restricting its use when determining whether the manufacture, distribution, use, or disposal of a substance presents an unreasonable risk of injury to health or the environment.

Language in the Occupational Safety and Health Act specifies that the Occupational Safety & Health Administration (OSHA) must "adequately assure(s) to the extent feasible...that no employee will suffer material impairment of health or functional capacity" (145). This statutory language also requires balancing of risks and costs, but is particularly interesting because the dual requirements of "feasibility" and "no employee will suffer" may be impossible to reconcile in certain situations (163).

While the narrative terms *unreasonable risk* and *ample margin of safety* have not been clearly or consistently defined across agencies or across statutes, over the past decade, agencies have generally interpreted this language as requiring a qualitative, and frequently quantitative, estimate of the health risks associated with an exposure and the reduction in risks resulting from regulatory action. A major factor in the increased use of risk analysis by regulatory agencies was the 1980 Supreme Court decision in Industrial Union Department v. American Petroleum Institute. In this case, OSHA proposed lowering the occupational standard for benzene from 10 ppm to 1 ppm on the basis that benzene was a carcinogen, that any reduction in exposure would result in a reduction in risk, and that 1 ppm was technologically feasible. The Supreme Court did not find for the Union, stating that "Before he can promulgate any permanent health or safety standard, the Secretary [of Labor] is required to make a threshold finding that a place of employment is unsafe—in the sense that significant risks are present and can be eliminated or lessened by a change in practices" (85). The Court left the decision of what constitutes a "significant risk" to the OSHA. This landmark decision has had a major impact on agencies in addition to OSHA, resulting in an increase in the development and use of tools to quantify risks from exposure to environmental chemicals.

Perhaps one of the most far-reaching (and likely precedent-setting) statutes in recent years is the Food Quality Protection Act (FQPA) of 1996. This statute, which addresses risks from pesticides in food through the setting of tolerance limits, is primarily risk based with limitations on the extent to which EPA can consider benefits. This is in contrast to the risk/benefit balancing requirements of the FFDCA noted earlier. Only in certain narrow circumstances under the FQPA can EPA set pesticide tolerance levels that do not meet health-based criteria. Specifically, the circumstances comprise those situations where the use of the pesticide prevents even greater risks from occurring to consumers (a risk/risk balancing) or where the lack of the pesticide would result in "a significant disruption in domestic production of an adequate, wholesome, and economical food supply." In addition, the FQPA eliminates certain aspects of the "Delaney Paradox" discussed earlier. Tolerance limits for pesticides in both raw agricultural products and processed foods, for both carcinogens and noncarcinogens (the Delaney clause considered carcinogens only), are now to be based on health only. Other important provisions of the FQPA include the requirement that EPA specifically consider exposures and risks to infants and young children in setting pesticide tolerance limits, allowing up to an additional 10-fold safety factor, the need to consider all pathways of exposure (e.g., drinking water, soil/dust ingestion, etc.) to a pesticide in setting tolerance limits for that pesticide in food; the need to consider the cumulative risk for multiple pesticides that act via a common mechanism of action when setting a tolerance limit for any single pesticide of the "common mechanism" class; and the establishment of a very ambitious comprehensive screening program for pesticides that exert estrogenic and possibly other endocrine effects (190). The statute represents a landmark piece of legislation not only in terms of the regulatory implications, but also with respect to the advancement in scientific understanding required to implement the statute.

The combined effect of the increasing use of risk assessment to help make regulatory decisions and the significant uncertainty that accompanies most quantitative estimates of toxicological risk has resulted in considerable debate about the practice of risk assessment. On one side of the debate, the EPA, the FDA, and other agencies have been criticized by the Office of Management and Budget (OMB) and many representatives of the regulated community for being too conservative in their risk assessment procedures (146). On the other side, environmental advocacy groups such as Greenpeace have claimed that "In the real world, quantitative risk assessments are used almost exclusively to justify pollution" (175). Others have noted that "current risk estimates are by no means routinely exaggerated, either for the entire populations they apply to or for highly exposed or highly susceptible individuals within those populations" (58). Much of this difference in opinion is perhaps due to the fact that risk estimates are frequently inadequately defined and presented. Often, risk assessors produce single-value estimates of risk that may apply to some unknown percentage of the population. Because the variability in the exposure and dose-response characteristics of a population are so large, the risk estimates for a small, highly exposed or sensitive subpopulation will generally be very different from the estimates of the most likely risks for the entire population. Although the risk assessment results are supposed to be qualified and uncertainty discussed, the risk number is often used without appropriate explanation of the inherent

variability. In a recent effort to address this problem, the EPA prepared guidance to risk assessors on the need to provide fuller, more explicit descriptions of risk when providing such information not only to risk

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_27.html[2010/10/28 18:30:43]

managers but also to the general public (199). For example, the guidance recommends multiple descriptions of risk (e.g., sensitive receptors and general population) as well as clear descriptions of the uncertainties in the risk assessment.

Governmental and nongovernmental agencies other than those already discussed can influence the regulatory process as well. The American Conference of Governmental Industrial Hygienists (ACGIH) sets exposure limits based solely on health protection for approximately 600 workplace chemicals. These exposure limits, known as threshold limit values or TLVs (7), do not carry any regulatory weight, but it is not uncommon for workplaces to adhere to the TLVs for chemicals that OSHA does not regulate or which have an exposure limit that has not been revised since the inception of the OSHA in 1970. The TLVs have also been used by several state environmental agencies to derive acceptable ambient levels for toxic air pollutants.

Agencies in the Department of Health and Human Ser-vices that influence the regulatory process include the National Cancer Institute; the National Institute of Environmental Health Sciences, in particular the National Toxicology Program; the National Institute for Occupational Safety and Health (NIOSH) and the Center for Environmental Health (part of the Centers for Disease Control and Prevention, CDC); and the Agency for Toxic Substance and Disease Registry (ATSDR) (183). These agencies affect the regulatory process in several ways, ranging from decisions on which chemicals to test in long-term cancer bioassays, to defining principles for evaluating carcinogens, to conducting site-specific (as with a hazardous waste site) and chemical-specific risk assessments. International organizations such as the World Health Organization (WHO) and the International Agency for Research on Cancer (IARC) also have a significant role in the use of information by regulatory agencies.

The primary focus of this chapter is on the use of regulatory toxicology at the federal level. However, state governments have also been active in regulating exposure to toxins in the environment. For example, in 1986, voters in California overwhelmingly adopted Proposition 65, the Safe Drinking Water and Toxic Enforcement Act of 1986. This act contains two major provisions—one prohibiting the "discharge or release [of] a chemical known to the state to cause cancer or reproductive toxicity into water" and the other, a labeling requirement, mandating that no person expose another individual to any carcinogen or reproductive toxin without providing "clear and reasonable warning." Exemptions for the discharge requirements are provided for carcinogens at discharge levels that will pose lifetime cancer risk to a person drinking the water of less than 1×10^{-5}, or for reproductive toxins for discharges resulting in exposure levels less than 1000 times smaller than the "no-observable-effect level" (NOEL) for reproductive effects.

Some states have also developed their own risk assessment procedures or standards. In the absence of emissions standards for hazardous air pollutants at the federal level, many states developed their own emissions standards for hazardous air pollutants. Under the CWA, states can develop water quality criteria for certain water bodies in the state. Many states also have Superfund-type laws for the cleanup of abandoned hazardous waste sites, and have consequently developed risk assessment procedures for these sites.

RISK ASSESSMENT PARADIGM

In response to a directive from the United States Congress, the FDA contracted with the National Research Council (NRC) of the National Academy of Sciences to evaluate the risk assessment process in the federal government and to make recommendations on how the process could be improved. As a result of this effort, the Committee on the Institutional Means for Assessment of Risks to Public Health published a book in 1983 entitled *Risk Assessment in the Federal Government: Managing the Process* (136). The book summarized past experiences, and although it did not propose new ways to evaluate risks from environmental chemicals, it has nevertheless had an important effect on the use of scientific information by regulatory agencies in its codification of the risk assessment process.

The report has been particularly influential in two areas: (a) the separation of the risk assessment process from the risk management process, and (b) the classification of the risk assessment process into four broad components: *hazard identification, dose-response assessment, exposure assessment,* and *risk characterization.* These concepts are illustrated in Figure 2.1.

More recently, in response to Congressional mandates, both the Committee on Risk Assessment of Hazardous Air Pollutants (established by the NRC under the direction of the EPA) and the Presidential/Congressional Commission on Risk Assessment and Risk Management (CRARM) have reevaluated risk assessment and risk management approaches. The findings of the NRC committee are published in a 1994 book entitled *Science and Judgment in Risk Assessment* (133), and the findings of CRARM are published in a 1997 report entitled *Risk Assessment and Risk Management in Regulatory*

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_28.html[2010/10/28 18:30:43]

Decision-Making (155). While the four components making up the basic risk assessment paradigm and the separation of risk assessment and risk management remain key underlying principles, both committees recommended refinements in risk assessment and risk management

Page 29

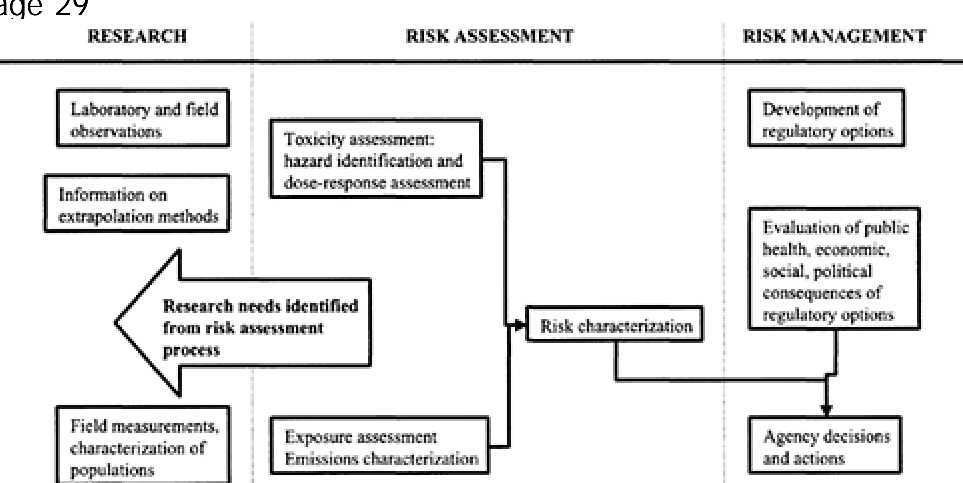

FIG. 2.1. NAS/NRC risk assessment/management paradigm. Adapted from NRC (133).

approaches. For example, the NRC committee highlights the importance of an iterative approach to risk assessment to reduce uncertainties, with each iteration incorporating fewer default assumptions and more specific information, balancing the use of "better science" with the constraints of the available resources (133). CRARM proposes a framework for risk management that encourages early and frequent involvement of all groups affected by the risk management problem, and decision making based on consideration of the risk management problem in the context of the broader, real-world goals of risk reduction and improved health status (155).

Risk assessment is defined as the "systematic, scientific characterization of potential adverse effects of human or ecological exposures to hazardous agents or activities," and involves assessment of the strength of the evidence as well as evaluation of the uncertainties associated with risk estimates (155). In contrast, risk management is "the process of identifying, evaluating, selecting, and implementing actions to reduce risk to human health and ecosystems" (155). Risk managers choose actions that will mitigate risks, considering not only the information derived from risk assessment, but also cultural, ethical, political, social, economic, and engineering information in the decision process.

The distinction between risk assessment and risk management is critical (136). The influence of risk management issues, such as the economic significance of a product, on the risk assessment process can seriously undermine the credibility of the risk assessment. This concern is exemplified in the separation between NIOSH and OSHA. NIOSH, part of the Department of Health and Human Services, is responsible for recommending health-based standards for workplace exposures to OSHA, part of the Department of Labor. As the federal agency actually responsible for setting standards for work place exposures and for implementing them, OSHA is also required to consider feasibility in the choice of exposure limits. It is not uncommon to find that exposure levels permitted by OSHA are different from NIOSH recommended exposure levels (182).

Of course, the distinction between risk assessment and risk management is not nearly so clear in practice. This is because each component of a chemical risk assessment is associated with considerable uncertainty. In the face of this uncertainty, regulatory officials have generally resorted to erring on the side of caution by including health-protective assumptions in their risk assessments. For example, the choice of a low-dose extrapolation model for carcinogens, which leads to a higher estimate of risk than other models, represents a risk management decision as much as a science policy decision. That is, the approach is conservative and provides the regulator with a greater level of confidence that the true risk to the human population is likely to be less than that expressed through the model. This approach has historically been justified as consistent with prudent public health policy when uncertainty is so great that it is difficult to provide a precise estimate of risk (i.e., in the face of uncertainty, it is easier to say the risk is less than *x* than to say the risk equals *y*). However, this practice can lead to inconsistent levels of protection for different chemicals and may direct resources away from the more significant risks (142). For example, the potential cancer risks associated with chemical disinfectants should be compared to the risks of waterborne microbial diseases when making decisions about treating public drinking water supplies, yet such risk/risk trade-offs

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_29.html[2010/10/28 18:30:44]

cannot be accurately weighed if health-protective assumptions have been used to different extents in the underlying risk assessments (67). As noted earlier, the practice of using health-protective assumptions in conducting risk assessments has been identified as an inappropriate application of risk management to the risk assessment process (146).

Although risk assessments are commonplace at many federal and state agencies, there are no uniform guidelines that specify how regulatory officials should calculate chemical risks. There are also no uniform criteria that indicate how the findings of a risk assessment should influence regulatory decisions (165). As a result, potency estimates developed by different regulatory agencies for the same chemical can vary substantially (12). Furthermore, the level of risk sufficient to trigger regulatory action has varied considerably between agencies and even between different programs within a single agency (180). EPA's postregulatory "acceptable" risk levels for arsenic under one statute (the CAA) vary by four orders of magnitude (179).

As discussed earlier, risk assessment is commonly broken down into four components. The first component of risk assessment, *hazard identification,* involves an evaluation of whether a particular chemical can cause an adverse health effect in humans. The hazard identification process can be considered to be a qualitative risk assessment. It involves identifying the potential for exposure as well as the nature of the adverse effect expected. The types of information used in hazard identification include all categories described in the previous section. In hazard identification, the risk assessor must evaluate the quality of the studies (choice of appropriate control groups, sufficient numbers of animals, etc.), the severity of the effect described, the relevance of the toxic mechanisms in animals to those in humans, and many other factors.

The result is a scientific judgment that the chemical can, at some exposure concentrations, cause a particular adverse health effect in humans. The result is not a simple yes-or-no evaluation but a weight-of-evidence estimation of the likelihood that the particular chemical has the potential to cause the particular effect. For example, studies showing that ozone can suppress pulmonary defenses against microbial agents in several species of animals (129), and information on similarities in pulmonary defenses between humans and animals (68), would lead to the conclusion that ozone exposure in humans could, under certain conditions, result in an increased susceptibility to infection (205).

The hazard identification process has been codified mainly for carcinogens. as exemplified in the classification schemes from a variety of agencies including IARC (111), EPA (208), and OSHA (144). These schemes are discussed in more detail later in this chapter.

Dose-response evaluation, the second component of the risk assessment process, involves quantitative characterization of chemical potency, that is, the relationship between the dose of a chemical administered or received and the incidence or severity of an adverse health effect in the exposed population. Characterizing the dose-response relationship involves understanding the importance of the intensity of exposure, the concentration×time relationship, whether a chemical has a threshold, and the shape of the dose-response curve. The metabolism of a chemical at different doses, its persistence over time, and an estimate of the similarities in disposition of a chemical between humans and animals are also important aspects of a dose-response evaluation. While the National Academy of Science report considers dose-response estimates mostly in terms of carcinogens, the evaluation of the dose-response relationships has long been a key component of pharmacology and toxicology for many chemicals (136). Recent advances in dose-response assessment for noncancer risk assessment are described in chapter 8 by Rodericks et al. and in a later section of this chapter.

In *exposure assessment,* the third component of the risk assessment process, a determination is made of the amount of a chemical to which humans are exposed. Data are often very limited for exposure assessment. Measures of chemicals in environmental media, such as air or soil, or in food may be available; however, the extrapolation of those levels to a dose received by humans has many uncertainties. Models exist that can describe the movement of chemicals through a particular medium, and assumptions can be made regarding inhalation, ingestion, or dermal contact rates and the bioavailability of the chemical. This information can then be used to derive an estimate of the dose taken up by humans. Host factors, such as exercise, the use of certain consumer products, or the consumption of particular foodstuffs, will complicate the exposure assessment (see chapter 9, Exposure Assessment).

The use of biological monitoring such as measurement of volatile organic chemicals in exhaled breath for example (219)—and the use of personal sampling devices, such as respirable particulate monitors (178), represent new ways in which the uncertainties of exposure assessment can be reduced. Blood lead testing is another example of biological monitoring that has the ability to reduce the uncertainty in

quantifying exposure and in extrapolating from exposure to dose.

The last stage of the risk assessment process, *risk characterization*, involves a prediction of the frequency and severity of effects in the exposed population. That is, the information from the dose-response evaluation (what dose is necessary to cause the effect?) is combined with the information from the exposure assessment (what dose is the population receiving?) to produce an estimate

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_30.html[2010/10/28 18:30:44]

of the likelihood of observing the effect in the population being studied. Most risk assessments, particularly for cancer, performed in the regulatory arena produce a single-number estimate of risk (e.g., lung cancer risk of 1 in a million). These are often designed to represent the risk to the reasonable maximally exposed (RME) individual in a potentially exposed population.

Substantial *variability* exists within any potentially exposed population in exposure rates, intake and uptake rates, and sensitivity to the effect. This variability is such that the risk to the most highly exposed and sensitive portion of the population may be orders of magnitude higher than the risks to the majority of the population. For example, some individuals in a population may never eat locally caught fish, while other individuals may subsist on locally caught fish. The fish intakes of these respective individuals will consequently vary by orders of magnitude. Information should generally be provided on both the risk to individuals and the aggregate risk of the exposed population. Point estimates of risk to a single individual in the population can be misleading when no information is provided to indicate whether that individual's exposure is typical of 50% or 0.001% of the exposed population.

In addition to population variability, there is also significant *uncertainty* present in risk estimates, due to uncertainty in many of the risk assessment components (e.g., model and measurement error). It is critical that the risk characterization step of the risk assessment process describes the biological and statistical uncertainties in the final estimation and identify which component of the risk assessment process (hazard identification, dose-response, or exposure) involved the greatest degree of uncertainty. For example, the dose-response evaluation is generally highly uncertain. This is often due to the model error in extrapolating from animals to humans or short-term to life-time exposures. Information may not be available to characterize the active species, mechanism of effect, the effective dose, or absorption, metabolism, and excretion rates. McKone and Bogen (126) determined that 65% of the variance in the risk assessment results for a case study of tetrachloroethylene in groundwater was due to variance in the estimate of the chemical potency. Because the degree of uncertainty varies greatly among risk assessments for different chemicals, lack of consideration of uncertainty can lead to inappropriate levels of concern for different chemicals.

Monte Carlo uncertainty analysis techniques have been applied to the risk assessment process as one method of attempting to more fully characterize the distribution of potential risks in a population. Rather than using single values to represent input parameters such as contaminant ingestion rates, body weights, and chemical potencies, Monte Carlo analysis uses the range of potential values for each particular input parameter, as well as an estimate of how these values are distributed (termed the probability density function). These individual probability density functions are then used to calculate a probability density function for the risk estimate (47, 174, 193). Figure 2.2 shows a probability density function, produced by a Monte-Carlo analysis, which was calculated using probability density functions for individual input parameters. Although these techniques provide more information on the distribution of potential risk than a single number risk estimate, they are limited by the availability of information with which to characterize the input probability density functions. Particularly uncertain are estimates of chemical potency, which can vary by orders of magnitude depending upon beliefs regarding carcinogenic mechanisms.

The Committee on Risk Characterization, convened by the NRC, makes recommendations for improving the risk characterization process in its 1996 book entitled *Understanding Risk, Informing Decisions in a Democratic Society* (132). Rather than just a presentation of numerical risk results and associated uncertainties, a risk characterization should also convey the information in a clear and easily understandable way that is useful to risk managers in making informed decisions and that addresses the concerns of interested and affected parties. Therefore, the rigorous scientific analyses involved in risk characterization must be performed in conjunction with frequent deliberations with all interested and affected parties. As explained by the NRC Committee on Risk Characterization, "developing an accurate, balanced, and informative synthesis" involves "getting the science right," "getting the right science," "getting the right participation," and "getting the participation right" (132). The EPA adopted similar values in its 1995 risk characterization guidance (196).

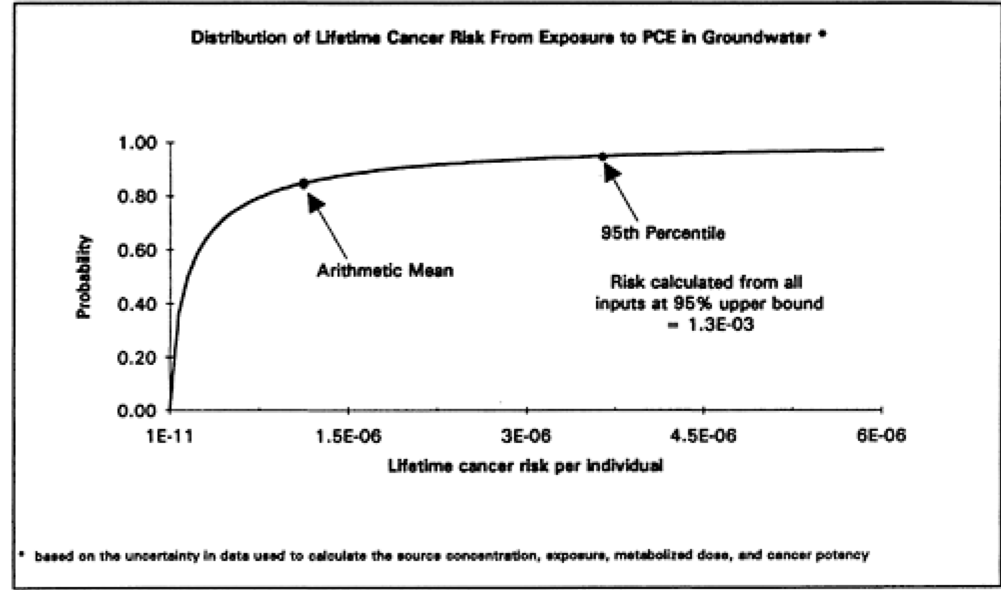
TOXICOLOGY INFORMATION USED IN THE REGULATORY PROCESS

Three main categories of scientific information are employed by agencies in the evaluation and regulation of toxic chemicals in the environment: (a) epidemiology, (b) controlled clinical exposures, and (c) animal toxicology. In vitro studies and structure-activity relationships are typically used by regulatory agencies to support the interpretation of information from the three major categories, and are only occasionally used as a primary source of information.

Epidemiology, studies of clinical exposures, and animal toxicology provide qualitatively different

information, with unique advantages and limitations. Environmental epidemiology studies, which attempt to associate disease or other adverse health outcomes with an environmental exposure, have the advantage of measuring an effect in

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_31.html[2010/10/28 18:30:45]



Selected Input Parameters and Distributions

Parameter	Units	Distribution Type	Min	Max	Arithmetic Mean	Arithmetic Std. Dev.	Geometric Std. Dev.
PCE concentration in water	mg/L	empirical			0.0003	0.00035	2.5
Breathing rate per unit body weight	m3/kg-day	lognormal			0.4	0.5	2.7
PCE metabolized cancer potency	kg-day/mg	empirical			0.11	0.14	4.8
Exposure time in house	h/day	uniform	8	20	14		
Skin permeability	m/h	uniform	0.004	0.01	0.007		

FIG. 2.2. Monte Carlo analysis of risk: tetrachloroethylene (PCE) in groundwater. Adapted from McKone and Bogen (126).

humans at exposure conditions that are by definition realistic. The first demonstration that benzene was a carcinogen came from epidemiological studies of rubber workers (86). It wasn't until several years after these studies that benzene was shown to cause cancer in animal studies (124). Studies of the London smog pollution episode in 1952 demonstrated that high levels of pollution from coal combustion could cause mortality, particularly in the very young, the elderly, and those individuals with preexisting cardiopulmonary disease (122). Evaluation of similar effects in animal studies would be difficult, given the complexity of the exposure in London and the lack of good animal models for susceptible populations, such as asthmatics. In general, epidemiology has been particularly helpful in the evaluation of working environments or other environments where exposure concentrations are relatively high.

Several factors limit the use of epidemiological studies by regulatory agencies. One of the major limitations is the lack of well-defined exposure information, both for chemical species and for actual concentrations. For example, the lack of accurate total exposure information limits the ability to quantify the effects of ambient air pollution in the United States. The Harvard University Six City Study showed that outdoor NO_2-monitoring devices are inadequate in accurately assessing total exposure to NO_2, due to the importance of indoor exposure (157). Subsequently, the EPA conducted Total

Exposure Assessment Measurement (TEAM) studies in which personal exposure to VOCs and pesticides were measured and found to be significantly higher than exposures estimated using stationary monitors for indoor or outdoor air (218). In some cases, the use of biological markers of exposure, such as measurements of arsenic levels in urine or lead levels in blood, can provide more accurate information about exposure and help reduce uncertainties in the results of epidemiological studies.

It is also difficult to define the causal element in epidemiological investigations, particularly when complex exposures are involved. For example, several indicators of pollution were measured during the London smog episodes that occurred between 1958 and 1972. Initial evaluations focused on the role of total particulate and SO_2 as causative agents for the elevated mortality levels; however, subsequent analyses of the London studies, as well as studies from other cities, indicate the importance of acid sulfates on mortality (176).

Another limitation is that epidemiological studies are frequently of worker populations, and such studies can be difficult to apply to prediction of health effects in the general population. Occupational studies, in general, focus on healthy adult male workers. The general population is more heterogeneous than the worker population and, for some pollutants, may exhibit a greater range in susceptibility. In general, only more recent epidemiology studies have considered adverse health effects of chemicals specific to women and children, such as developmental, reproductive, or hormonally mediated effects, including cancer. An example of the limitations of occupational epidemiology involves studies of peripheral nerve function in lead-exposed workers, which would underestimate risk of lead exposure in young children, for whom the primary concern is neurobehavioral effects resulting from relatively low-level exposures (217). At the same time, it must be recognized that the young and elderly are not always more susceptible to the effects of chemicals. As noted by Calabrese (25), adults, rather than the young or the elderly, are more susceptible to the renal toxicity of fluorides and mercury. High-risk subgroups are discussed in more detail in a later section of this chapter.

Epidemiology studies are frequently limited by the need for a relatively large increase in disease incidence (twofold or more), given the sample sizes generally available for such investigations. Enterline (55) notes that it would require a large population (1000 deaths, using the Peto model) to detect a 50% excess in deaths from lung cancer at an asbestos level of 2 fibers/cm^3 air.

Controlled clinical studies of humans exposed to pollutants address some of the difficulties of epidemiology studies. The exposures can be controlled and quantified, the effects are observed in humans, and the exposed population can be chosen to consist of susceptible individuals, such as asthmatics or exercising individuals. Thus, changes in airway resistance in asthmatics exposed to SO_2 during exercise (18, 164) have been important in the EPA evaluation of the National Ambient Air Quality Standard (NAAQS) for SO_2 (210), because these effects reflect the response of the susceptible population, using an appropriate exposure concentration and a relevant averaging time. Given the subtlety of these changes (nonsymptomatic bronchoconstrictions) and the fact that they occur only in a selected subset of the general population (asthmatics constitute about 4% of the total population), these effects would not have been detectable in the general population.

One of the advantages of controlled clinical exposure studies, that they are performed with humans, is also a major limitation. Since these studies must be limited to short-term effects that are readily reversible, they cannot be used to evaluate the potential of a chemical to cause chronic disease. Furthermore, because of the mildness of the changes observed in these studies, one may question their clinical significance. For example, how does one interpret the change in resistance observed with SO_2 exposure, given that, if not perceptible, the relationship to physical performance may be questionable (72)? Also, although some susceptible populations, such as mild asthmatics, can be tested, individuals with a greater degree of impairment, such as asthmatics who require continual medication, are usually not considered to be appropriate subjects for these studies because of the greater potential for harm during exposure. Later sections in this chapter address the questions of severity of effect on susceptible populations in greater detail.

Animal toxicology studies constitute the third major source of information for assessing the toxicity of chemicals. Animal toxicology studies allow the investigator the greatest degree of control over the exposure conditions, the population exposed, and the effects measured. One can readily evaluate subtle effects of acute and chronic exposure. For example, morphological and numerical changes in the pulmonary type I and type II cell populations, as well as interstitial fibrosis, have been observed in rats exposed to 0.06 to 0.25 ppm O_3 (35, 63). It would have been very difficult to describe this effect with other experimental approaches, and yet the effect is clearly of concern for humans who are exposed to comparable concentrations of ozone in certain urban environments.

In animal experiments, the ability to manipulate the experimental conditions permits the evaluation of many variables on the response to toxic chemicals. Thus, Elsayed and Mustafa (53) were able to demonstrate the protective effect of vitamin E on the acute toxicity of NO_2 in mice. In addition, the role of metabolism in susceptibility to polycyclic aromatic hydrocarbon-induced carcinogenesis has been evaluated in

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_33.html[2010/10/28 18:30:46]

studies of genetic variants in mice (120, 138). Such studies can be important in predicting modifiers of toxicity in humans and in identifying the susceptible human populations.

The limitations of animal studies fall into two broad categories: (a) those due to uncertainties in extrapolating from animals to humans, and (b) those due to uncertainties in extrapolating from the high exposures in animal studies to the lower exposures typically experienced by humans. Interspecies extrapolation is complicated by the greater homogeneity of laboratory animals than humans, the controlled conditions of housing and diet, innate genetic factors, and other variables. The relevance of trichloroethylene (TCE)-induced hepatocarcinogenesis in the mouse to humans has been questioned on the basis of differences in peroxisomal proliferation in the liver in the two species (52). Similarly, high exposure concentrations typically used in animal studies may result in saturation of detoxification pathways and thus may produce effects that are not relevant to effects produced at ambient exposure concentrations, where detoxification pathways are not saturated. Increased numbers of macrophages and impairment of alveolar clearance are observed in rats exposed to relatively high concentrations of diesel particulates (80). The significance to humans who are exposed to ambient levels of diesel particulates much lower than those employed in the animal studies is uncertain (143).

Historically, in vitro studies and analysis of structure-activity relationships have been used to help set priorities for chemical testing. For example, structure-activity relationships have been used to predict mutagenicity, lethality, and carcinogenicity (54). This type of information can be very useful, for example, in selecting compounds for longer term testing in animals or eliminating chemicals being considered for potential industrial or pharmaceutical applications due to toxicological concerns.

Short-term tests have typically been used indirectly in the regulatory process to support decision making, rather than as a basis per se for decision making. For example, evidence that a chemical is a point mutagen in an in vitro test system might be used to support the classification of a chemical as a possible human carcinogen or the use of a linear dose-response model for carcinogenesis. Metabolism, pharmacokinetic, and mechanistic studies can also provide information to reduce uncertainties in the use of toxicology information. For example, metabolic studies showing that a critical reactive metabolite in rodents is also formed in humans could reduce uncertainties in extrapolating from animals to humans, while mechanistic studies could indicate whether a subtle effect observed in a clinical study is a precursor for later, more serious health endpoints, and therefore of concern as a biomarker of effect.

In some circumstances, short-term tests and structure-activity relationships may be used directly to provide a basis for decision making. For example, Beck and co-workers (16) estimated permissible levels for alkylphenols in water, based on the ability of different alkylphenols to inhibit cyclooxygenase and by comparison with toxic effects of aspirin, a well known cyclooxygenase inhibitor. A critical element in this example is that adequate toxicological data were available for some members of the classes of chemicals being studied and that estimates of risk were applied within a class of chemicals of similar physical/chemical properties.

A summary comparing the differences between epidemiology, controlled clinical exposure, and animal toxicology studies is provided in Tables 2.2 to 2.4.

We can conclude from the preceding discussion that there is no “best” source of information for regulatory agencies. The rational approach is to examine all avail-

Table 2.2 Advantages and disadvantages of epidemiological studies

Advantages	Disadvantages
Exposure conditions realistic	Costly and time-consuming
Occurrence of interactive effects among individual chemicals	Post facto, not protective of public health*a*
Effects measured in humans	Difficulty in defining exposure, problems with confounding exposure
Full range of human susceptibility frequently expressed	Increase in risk must frequently be about twofold to be detected
	Effects measured often relatively crude (morbidity, mortality)

a Use of biomarkers in epidemiological studies, rather than disease endpoints, can allow such studies to be public health protective.

Table 2.3 Advantages and disadvantages of controlled clinical studies

Advantages	Disadvantages
Well-defined, controlled exposure conditions	Costly
Responses measured in humans	Relatively low exposure concentrations and short-term exposures
Potential to study subpopulations (e.g., asthmatics)	Limited to relatively small groups (usually <50 individuals)
Ability to measure relatively subtle effects	Limited to short-term, minor, reversible effects Usually most susceptible group not appropriate for study

Table 2.4 Advantages and disadvantages of animal toxicology studies

Advantages	Disadvantages
Readily manipulated exposure conditions	Uncertainties in relevance of animal response to human exposure
Ability to measure many types of responses	Controlled housing, diet, etc., of questionable relevance to humans
Ability to assess effect of host characteristics (e.g., gender, age, genetics) and other modifiers (e.g., diet) of response	Exposure concentrations and time frames often very different from those experienced by humans
Potential to evaluate mechanisms	

able sources of information in the evaluation of toxic chemicals. Some kinds of information may be especially useful in hazard identification, the likelihood that a chemical will be toxic to humans, whereas other types of information will be more appropriately applied to the estimation of the dose-response relationship.

EVALUATION OF CARCINOGENS

Background

The public demand for zero risk has made the regulation of carcinogens a formidable challenge. Within the scientific community, there is still no consensus on how to define a potential human carcinogen, much less how to estimate cancer risks under practical conditions of chemical exposure. This uncertainty is due largely to the fact that mechanisms of carcinogenesis for many chemicals are still poorly understood, and different carcinogens act in different ways to induce cancer. The task of regulating carcinogens has been complicated, rather than simplified, by many of the mechanistic discoveries of recent years. The simple picture of the 1950s, when only a very small number of chemicals were thought to be carcinogens, has been replaced by the realization that chemical carcinogenesis takes place in multiple stages, some with reversible steps, which have different dose-response relationships. Essential nutrients and hormones can be carcinogenic in some circumstances. The same chemical can promote or inhibit carcinogenesis, depending on the circumstances of exposure (75, 121). Public pressure to regulate carcinogens, even where very little toxicological information exists, has in many circumstances compelled regulatory agencies to treat carcinogens as though they all act by the same mechanisms, even as it has become apparent that they do not. Despite virtual consensus in the scientific and regulatory communities that carcinogens should be regulated in a way that reflects their mechanism of action, sufficient information to allow this to be done does not exist for many chemicals.

From a public health standpoint, the regulatory agencies have generally regulated carcinogens at exposure levels that reflect a very low probability of tumor production (e.g., excess cancer risk of 1 per million exposed). However, for practical reasons, it is impossible to conduct animal studies of a size that would allow observation of effects following treatment at such low doses. The practice has therefore been to conduct animal studies at high dose levels and then extrapolate the results from high to low dose and from animals to humans. Thus, the chronic animal bioassay results, the extrapolation from high to low doses, and the extrapolation across species

are used to derive potency factors (i.e., indicators of carcinogenic potency) for carcinogens. These potency factors enable one to relate a dose in humans to a probability of tumor occurring as a result of that dose. It should be noted that even with established human carcinogens, extrapolation procedures are still used to extrapolate carcinogenic response from high to low dose or from one type of exposure condition (e.g., intermittent, subchronic) to another exposure condition (e.g., continuous chronic).

This section on carcinogens first provides some basic information on mechanisms of carcinogenesis. We then describe some of the key issues that agencies address in the interpretation and application of scientific data on carcinogens. These issues fall into the categories of hazard identification and dose-response assessment (136). Hazard identification for carcinogens addresses two questions: (a) What is the evidence that a particular chemical is an animal carcinogen? (b) What is the likelihood that an animal carcinogen is a human carcinogen? Dose-response assessment attempts to determine the probability of tumor production, given a particular exposure or dose level. The dose-response assessment section of this chapter discusses mathematical models used to extrapolate from high to low doses, physiologically based pharmacokinetic (PBPK) modeling to relate administered and effective doses in animals and humans, and issues concerning the relationship between effective dose and response.

Mechanisms of Carcinogenesis

Carcinogenesis is currently understood to be a multistage process that has been described as involving the initiation, promotion, and progression of normal cells into neoplastic cells. Chemicals can act at one or more of these stages, and can act directly (e.g., mutagen) or indirectly (e.g., immune suppression).

Initiation is generally understood to be a permanent and irreversible event involving DNA mutation, and the first step in the process of carcinogenesis. Many genotoxic agents are considered to be initiators, thus having the potential to begin the transition from normal to cancer cells. Genotoxic materials have been considered to act via a nonthreshold mechanism, and this belief has formed the basis for linear extrapolation of effects seen at high doses down to low doses. Inferences as to the absence of a threshold for initiating agents comes from the study of mutations that result from these agents. In addition, studies investigating the number of preneoplastic focal lesions induced by an initiating agent did not find a measurable threshold (149). Ionizing radiation is an example of an initiating agent. In addition, certain chemicals (e.g., aflatoxin B1, diethylnitrosamine, tobacco smoke) are considered to be complete carcinogens, capable of initiation, pro motion, and progression. Potential factors modifying the efficiency of initiation include rates of cell division and DNA synthesis as well as the rate of metabolism of a chemical to its active form or rate of metabolic detoxification. (It should therefore be noted that even the no-threshold concept may not be applicable to all genotoxic carcinogens, due to the existence of repair mechanisms and other factors that reduce or eliminate responses at low exposure levels.)

The promotion stage is characterized by clonal expansion of the initiated cells. Promoting agents can act by various mechanisms to increase rates of cell proliferation or decrease rates of cell death. For example, cell proliferation can be induced by cytoxic agents or mitotic agents. Interference with intercellular communication may also be responsible for clonal expansion of initiated cells (181). An important feature of this stage is its reversibility and, in some cases, the existence of a threshold for the effect. In many cancer model systems, withdrawal of the promoting agent halts the development of tumors. The promotion stage is also easily modulated by environmental factors including frequency of dosing, age of test animal, and diet (149, 195). Promoting agents are generally thought to exhibit a threshold (or inflection point) in the dose-response curve. Examples of promoting agents include hormones, alcohol, and dietary fat.

Progression is an irreversible stage characterized by the development of malignant neoplasms, and is understood to require a second genetic mutation. Agents that act only during progression, or advance a cell from promotion to progression, have not yet been definitively characterized. It has been hypothesized that malignant neoplasms may all exhibit an abnormal expression of one or more proto- and cellular oncogenes (149). In this scenario, initiation is defined by the first mutation event and progression as the second mutation, resulting in homozygosity at the anti-oncogene locus, and total loss of growth control (130).

Hazard Identification

The question of how to decide whether a particular chemical is a potential human carcinogen is currently the subject of considerable scientific debate. It is an important question because the act of labeling some chemicals "carcinogens" and not labeling others has profound regulatory and societal implications (66). This regulatory paradigm, whereby chemicals are regulated either as carcinogens or as noncarcinogens, requires that the question of whether a particular chemical is a carcinogen or not be

answered with a "yes" or "no." In the United States, most regulatory agencies have historically regulated all carcinogens as though they operate via the same no-threshold mechanism. However,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_36.html[2010/10/28 18:30:48]

different chemicals may act in different ways during the various stages of cancer formation to impact the development of the tumor. These various mechanisms of tumor formation are not all consistent with the mechanistic assumptions that form the basis of the regulatory framework for carcinogens. Thus, the more we learn about carcinogenesis, the less the simple regulatory approach is able to accommodate the new information. A chemical may be carcinogenic via certain routes of exposure and not others, or only above certain dose levels. More flexible classification approaches are being developed (e.g., ref. 195) that allow the incorporation of more science into the classification process.

In the next section, we describe current classification approaches, but the reader is reminded that the current scientific debate on these schemes is continuing to fuel new approaches. Regulatory agencies generally classify potential carcinogens, based on an evaluation of both human and animal studies, as well as supporting information from short-term tests for mutagenicity and structure-activity relationships. Because human evidence exists for so few chemicals, animal studies generally provide most of the available information about the potential carcinogenicity of a chemical to humans.

Animal Studies

The evidence that a chemical is an animal carcinogen frequently derives from long-term animal bioassays. Such studies usually consist of exposing groups of about 50 animals (typically rats or mice) to two concentrations of a chemical over the lifetime of the animals. Sex- and age-matched unexposed animals constitute the control group. At the termination of the bioassay, the animals are killed and the number of tumor-bearing animals and the number and type of tumors per animal are quantified. Interim examinations may be performed, particularly on animals that appear moribund.

The maximum tolerated dose. Dose selection plays a key issue in the design and interpretation of the animal bioassay. Animals are typically exposed at two dose levels: the maximum tolerated dose (MTD) and half the MTD. The MTD is predicted from subchronic toxicity studies as the dose "that causes no more than a 10% weight decrement, as compared to the appropriate control groups, and does not produce mortality, clinical signs of toxicity or pathologic lesions (other than those related to a neoplastic response) that would be predicted [in the long-term bioassay] to shorten an animal's natural lifespan" (171). The MTD is not a nontoxic dose and is expected to produce some level of acceptable toxicity to indicate that the animals were sufficiently challenged by the chemical. The MTD has been justified as a means of increasing the sensitivity of an animal bioassay involving limited numbers of animals so as to be able to predict risks in large numbers of humans (76).

An objection to the use of MTDs has been that metabolic overloading may occur at high dose levels, leading to an abnormal handling of the test compound (131). For example, toxic metabolites could be produced as a consequence of saturation of detoxification pathways. Organ toxicity could occur that might not happen at lower concentrations of the chemical (127), particularly at those concentrations to which humans are typically exposed. Thus, it has been argued that nongenotoxic agents that are determined to be positive in rodent carcinogenicity bioassays, due to target organ toxicity and subsequent cell proliferation, should not be assumed to be carcinogenic at low doses (37).

Ames and co-workers (9,10) have suggested that target-organ toxicity and subsequent mitogenesis is responsible for the fact that over half of all chemicals tested in chronic bioassays at the MTD are determined to be carcinogens in rodents. They observed that both genotoxic and nongenotoxic agents tested at the MTD cause increased rates of mitogenesis, thus increasing the rate of mutation. For several chemicals, induction of tumors was more strongly correlated with cell division than with DNA adducts or mutagenic activity. Others have reported that cancer potency and MTD are inversely correlated and that, consequently, the potency estimate is simply an artifact of the experimental design (161). Goodman and Wilson (65) found that cancer potency and the MTD were more strongly related for nonmutagens than for mutagens in rat bioassays, indicating that the carcinogenic effect and toxicity were more closely associated for nonmutagens than for mutagens. However, they noted that even for most mutagens, their findings suggested that, at high doses, carcinogenicity is induced via mechanisms associated with toxicity.

Haseman and Lockhart (77) compared the sensitivity of the rodent bioassay for detecting carcinogens at the MTD as compared to lower doses. Approximately two-thirds of the chemicals that were positive at the MTD in rodents were also positive at the lower dose, albeit often for fewer tumor sites. One tumor site that was affected disproportionately was the kidney, where a positive response was observed at the lower dose only about one third of the time as compared to the higher dose.

The EPA (195) noted that bioassay results at doses that exceeded the MTD can be rejected if toxic damage to target organs compromises study interpretation. The reason is that dosing above the MTD in a study may result in tumor production secondary to tissue damage rather than a direct carcinogenic

influence of the agent tested.
Thus, use of information from testing at fractional doses of the MTD may yield results that are more relevant to human risk. Overall there would be a somewhat modest (except for kidney-only carcinogens) reduction in the total number of carcinogens. It should also be noted that

it is still possible that mechanisms may occur at fractional MTD levels that would not occur at the typically lower human exposure levels.

Other issues in hazard identification. Another key issue in the evaluation of animal bioassays is the analysis of the tumors themselves. Considerations include the categorization of benign tumors and whether tumor analysis should be site-specific or based on all sites. The position of the IARC (110) is that "few, if any chemicals exist which produce only benign tumors and no malignant tumors in any species" and that chemicals that cause a marked increase in the number of benign tumors "are now viewed with almost as much suspicion as potential human hazards as they would have been if the induced tumors had been malignant." Thus, it has been the general policy of regulatory agencies to accord almost the same weight to benign tumors as to malignant tumors, especially if there is evidence that the benign tumors could progress to malignancy (208).

It is sometimes stated that one should consider only the overall incidence of tumors, since, from a public health perspective, the concern is with total cancer risk for humans rather than risk at any one site. While this position has an innate appeal, it is difficult to apply in practice for two main reasons:

- This approach greatly decreases the ability of the bioassay to detect a positive effect, given the high background incidence of some tumor types in rodents. For example, the incidence of testicular tumors can be as high as 82% in rats and liver tumors can be as high as 25% in mice (74).
- The grouping of tumor types that do not share a common cellular origin is of questionable biological relevance, since the mechanisms involved in the production of the different tumor types could differ. Furthermore, the metastatic potential of different tumor types is highly variable and would have an important influence on the lethality of a particular type of cancer.

It should also be noted that reductions in tumor incidence are frequently observed in the same cancer bioassays in which tumor increases are observed. A recent analysis by Linkov and co-workers (121) indicates the anticarcinogenic effects observed in rodent bioassays are not explained by random effects. The basis for the reduction is not known and could be a consequence of perturbations in the animal's physiology. These observations lend credence to the concept that animal bioassays must be interpreted with special attention as to whether biological phenomena are induced at high doses that may not occur (or occur with a much lower frequency) at low doses. A similar observation is found in the evaluation of some human carcinogens, in particular those which act through hormonal processes. For example, oral contraceptives are associated with an increased risk of breast cancer, but a decreased risk of ovarian and endometrial cancer (Table 2.5). Anticarcinogenic properties of carcinogens are typically not considered as part of the regulatory process for carcinogens.

In addition, the standard NTP-type 2-year cancer bioassay may not be sensitive to hormonally regulated cancers such as breast cancer. This is because the mouse and rat strains used to perform these bioassays are selected because they are known to be susceptible to liver, kidney, or lung tumors in particular. It has not been demonstrated that these strains are also susceptible to cancers at hormonally sensitive sites. Thus, these bioassays may not detect certain cancer effects that are hormonally regulated (172).

Carcinogen Classification Schemes

The IARC, the European Union (EU), the EPA, the National Toxicology Program (NTP), the German Commission for Investigation of Health Hazards, Health Canada, and the ACGIH have developed classification schemes for carcinogens, based on a weight-of-evidence or strength-of-evidence evaluation of available human and animal studies. These seven classification systems are shown in Table 2.6. The EPA developed guidelines in 1986 (208) and proposed new guidelines in 1996 (195) (Tables 2.7–2.10). Some classification schemes are based on the weight of evidence considering positive and negative evidence (e.g., EPA), whereas others (e.g., IARC) classify chemicals as carcinogens, based on a strength-of-evidence (positive evidence only) basis. The different guidelines use mechanistic information to different degrees.

The EPA (208), IARC (111), and other agencies typically conclude that a chemical demonstrating "sufficient evidence of carcinogenicity" from animal experiments is a potential human carcinogen. To some degree this conclusion is supported by evaluation of known human carcinogens in animal bioassays. For the 67 chemicals, processes or environmental factors associated with cancer indication in humans by IARC (112, 177), more than half of those that have been tested have also been positive in animal bioassays (Table 2.5). Recent understanding of carcinogenesis indicates that this assumption is not valid for all animal carcinogens. Species-specific responses or high-dose-only effects indicate that positive animal results are not always evidence of human carcinogenicity.

In 1996, EPA proposed new cancer guidelines (195). These proposed guidelines, in their flexibility and

incorporation of new science, represent a significant advance in carcinogen classification schemes. The new guidelines take a weight-of-evidence approach in which human (Table 2.7), animal (Table 2.8), and other relevant

Page 39

Table 2.5 Chemicals, industrial processes, and environmental factors associated with cancer induction in humans: target organs and main routes of exposure in humans and degree of supporting evidence in animals (IARC)

Chemical or industrial process	Humans: Main type of exposure[a]	Humans: Target organ(s)[b]	Animals, degree of evidence for carcinogenicity
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (methyl-CCNU)	Medicinal	Leukemia	Limited
1,4-Butanediol dimethanesulfonate (Myleran)	Medicinal	Leukemia	Limited
2-Naphthylamine	Occupational	Bladder (liver)	Sufficient
4-Aminobiphenyl	Occupational	Bladder	Sufficient
8-Methoxypsoralen (Methoxsalen) plus UV radiation	Medicinal	Skin	Sufficient
Aflatoxins	Environmental	Liver (lung)	Sufficient
Alcoholic beverages	Cultural	Oral cavity, pharynx, larynx, esophagus, liver (breast)	Inadequate
Aluminum production	Occupational	Lung, bladder (lymphoma, esophagus, stomach)	No data
Arsenic compounds[c]	Occupational, medicinal, and environmental	Skin, lung (liver, hematopoietic system, gastrointestinal tract, kidney)	Limited
Asbestos	Occupational	Lung, pleura, peritoneum, gastrointestinal tract, larynx	Sufficient
Auramine manufacture	Occupational	Bladder	No data
Azathioprine	Medicinal	Lymphoma, skin, mesenchymal tumors, hepatobiliary system	Limited
Benzene	Occupational	Leukemia	Sufficient
Benzidine	Occupational	Bladder	Sufficient
Beryllium and beryllium compounds[d]	Occupational	Lung	Sufficient
Betel quid (with tobacco)	Cultural	Oral cavity (pharynx, larynx, esophagus)	Limited
Bis(chloromethyl) ether and chloromethyl methyl ether (technical grade)	Occupational	Lung	Sufficient
Boot and shoe manufacture and repair	Occupational	Leukemia, nasal sinus (bladder, digestive tract)	No data
Cadmium and cadmium compounds[e]	Occupational	Lung	Sufficient
Chlorambucil	Medicinal	Leukemia	Sufficient
Chromium compounds (hexavalent)[f]	Occupational	Lung (gastrointestinal tract)	Sufficient
Ciclosporin[e] (U.S.: cyclosporin)	Medicinal	Lymphoma, Kaposi's sarcoma	Limited
Coal tars and pitches, mineral and shale oils, and soots[f]	Occupational, environmental	Skin, lung, bladder (gastrointestinal tract, leukemia, colon)	Sufficient
Cyclophosphamide	Medicinal	Bladder, leukemia	Sufficient
Diethylstilbestrol	Medicinal	Cervix/vagina, breast, testis (endometrium)	Sufficient
Epstein–Barr virus[h]	Environmental	Lymphomas, nasopharyngeal carcinoma	Sufficient
Erionite	Environmental, cultural	Pleura, peritoneum	Sufficient
Estrogens (steroidal, nonsteroidal)[e]	Medicinal	Endometrium, breast, cervix/vagina, testis	Sufficient
Estrogen therapy, postmenopausal[f]	Medicinal	Endometrium, breast	No data
Ethylene oxide[e]	Occupational	Lymphatic and hematopoietic systems	Sufficient
Furniture and cabinet making	Occupational	Nasal sinus	Inadequate
Helicobacter pylori[h]	Environmental	Stomach	No data
Hematite mining (with radon exposure)	Occupational	Lung	Inadequate
Hepatitis B virus[f]	Environmental	Liver	Inadequate

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_39.html[2010/10/28 18:30:49]

Chemical or industrial process	Humans: Main type of exposure[a]	Humans: Target organ(s)[b]	Animals, degree of evidence for carcinogenicity
Hepatitis C virus[m]	Environmental	Liver	Inadequate
Human immunodeficiency virus Type 1[e]	Environmental	Kaposi's sarcoma, non-Hodgkin's lymphoma	Inadequate
Human papilloma virus Types 16 and 18[e]	Environmental	Cervix	None
Human T-cell lymphotropic virus Type I[f]	Environmental	Adult T-cell leukemia/lymphoma	Inadequate
Ionizing radiation	Environmental	Leukemia, skin, various internal organs	Sufficient
Iron and steel founding	Occupational	Lung (digestive tract, genito-urinary tract, leukemia)	No data
Isopropyl alcohol manufacture (strong acid process)	Occupational	Nasal sinus (larynx)	Inadequate
Magenta manufacture	Occupational	Bladder	Inadequate
Melphalan	Medicinal	Leukemia	Sufficient
MOPP and other combined chemotherapy including alkylating agents	Medicinal	Leukemia	No data
Mustard gas	Occupational	Lung, larynx, pharynx	Limited
Nickel and nickel compounds[f]	Occupational	Nasal sinus, lung (larynx)	Sufficient
N, *N*-Bis(2-chloroethyl)-2-naphthylamine (Chlornaphazine)	Medicinal	Bladder	Limited
Opisthorchis viverrini[g]	Environmental	Liver	Limited
Oral contraceptives, combined[i,j]	Medicinal	Liver (also protective effect against cancers of the ovary and endometrium)	Sufficient
Oral contraceptives, sequential	Medicinal	Endometrium	Sufficient
Painters (occupational exposures as)	Occupational	Lung (esophagus, stomach, bladder)	No data
Phenacetin (in analgesic mixtures)	Medicinal	Renal pelvis/ureter, bladder	Limited
Radon and its decay products	Environmental	Lung	Sufficient
Rubber industry	Occupational	Bladder, leukemia (lymphoma, lung, renal tract, digestive tract, skin, liver, larynx, brain, stomach)	Inadequate
Salted fish[e]	Environmental	Nasopharynx	Limited
Schistosoma haematobium[g]	Environmental	Urinary bladder	Limited
Silica, crystalline[e]	Occupational	Lung	Sufficient
Solar radiation[e]	Environmental	Skin	Sufficient
Talc containing asbestos fibers	Occupational	Lung (pleura)	Inadequate
Tamoxifen[e]	Medicinal	Endometrium (reduces risk for contralateral breast cancer in women with previous diagnosis of breast cancer)	Sufficient
2,3,7,8-Tetrachlorodibenzo-*para*-dioxin[e]	Occupational	Multi-site with no site predominating	Sufficient
Thiotepa[l]	Medicinal	Leukemia	Sufficient
Tobacco products, smokeless	Environmental, cultural	Oral cavity (pharynx, esophagus)	Inadequate
Tobacco smoke	Environmental, cultural	Lung, bladder, oral cavity, larynx, pharynx, esophagus, pancreas, renal pelvis (stomach, liver, cervix)	Sufficient
Treosulphan	Medicinal	Leukemia	No data
Vinyl chloride	Occupational	Liver, lung, brain, lymphatic and hematopoietic system (gastrointestinal tract)	Sufficient
Wood dust[m]	Occupational	Nasal cavity, paranasal sinus	Inadequate

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_40.html[2010/10/28 18:30:50]

toxicological (Table 2.9) evidence are evaluated. As part of this evaluation, the quality of an individual study, as well as the overall consistency across studies, is considered. Demonstration of cancer in humans at the same organ site in multiple studies with well-characterized exposure in the absence of confounding exposures enhances confidence that a chemical is the likely cause of cancer. In contrast to the 1986 guidelines, other evidence relevant to carcinogenicity, such as mechanistic information in animals that attests to the relevance (or lack of relevance) of a particular tumor response, is explicitly considered. Data from human, animal, and other sources are combined to weigh the totality of evidence (Table 2.10) to classify the human carcinogenic potential of a particular chemical. Three descriptors have been proposed:

• Known/likely—Applies to chemicals for which there is convincing human evidence of carcinogenicity or limited (or no) human evidence combined with strong animal evidence that is relevant to the human response.

• Cannot be determined—Applies to chemicals where a conclusion regarding carcinogenicity cannot be drawn for reasons including the presence of conflicting or inadequate data, or suggestive data not sufficiently strong to draw any conclusion.

• Not likely—Applies to chemicals for which there is experimental evidence (in the absence of human data suggesting a carcinogenic potential) that indicates a lack of human hazard potential. Types of evidence include demonstration that a response in animals (e.g., male rat kidney cancer due to $\alpha 2\mu$-globulin nephropathy) is not relevant to humans or that well-conducted animal cancer bioassays are negative for carcinogenicity. One noteworthy aspect of the "not likely" category is that, in contrast to the 1986 guidelines, this category allows for conditional classification. For example, a chemical may be classified as likely to be a human carcinogen only with respect to a particular route of exposure, or only above a certain dose level.

Perchloroethylene provides a useful example of how different agencies classify carcinogens. For example, IARC considers perchloroethylene a probable human carcinogen (category 2A), based on limited evidence in humans and sufficient evidence in animals (114). In contrast, Health Canada (123) and ACGIH (6) both consider perchloroethylene as probably not carcinogenic to humans (categories A5 and Group V, respectively). IARC placed greater weight on often times conflicting epidemiological evidence than did ACGIH or Health Canada. For example, IARC considered the positive association between perchloroethylene and certain types of cancer (e.g., non-Hodgkin's lymphoma) as unlikely to be due to chance, while still acknowledging the possible role of confounding factors (e.g., exposure to other solvents). In contrast, Health Canada (123) considered the weaknesses in the epidemiological studies sufficiently large as to make the studies inadequate for drawing any conclusions on perchloroethylene carcinogenicity. With respect to animal studies, both IARC and Health Canada concluded that perchloroethylene causes liver cancer in mice. However, Health Canada concluded that the liver tumors in mice are unlikely to be relevant to humans, based on metabolic differences between humans and mice [humans produce much less trichloroactic acid (TCA) the relevant metabolite in the liver] and species-specific response differences to TCA (humans show little, if any, peroxisomal proliferation, which is likely to play a critical role in hepatic carcinogenesis in response to TCA). Overall, IARC gave greater weight to positive evidence than to negative or conflicting evi-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_41.html[2010/10/28 18:30:50]

Table 2.6 Summary of the classification schemes for carcinogens

Agency	Classification	Meaning
DFG/MAK	A1:	Induces malignant tumors in humans.
	A2:	Clearly carcinogenic in animal studies.
	B	Justifiably suspected of having carcinogenic potential.
EU	1	Carcinogenic to humans.
	2	Should be regarded as if carcinogenic to humans.
	3	Cause for concern in humans.
		3A. Substances that are well investigated.
		3B. Substances that are insufficiently investigated.
IARC	1	Carcinogenic to humans.
	2	Reasonably anticipated to be a carcinogen.
		2A. Probably carcinogenic in humans: limited human evidence, sufficient animal evidence.
		2B. Possibly carcinogenic in humans: limited human evidence in the absence of sufficient animal evidence.
	3	Not classified.
	4	Probably not carcinogenic to humans.
ACGIH	A1	Confirmed human carcinogen.
	A2	Suspected human carcinogen, limited human evidence and sufficient relevant animal evidence
	A3	Confirmed animal carcinogen with unknown relevance to human, epidemiologic studies do not confirm risk to humans.
	A4	Not classifiable.
	A5	Not suspected as human carcinogen, based on properly conducted epidemiologic studies or evidence in animal studies.
Health Canada	Group I	Carcinogenic to humans.
	Group II	Probably carcinogenic to humans. Inadequate epidemiologic evidence; sufficient evidence in animal species.
	Group III	Possibly carcinogenic to humans. Inadequate or flawed epidemiologic studies. Limited animal evidence, or adequate animal evidence, but involves epigenetic mechanisms.
	Group IV	Unlikely to be carcinogenic in humans. No evidence in adequate epidemiologic studies; positive animal studies of limited or unlikely relevance to humans.
	Group V	Probably not carcinogenic in humans. No evidence in adequate epidemiologic studies. No evidence or inadequate evidence in animal studies.
U.S. EPA	–A	Human carcinogen. Sufficient epidemiologic evidence.
	–B	Probable human carcinogen.
		B1. Limited epidemiologic evidence, sufficient animal evidence.
		B2. Inadequate or no epidemiologic evidence, sufficient animal evidence.
	–C	Possible human carcinogen. Limited animal evidence, no epidemiologic evidence.
	–D	Not classifiable. Inadequate or no human or animal evidence.
	–E	Evidence of non-carcinogenicity for humans. No evidence for carcinogenicity in at least two adequate animal species in both adequate epidemiologic and animal studies.
NTP	–1	Known to be a carcinogen.
	–2	Reasonably anticipated to be a carcinogen.
		A. Limited evidence in human studies indicating credible causal relationship evidence in human studies.
		B. Sufficient evidence in animal studies.

Table 2.7 Factors for weighing human evidence

Increase Weight	Decrease Weight
Number of independent studies with consistent results	Few studies Equally well designed and conducted studies with null results
Most causal criteria satisfied: •Temporal relationship •Strong association •Reliable exposure data •Dose response relationship •Freedom from bias and confounding or results cannot be explained by bias and confounding •Biological plausibility •High statistical significance	Few causal criteria satisfied

Note. Adapted from U.S. EPA (195).

Table 2.8 Factors for weighing animal evidence

Increase Weight	Decrease Weight
Number of independent studies with consistent results	Single study; inconsistent results
Same site across species, similar response with structural analogues	Single site/species/sex
Multiple positive observations across species, sexes, tumor sites	
Severity and progression of lesions	Benign tumors only
• Early in life tumors/malignancy	
• Lesion progression through malignancy	Hight background of incidence tumors
• Uncommon tumor	
Route of administration like human exposure	Route of administration unlike human exposure

Note. Adapted from U.S. EPA (195).

dence on mechanistic data. In contrast, Health Canada took more of a weight-of-evidence approach, similar to that proposed by EPA in the 1996 guidelines (195).

Dose-Response Assessment

One of the most contentious aspects of the evaluation of animal carcinogens by regulatory agencies is characterizing the dose-response relationship at the exposure levels to which humans are likely to be exposed. Animals are typically exposed to carcinogens at levels that are orders of magnitude greater than those likely to be encountered in the environment by humans. It would be impossible to perform animal experiments with a large enough number of animals to directly estimate the level of risk at low exposure levels. Thus, to obtain a quantitative estimate of the risks that humans are likely to encounter at ambient exposures requires the extrapolation of effects observed at high doses to low doses,

Table 2.9 Factors for weighing other key evidence

Increase Weight	Decrease Weight
A rich set of other key data are available	Few or poor data
Physicochemical data (e.g., electropholicity) support hazard potential	or
Data indicate reactivity with macromolecules	Inadequate data necessitating use of default assumptions
Structure-activity relationships support hazard potential	or
Comparable metabolism and toxicokinetics across species	Mechanistic and other data show that animal findings are not relevant to humans
Toxicological and human clinical data support tumor findings	
Biomarker data support attribution of effects to agent	
Mode-of-action data support causal interpretation of human evidence or relevance of animal evidence	

Note. Adapted from U.S. EPA (195).

Table 2.10 Factors for weighing totality of evidence

Increase weight	Decrease weight
Evidence of human causality	Data not available or do not show causality
Evidence of animal effects relevant to humans	Data not available or not relevant
Consistency across studies	Conflicting data
Comparable metabolism and toxicokinetics between species	Metabolism and toxicokinetics not comparable
Mode of action comparable across species	Mode of action not comparable across species

Note. Adapted from U.S. EPA (195).

and from effects observed in animals to humans. Even the use of carcinogenicity data from human studies (mostly occupational studies) frequently requires the use of extrapolation models to estimate risks to humans exposed at lower ambient levels.

Mechanistic models are being developed to assist in dose-response assessment. Pharmacokinetic models attempt to describe the relationship between exposure and biologically relevant dose to the target tissue. These models characterize absorption, distribution, metabolism, and excretion of chemicals. Pharmacodynamic models attempt to describe the relationship between the dose to target tissue and response. Both of these types of models can assist in extrapolation from high to low doses and across species.

Low-Dose Extrapolation

Extrapolation from high to low dose is done using mathematical models that are hypothesized to characterize the dose-response relationship of carcinogens at both the high dose and response levels observed in animal or human occupational studies and the low dose and response levels of interest for human exposures. The choice of mathematical model depends on two factors: (a) the hypothesis for the mechanism of carcinogenesis for a particular chemical, and (b) the science policy decision to choose, in the absence of data firmly supporting one model or another, the more conservative model (of several biologically plausible models) or to present results from a range of plausible models.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_44.html[2010/10/28 18:30:52]

Threshold versus nonthreshold mechanisms. The determination of whether carcinogenesis is a threshold or nonthreshold phenomenon is a key consideration in the choice of the model used to characterize the dose-response relationship. It is considered plausible that carcinogenesis could be a nonthreshold phenomenon for genotoxic agents, particularly those that act directly to cause mutations. For example, the human carcinogen vinyl chloride is an electrophilic agent and is understood to interact with DNA (220). However, there is much debate over whether carcinogenesis is a threshold phenomenon for many chemicals that do not interact directly with DNA (not directly genotoxic) and that may induce cancer through epigenetic mechanisms.

In addition, for many carcinogens, it is unclear whether the dose-response relationship observed at high doses is necessarily the same as the dose-response relationship that might occur at low doses. Because the measure of a chemical's carcinogenic potency is typically determined by fitting a model to the observed data and then extrapolating to low doses, the implicit assumption is that the dose-response relationship is the same at high and low doses. For many chemicals that cause cell damage at high doses, or for chemicals for which detoxification pathways become saturated at high doses, it is likely that a different dose-response relationship will be observed at high and low doses, even for those chemicals where a non-zero slope is plausible at any dose.

Butterworth (22) has noted that there are many different classes of non-DNA-reactive carcinogens, and that the characterization of carcinogens as either genotoxic or nongenotoxic is too simple to adequately reflect the numerous mechanisms by which nongenotoxic carcinogens exert their effects. For example, the potent promoter TCDD, which is characterized as a hormone-type carcinogen, acts by binding to a specific receptor, resulting in enzyme induction via an apparent no-threshold mechanism. Thus, Portier and co-workers have postulated that TCDD may cause cancer by a nonthreshold mechanism despite its characterization as a nongenotoxic carcinogen (152). Other types of nongenotoxic carcinogens include phenobarbital, a non-DNA-reactive carcinogen that is understood to act by altering growth control (increasing mitogenesis), and saccharin, which appears to exhibit initiating/promotional and/or carcinogenic activity as secondary events to the cytotoxicity and increased cell proliferation caused by the high dose levels used in animal bioassays (22). Thus, saccharin would not be anticipated to increase tumor production at doses that do not cause cytotoxicity, and phenobarbital might not be expected to cause cancer at doses that do not affect growth control.

Zeise et al. (222) reviewed the experimental evidence for various shapes of dose-response relationships for carcinogens. They concluded that "reliable high dose data from human studies contains examples of superlinearity (radium injections and bone cancer), linearity (various radiation exposures), and sublinearity (smoking)." (p. 301). Their analysis of animal studies indicated that the "variety of shapes of dose-response curves observed for humans was also seen for animals." Zeise et al. noted that there are no data to indicate the shape of dose-response relationships at doses corresponding to lifetime risks of one in a million; in humans there are some data for incidence rates as low as 1%, and in animals there are two large studies that provide data at lifetime risks of a few tenths of a percent. Because carcinogens act by different mechanisms, it is very likely that different carcinogens, or classes of carcinogens, will exhibit different types of dose-response relationships. Moreover the same carcinogen may cause cancer at different tumor sites via different mechanisms.

A striking example of different dose-response relationships for a single carcinogen is the example of 2-acetylaminofluorene (2-AAF) (40). 2-AAF is a potent mutagenic carcinogen. The dose-response relationship for 2-AAF-induced liver cancer exhibits the expected (for a genotoxic carcinogen) linear dose-response relationship, whereas the dose-response relationship for bladder cancer is highly nonlinear, demonstrating an apparent threshold. The mechanistic basis for the different dose-response relationships appears to involve differences in the relative importance of genetic damage (the likely key event in liver cancer) versus genetic damage *and* hyperplasia of the bladder urothelium (the likely key events in bladder cancer). Thus, selection of the appropriate shape of the dose-response relationship for *any* chemical requires understanding of the mechanism by which tumors are induced.

Mathematical models. The choice of the low-dose extrapolation model can have a major impact on the estimate of risk at low exposure levels. Figure 2.3 shows the estimate of risk from 2-acetylaminofiuorene at low exposure levels, using different models. The level of risk varies by many orders of magnitude at the same exposure level, depending on the model chosen to characterize the dose-response curve in the unobservable region. One of the more common models used by regulatory agencies particularly in the United States has been the linearized multistage model (12). The EPA has used the upper 95% confidence limit of this model on the basis of its biological plausibility (it assumes a nonthreshold) and its conservatism (it is unlikely to underestimate risk at low exposure levels) (208) to develop cancer

slope factors (CSF), in units of $(mg/kg\text{-}day)^{-1}$. CSFs relate dosage (mg/kg-day) to the probability of an individual developing cancer. Cancer potency estimates for chemicals are highly dependent on model choice. Anderson (12) analyzed cancer potency estimates for TCDD, derived by using different low dose extrapolation

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_45.html[2010/10/28 18:30:52]

page_46

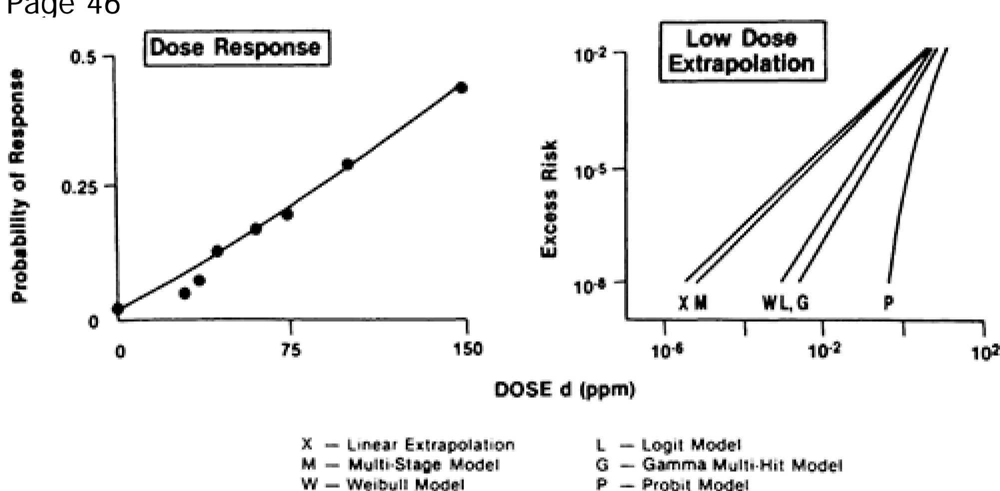

FIG. 2.3. Low-dose extrapolation for 2-acetylaminofluorene under several mathematical models. From Bickis and Krewski (19a).

models and different selection and treatment of bioassay data, and found that model choice alone (Weibull, multistage, log probit) would account for a difference in calculated cancer potency of 13 orders of magnitude.

One difficulty with the use of the upper 95% confidence limit of this model is that this approach basically reduces the model to worst-case curve fitting and does not take basic carcinogenic mechanisms into account. Thus, Cook et al. (43) have stated that if the multistage model as they defined it for carcinogenesis were correct, then the value of *k*, or the number of stages of cellular transformation, would generally be from four to six. However, the algorithm used in the calculation of cancer risk by the EPA for the multistage model requires *k* to assume a value not greater than the number of dose levels used in the study. Because three dose levels are usually employed—the MTD, half the MTD, and controls—the value of *k* is restrained to be, at most, equal to 3. Furthermore, when the MTD dose has been overestimated and excessive mortality occurs, the MTD cannot be used for risk assessment, thereby reducing *k* from 3 to 2. Allowing the value of *k* to be determined by the number of dose levels in a study, rather than on an understanding of the process of carcinogenesis, results in risk estimations of the multistage model that have reduced biologic relevance (43).

Because of the uncertainties in dose-response modeling for low dose cancer risk and the growing acceptance of a threshold dose-response relationship for some carcinogens, in the proposed 1996 cancer risk assessment guidelines, the EPA revised the approach to dose-response assessment (195). If sufficient data are available, a biologically based dose-response model rep resents the most appropriate method for evaluating the observed data and for extrapolating to exposures below the observed dose range. Data are not available for most carcinogens for development of biologically based models. In this case, a "point of departure" approach is recommended. The point of departure represents a dose, within the range of observed data, associated with a 10% extra tumor risk. The point of departure is developed using the linearized multistage model and expressed as the lower 95% confidence limit on the dose associated with 10% extra risk (LED10). Risks below the LED10 are characterized either through linear extrapolation (for chemicals believed to act via a linear dose-response relationship (e.g., genotoxic carcinogens), or through a margin-of-exposure analysis (for chemicals whose dose-response relationship is likely to be either threshold or nonlinear). For chemicals where data might support either linear extrapolation or a margin-of-exposure analysis, both analyses are to be presented.

A panel organized by the International Life Sciences Institute (ILSI) recently applied the 1996 EPA guidelines to an assessment of the dose-response relationship for chloroform (64). The ILSI panel evaluated the large database of information relevant to the mode of action by which chloroform induces liver tumors in rodents. The group identified a number of key elements important to chloroform's likely mode of action: lack of evidence of genotoxicity; tumor induction at doses associated with frank toxicity at the tumor sites; and the role of cytotoxicity and compensatory cell proliferation in tumor induction. The group concluded that the evidence did not support a linear dose-response relationship. A margin-of-exposure analysis was considered to represent

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_46.html[2010/10/28 18:30:53]

the most appropriate method for evaluating the potential hazards of chloroform at low doses. The significance of such an approach is potentially quite large with respect to regulatory decision making. In the case of chloroform, use of the margin-of-exposure analysis would yield a permissible level in drinking water in the United States of 300 μg/L, a 60-fold increase beyond the present permissible level of 5 μg/L.

The linearized multistage model is clearly not appropriate for estimating the low-dose carcinogenic potency of some carcinogens. This is largely because experimental evidence indicates that for most chemicals, the dose-response relationship at the high doses used for model fitting is likely to be different than that at low doses. Pharmacokinetic and pharmacodynamic models can and should be used to more accurately characterize the dose-response relationship at low doses. In the absence of information to perform such assessments, alternative approaches, such as those proposed by the U.S. EPA (195), represent a reasonable interim measure.

EVALUATION OF SYSTEMIC TOXICANTS

In its broadest sense, systemic toxicity refers to all adverse effects, but in general it is applied only to chemicals that are postulated to induce an adverse effect through a threshold mechanism. That is, for these chemicals, there is a level of exposure below which there is minimal, if any, chance for an adverse effect. The effects range from skin and eye irritation to subchronic or chronic damage to any organ system, such as pulmonary fibrosis.

The underlying hypothesis for the threshold model for systemic toxicants is that multiple cells must be injured before an adverse effect is experienced, and that the injury must occur at a rate that exceeds the rate of repair. This is in contrast to the commonly used paradigm for carcinogenesis, in which a genotoxic insult to a single cell is theoretically sufficient to allow that cell to grow to a malignant tumor (215). An example of a threshold-type injury can be seen with pulmonary fibrosis due to mineral dust exposure. Fibrotic areas may be present and observed as radiographic or histopathologic changes in the lungs of miners as a consequence of mineral dust exposure in the absence of any physiological impairment such as reduced forced expiratory volume in 1s (FEV1) or in the absence of changes in lung volume. Physiological impairment will occur as the fibrosis increases and the fibrotic areas begin to coalesce (223).

For effects other than cancer, which still involve genotoxic mechanisms, such as developmental effects, a threshold model may still be the most appropriate choice of dose-response model. This is because multiple cells must still be injured before an effect can be manifested. For example, the prenatal death of a single retinal cell, even through genetic damage, would not result in blindness because of the existence of many retinal cells.

The RfD and Uncertainty Factors

The general approach for setting exposure limits for systemic toxicants differs from that commonly used for carcinogens. Basically, appropriate uncertainty factors are applied to an experimental exposure to yield a level classically defined as the *acceptable daily intake* (ADI). The ADI represents a daily intake level of a chemical in humans that is associated with minimal or no risk of adverse effects. The ADI is expressed in terms of milligrams of chemical per kilogram of body weight per day (135). The EPA refers to such an exposure level as the *risk reference dose* or RfD. The basis for the change in terminology is that the ADI does not represent a magic dividing line between safe and nonsafe, but represents an estimated dose, derived through a consistent methodology, at which the chance of adverse effects is estimated to be negligible. The lack of precision is reflected in EPA's description of the RfD as having an uncertainty perhaps spanning an order of magnitude (200).

An ADI or RfD is typically based on either a no-observed-adverse-effect level (NOAEL) or a lowest-observed-adverse-effect level (LOAEL) from an epidemiology or animal toxicology study. "Uncertainty" factors (UFs), also termed "safety" factors, are then applied to the NOAEL or LOAEL to account for uncertainties in the relationship between exposure to a chemical in an animal study and a particular effect, and the relationship between lifetime daily exposure to the same chemical in the general population of humans and the likelihood of a particular effect.

The history as well as the experimental support for UFs in developing a permissible dose for production against systemic toxicity in humans have been described by Dourson and Stara (51). These authors describe four categories of UFs:

- UFH: An up to 10-fold uncertainty factor to account for variations in susceptibility in humans. Thus, if a NOAEL was defined from a long-term study in humans, this would be the only UF applied. In a later section of this chapter we discuss in detail the variability in human responsiveness to environmental pollutants and its relevance to the regulatory process.

• UFA: An up to 10-fold uncertainty factor to extrapolate from animal data to human data. This factor is used for animal studies and is based on the assumption that some humans may be more susceptible than experimental animals to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_47.html[2010/10/28 18:30:54]

a particular chemical. The default assumption is that the magnitude of the increased susceptibility is within a factor of 10.
• UFS: An up to 10-fold uncertainty factor to extrapolate from a subchronic exposure to a chronic exposure. This factor is used for studies that involve less than lifetime exposure and is based on the assumption that if the chemical were given over the lifetime of the animal rather than over a fraction of the lifetime, a smaller amount of chemical would result in the same NOAEL.
• UFL: An up to 10-fold uncertainty factor to extrapolate from a LOAEL to a NOAEL. This factor is used for studies in which a NOAEL was not identified. The default assumption is that a dose at 1/10 the LOAEL would result in a NOAEL.
More recently, EPA has developed a fifth uncertainty factor, UFD, which may be applied when the database is incomplete (203). The assumption here is that when the database for a chemical is limited, there is uncertainty as to whether the identified NOAEL might be significantly lower if other studies were performed, or whether a different NOAEL might have been identified if additional health endpoints (such as reproductive toxicity) had been evaluated. A complete database is defined as having two chronic mammalian studies, one mammalian multigeneration study, and two mammalian developmental toxicity studies. If these five studies are available, then there is a high degree of confidence that one has approximated the lowest NOAEL.
Uncertainty factors are used multiplicatively. To derive the RfD, EPA divides the exposure level from the toxicity study by the UFs. Mathematically, this is represented as

$$\mathrm{RfD} = \frac{\mathrm{LOAEL\ or\ NOAEL}}{\mathrm{UF}_1 \times \mathrm{UF}_2 \ldots \mathrm{UF}_n}$$

The use of all five UFs (UFH, UFA, UFS, UFL, UFD), each representing an order of magnitude, could in theory lead to a total uncertainty factor of 100,000. This would occur if data were from a subchronic animal study that identified only a LOAEL and the database was limited. However, since the multiplication of four or five factors of 10 each is likely to yield unrealistically conservative RfDs, EPA has restricted the total uncertainty factor calculation as follows: when uncertainty exists in four areas, EPA uses a 3000-fold total uncertainty factor, and when uncertainty exists in five areas, EPA uses a 10,000-fold total uncertainty factor (203).
Although 10 represents the default value for a UF, values less than 10 may also be used, depending upon the nature of the available information. For example, in deriving an RfD for chromium(VI), a factor of 3 was applied for the UFs, to account for the fact that the one year exposure duration in the principal study was less than lifetime, but longer than typical subchronic studies in rodents (186). No UFs were used in developing the RfD for fluoride because the NOAEL for the critical effect (dental fluorosis) was observed in the sensitive population (children) for a sufficiently long exposure duration (188).
In addition, a modifying factor (MF) that is greater than 0 and less than or equal to 10 may be used to address uncertainties not addressed in the other factors. For example, the use of a very large number of animals in a study may enhance certainty in the RfD, resulting in the use of a MF less than 1, but greater than 0. Alternatively, when an RfD is based on a very limited number of animals, an MF greater than 1 but less than or equal to 10 may be appropriate (203).
The RfD approach represents a generally accepted (NAS, FDA, and EPA, among others) method for setting lifetime exposure limits for humans, and the use of default 10-fold uncertainty factors has some experimental support, particularly as upper bound estimates (51). For example, the ratio between the subchronic and chronic NOAEL or LOAEL for 52 chemicals was less than 10 in 96% of the cases, as described in the analysis by Dourson and Stara (51). Thus, the uncertainty factor of 10 would be an underestimate for only 4% of these chemicals. A similar analysis regarding subchronic to chronic was performed by Lewis (15), who observed that for 18 chemicals, the ratio of the subchronic to the chronic NOAEL had a ratio of 3.5 or less for 14 chemicals and only 1 had a ratio of greater than 10. If the chemical with a ratio greater than 10 were excluded from the analysis, the mean subchronic to chronic NOAEL ratio was 3.3. Thus, the default UF of 10 for extrapolating from subchronic to chronic exposures would be very protective for most chemicals, and an UF of 3 may be more appropriate than the default value of 10 for many chemicals.
There are several limitations in the RfD approach, the net result of which is that exposures resulting in the same RfD do not imply the same level of risk for all chemicals, and that exposures above the RfD do not represent the same increase in risk for all chemicals. First, the choice of a LOAEL or a NOAEL does not take into consideration the greater experimental confidence associated with, for example, studies using more experimental animals. An exposure concentration defined as a NOAEL in one experiment

could turn out to be a LOAEL, had more experimental animals been used (i.e., an effect might have been detected using more animals). As a result, poor experiments may yield anticonservative RfDs, since studies using fewer animals may result in a higher RfD than studies using larger numbers of animals (46).

In addition, the RfD approach does not make use of dose-response information, which is a key determinant in assessing the likelihood of effects. Thus, a chemical

with a steep dose-response curve would be associated with a greater likelihood of effects as exposure increased above the RfD and a smaller likelihood of effects with exposures below the RfD than would a chemical with a more shallow dose-response curve (50).

There are also difficulties with the implications of specific UFs. The default value of 10 for the interspecies uncertainty factor (UF*A*) is a reasonable assumption in some cases, but in other cases may not be appropriate. For chemicals for which metabolism is a key determinant of toxicity, interspecies differences may be due mainly to physiological and metabolic differences across species (32). Under this assumption, interspecies differences are believed to scale according to allometric principles, that is, when the dose is expressed on a dose-per-unit surface area, different species are presumed equally sensitive to a chemical (51). According to this interpretation, then, a scaling factor based on surface area (body weight2/3) should account for interspecies differences (32, 51). For rodent toxicity studies (most commonly used in toxicological risk assessments), such a scaling factor would be about 8 for rats and 13 for mice, similar to the default value of 10 for the UF*A*. However, using this interpretation the default value of 10 would not be adequately protective for much smaller animals, and would be overly protective for much larger animals.

If, however, pharmacokinetic modeling has been used to estimate a biologically effective dose and to extrapolate dose across species, the use of an interspecies UF*A* may be unnecessary. For example, this may apply to chloroform, for which a mechanistically based dose-response model for hepatotoxicity has been developed (42). A similar conclusion has been reached by Jarabek and co-workers, who have developed a methodology for estimating the *reference concentration,* or RfC (116). The RfC is an air concentration of a chemical that is expected to be associated with minimal risk, if any, for adverse effects in humans, including susceptible populations (116, 204). As such, the RfC is the functional equivalent of the RfD, except that it is based on an air concentration, rather than an administered dose. Overton and Jarabek (148) noted that when dosimetric adjustments (e.g., through physiologically based pharmacokinetic modeling) are made, use of the value of 10 for the UF*A* for cross-species extrapolation may be inappropriate. This is because the dosimetric adjustment has already addressed some of the basis for interspecies variability. (Additional description of the RfC methodology is provided in chapter 8 by Rodricks et al.)

Differences in metabolism, however, are insufficient to explain all interspecies differences in toxicity. For some chemicals, innate differences in responsiveness are responsible. For example, the difference in susceptibility to the lethal effects of 2,3,7,8-tetrachlorodibenzodioxin is about 10,000-fold greater in guinea pigs than in hamsters and is likely a reflection of differences in Ah receptor activity and other genetic elements (158). Another example is seen in studies involving the fibrogenic mineral dust alpha-quartz. Macrophages of different animal species, when exposed to the fibrogenic mineral dust, alpha-quartz, do not demonstrate the same response in terms of levels or characteristics of fibroblast stimulating factor (73, 81). These differences are consistent with differences in the nature and extent of the fibrotic response to intratracheally instilled alpha-quartz (3, 21, 70).

Alternative Approaches to the RfD

There are alternative approaches to the standard RfD approach. By employing dose-response modeling and statistics, these alternative approaches can address issues of experimental quality, the shape of the dose-response curve, and other limitations of the RfD approach. Examples include the *benchmark dose* method (57, 198), probabilistic RfD approaches (13, 169), and distributional population approaches. These methods are described next.

The EPA defines a *benchmark dose* (BMD) as "a statistical lower confidence limit on the dose producing a predetermined level of change in adverse response compared with the response in untreated animals" (198). For example, a BMD could represent the 95% lower confidence limit on a dose that produces a 10% increase in a particular adverse health effect. The BMD is then used like a NOAEL or LOAEL, and appropriate UFs are applied to derive an RfD based on a BMD. Calculation of a BMD is illustrated in Figure 2.4.

The BMD approach overcomes many of the weaknesses of the RfD approach (57, 198). Because BMDs are determined based on statistical modeling of dose-response data, the approach incorporates information on the sample size and the shape of the dose-response curve, information that is not taken into account using the standard RfD approach. Unlike NOAELs or LOAELs, BMD values are not constrained to be based on one of the experimental doses tested, and are less dependent on the study design. Also, the BMD approach can be used for both threshold and nonthreshold adverse health effects, as well as for both quantal and continuous toxicity data. The BMD approach allows for greater consistency between values derived for different chemicals. A further benefit of the BMD approach is

that it allows for possible future harmonization of cancer and noncancer risk assessment methods (45). For any particular chemical, uncertainty factors applied to NOAELs or LOAELs using the standard RfD approach may not be appropriate to apply to a

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_49.html[2010/10/28 18:30:55]

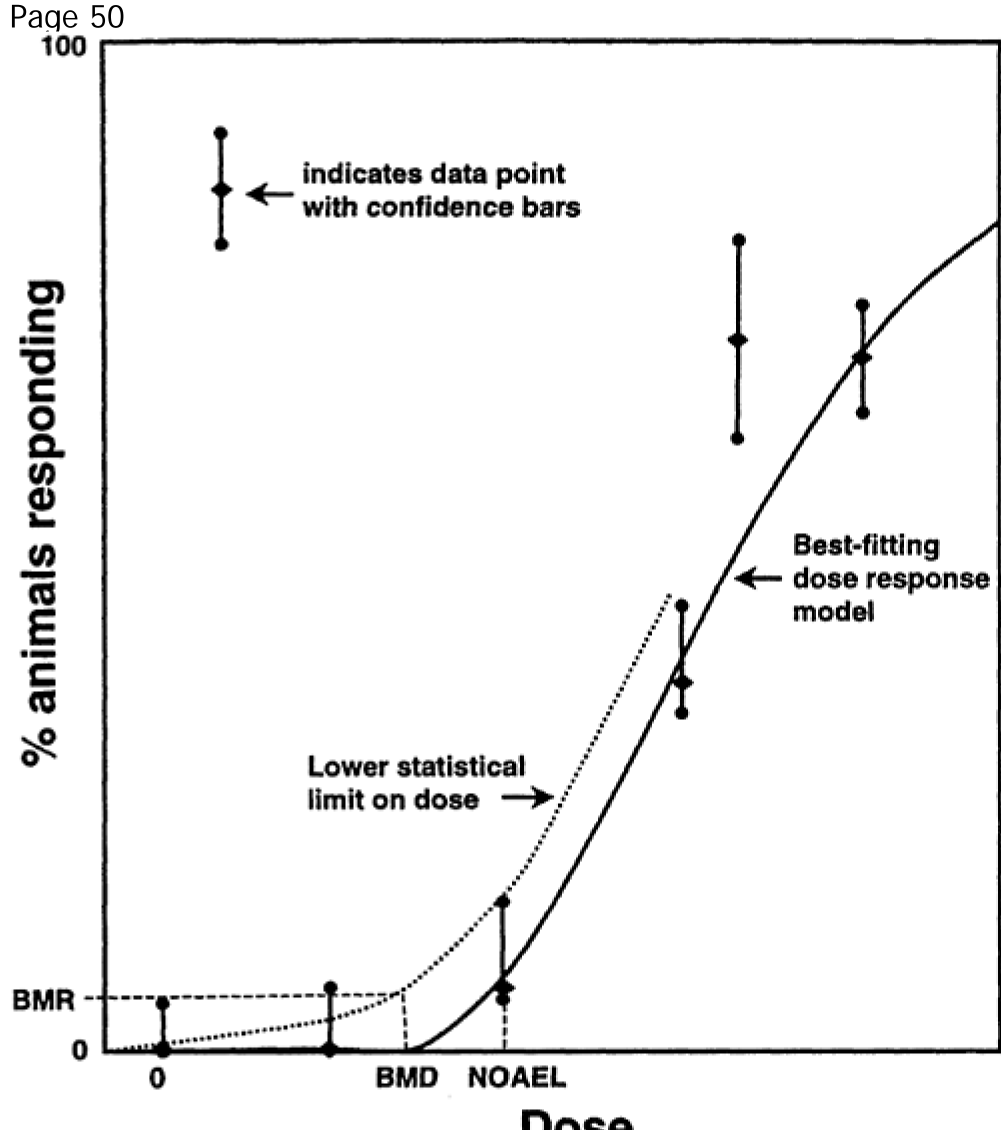

FIG. 2.4. Example of calculation of a BMD. Source: U.S. EPA (198).

BMD. This is because additional dose-response information has already been incorporated into the BMD. For example, when using a BMD, a steeper dose-response curve or a less severe critical effect may warrant a smaller value for UF*L* than would a more shallow dose-response curve or a more severe effect (50).

Recently, the EPA has adopted the BMD approach in developing RfDs for a number of chemicals, including beryllium, methylmercury, and tributyltin oxide (185). Similarly, benchmark concentrations (BMC) have been used to develop RfCs for antimony trioxide, carbon disulfide, methylene diphenyl diisocyanate, methyl methacrylate, phosphoric acid, 1,1,1,2-tetrafluoroethane, and chromium(VI) particulates (185). For all chemicals listed, a 10% relative change was chosen as the benchmark response. Although the EPA has performed a benchmark dose analysis for naphthalene, the resulting RfD (3×10^{-2} mg/kg-day) was very similar to the value derived using a standard NOAEL/RfD approach (2×10^{-2} mg/kg-day), and the EPA decided to use the NOAEL/RfD approach in deriving the final EPArecommended value (189).

A probabilistic approach for developing RfD or ADI values, combining distributions for each uncertainty factor using a probabilistic approach to generate an overall distribution for the no-adverse-effect level in sensitive human subpopulations, has been recommended by the Netherlands National Institute of Public Health and the Environment (169). This approach allows consideration of all available data on various uncertainties, and minimizes the conservatisms introduced by multiplying numerous UFs. A similar approach has also been recommended by Baird and co-workers (13).

For compounds that have been well studied, particularly in humans (both in terms of exposure and in terms of toxicity), distributional population approaches have been used to evaluate toxicity and to

provide input into the decision-making process. Such approaches have been

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_50.html[2010/10/28 18:30:55]

applied mainly to evaluation of the National Ambient Air Quality Standards (NAAQS)—standards for moderately toxic air contaminants that are ubiquitous in the United States. Much of the basis for selection of a NAAQS is based upon human toxicological data, although animal data are used in a supporting role.

An example of a distributional population approach can be seen in the recent evaluation of carbon monoxide (CO) toxicity and exposure by EPA's Ambient Standards Branch (201). As part of this assessment, EPA reviewed several studies that evaluated the relationship between exposure to carbon monoxide, using carboxyhemoglobin (COHb) in blood as an indicator of exposure, and percent decrease in time to angina or pain in the chest, as an indicator of effect. Most of the studies showed an impact of low COHb levels on angina. However, there was no consistent dose-response relationship when studies were analyzed in the aggregate. This may have been due to differences in study design, study populations, and other factors. Because of the lack of a clear dose relationship, EPA evaluated the impact of different concentrations of CO in air upon various "cutoff' points of COHb, from 2.1 to 3.0%. These cutoff points are conceptually similar to the LOAEL used in RfD development. Levels of CO that result in COHb of 2.9 to 3.0% or higher might constitute frank effect levels (FEL). This is because levels of COHb of 2.9 to 3.0% or higher in persons with heart disease are considered as possibly increasing the risk of myocardial ischemia and diminishing blood flow to the heart.

The risk of CO exposure to people with heart disease in Denver, CO (36, 345 individuals at the time), was estimated under different carbon monoxide levels (201). The number of person-days where individuals might have at least one hourly COHb level greater than or equal to a defined percent COHb was estimated. Table 2.11 presents some of the results of this analysis. For example, under conditions at the time (considering both indoor and outdoor sources of carbon monoxide), there were approximately 488 person-days in which the Denver population with preexisting heart disease would experience COHb levels greater than 2.1%. If only ambient air is considered, then the person-days drops to 72. If the NAAQS for CO is attained, then the person-days drops to 457 for all sources and 0 for ambient air only. This type of analysis is useful in showing the benefits of CO reduction, as well as identifying the significance of different sources.

Distributional population approaches to evaluating environmental chemicals provide a more comprehensive evaluation of risks than the RfD approach. Rather than focusing on point estimates (e.g., above or below the RfD), this method allows one to more fully characterize variability in responsiveness to chemicals and variability in exposure levels among defined populations. However, this approach is feasible only for a limited number of chemicals and is quite resource intensive.

Endpoints—Developmental Toxicity

Recent refinements in the evaluation of systemic toxicants have focused on specific target-organ systems, such as the nervous system or the developing fetus. In this section, we focus on developmental toxicity as illustrative of the use of a specific endpoint in regulatory toxicology, including, for example, classification schemes and approaches toward setting permissible levels. Evaluation of developmental toxicants presents some unique challenges in risk assessment. This is because standard chronic and subchronic toxicity tests cannot be used to provide information on developmental effects in the offspring of exposed mothers. Rather, animal selection and exposure conditions must be designed specifically to assess developmental effects.

Developmental toxicity has been defined to include "any detrimental effect produced by exposures during embryonic stages of development" (135). These effects may include structural abnormalities, functional abnormalities, growth retardation, or lethality (202).

Table 2.11 Heart person-days with at least one hourly COHb estimate greater than or equal to value for four alternative scenarios

	"As is" air quality		"Just attain" air quality	
Exposure indicators	"Ambient air" plus internal sources	"Ambient air" without internal sources	"Ambient air" plus internal sources	"Ambient air" without internal sources
COHb≥2.1%	488	72	457	0
COHb≥3.0%	37	0	24	0

Note. Adapted from U.S. EPA (201).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_51.html[2010/10/28 18:30:56]

The effects may be reversible, such as a temporary reduction in growth rate, or irreversible, such as an overt physical malformation.

We discuss the evaluation of developmental toxicants in the regulatory process by focusing on four main issues:

• Selection of testing protocols.
• Relevance of animal studies to hazard identification in humans, including weight of evidence classifications.
• Use of the RfD approach to assess risk.
• Use of other approaches to assess risk.

Selection of Testing Protocols

The use of animal studies is particularly critical in evaluating developmental toxicants, as compared to chemicals that induce other effects. Reasons for this include the emphasis on adult males in occupational epidemiology studies, the lack of a long-term national registry of birth defects, and the difficulty in identifying certain endpoints, such as resorptions.

Types of studies used to evaluate developmental toxicity include the conventional "segment 2" study, in which the dams are exposed typically during the period of fetal organogenesis, and litters are evaluated for a number of endpoints, including number of viable offspring, types and incidence of skeletal or visceral malformations or variations, and body weight (119, 202). Segment 1 tests focus on fertility and reproductive performance of males and females. Segment 3 tests include perinatal and postnatal study after treatment of females only and, as such, may be considered sequential to the segment 2 test. In addition, multigeneration studies are also performed to assess fertility, reproductive performance, and, sometimes, teratology (119).

In the segment 2 tests, maternal toxicity endpoints, such as organ weights and clinical histopathology, are also evaluated. Of particular concern are those compounds that induce toxicity in the offspring in the absence of significant maternal toxicity.

There are significant differences in the protocols for segment 2 tests, particularly between countries. These include differences in animal species, dosing regimen, and specific endpoints evaluated. For example, the Japanese protocol requires that some females be allowed to litter and the pups in the litter are examined for physical, reproductive, and functional development (119), which contrasts with typical U.S. protocols where littering does not occur and only in utero pups are examined.

These differences may be significant, with potential implications for regulatory action. For example, functional deficits in offspring could be observed in the Japanese segment 2 protocol, but not in the standard U.S. segment 2 protocol, where additional testing (segment 3) would be required to detect such effects.

Because of the implication of test differences between countries, an expert panel of scientists has proposed that efforts be made toward "harmonization" of guidelines for reproductive and developmental toxicity testing (119). Harmonization would result in international guidelines for reproductive and developmental toxicity testing to improve the comparability of data from studies. In addition, harmonization of testing schemes would allow for more efficient use of resources and possibly would reduce the need for animal testing, since one country could more readily use the results of studies performed in other countries than is now possible.

In addition to the standard methods, specialized developmental toxicity methods involving, for example, developmental neurotoxicity testing, are available. These can be either an addition to a segment 2 test, or a distinct test. Developmental neurotoxicity testing may be especially critical in evaluating certain chemicals such as lead (217) or polychlorinated biphenyls (PCBs) (216), which have been associated with subtle neurobehavioral changes in offspring from relatively low-level prenatal exposures.

Short-term screening tests and in vitro tests, such as the Chernoff/Kavlock (36), have also been used to evaluate developmental toxicants. In general, these tests are insufficient for performing quantitative risk assessments. However, they may be useful in selecting chemicals for further analysis and in helping to guide the nature of further analyses.

Short-term tests are of particular use when one considers the complexities of animal testing and the relatively high frequency of developmental abnormalities. For example, about 3% of infants are born with major congenital malformations that are recognized in the first year of life (125).

Relevance of Animal Studies to Hazard Identification in Humans, Including Weight-of-Evidence Classifications

Significant species differences have been observed with respect to susceptibility of chemicals to induce developmental toxicity. Perhaps the classic example of species differences is thalidomide. Thalidomide

exposure induces comparable target-organ specificity for limb defects in rabbits and various primates, but not in rats. Had initial toxicity tests on thalidomide involved more appropriate animal species, the human tragedy of thalidomide might have been mitigated (125).

Attempts have been made to develop categorical classification schemes and to provide interpretative descriptions of developmental toxicity data. Overall, the aim of such evaluations is to assess the likelihood that a chemical can cause developmental effects in humans. Although not as codified as the cancer classification

Table 2.12 Classification of chemicals based on teratogenic potential

Criteria	Category A	Category B	Category C	Category D
1. Ratio: minimum maternotoxic dose to minimum teratogenic dose	Much greater than 1	Generally greater than 1, teratogenic range starts below the maternotoxic dose range*a* and overlaps it	≤1	No teratogenicity even at maternotoxic doses
2. Incidence of malformations	Dose-related and high	Dose related and high	Dose relatedness of each malformation less obvious, incidence low	—
3. Type of malformation at lower doses	Organ systems involved are specific	Characteristics, possibly specific, generally multiple	Nonspecific involving different organ systems	—
4. Target cell	Specific cells	Specific cells	Nonspecific and generalized	Not known
5. Range of safety factor	1–400	1–300	1–250	1–100

a The maternotoxic dose range extends between the dose initiating signs of toxicity and the dose causing 50% mortality (LD50). Source: Khera et al. (119).

schemes described earlier, the use of such schemes for developmental toxicants could be further developed to form a more integral part of the regulatory process. For example, weight-of-evidence schemes could be used for developing regulatory priorities.

A classification scheme for developmental toxicants is shown in Table 2.12. This scheme categorizes chemicals, based on teratogenic potential. Given equal exposure levels, chemicals in category A would present the greatest concern for teratogenic potential. This particular scheme includes several elements: relationship of maternally toxic dose to developmentally toxic dose; shape of the dose-response curve; and the nature of the malformations. The scheme differs from most carcinogen classification schemes in that it takes into consideration elements of the dose-response relationship. For example, the scheme considers the relationship between the maternally toxic and the developmentally toxic dose, and proposes a range of "safety factors" for extrapolating to human risks, depending on category.

An alternative to classification schemes for developmental toxicants is the use of text descriptors of hazard and other risk elements. This approach was recently used by the Institute for Evaluating Health Risk (IEHR) in the report "An Evaluative Process for Determining Human Reproductive and Developmental Toxicity of Agents" (83). This document contains the deliberations of an ad hoc group of industry and government scientists. Using a hypothetical chemical "terminator", the relevance of animal toxicological data for human risk was evaluated, using expert opinion and consensus development, considering factors such as pharmacokinetic differences between humans and animals, absorption potential through different body interfaces, and biological monitoring data. As noted earlier, rather than yield a rigid categorization scheme, the analysis resulted in text descriptors to assist in the interpretation of animal toxicological studies, with respect to potential for hazard in humans.

The use of classification schemes or interpretive text descriptors to evaluate the relevance of animal developmental studies to humans, as described earlier, could significantly improve the use of developmental toxicity data in the regulatory process. In addition, similar approaches are warranted for other endpoints, such as immunotoxicity.

Use of the RfD to Assess Risk

RfDs may be derived for developmental effects, using essentially the same methodology as described earlier for systemic toxicants in which case the value is an RfDDT (202). The RfDDT is derived from a LOAEL or NOAEL from a developmental toxicity study. However, because the relevant exposure period is not chronic, but is the in utero and possibly earlier time period, the RfDDT applies not to a lifetime exposure but only to the study exposure period. At present, RfDDT values are available for only a limited number of chemicals. In general, the use of RfDs for specific endpoints and periods of exposure duration could allow greater comparability of RfDs and better use of toxicological information.

Use of other Methods to Assess Risk

Alternative methods to the RfDDT have been developed to assess risks or to develop protective levels for developmental toxicants. One method described earlier in Table 2.12 involves the use of different

safety factors applied to the minimum teratogenic dose depending upon the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_53.html[2010/10/28 18:30:57]

teratogenic potential category (A-D) to which the chemical belonged. The use of variable "safety" (now termed *uncertainty*) factors for developing permissible levels from a NOAEL or a LOAEL allows better use of information about the specific developmental endpoint and the likelihood of hazard for humans. Nonetheless, this approach still suffers from the basic flaws as the RfD approach, such as the difficulty in evaluating excursions above the RfD level.

The benchmark dose (BMD) approach has also been proposed to improve assessments of developmental toxicants (117). Briefly, the benchmark dose (defined in a previous section) is developed through the use of dose-response modeling and reflects the dose (or the lower confidence limit on the dose) associated with a certain percent response in the population.

Incorporating Information on Severity of Effect

A critical difference in evaluating risks for carcinogenicity versus risks for systemic effects is that, from a regulatory perspective, almost all types of cancer are considered equally severe, while the severity of systemic effects can vary significantly. In general, there is little basis from a regulatory perspective for distinguishing among carcinogens on the basis of malignancy or tumor type. Despite advances in earlier diagnosis and treatment, the fatality rate for cancer is still relatively high. For example, the relative 5-year survival rate for all cancers from 1986 to 1993, excluding nonmelanoma skin cancer, was 60% for whites and 44% for blacks (4). Nonmelanoma skin cancer includes squamous- and basal-cell carcinoma, which can be induced by agents such as ultraviolet light and arsenic and has relatively low (<10%) fatality rates, even when untreated (206).

In contrast, target-organ effects range greatly in severity. For example, using the same target organ and susceptible population—namely, airways in asthmatics—responses may range from imperceptible mild bronchoconstriction induced by low levels of SO_2 to a fatal asthmatic response, as may have been due to acid sulfate pollution in the London smog episode (176, 210).

Consideration of severity then becomes important for regulatory development in several ways. For RfD development, is an effect such as a 2% decrease in weight a NOAEL or a LOAEL? Is an effect of sufficient severity to warrant protection of 95% of the population or 99%? Thus, several agencies and groups have developed approaches to incorporate information on severity of effect into the risk assessment or risk management process for environmental chemicals.

In 1985, the American Thoracic Society (ATS) defined an adverse respiratory effect (8). Rather than providing a clear demarcation between nonadverse and adverse, the ATS described a continuum of respiratory effects from mild effects of limited, if any, medical significance (e.g., occasional cough, runny nose) to effects of obvious adverseness and medical significance (e.g., an asthmatic attack). To the extent that the effect caused discomfort and impaired daily function and quality of life, it was viewed as more adverse.

Similarly, EPA has considered severity in its evaluation on the effects of ozone as part of the NAAQS setting process. For example, based on lung function changes, duration of effect, symptoms, and impact on activity level, EPA categorized ozone responses into four categories: mild, moderate, severe, and incapacitating. The mild category includes FEV_1 declines of 5 to 10% and no impact on activity. The EPA (205) recommended that the responses in the mild category *not* be considered an adverse respiratory effect in adults for purposes of defining the NAAQS for ozone.

As noted earlier, the concept of severity of effect is also incorporated into the process for developing the RfD. Specifically, the RfD is based on an effect that, by definition, considers adverseness. The critical effect is adverse, because it may result in functional or structural impairment or is a precursor state to irreversible toxicity (203). For example, fatty infiltration of the liver or a greater than 10% reduction in weight gain versus controls would be considered adverse effects, and the associated dose would be a LOAEL. As the dose increases, the fraction of that population experiencing such effects would increase. Frank effect levels (FELs) are dose levels that result in overt, often clinically apparent toxicity, and are considered "too adverse" to be used in the development of the RfD. Examples of frank effects include liver necrosis or cirrhosis, which are severe and may be irreversible. FELs are not considered appropriate for RfD development because the protection level would be inadequate.

Information on severity has been incorporated into the *reportable quantity* (RQ) definition, under CERCLA. Under this statute, releases of chemicals in amounts greater than some predetermined level, defined as the RQ, require that EPA be notified of the release (48). The amount of release that triggers notification is based on an assessment of the potency of the chemical and the severity of the effect at the dose level where the potency was quantified. The ranking of severity is shown in Table 2.13 (48), where it can be seen that effects range from slight biochemical changes through gross toxicity, including lethality. Unlike the RfD process, this scoring is not restricted to data sets containing information on

mildly adverse effects, from subchronic or chronic studies. The RQ process can result in development of scoring indicators from lower quality data sets, involving shorter time periods of exposure and more severe toxicity.

Table 2.13 Rating values for NOAELS, LOAELS, and FELs used to rank chronic toxicity

Rating	Effects
1	Enzyme induction or other biochemical change with no pathologic changes and no change in organ weights.
2	Enzyme induction and subcellular proliferation or other changes in organelles, but no other apparent effects.
3	Hyperplasia, hypertrophy, or atrophy, but no change in organ weights.
4	Hyperplasia, hypertrophy, or atrophy with changes in organ weights.
5	Reversible cellular changes: cloudy swelling, hydropic change, or fatty changes.
6	Necrosis, or metaplasia with no apparent decrement of organ function. Any neuropathy without apparent behavioral, sensory, or physiologic changes.
7	Necrosis, atrophy, hypertrophy, or metaplasia with a detectable decrement of organ functions. Any neuropathy with a measurable change in behavioral, sensory, or physiologic activity.
8	Necrosis, atrophy, hypertrophy, or metaplasia with definitive organ dysfunction. Any neuropathy with gross changes in behavior, sensory or motor performance. Any decrease in reproductive capacity. Any evidence of fetotoxicity.
9	Pronounced pathologic changes with severe organ dysfunction. Any neuropathy with loss of behavioral or motor control or loss of sensory ability. Reproductive dysfunction. Any teratogenic effect with maternal toxicity.
10	Death or pronounced life shortening. Any teratogenic effect without signs of maternal toxicity.

Note. Source: deRosa et al. (48).

The RQ process demonstrates the use of severity information in both risk assessment (developing RQ indicators) and risk management (defining release levels requiring notification as associated with defined RQ values).

Recent efforts involving the use of categorical exposure response modeling demonstrate additional approaches towards consideration of severity. For example Guth and co-workers (as cited in ref. 15) analyzed acute effects resulting from methyl isocyanate exposures of less than 8 h in duration (as seen in Figure 2.5). Effects were separated into three categories: NOAEL (circles), adverse effect level (AEL) (triangles), and lethal (squares). Effect categories were then analyzed on the basis of concentration and time, using logistic regression. Figure 2.5 presents a line above which there is a 90% probability that the true NOAEL lies. This method allows the use of data from a range of severity endpoints and considers various combinations of exposure level and exposure duration. Conceivably, this type of approach could lead to the development of concentration time nomograms for definition of NOAELs for different exposure durations.

PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELS

One of the areas of recent regulatory attention is that of physiologically based pharmacokinetic (PBPK) models and their potential use in risk assessment. This issue is discussed in depth in the chapter 5 by Krishnan and Andersen and chapter 8 by Rodricks et al., we discuss the topic here in terms of regulatory implications.

PBPK models are essentially mechanistic models that describe quantitatively the pharmacokinetic processes affecting the disposition of a chemical and its metabolism from the time it is absorbed to the interaction with different and various body tissues. Once it is determined whether the parent compound or its metabolites are the likely cause of a carcinogenic response, a PBPK model may be developed to quantify the magnitude and the time course of exposure to this agent at the critical target site in the animal model. After the estimates of target tissue dose in the animal model have been made and validated, the information can then be scaled to the human to obtain an estimate of target-organ dose in humans. This estimate may then be used to predict human cancer risk under dif-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_55.html[2010/10/28 18:30:58]

Page 56

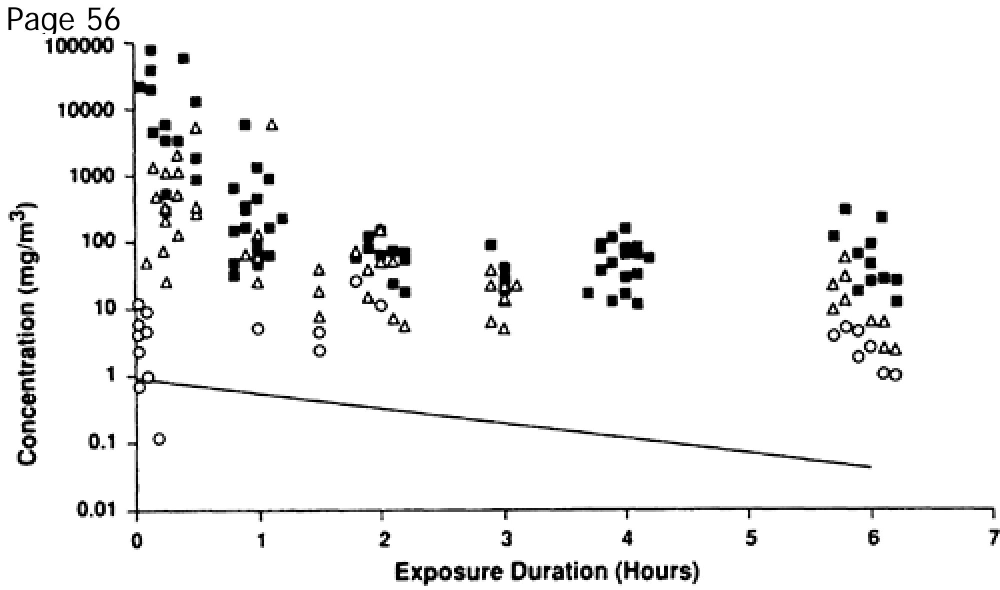

FIG. 2.5. Categorical data from published results on methyl isocyanate for exposures of less than 8 h in duration and shown as NOAEL (circles), AEL (triangles), or lethality (squares). The maximum likelihood model fit is shown by the line representing the model prediction of *p*=.1 that severity is greater than the NOAEL category at the corresponding exposure concentration and duration.

ferent exposure conditions or to develop more precise estimates of the reference dose. It should be emphasized that the PBPK model does not offer an explanation of the most appropriate dose-response relationship, once the dose to target is estimated (11, 24). Furthermore, full validation of the model at the relatively low levels of environmental chemicals to which humans are exposed can be difficult. Despite these limitations, PBPK modeling does offer an important tool for researchers and regulators alike. PBPK models can be used to quantify target organ doses between species and to extrapolate from high to low doses. Of added significance is that new information about the pharmacokinetics of a chemical can be incorporated into the model without affecting the basic structure of the model, thus enhancing its predictive capability.

The use of PBPK models also provides important advantages over conventional pharmacokinetic analyses (11, 24). In typical pharmacokinetic modeling, timecourse curves are determined for the concentration of the administered agent or its metabolite(s) in blood or some other body compartment. The resulting curves are then described by curve-fitting biostatistical techniques. The approach of conventional pharmacokinetics may be criticized for being more dependent on the mathematical model than on the biological system it purports to represent. However, PBPK models are designed to predict kinetic behavior over a wide range of doses and exposure conditions, and are based on basic physiologic and metabolic parameters. This modeling requires many data on anatomical and physiological parameters, the partitioning of test agents into selected tissues, and the biochemical constants for tissue binding and metabolism in various organs. From these data, a series of mass balance differential equations can be written to describe the interactions between the chemical and the animal model.

PBPK modeling can improve dose-response assessment by accounting for sources of change in the proportions of applied to delivered dose in animals versus humans, and at high versus low doses. Although this approach does not account for the fact that the sensitivity of the target tissue to the delivered dose may differ in humans and animals or between high and low doses, it still addresses some major areas of uncertainty in risk assessment. In fact, many sources of potential nonlinearity in applied dose-response involve saturation or induction of enzymatic processes at high doses, or differences in toxification/detoxification pathways between humans and animals or across doses.

PBPK modeling has been applied to several agents, including methylene chloride and ethylene dichloride (11, 24, 38). A look at the methylene chloride case illustrates the powerful implications of this approach. Anderson et al. (11) developed a PBPK model based on data indicating two routes of metabolism, one dependent on oxidation by mixed-function oxidase (MFO) and the other dependent on glutathione *S*-transferase (GST) in four species (mouse, rat, hamster, human).

Models were designed to quantify the contributions of the two metabolic pathways in the lung and liver and to allow for extrapolation from rodents to humans. Kinetic constants for the model were obtained from experiments or the literature, with model validation involving a comparison of predicted blood concentration time-course data in rats, mice, and humans, with experimental data from these species. The capacity of methylene chloride to cause tumors in mice was associated with the target tissue dose and was closely related to the amount of methylene chloride metabolized by the GST but not the MFO pathway. Using the PBPK model, the target tissue doses in humans exposed to low concentrations of methylene chloride were between approximately 50- and 200-fold lower than would have been predicted by the linear extrapolation and body surface area factors used in conventional risk assessment methods. Thus, the PBPK analysis suggested that conventional risk analysis greatly overestimated the risk to humans exposed to low levels of methylene chloride. One of the major uncertainties, however, is the metabolic capacity of the body at low exposure levels where metabolism may not be saturated. Also, the dominant pathway for methylene chloride metabolism at other organ sites has not been determined. Still, the PBPK approach represents an attractive development, since it can increase the biological plausibility of predictive approaches while still incorporating biomathematical approaches for low-dose risk prediction. The EPA has incorporated this pharmacokinetic information into its cancer risk assessment for methylene chloride exposure via inhalation (187).

It is important to note that there are substantial uncertainties in PBPK modeling. For example, Hattis et al. (78) compared PBPK models for perchloroethylene developed by seven different authors and found appreciable differences among the model predictions. Given identical exposure levels in humans, the range of values for metabolized perchloroethylene span a 50-fold range, with 6 of the 7 models having predictions with a 14-fold range. With respect to methylene chloride, Clewell (38) noted the importance of the tissue distribution of GST enzyme activity across species, especially in humans as a source of model uncertainty. Studies to refine estimates of GST enzyme activity across species and within the human population will serve to provide more refined estimates of dose across humans and hence of potential differences in susceptibility.

ROLE OF HIGH-RISK GROUPS

In a previous section, we described the RfD concept as used by regulatory agencies to estimate acceptable levels for noncancer effects. One of the factors in the derivation of this level was to account for variations in population susceptibility. The purpose of this section is to expand upon that issue, to describe the basis for variations in susceptibility and the magnitude of that variation, and to demonstrate the relationship of this issue to the regulatory process. (For more detail the reader is referred to refs. 14, 25, and 139).

There is a high degree of variability in the response of humans to different exposure levels of environmental pollutants (25, 44). In fact, the variability in the dose-response relationship in a heterogeneous population makes it difficult to estimate an acceptable level for chemical contaminants that would be protective of the whole population. Perhaps the most critical question is not what is a "safe" numerical standard, but how many individuals are adversely affected at different levels of exposure (33).

Knowing which groups of individuals are at high risk with respect to pollutants is very important in answering this question, since these individuals will be the first to experience morbidity and mortality as pollutant levels increase. If the high risk segments are protected, then the entire population is also protected. Information concerning both the identification and quantification of high-risk groups should play an integral role in the derivation of environmental health standards.

Use of Uncertainty Factors for High-Risk Groups

In trying to assess the role of high-risk groups in the derivation of environmental health standards, it is useful to consider the extent to which the EPA has utilized the concept of high risk groups within the standard setting process. Perhaps the most common approach utilized by the EPA and other regulatory agencies has been the implementation of uncertainty factors for noncancer endpoints. While this approach implicitly recognizes that certain people are more sensitive to pollutants than others, it is inherently imprecise. The precise difference in sensitivity between a statistically "normal" individual and groups at increased risk will vary for the different causes of the high-risk condition and for different pollutants.

The EPA has utilized the uncertainty factor approach in attempting to deal with protection of high risk individuals, as illustrated by the national drinking-water standards for noncarcinogenic chlorinated hydrocarbon insecticides (25). These substances were tested in two animal species, the rat and the dog. Chronic toxicity testing provided an estimate of the lowest level of pollutant (on a milligram of dose per

kilogram of body weight) that the animal could ingest with either minimal or no toxic effects. In the absence of data to indicate a basis for

an alternative choice, the species that was the most sensitive to the substances was chosen to derive the standard, implying that humans are as sensitive as the most sensitive animal species. In the absence of supporting human exposure data, an uncertainty factor of 500 was applied to the minimally toxic dose in the most sensitive animal species (i.e., the minimally toxic dose was divided by 500). It should be noted that this methodology differs from that of the RfD approach described earlier, in which case a factor of 100 would have been applied. This number was taken to be the total amount of insecticide to which a human could be exposed each day, over an unspecified period of time, without suffering any adverse health effects.

Several questions occur when evaluating such a methodological scheme. For example, on what basis can we assume that the most sensitive humans have the same degree of responsiveness as the most sensitive animals? Why was 500 chosen as a safety factor? What assurances exist that it would provide sufficient protection for the general population as well as high risk groups for these chemicals? Who, in fact, are the groups considered at increased risk?

The main problem with an uncertainty factor approach is its lack of specificity in identifying susceptible subpopulations, the extent of their susceptibility, and, most importantly, what fraction is protected by different standard levels. It should also be realized, however, that when only limited data are available, imprecise safety factors are the only realistic options available. Still, this approach will result in uncertain levels of protection. Alternative approaches must be developed to reduce the magnitude of that uncertainty.

Consideration of Specific High-Risk Groups

A better approach, when data are available to support it, is to consider specific groups at high risk on a chemical-by-chemical basis. There are clear examples of groups more susceptible to particular chemicals and cancer and non-cancer health effects (reviewed in refs. 20, 60, and 69). These include:

- Individuals with genetic variations in metabolism. For example, a slow acetylator phenotype is associated with an increased risk of bladder cancer following exposure to aromatic amine dyes (69).
- Individuals with enzymatic genetic polymorphisms. For example, polymorphisms in cytochrome P450 enzymes can result in differential detoxification or bioactivation of environmental chemicals (60).
- Individuals with inherited genetic defects. For example, xeroderma pigmentosum, an autosomal recessive disease, results in altered DNA repair capacity and increases the risk of skin cancer by more than 1500-fold (60).
- Individuals with preexisting illness. For example, asthmatics may be more susceptible to ozone (20), and those with hepatitis B are more susceptible to liver cancer (69).

Other factors that can affect susceptibility to environmental chemicals include gender, age, and life-style (i.e., cigarettes, alcohol, diet). The role of diet and certain types of cancer is shown in studies demonstrating an inverse relationship between the amount of vitamin A in the diet and susceptibility to hydrocarbon-induced epithelial cancers (41). Also, certain subgroups may be at greater risk, not because of an inherent difference in toxicological susceptibility, but because they are more likely to be exposed. For example, young children are at greater risk from soil contaminants because they tend to accidentally ingest more soil and dust than older children and adults, due to their significant hand-to-mouth activity. Thus, it is likely that, even given the same exposure, individuals are not equally susceptible to the induction of cancer and other adverse health effects, and in many cases the differential susceptibility may be very large.

Recently, there has been increasing attention on the potential for children to be more susceptible to environmental chemicals. In 1996, the EPA emphasized its focus of protecting infants and children in a report entitled "A National Agenda to Protect Children's Health from Environmental Threats" (194). The 1996 FQPA requires use of an additional 10-fold UF for pesticides to account for potential prenatal and postnatal developmental toxicity (191). As noted by Roberts (162), children may be more susceptible because many cells and organs are undergoing growth and development and have not yet matured. A child's diet and physical environment, and therefore his or her exposure potential, may vary significantly from that of an adult. For many routes of exposure (air, food, water, and dermal), chemical intake (on a per kilogram body weight basis) is generally greater for infants and children than adults (150).

However, a subgroup at high risk for one chemical is not necessarily at high risk for other chemical exposures. For example, although children are often assumed to be more sensitive than adults, this is not always the case. Reactions to pharmaceuticals, since they are more widely studied than responses to environmental exposures, can be considered as examples. Acute overdoses of acetaminophen result in less hepatotoxicity in children than in adults with comparable plasma concentrations, possibly due to differences in metabolism (118).

There is currently debate about whether current risk assessment methods adequately account for more highly susceptible groups. In general, setting of levels for

< previous page page_58 next page >

Page 59
carcinogen exposure has not addressed the role of population variability in susceptibility to carcinogens. Consequently, groups at high risk to environmental carcinogens, with the obvious exceptions of smoking as a risk factor for exposure to asbestos, uranium, and coke-oven emission-related cancer, have not generally been addressed. It should be noted, however, that the conservatism of the cancer risk assessment process might result in adequate protection of high-risk groups.

For noncancer effects, there is debate over the appropriate uncertainty factors to account for high-risk subgroups. At a conference organized by the ILSI and the EPA (71), "it was suggested that, in many cases, genetic variation in human susceptibility may be greater than an order of magnitude when comparing differences between children and adults." A coalition of farm food, manufacturing, and pest management organizations concluded that the additional UF of 10 required by the FQPA is not necessary to use "across the board" to protect infants and children (84). They also concluded that the standard default UFs are adequate for a pesticide with a complete and reliable database, and that an additional UF "should only be applied to an endpoint that is relevant to protection of fetuses, infants, and/or children" (84). The EPA is looking into establishing criteria for appropriate use of the 10-fold additional FQPA uncertainty factor (191,192). Overall, the best approach is to consider more susceptible subgroups on a caseby-case basis when data are available, for both carcinogens and noncarcinogens.

Regulatory Applications

The role of population variability should be considered by regulatory agencies in risk assessments for both carcinogens and noncarcinogens. Identification and quantitative characterization of susceptible populations could provide decision makers with a theoretical framework on which to base regulatory action. For example, Tamplin and Gofman (173) have employed knowledge of susceptible populations in predicting the incidence of cancer from radiation pollution in drinking water to help define acceptable levels of exposure. They assumed that the latency period is shorter for in utero exposure than for all radiation exposure beyond birth (i.e., 5 years vs. 15 years). Consideration of the increased susceptibility of the fetus to radiation-induced cancer resulted in greater estimates of cancer risk as compared with traditional methodological approaches, which predict carcinogenic effects at low doses, based on high levels of exposure in adults (160).

The EPA has specifically evaluated the increased sensitivity of specific high-risk groups in setting National Ambient Air Quality Standards for carbon monoxide, lead, nitrogen dioxide, ozone, particulates, and sulfur dioxide, and in establishing drinking-water standards for some environmental chemicals. Examples of the high-risk groups considered are shown in Table 2.14. For instance, the NAAQS for lead considers high-risk populations in a more quantitative way by estimating the fraction of the susceptible subpopulation (children) that would be protected at different air levels of lead (209). Following is a detailed description of the EPA consideration of high-risk groups in the derivation of drinking-water standards for nitrates and cadmium.

Nitrates in Drinking Water

The drinking water standard of 10 mg nitrat (NO_3^2) as milligrams nitrogen per liter is designed to prevent the formation of elevated levels of methemoglobin (MetHb) in infants. In the presence of nitrite (NO_2^-), formed from nitrate in infants, hemoglobin is oxidized to MetHb, which is not able to reversibly combine with oxygen. Levels of 1–2% and 2–5% MetHb are typical in the blood of adults and infants, respectively. When concentrations are less than 5% MetHb, there are no obvious indications of toxicity. However, with levels of MetHb from 5 to 10%, clinical signs of toxicity (e.g., cyanosis) may appear (25). Infants are at considerable risk for nitrate-related toxicity, as compared to adults. Factors that predispose infants to the development of MetHb formation include:

1. The incompletely developed ability to secrete gastric acid. This permits the gastric pH to be high enough (5–7 pH) to permit the growth of nitrate-reducing bacteria in the gastrointestinal tract, thereby converting nitrate to nitrite before absorption into the circulation (184).
2. The higher levels of fetal hemoglobin in infants. This form of hemoglobin is more susceptible than adult hemoglobin to oxidation to MetHb (19).
3. The diminished enzymatic capability of infants to reduce MetHb to hemoglobin (166).

Research has revealed that levels of nitrate beyond 20 mg/L resulted in a marked upshift in the frequency of methemoglobinemia in infants but not in adults (25). Consequently, a standard of 10 mg/L is principally designed to prevent the occurrence of elevated levels of MetHb in infants. Concentrations twice as great would still protect adults.

Cadmium

Studies with rats show that at a kidney concentration of 200 ppm cadmium (Cd) (211), renal damage is

initiated. The EPA calculated that humans would need to ingest 50 g Cd/day for 50 years to reach a level of 200 ppm in their kidneys. In the derivation of the Cd drinking-water standard, the EPA assumed a daily Cd

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_59.html[2010/10/28 18:31:00]

Page 60

Table 2.14 High-risk groups in the derivation of standards by the U.S. EPA

A. Drinking-Water Standards

Substance	High-risk condition considered
Arsenic	None
Barium	No specific groups; but a safety factor of 2 incorporated to account for variation (or increased susceptibility) within the human population
Cadmium	None
Fluoride	Children—to prevent mottling of teeth
Lead	Children—to prevent neurological disorders
Mercury	Based on humans who exhibited toxicity at the lowest level of exposure from a group of mercury-poisoned adults
Nitrate	Infants—to protect against methemoglobinemia
Selenium	None
Sodium (no standard)	Individuals with heart and kidney disease
Chlorinated hydrocarbon insecticides (noncarcinogenic)	None
Chlorophenoxy herbicides (noncarcinogenic)	None

B. National Ambient Air Quality Standards

Substance	Original group	Primary groups currently considered
Carbon monoxide	Individuals with neurological or visual impairment	Adults with heart disease (angina, coronary artery disease)
Lead	Children—to protect against neurological and hematological impairment	Same
Nitrogen dioxide	Children—to protect against respiratory infections, also concern for changes in lung structure	Same
Ozone	Asthmatics	Exercisers, individuals with pre existing disease
Particulates	Elderly, individuals with cardiopulmonary disease	Same
Sulfur dioxide	Elderly, individuals with cardiopulmonary disease	Asthmatics

exposure of 75 μg from the diet and 20 μg from water. This 20 μg Cd/day from drinking water would occur at a level of 0.01 mg/L. The total daily Cd exposure is therefore approximately 95 μg Cd/day, and thus a safety factor of 4 was assumed.

In proposing their drinking water standard for cadmium, the EPA requested feedback from the public as to whether the standard should include additional protection for cigarette smokers, since smoking is a source of appreciable cadmium exposure (e.g., approximately 1.5 μg Cd/cigarette) (25). It is interesting to note that of the 52 comments received by the EPA on this issue, only 3 suggested that this standard be modified to include protection for the cigarette smokers. The EPA decided not to incorporate additional safety factors to protect smokers (208). Thus, this example describes a situation

in which protection of a high-risk group was not taken into account in derivation of a standard.

HORMESIS

As described in the sections on evaluation of carcinogens and of systemic toxicants, the risk assessment process, as articulated by most regulatory agencies, has generally (but not always) assumed that the shape of the dose-response curve is either, for noncarcinogens, a threshold response below which no toxicity is observed or, for carcinogens, a linear relationship for which there is no exposure without an estimated effect.

Such risk assessment assumptions concerning the nature of the dose-response relationship for different biological endpoints have been challenged in recent years by the recognition that there are many exceptions to the threshold and linearity assumptions. A key exception to the two basic assumptions is that of the U- or inverted U-shaped dose-response relationship (Figure 2.6). Whether a dose-response relationship takes the U or inverted U form is dependent on the endpoint measured. In the case of U-shaped dose-response relationships, the endpoints could be various biological effects or diseases, such as mutation rate, birth defects, and cancer incidence (see ref. 30 for review). In the case of inverted U-shaped dose-response relationships, the types of endpoints include growth rate, fecundity (see ref. 27 for review), and longevity, among others. The phenomenon of stimulatory effects of low-level exposures has been termed *hormesis* and has been applied to both chemicals and radiation. Typical extrapolation processes for both threshold and nonthreshold phenomena ignore such possible U- or inverted U-shaped responses in the low-dose zone. A key implication of U- and the inverted U-shaped dose-response relationships is that, when such phenomena occur, the low-dose response (e.g., disease, incidence, longevity) cannot be readily predicted by responses at higher doses. The rest of this section presents background information on chemical hormesis and discusses some practical implications for both study design and risk-based standards development.

Although the concept of hormesis was seemingly well established by the 1920s at least as far as chemical hormesis is considered, the concept became marginalized within the scientific community in the 1930s and never had any serious impact on the modern concept of the dose-response relationship (26). The principal factors for the demise of the concept are complex, but include the following. One difficulty in differentiating the low-dose stimulatory phenomenon from normal variation was the lack of a study design with an adequate number of appropriately placed doses in the low dose range; this difficulty was further magnified by the fact that

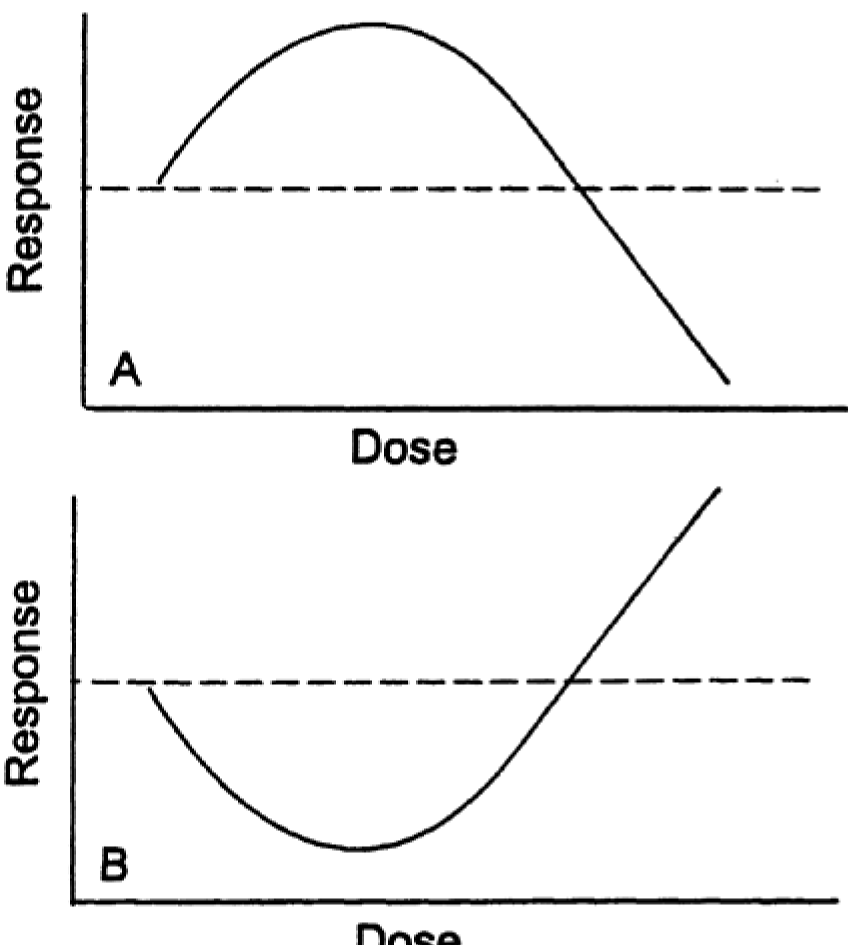

FIG. 2.6. Dose-response curves for hormesis. (A) The most common form of the hormetic dose-response curve depicting low-dose stimulatory and high-dose inhibitory responses, the *β* or inverted U-shaped curve. Examples of endpoints demonstrating the *β*- or inverted U-shaped dose-response curve include growth, longevity, fecundity, and weight gain. (B) The hormetic dose-response curve depicting low-dose reduction and high-dose enhancement of adverse effects, the J- or U-shaped curve. Examples of endpoints demonstrating the J- or U-shaped dose-response curves include mutations, cancer incidence, and birth-defects incidence. Source: Calabrese and Baldwin (28).

the magnitude of the low-dose stimulatory response has a maximum average of about 30–60% above the control (Figure 2.7). Lack of appreciation for what the hormetic dose-response was coupled with inadequate study design features led to criticism that the phenomenon was simply normal variation. Over the past several years, Calabrese and Baldwin (30, 31) have reinvestigated the hormesis hypothesis and developed rigorous a priori criteria for its evaluation. This investigation has uncovered several thousand examples of well-designed studies published in the peer-reviewed literature that are consistent with the hormesis phenomenon. The hormesis phenomenon has been proposed to result from a modest overcompensation to a disruption in homeostasis. More specifically, the investigation of minor damage induces a generalized repair response. In order to assure that the damage is adequately

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_61.html[2010/10/28 18:31:01]

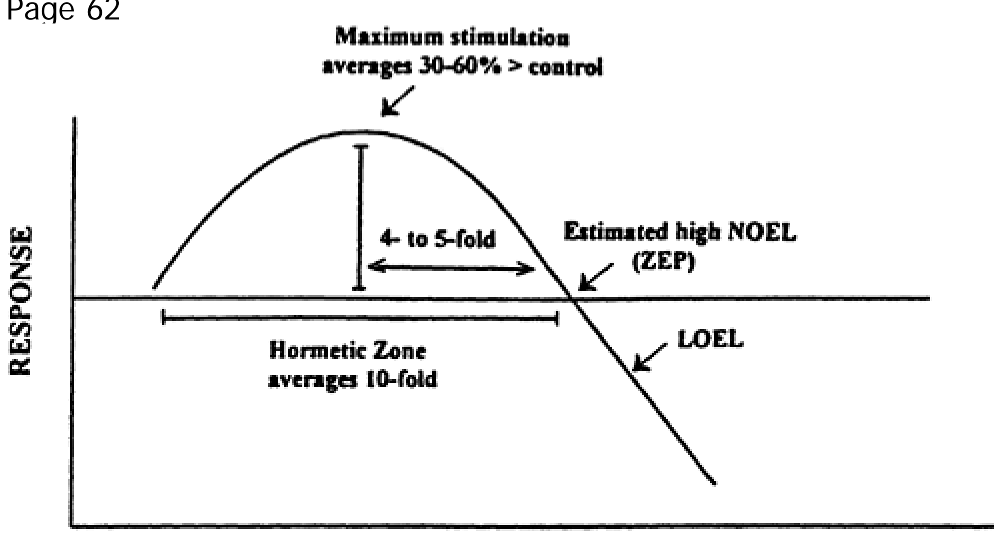

FIG. 2.7. Characteristics of the chemical hormetic zone. Abbreviations: NOEL, no-observed-effect level; LOEL, lowest-observed-effect level; ZEP, zero equivalent point. Source: Calabrese and Baldwin (31).

repaired, there is a slight overcompensation in repair responses. As the dose increases, the capacity to repair the damage decreases and eventually the capacity to repair equals the level of damage when the zero equivalent point (ZEP) is reached [i.e., the no observed adverse effect level (NOAEL)]. At higher doses, frank toxicity occurs. This process provides a framework to understand the basis for the observation that the stimulatory range is modest by up to about 10-fold, that the maximum stimulation averages about 50% above the control, and that the NOAEL/ZEP is only three- to five-fold greater than the maximum stimulatory response. Hormetic responses appear to be generalizable with respect to biological model, chemical class, and toxicological endpoint measured, including critical risk assessment endpoints such as tumor incidence, longevity, and various disease incidences.

Even in the situation where U-shaped dose-response relationships may exist. study design and other factors may reduce the capacity to detect such a relationship (Table 2.15). For example, it is not possible to assess hormesis with the use of certain toxicological parameters such as liver damage as reflected by increased serum enzymes.

To the extent that hormesis exists for a specific chemical, there are several implications for both noncarcinogenic and carcinogenic risk assessment. (a) The dose-response curve would be similar for both the carcinogenic and noncarcinogenic responses. (b) Thresholds would exist for both carcinogens and noncarcinogens. (c) At certain doses below the NOAEL (or ZEP) there would be less damage in the exposed group than observed in the control group. (d) Based on a review of hormetic dose-response relationships, the initial disruption in homeostasis typically occurs approximately 5- to 10-fold below the traditional NOAEL. However, this initial disruption is not only adequately repaired by the induction of adaptive mechanisms, but then background biological damage is also reduced by the induced adaptive mechanisms. (e) Current experimental approaches to assess the dose-response relationship in the hazard assessment process are inadequate since many studies only emphasize the relatively high-dose aspect of the dose-response curve. Thus, the hormetic perspective suggests that new study

Table 2.15 Factors contributing to the inability to detect a hormetic response when one exists

Inappropriate dose range.
Inappropriate spacing of doses.
Inappropriate number of doses.
Inappropriate temporal measurements in relationship to endpoint.
Inappropriate endpoint selection (e.g., serum enzyme levels as bioindicators of liver damage).
Condition of model organism.
Interindividual variability.
Low background in relationship to showing a U- or inverted U-shaped dose-response curve.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_62.html[2010/10/28 18:31:02]

design criteria become incorporated into the hazard assessment protocol and that new default parameters become incorporated into the risk assessment framework incorporating the hormetic assumption.

Practical Implications of Hormesis for Quantitative Risk Assessment

Hormesis and Carcinogens

In a recent issue of the BELLE Newsletter, Sielken and Stevenson (168) identified seven ways in which the concept of hormesis should affect quantitative risk assessment (Table 2.16). The seven factors provided by Sielken and Stevenson (168) offer an important and clear blueprint for how the current approaches for both chemical and radiation cancer risk assessment modeling could both include and take advantage of the concept of hormesis and its underlying database. Many of these recommended changes reflect a less biased approach as well. For example, the parameters in the multistage model are typically required for regulatory purposes to be nonnegative values. This restriction determines that the probabilities in the multistage model be increasing as

Table 2.16 Implications of hormesis for quantitative risk assessment

Dose-response models need greater flexibility to fit the observed shape of the dose-response data; such models should not be constructed to be forced to always be linearly decreasing at low doses.

Hazard assessment evaluations need to incorporate greater opportunity to identify the hormetic portion of the dose-response relationship.

New dose metrics should be used that incorporate age or time dependence on the dose level rather than a lifetime average daily dose or its analog for a shorter time period.

Low-dose risk characterization should include the likelihood of beneficial effects and the likelihood that a dose level has reasonable certainty of no appreciable adverse health effects.

Exposure assessments should fully characterize the distribution of actual doses from exposure rather than the just upper bounds.

Uncertainty characterizations should include both upper and lower bounds.

Risk should be characterized in terms of the net effect of a dose on health instead of a single dose's effect on a single disease endpoint (i.e., total mortality rather than a specific type of fatal disease).

Note. Adapted from Sielken and Stevenson (168).

the dose increases. Sielken and Stevenson (168) argue that such nonnegativity restrictions for the parameters in the multistage model should be removed so that the fitted model may reflect the shape of the reported dose-response data. Furthermore, such a change would allow the multistage model enhanced flexibility to explicitly address hormetic effects seen in actual reported data. In addition, when an hormetic effect is present the risk at low dose would be less than for the control group. The lower bound on the "added" risk in the case of hormesis is no longer the zero risk as is now assumed, but would be negative. Clearly, therefore, both upper and lower bounds of uncertainty should be incorporated.

Hormesis and Noncarcinogens

The role of hormesis in affecting the risk assessment process for noncarcinogens has also been discussed (28, 29, 62, 197). As discussed in earlier sections, independent of whether hormesis exists or not, the major goal of the hazard assessment process is the derivation of the NOAEL (or in some cases the BMD).

Calabrese and Baldwin (29) have noted that the estimation of the BMD or the NOAEL can be affected by the existence of U-shaped dose-responses in two ways: (a) doses residing in the hormetic zone by affecting the modeling involved in the BMD derivation process, or (b) a dose within the hormetic zone could be selected as the NOAEL. With respect to the former possibility (i.e., BMD derivation), the occurrence of hormetic responses would tend to flatten the model-based dose-response relationship, thereby requiring a higher response to achieve the BMD05/10 response. In the latter case (i.e., where the highest dose is not different from the control), a dose with a value lower than the zero equivalent point (ZEP) would be designated the NOAEL. This may be illustrated in Figure 2.8, which shows a typi-

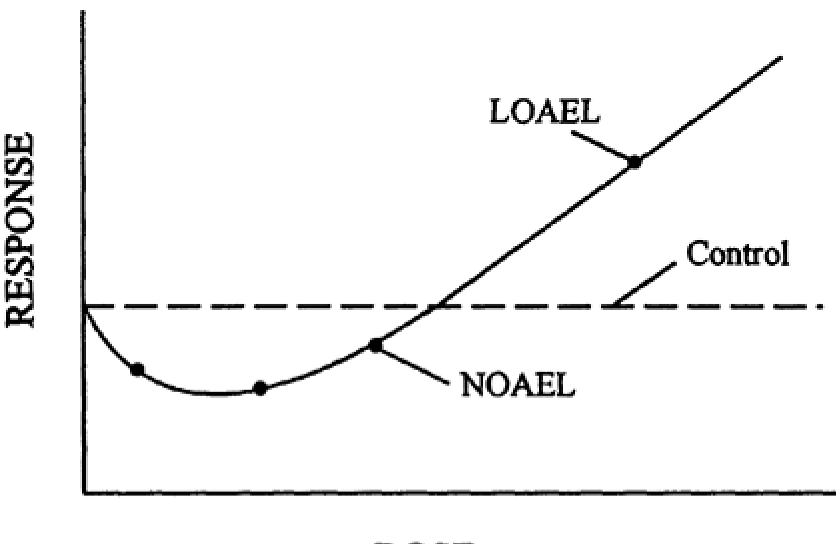

FIG. 2.8. Dose-response relationship presenting NOAEL in the hormetic zone. Source: Calabrese and Baldwin (29).

cal U-shaped dose-response relationship. The highest dose causes a significant toxic effect and is designated the LOAEL. The dose immediately below the highest dose exhibits a response lower than the reference or control group. This hormetic dose would become the NOAEL since it is the highest dose not significantly different with regard to an adverse effect and satisfies the above definitional criteria. Therefore, in these two cases, the concept of the NOAEL is (a) affected by the presence of hormetic doses in the application of the BMD process and (b) being explicitly incorporated into the hormetic portion of the dose-response curve (i.e., traditional NOAEL derivation process).

While the U-shaped dose-response is often seen and appears to be highly generalizable, it is not seen in numerous instances (Table 2.15). For example, it is not possible to assess hormesis if tumor incidence of the background (or control) is very low. This lack of ability to make judgments about hormesis is further seen with respect to other toxicological parameters such as liver damage, which is inferred by increased serum enzymes. Even though the current methods cannot assess hormesis under these conditions, this does not suggest that it does not exist. In fact, hormesis may be predicted to exist independent of the biological incidence of the disease under study.

If hormetic effects were to have an opportunity to affect the RfD derivation process, the hazard assessment process would have to expand the toxicological testing process into the low dose zone by increasing the number of doses from 2–3 to 6–7 doses with an assurance that at least three doses were below the traditional toxicological NOAEL (31). This would help insure that the hormetic phenomenon would have been properly evaluated. Such an expansion of the hazard assessment process would add considerable cost and time to the testing process. An alternative to the expanded testing strategy would be to incorporate hormesis as a default assumption in the RfD derivation process. If hormesis were a default parameter, the current hazard assessment process could remain as is. The RfD process would have to proceed by first adjusting the NOAEL value to equal the ZEP dose by a model-based procedure, thereby deriving an adjusted ZEP-based NOAEL, and then employing a hormesis optimization scheme to facilitate the RfD derivation (23, 62).

Calabrese and Baldwin (29) have offered the following considerations in order to establish a decision-making framework for assessing whether hormesis could achieve default parameter status and be incorporated into RfD development. The concept of default parameter status implies a highly generalizable phenomenon with regard to chemical class, biological model, and endpoint, which is linked to the risk assessment process. Consequently, the concept of hormesis would first need to permeate the broad classes of inorganic and organic contaminants. especially those containing agents that are of regulatory concern. Second, the phenomenon of hormesis must be generalizable across species to ensure that hormesis for a particular chemical does not reflect a species- or strain-specific response. The third factor for assessing hormesis as a default parameter in the RfD derivation process concerns biological endpoint. Regulatory actions focus predominantly on adverse endpoints such as organ-specific toxicity, biomarkers of toxic response (e.g., blood lead levels, serum cholinesterase activity), and teratogenic and other reproductive effects, as well as tumor formation. The influence of hormesis is not only in the reduction of already indicated adverse effects and biomarker responses, but also in the enhancement of outcomes such as increased longevity, improved performance, and reduction of disease incidence below background. The ability to incorporate what society considers both beneficial and harmful effects of a chemical into decision making presents a challenge to regulators. Consider, for example, the difficulties in making recommendations on alcohol consumption where moderate levels can reduce risk of heart disease, but excessive drinking clearly takes a toll in terms of morbidity and premature mortality.

The recently developed chemical hormesis database (30) evaluates toxicological investigations for their capacity to demonstrate evidence consistent with the hormesis hypothesis based on study design attributes, response criteria, statistical power, and reproducibility. This database provides evidence that hormesis is likely to be generalizable across the three critical areas listed here and that its relationship to the NOAEL is readily estimated, thus allowing practical incorporation into the risk assessment process. Based on this information, we recommend that regulatory agencies consider the concept of hormesis as a default parameter in the risk assessment process. What would be the practical implication if hormesis were accepted as a default assumption for the RfD derivation process? First, consideration of hormesis would redefine the concept of NOAEL for regulatory purposes. In addition, consideration of hormesis would allow an optimizing process to estimate the dose providing the best balance between preventing the agent-induced adverse effects and enhancing hormetic/ adaptive responses within the population.

IMPLICATIONS OF CHEMICAL INTERACTIONS FOR THE REGULATORY PROCESS

One of the major difficulties in current environmental public health practice is that the focus is on a

limited number of environmental contaminants, with limited consideration of interactive effects among pollutants. In fact, the number of environmental pollutants in differ-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_64.html[2010/10/28 18:31:03]

ent media is large, making it difficult to estimate the degree of public health protection afforded by our present regulatory apparatus. Still, it is clear that the scientific and regulatory communities must address the issue of multiple chemical exposures. In fact, animal models and human epidemiological studies show that interactions do occur among chemicals and that this can result, under certain circumstances, in greater than additive effects. For example, uranium miners who smoke have a fourfold greater risk of cancer than nonsmokers. However, uranium miners who smoke display a 40-fold greater cancer risk than the general population of nonsmokers (137).

Interactions have been studied for many years by the drug industry, insecticide manufacturers, and forensic/ clinical toxicologists. Given the widespread use of multiple drug therapy, the need to anticipate possible interactions has been essential. Thus, much of the basis of our current understanding of toxicological interactions is derived from the pharmaceutical industry. It should be recognized that there is uncertainty in extrapolating from drug exposures where doses are relatively high, that is, by definition at pharmacologically active doses, to environmental exposures, which are typically much lower.

Chemical interactions have been broadly classified by three general terms: *addition* (additivity), when the toxic effect produced by two or more chemicals in combination is equivalent to that expected by simple summation of their individual effects; *antagonism,* when the effect of a combination is less than the sum of the individual effects; and *synergism,* when the effect of the combination is greater than would be predicted by summation of the individual effects. Other terms have been used, such as *indifference and potentiation,* which represent specialized aspects of antagonism and synergism, respectively.

In testing for possible interactions, at least two important considerations must be addressed. These include temporal (time) factors and response-endpoint considerations.

Time Factor

While most screening tests for interactions employ simultaneous exposure, this type of exposure approach has the chance of reducing the likelihood of detecting some potential interactions. For example, two agents may affect the same cellular mechanism but may have markedly different times of onset to expression. If a critical threshold of reversible cellular injury is required for the adverse effect, tests of acute toxicity of combinations given simultaneously may show antagonism, whereas an additive action would be observed if the dosing and observation periods were spaced to cause the maximum effect.

Toxic Effect

Since most toxic substances have multiple toxic effects, the nature of any chemical interaction may vary, depending on the measured responses. For example, since chlorinated insecticides and halogenated solvents produce liver injury independently, it is plausible that they could under certain circumstances act in an additive or synergistic manner when combined. However, the insecticide is likely to be a central nervous system stimulant, whereas the solvent may be a central nervous system depressant. Thus, as measured by neurological tests, these chemicals could interact in an antagonistic way.

Predictive Models

Development of predictive models of chemical interaction must rely on an understanding of the basic toxicological principles concerning kinetics of reactions of chemicals with primary sites of action (tissue receptor sites) and with secondary tissue sites of reaction. Four factors have been identified as of central importance:

1. Relative affinities of the individual chemicals for sites of action (e.g., target enzymes, cellular membranes, etc.).
2. Relative affinities for sites of loss of the chemical (e.g., detoxifying enzymes, nonvital tissue binding sites, pathways of excretion, and storage sites).
3. Intrinsic activity of the agents at their sites of action.
4. Sites of bioactivation.

While many of the examples are derived from the pharmacology literature, similar interactions could occur among environmental chemicals.

Pharmacokinetic Drug/Pollutant Interactions

The four factors listed allow us to predict how toxicological interactions may occur. The biological damage caused by a toxic agent is proportional to the amount of the biologically active form of the agents able to react with critical cellular macromolecules. An interaction may occur when the availability of an active chemical is altered by the presence of another agent, or when its reactivity with critical macromolecules is altered by the presence of another agent. The first case involves a site of loss of active chemical, whereas the second involves an interaction at a site of action. Thus, considerable

research activity has investigated the capacity of a chemi-

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_65.html[2010/10/28 18:31:04]

cal to affect the absorption, distribution, metabolism, and excretion of another chemical.

Absorption

Absorption of an agent may be affected by a second drug that alters pH or gut motility. For example, aspirin is absorbed more rapidly at low pH because more of the drug is present in the readily diffusible nonionized lipid soluble form. Agents that cause an increase in the pH will slow down the gastric absorption of aspirin when taken simultaneously. Similarly, the absorption of tetracycline is reduced by aluminum hydroxide gels and readily ionized salts of calcium and magnesium. In contrast, the gastrointestinal absorption of acetaminophen is enhanced in the presence of sorbitol.

Protein Binding

Drugs may compete for the same protein binding sites in plasma. When this occurs, the effective biological concentrations of the displaced drug can rise markedly. For example, usually 98% of the anticoagulant drug warfarin is bound to the plasma protein albumin, so that only 2% of the total drug in the plasma is biologically active. If the effect of another drug competing for the same plasma albumin site is to reduce the binding of warfarin from 98 to 96%, the concentration of pharmacologically active warfarin would be doubled. This interaction would have approximately the same effect on clotting time as would doubling the dose of the anticoagulant. This type of interaction with an anticoagulant drug has resulted in a number of clinical incidents, with some resulting in fatal hemorrhagic complications.

Metabolism

Many chemicals, including drugs and environmental contaminants, enhance the metabolic capacity of the liver. Other chemicals may diminish the metabolic capacity of the liver. These interactions could have profound implications. In fact, it is now recognized that several of the insecticide synergists (i.e., agents that, when administered along with insecticides, markedly enhance the insecticide's ability to kill insects) act by blocking the enzymes normally affecting insecticide detoxification (221). For example, the toxicity of the insecticide carbaryl against susceptible female houseflies is enhanced by over 200-fold by certain chemical synergists. Thus, knowledge of synergy has been used to develop more effective insecticide formulations.

Insecticides provide another example of how agencies use information on chemical interactions. In 1957, Frawley et al. (61) reported the first synergistic interaction of two organophosphate insecticides (i.e., malathion and ethyl *p*-nitrophenyl phenyl phosphonothionate or EPN), which led to the development of the FDA requirement that all newly registered organophosphate insecticides be evaluated for possible synergisms with all the already-registered organophosphate insecticides. As more organophosphate insecticides were developed, this regulatory requirement became an extreme testing burden. However, with elucidation of the biochemical mechanism1 for this interaction, it became possible to assess possible interactions of organophosphate insecticides via biochemical means and thereby circumvent the time-consuming and costly toxicological testing of whole animals. In both examples, that of making a more efficient insecticidal preparation and that of predicting adverse public health effects from multiple agent exposures, chemical interaction predictions were markedly enhanced with a clear understanding of the mechanisms of toxicity.

Implications

The examples just given represent ideal situations, since the mechanisms of toxicity of the insecticides were very well characterized. More frequently, little information is available on toxic mechanisms. Regulatory agencies need to develop approaches in such situations when reasonable mechanistic predictions cannot be made. To this end, Finney (59) developed a theoretical mathematical approach for predicting the degree of toxicity derived from various types of chemical interactions. Pozzani et al. (154) indicated that only 2 of the 36 pairs of mixtures of industrial vapors tested for acute toxicity in rats deviated significantly from the calculations of Finney's theoretical approach for additive joint toxicity. According to Smyth et al. (170), the study by Pozzani et al. (154) supported the hypothesis that the acute toxicity of chemical mixtures randomly chosen has a high likelihood of being accurately predicted by Finney's theoretical formula for additive joint toxicity. In an attempt "to evaluate the overall confidence that can be placed on the prediction of the joint toxicity of many chemical pairs," Smyth et al. (170) studied the toxicity of 27 industrial chemicals in all possible pairs to rats. Their results were consistent with the prediction of Finney (59) that most interactions should be considered as additive until proven otherwise. Smyth et al. (170), in agreement with the general findings of Pozzani et al. (154), concluded that approximately 5% of the various combinations tested exhibited more or less than additive effects.

Most studies have evaluated synergism at only very high or acute levels of exposure. It is important, however, to ask whether synergisms would occur at lower (more realistic) concentrations. Recent

investigations using complex mixtures, tested at relatively low levels of

1 EPN inhibits the nonspecific enzyme carboxyesterase that detoxifies malathion. Thus, in the presence of EPN, malathion is more persistent and causes a greater effect as a cholinesterase inhibitor than would have occurred had enzymatic detoxification mechanisms not been affected.

exposure, indicate that the potential for interactions is likely dose dependent.
Their studies indicated that synergistic interactions, the type of interactions of greatest regulatory concern, may be less likely to occur at environmentally relevant exposure levels than at higher (e.g., pharmaceutical or some occupational) exposure levels.

Approaches Used by Regulatory Agencies to Assess Interactions

Despite the frequent lack of a clear mechanistic understanding of how chemicals may interact, regulatory agencies have developed interim approaches to facilitate the decision-making process. In this section, we highlight some of the typical approaches used by agencies with illustrative examples.

The Hazard Index Approach

Perhaps the simplest approach is the assumption of additivity of hazard. In this approach (applied to noncarcinogens), hazard indices (the ratio between the estimated dose and the reference dose; see section on evaluation of systemic toxicants) are summed across chemicals and across routes of exposure to obtain a total hazard index for a particular exposure setting (207). If the decision criterion of a total hazard index of 1 is exceeded, further review is performed to determine which chemicals act at the same target organ. A subsequent summation is performed for those chemicals only. While this approach is useful as a screening approach, it has several limitations that must be considered when interpreting the results. These include (but are not limited to) the following:

- Reference doses (the denominator in the hazard index) for different chemicals contain different types and magnitudes of uncertainty factors. Thus, differences in the magnitude of a hazard index for a particular chemical or a pathway of exposure may reflect intrinsic differences in hazard as well as differences in the uncertainty of a particular toxicity value.
- Different types of interactive effects are possible, even for chemicals that act at the same target organ. For example, organophosphates that act via the inhibition of acetylcholinesterase at nerve endings would generally be presumed to act in an additive manner (128). In contrast, trichloroethylene (TCE) and alcohol, both of which affect the central nervous system, can when consumed simultaneously, act synergistically (e.g., producing “degreaser’s flush”); however, chronic alcohol consumption can, by induction of metabolizing enzymes, diminish the response to TCE (2).

The Toxicity Equivalency Factor Approach

The toxicity equivalency factor (TEF) approach has been applied to a mixture that contains toxicologically and structurally similar chemicals. Perhaps one of the best known examples of the TEF approach is the approach developed by the U.S. EPA (17) for polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs). This approach is based on the assumption that PCDDs and PCDFs exert their toxicity through binding to the Ah receptor with subsequent effects on transcription and translational events responsible for toxicity. The most potent PCDD, 2,3,7,8-tetrachlorodibenzodioxin, has the greatest affinity for the Ah receptor and, hence, is the most potent member of this class. TEFs are developed for individual PCDDs and PCDFs, expressed as a fraction (typically in orders of magnitude) of that of TCDD, which is given a TEF of 1.0. Thus, RfDs and cancer slope factors (CSFs) are calculated as a ratio to the RfD and CSF for 2,3,7,8-TCDD. While there is experimental support, based on mixtures of PCDDs and PCDFs, for this approach, there are few, if any, data from long-term studies (17). Other uncertainties in this approach include the assumption of additivity, where competitive interactions may occur at sufficiently high doses, and the choice of a particular TEF value, which can be influenced by selection of endpoint, exposure duration, and dose (151).

The Complex Mixture Approach

There are certain classes of chemicals for which toxicological data exist primary for the complex mixture itself, with limited data for individual constituents. An example of this type of mixture is polychlorinated biphenyls or PCBs. PCBs were manufactured in the United States under the trade name of Aroclors for use in electrical capacitors. Different Aroclor mixtures contained different percentages of chlorine. For example, Aroclor 1242 contained approximately 42% chlorine (159). Much of the toxicity testing of PCBs consists of studies of different Aroclor mixtures (39, 159). As a result, toxicity criteria for PCBs are typically expressed as Aroclor-specific values. In the case of Aroclor 1254, for example, the Agency for Toxic Substances and Disease Registry (ATSDR) developed a chronic minimum risk level or MRL, a value conceptually to the RfD, based on immunological effects in monkeys exposed to Aroclor 1254 in feed for 23 months (151). While this approach does not require assumptions on how individual constituents will interact, it does assume that the characteristics of the mixture in the environment are the same as in the laboratory studies. Unfortunately, this assumption is not always correct, since complex mixtures

frequently undergo chemical transformations in the environment. Moreover, the individual constituents may partition differently in the environment. In the case of PCBs, for example, the more chlorinated forms bioaccummulate in fish more readily than the less chlorinated forms (39).

Consideration of interactive effects in the regulatory arena is an evolving process. Because data are limited in many cases, simplifying assumptions are often used, such as the assumption of hazard index additivity for chemicals that act via the same target organ. As scientists acquire greater mechanistic understanding of interactive effects in complex mixtures, approaches that better reflect molecular events can be developed, such as the use of TEF approach. Nonetheless, it must be recognized that there is still uncertainty regarding the extent to which such effects occur at environmentally relevant exposure levels and under exposure conditions that do not mimic those tested in the laboratory (e.g., intermittent vs. chronic exposures).

CONCLUSIONS

In this chapter, we have demonstrated the multiple applications of toxicology to the regulatory process. Applications include developing and evaluating chemical testing protocols, such as for developmental toxicants; developing classification schemes (so far mainly for carcinogens) aimed at characterizing the types of toxic effects that might be observed in humans; and developing health-based criteria for chemicals in various media (food, water, air, soil) or notification levels for release of chemicals under accidental circumstances.

In addition, toxicology is used in the regulatory process to help assess potential risk associated with defined exposure levels. The traditional paradigm for assessing such risks is as follows: For carcinogens, potential risk is defined as an upper bound estimate of excess cancer risk based on cancer incidence at high dose levels, and for noncarcinogens, potential risk is defined as the ratio of the estimated exposure to an exposure level associated with negligible, if any, risk. Recent advances in the understanding of toxicological mechanisms indicate that these methodologies are not appropriate in all circumstances. Some carcinogens, such as those that operate by receptor-mediated or cytotoxic mechanisms, may exhibit a threshold or nonlinear dose-response relationship, and thus exposure levels associated with virtually zero risk might be defined. Examples of chemicals with these types of dose-response relationships are saccharin and phenobarbital. The U.S. EPA recent cancer risk assessment guidelines, which consider different dose-response relationships for different carcinogens, represent an important development in this area. Our understanding of certain noncarcinogenic effects, such as angina associated with CO exposure, is reasonably advanced; in this example, risks from CO are more fully described in terms of number of individuals with heart disease who might be expected to exceed defined COHb levels under certain exposure conditions. Benchmark dose and categorical exposure-response modeling represent additional examples of recent advances in noncarcinogenic risk assessment.

Toxicology is frequently applied in the regulatory context of developing permissible exposure levels in different exposure media, such as ambient air, drinking water, or food. As discussed in this chapter, definition of the health-based permissible exposure level is only one part of developing a regulatory standard. Other important factors in the regulatory process include risk management issues such as the definition of acceptable risk, the weighing of the costs and technical feasibility of reducing risk, the availability of alternatives, and the new risks possibly created by reducing the original risk (e.g., use of a less well tested substitute chemical). Issues of equity and whether certain members of the population are unfairly burdened by chemical exposure represent other considerations.

A critical role for toxicologists participating in the regulatory process is to effectively communicate not only the results of a risk assessment, but also the uncertainties associated with risk evaluations, in order to provide risk managers with the full information needed for making sound decisions. In addition, despite pressure to employ older methods for the sake of consistency, toxicologists must work to develop and encourage the use of new methodologies reflecting the advances in our understanding of toxicological mechanisms. We hope this chapter is useful as a guide to the use of better science in the regulatory process.

QUESTIONS

1. How do different approaches used for noncancer risk assessment (e.g., benchmark dose, reference dose, and the distributional population approach) address susceptible populations?
2. Under what circumstances would one use the following approach for assessing risks of complex mixtures: the hazard index approach, the toxicity equivalency factor approach, and the complex mixture?
3. What are some of the advantages and disadvantages of using cancer bioassay results at the

maximum tolerated dose (MTD) for interpreting likelihood of carcinogenicity to humans?

As stated in the title of this chapter, the metabolism of *xenobiotics*, compounds foreign to the normal biochemistry of cells, is a major determinant of their toxicity. Most often, toxicologists are interested in the metabolism of potentially toxic compounds to which species may be exposed; however, many of these same enzymes are

involved in the detoxication and metabolism of *endobiotics*, which are compounds produced during the normal biochemical reactions that maintain life. For example, some of these enzymes are involved in the detoxication of reactive oxygen species produced during aerobic metabolism that can produce oxidative stress and tissue damage. A toxicologist must have a fundamental knowledge of these detoxication systems to understand, predict, and determine the potential toxicity of a compound. It is our purpose to provide an overview of these various systems that can serve as a foundation for a more comprehensive study of their role in toxicology.

EVOLUTION OF XENOBIOTIC METABOLISM

As the first macromolecules began to organize into complex arrays with the basic attributes of life, environmental factors were present that represented disruptive forces. These forces were physical and chemical. Chemicals present in the early milieu of life could interact with these life forms, disrupting the delicate balance through which they maintained their integrity. Those life forms that developed protective mechanisms, such as the cell membrane, the ability to store energy, and motility, were able to survive. It does not stretch the imagination to hypothesize that these early life forms manufactured molecules capable of reacting with environmental chemicals, including increasing concentrations of oxygen, thereby decreasing their biological activity. An example of such a molecule is glutathione. This nucleophile can react nonenzymatically with many electrophilic chemicals to reduce their toxicity. An early step in the evolution of protective mechanisms may have been the development of macromolecular catalysis to chemically alter disruptive chemicals. These macromolecular catalyses were the first detoxification enzymes. Evidence for such a scenario exists in the occurrence of certain detoxication enzymes in both animal and plant species ranging from simple, single cellular to complex, multicellular organisms.

The cytochrome P450 (P450) monooxygenase system (discussed in detail later) is a large superfamily of hemoproteins whose evolutionary roots have recently been investigated (36, 59). This superfamily serves as an example of the evolution of enzymes capable of protecting the organism from toxic chemicals. In fact, its current nomenclature is based on evolutionary and genetic relationships between its isozymes. The P450 superfamily of hemoproteins consists of about 20 gene families, and the functional P450 genes in a mammalian species are estimated to be over 200. The amino acid sequences of more than 100 P450 hemoproteins are known. Phylogenetic trees based on these sequences have been developed to aid in understanding the evolution of these important enzymes (see (58, 95) for reviews).

The original ancestral P450 gene may date back 3 billion years or more. The wide distribution of these genes in prokaryotic and eukaryotic organisms emphasizes their importance in maintaining life. About 400 million years ago there appears to have been a major increase in the number of new genes in one of the P450 families (the CYP2 family). It is believed that this evolutionary burst of new genes was associated with animal colonization of land during the Devonian era. In an attempt to protect themselves, plants began to develop toxins to deter their consumption by land animals. This resulted in coevolution of animal cytochromes P450 to detoxify these plant toxins (58). As species began to fill specific ecological niches with unique environmental and dietary chemical challenges, the species diversity in expressed P450 genes that we encounter today developed. The evolution of this single xenobiotic metabolism system illustrates the significance of xenobiotic detoxication systems in the development and maintenance of the diversity of life we encounter on earth today.

An alternative to the hypothesis that the enzymes developed to metabolize foreign compounds is that they represent enzymes of normal anabolic and catabolic metabolism. These enzymes, in addition to functioning in their normal biochemical role, also function in xenobiotic metabolism. Examples of such enzymes certainly exist and include the methyltransferases involved in DNA synthesis and in detoxication, such as the metabolism of nicotine; however, it would appear fortuitous that normal anabolic and catabolic enzymes could have evolved to detoxify the broad array of chemical structures that are foreign to organisms. Another factor that diminishes the confidence in the alternative hypothesis is that many of the xenobiotic metabolizing enzymes can rapidly respond with increased activity to the presence of xenobiotics and environmental change. This would be unlikely if they simply represented enzymes of normal metabolism with the ability to metabolize alternative substrates. Many of the enzymes involved in xenobiotic metabolism are also involved in specific aspects of the metabolism of normal cellular biochemical constituents. Generally these enzymes are isozymes with higher substrate specificity for the endogenous compounds than the isozymes involved in xenobiotic metabolism. This could likely represent a process by which the cell used a preexisting xenobiotic metabolizing enzyme for metabolism of endogenous substrates instead of vice versa. Whatever the evolutionary source of the

xenobiotic metabolizing enzymes, it is obvious that they represent a distinct mechanism of metabolizing the thousands of naturally occurring and synthetic chemicals to which cells and tissues are exposed.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_78.html[2010/10/28 18:31:11]

GENERAL FEATURES AND BASIC CONCEPTS OF XENOBIOTIC METABOLISM

The majority of organisms studied have *biotransformation* enzymes, although there is diversity in the occurrence, function, and rates of specific enzymes. Certain bacteria contain more primitive or less highly developed systems and may lack certain pathways altogether. Even mammals demonstrate diversity in the activity or rates of specific systems, and, as would be expected of genetically controlled functions, there are species and individual differences. This diversity extends to the organ level in multicellular organisms. Specific organs show different levels of activity, and specific cell types within organs demonstrate variation in biotransformation capability. There is even subcellular diversity in that certain of these enzymes are compartmentalized whereas others are free in the cytoplasm.

The variety of chemicals to which organisms may be exposed requires that the biotransformation enzymes have broad substrate specificity. This characteristic is not shared by the majority of enzymes involved in anabolic and catabolic metabolism. In addition, the types of reactions catalyzed are diverse, as shown in Table 3.1, including oxidation, reduction, epoxidation, deamination, hydroxylation, sulfoxidation, dehalogenation, and conjugation with endogenous compounds, to name a few. Although it is logical to initially focus on one xenobiotic metabolizing system at a time, in many cases, xenobiotic metabolism involves more than a single metabolic route. In addition, the eventual toxicity of a xenobiotic may be modified by a number of factors, including age, gender, physiological status, nutrition, diet, and the presence or absence of disease, among others.

Exposure of an animal to certain xenobiotics can result in the *induction* of specific enzymes associated with xenobiotic metabolism. When induced, their activity can dramatically increase, compared to their basal level. Induction is sometimes coordinated with more than one enzyme induced. Induction results in an increase in the ability of animals to metabolize a xenobiotic, and in most cases this reduces their susceptibility to its toxicity. Induction generally lasts only a few days. When exposure ceases, the enzymes return to their basal levels.

Because xenobiotic metabolism does not always represent detoxication, the term *biotransformation* has come into general use to denote the actions of xenobiotic metabolizing enzymes, although it is still not semantically specific for xenobiotic metabolism. Biotransformation is divided into two distinct phases. *Phase I* reactions result in *functionalization,* the addition or the uncovering of specific functional groups that are required for subsequent metabolism by *phase II* enzymes. Phase II reactions are biosynthetic. These phase I and II reactions

Table 3.1 Examples of types of reactions and enzymes that participate in xenobiotic metabolism

Phase I Reactions	
Oxidation	Ester hydrolysis
P450 monooxygenase	Carboxylesterases
Xanthine oxidase	Amidases
Peroxidases	
Amine oxidase	Dehydrogenases
Monoamine oxidase	Alcohol dehydrogenases
Dioxygenases	Aldehyde dehydrogenases
Semicarbizide sensitive amine oxidase	
Reduction	Superoxide dismutase
P450 monooxygenase	
Ketoreductase	
Glutathione peroxidases	
Hydration	
Epoxide hydrolase	
Phase II Reactions	
Glucuronosyltransferase	Methylation
Sulfotransferase	*O*-Methyltransferases
Glutathione *S*-transferase	*N*-Methyltransferases
Glucosyltransferase	*S*-Methyltransferases
Thioltransferase	
Amide synthesis (transacylase)	Acetylation
	N-Acetyltransferase
	Acyltransferases
	Thiosulfate sulfurtransferase

(rhodanase)

are often coordinated, with the product of phase I reactions becoming the substrate for phase II enzymes. A commonality of biotransformation reactions is the conversion of hydrophobic xenobiotics into more polar, more easily excreted compounds. Because the composition of cells is more lipophilic than their environment, nonpolar compounds tend to accumulate. This could lead to bioconcentration of chemicals within the cell to levels higher than that of the environment and increase the likelihood of a cytotoxic event; however, conversion of nonpolar chemicals to more polar metabolites allows them to be more easily excreted by the cell. *Conjugation* of a xenobiotic with an endogenous compound, a phase II reaction, increases water solubility, and, in some cases, the added chemical group is recognized by specific carrier proteins or proteins involved in facilitated diffusion or active transport. This increases the cell's ability to remove the xenobiotic.

There are many diverse examples of xenobiotics whose toxicity is directly dependent on the activity of the biotransformation enzymes. For most chemicals,

increases in the activity of these enzymes result in decreases in toxicity, whereas decreases in activity result in increased toxicity; however, there are examples in which the product of xenobiotic metabolism is more toxic than the parent compound. Conversion of a foreign compound to a more toxic metabolite is termed *metabolic activation*. For example, the majority of genotoxic and carcinogenic chemicals require metabolic activation to highly reactive species capable of interacting with DNA. The enzymes that protect the animal from the toxicity of certain compounds may be responsible for the toxicity of others. An organism's susceptibility to the toxicity of a particular chemical is dependent, in many cases, on the delicate balance between detoxication and metabolic activation that exist during exposure to the xenobiotic. Due to the sensitivity of the enzymes of xenobiotic biotransformation to both endogenous and exogenous factors, this balance may differ among individuals and at different points in time.

BIOLOGICAL OXIDATION

Cytochrome P450-dependent Monooxygenase System

The P450-dependent monooxygenase system is central to the metabolism of most xenobiotics. Not only is it the primary enzymatic system for metabolism of many xenobiotics, but it is also involved as the initial functionalization step in the further metabolism of many others. Consequently, P450 plays essential roles in several areas of research, including biochemistry, pharmacology, toxicology, physiology, and medicine. Several names for the P450 system exist in the literature. The names most commonly encountered include

1. Mixed function oxidase
2. P450 system
3. P450-dependent monooxygenase system

Generally these names are related either to a specific function or are descriptive of a biochemical mechanism. Currently, it generally is referred to in terms of a monooxygenase system to denote its ability to incorporate one atom of molecule oxygen into its substrates.

Components of the Cytochromes P450 System

The history of the discovery of P450 and the elucidation of its functions and mechanisms of action are intriguing and have recently been reviewed by Estabrook (43). P450 was first described independently in 1958 by Klingenberg (86) and Garfinkel (52) in microsomes isolated from rat liver homogenates and pig liver homogenates, respectively. Klingenberg (86) noted that during 1955 in the laboratory of Britton Chance at the Johnson Foundation G.R.Williams was the first to observe the pigment. The name P450 derived from the occurrence of a pigment that, when reduced and treated with carbon monoxide, yielded a spectrophotometric Soret band at *450* nm. Six years after the publication of the original description of the P450 peak in hepatic microsomes, Omura and Sato (131, 132) published their pivotal papers describing P450 as a b-type hemocytochrome. Their work demonstrated that the cytochrome was located in hepatic *microsomes,* which form from the endoplasmic reticulum upon cellular disruption. Upon isolation from the membrane, using proteases, P450 is converted to a form whose reduced carbon monoxide complex produces a spectrophotometric peak at 420 nm. This form was termed *cytochrome P420* (P420) and was found inactive in metabolism. Conversion of P450 to the inactive cytochrome P420 upon isolation from the membrane was one of the major limitations encountered in early attempts to understand the mechanism of this membrane-bound monooxygenase.

Before the discovery of P450, Julius Axelrod and his colleagues (6), in the laboratory of Chemical Pharmacology at the National Heart Institute, were involved with studies on the metabolic disposition of drugs (6). They found that the oxidative metabolism of amphetamine required the co-factor NADPH and the presence of oxygen. An important publication by Estabrook et al. (42) brought together studies of P450 biochemistry and studies of biotransformation. They established that P450 was the terminal oxidase involved with the C-21 hydroxylation of steroids in adrenal cortical microsomes. This was followed by a study from Cooper (32) that demonstrated the involvement of P450 in both steroid and drug metabolism by hepatic microsomes. Many individuals and laboratories have played major roles in the development of the current knowledge concerning P450. Readers who become acquainted with the original literature will no doubt recognize the role of these pioneers in the development of a new field of study: xenobiotic biotransformation.

It soon became obvious that although P450 played a major role in the activity of the monooxygenase, it did not act alone. In 1950, Horecher (70) isolated a flavoprotein from the liver, but no function was identified. This flavoprotein used reducing equivalents from NADPH and was termed *NADPH-cytochrome c reductase* (EC 1.6.2.4). In 1955, La Du et al. (89) showed that cytochrome c could inhibit dealkylation of aminopyrine. This was followed by the studies of Gillette et al. (54) in 1957, which presented additional evidence that cytochrome c reductase was involved in xenobiotic metabolism. Williams and

Kamin (188) and Philips and Langdon (136) reported in 1962 that NADPH-

cytochrome c reductase occurred in the endoplasmic reticulum of liver cells and might be involved in drug and steroid oxidation. Further proof of the involvement of the flavoprotein came in 1969, when it was shown that antibodies to the reductase inhibited xenobiotic metabolism (88, 130), and Lu et al. (100, 101) demonstrated its requirement in monooxygenase activity reconstituted from isolated components.

One confusing aspect concerning this flavoprotein is its nomenclature. As previously mentioned, it is sometimes referred to as NADPH-cytochrome c reductase; however, no cytochrome c occurs in the endoplasmic reticulum, and cytochrome c is not its normal substrate. The more appropriate name is NADPH-cytochrome P450 reductase, indicating its natural substrate and function.

Although the major components of the P450-dependent monooxygenase system appear to be P450 and P450 reductase, other components may also be involved with metabolism of specific xenobiotics. Cytochrome b5 reductase has been proposed to participate in monooxygenase activity through electron transport to cytochrome b5 and, subsequently, to P450; however, several systems of electron transport in the endoplasmic reticulum and isolated microsomes, as well as other activities, such as peroxidation, have greatly complicated the elucidation of the role of cytochrome b5. Cytochrome b5 may affect P450-mediated xenobiotic metabolism by shunting electrons either toward or away from P450 (119). An elucidation of the role of cytochrome b5 must await further understanding of the complex electron transfer pathways that exist in the endoplasmic reticulum.

Although the catalytic activity of the monooxygenase system appears to require only two proteins—NADPH P450 reductase and P450—it is capable of carrying out a variety of different reactions on a large number of substrates. This ability is based on the occurrence of a variety of P450 isozymes, but it also is based on the basic reaction mechanism of the cytochromes and their apparent overlapping substrate specificity. The nonspecificity of the monooxygenase provides important flexibility to xenobiotic metabolism, but this flexibility comes with a price. Generally, the enzymatic reactions of anabolism and catabolism are both extremely specific in substrate specificity and catalytically efficient, resulting in high activity and high substrate turnover number. The turnover number and efficiency of P450 are considerably lower than most enzymes. This is probably related to the inefficient electron transfer due to the presence of a water molecule at the active site. Some substrates are more efficiently oxidized because they exclude water from the active site (137). Inefficiency of metabolism is more than made up for by the ability to metabolize a variety of chemical structures and the ability to catalyze a variety of reactions. An additional factor that compensates for the relatively low substrate turnover number is the high concentration of the system in organs important in detoxication.

Before a discussion of the various reactions catalyzed by P450, a discussion of the catalytic cycle is appropriate. Knowledge of the catalytic cycle will assist in understanding the various reactions catalyzed by the system and in predicting metabolic pathways for specific xenobiotics.

Catalytic Cycle of the P450-dependent Monooxygenase System

The reaction catalyzed by the cytochrome P450– dependent monooxygenase system and its stoichiometry is illustrated in Figure 3.1. One molecule of substrate reacts with one molecule of molecular oxygen and NADPH to yield oxidized substrate containing one atom from molecular oxygen, water (containing the other oxygen atom), and oxidized NADPH. The incorporation of one oxygen atom from molecular oxygen into the substrate is the source of the term *monooxygenase*. Oxidation of substrate and concomitant reduction of one atom of oxygen to water is the source of the name *mixed function oxidase*. Although the reaction stoichiometry appears simple, obtaining this stoichiometry in the laboratory is difficult (60). The main difficulty is the number of oxidation-reduction reactions that occur simultaneously in the endoplasmic reticulum. These reactions use oxygen and NADPH and may yield water and oxidized NADP. When these diverse reactions have been accounted for, the predicted stoichiometry has been obtained.

It is recommended that the reader carefully follow the reaction sequence illustrated in Figure. 3.2 during this discussion of the catalytic cycle. The initial step of the cycle is binding of the substrate (represented by S in Figure 3.2) to P450. As previously mentioned, P450 exists as a series of closely related isozymes, each of which demonstrates a degree of substrate specificity. This substrate specificity is not absolute, and some overlapping is evident. At any one time, several isozymes of P450 exist in the endoplasmic reticulum. This is dependent on the specific genetic, environmental, and physiological conditions of the organism. Therefore, binding of the substrate to the active site of P450 may represent binding to a single isozyme predominantly but not exclusively. The activity of the catalytic process, as well as the specific metabolites produced, is a function of the particular isozyme profile. Although our understanding of the structure of the active

$$RH + O_2 + NADPH + H^{\oplus} \longrightarrow ROH + H_2O + NADP^{\oplus}$$

FIG. 3.1. Reaction and stoichiometry of P450-dependent monooxygenase.

FIG. 3.2. Catalytic cycle of the P450-dependent monooxygenase. The second electron insertion step may be from b5 (as shown) or from NADPH P450 reductase.

site of P450 is developing (95, 96), more needs to be learned. From the nature of the hemoprotein and its substrates, the active site contains the heme and a hydrophobic region. The substrate must have a specific orientation within the active site.

As occurs with many other enzymes, the binding of the substrate to the hemoprotein appears to produce conformational alterations in the enzyme that assist its catalytic activity. For instance, substrate binding results in P450 being more easily reduced by P450 reductase, in part, by lowering its redox potential. Binding of the substrate to the active site changes the absorption spectrum of the cytochrome. Because the oxidized heme iron is paramagnetic, electron paramagnetic resonance (EPR) can be applied to probe the environment of the iron in the heme. These studies have revealed alterations in the EPR signal that correlate with the blue shift in the Soret band from about 419 nm to 390 nm, observed when substrates bind the cytochrome. EPR and visible spectra changes result from the substrate binding in close proximity to the heme iron with a concomitant displacement of a water molecule from the iron. Substrate binding is rapid, the heme is transformed from its low-spin form to the high-spin form, and the substrate is placed in close spatial proximity to the oxygen activation site on the heme. The relationships between the spin state of the cytochrome, interaction with the amino acids at the binding site, and substrate binding is more complex than described here. The reader is referred to discussions of changes in the spin state of P450 in (157, 95, 140, 137).

The next step in the catalytic cycle after substrate binding is the one-electron reduction of the substrate-P450 binary complex. As mentioned, substrate binding and the concomitant alterations in P450 may facilitate this reduction step. The ferric (Fe^{3+}) hemocytochrome P450-substrate complex is reduced by a single electron to the ferrous (Fe^{2+}) hemocytochrome P450-substrate complex. This electron is provided by NADPH through P450 reductase. This flavoprotein contains two flavins: flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). The flavoprotein appears to exist in its half-reduced (one-electron reduced) form, and upon reaction with NADPH, is fully reduced (two-electron reduced). The intramolecular electron flow appears to be from FAD to FMN. It is interesting that whereas the flavoprotein is a one-electron donor, its substrate, NADPH, provides two electrons. The mechanism for the two-electron shuttle by the one-electron donor flavoprotein is incompletely understood (7).

The flavoprotein has at least two domains, one of which is imbedded in the endoplasmic reticulum membrane and the other above the plane of the membrane on the cytosolic side. The domain solubilized in the membrane consists mainly of hydrophobic amino acids. The actual interaction with NADPH and oxidation-reduction takes place outside the membrane. Another interesting aspect of P450 reductase is that the quantity of P450 is in large excess to the quantity of reductase (as much as 15-fold to 20-fold or more, dependent upon conditions). This means that each flavoprotein must reduce several P450 molecules, indicating that the interaction between the

reductase and P450 is an important consideration, as discussed later.

Upon reduction of the ferric hemocytochrome P450-substrate binary complex to the ferrous state by the reductase, the complex binds oxygen. This results in the ternary complex, ferrous hemocytochrome P450-substrate-oxygen shown in Figure 3.2. The oxygen binds at the free ligand of the heme iron and is believed to be oriented spatially with the substrate binding portion of the active site. Uncoupling (interrupting the flow of electrons) the catalytic cycle at this point can produce the oxidized ferric P450 and a reduced form of oxygen, the superoxide radical. Other reactive oxygen species can be generated by P450 including hydrogen peroxide and the hydroxyl radical. Generation of active oxygen species by P450 has been reviewed in (8).

At this stage of the catalytic cycle, highly critical reactions take place that are still incompletely understood (140). The major event is the activation of the oxygen molecule. The ternary complex accepts a second electron required for reaction. The source of this electron can be either NADH or NADPH, dependent upon the mediator of electron transport. Because the purified, reconstituted system consisting of isolated P450, P450 reductase and phospholipid requires only the presence of NADPH, NADPH P450 reductase can mediate this step; however, as previously mentioned, in some systems it appears that cytochrome b5 can mediate the electron transfer employing reducing equivalents from NADH through NADH cytochrome b5 reductase. Whichever the source of the second electron, it results in the production of the peroxy P450-substrate complex, which has a net charge of −2. Determination of the various oxy complexes shown in brackets in Figure 3.2 is critical to understanding the oxygen activation reaction. Of the variety of mechanisms proposed for oxygen activation and insertion into the substrate, two appear to be generally accepted. The first mechanism involves heterolytic cleavage of diatomic oxygen with the abstraction of hydrogen from the substrate and the insertion of oxygen into the substrate. The second mechanism involves homolytic cleavage, whereby two oxygen radicals are generated. Whatever the mechanism, one atom of this reactive oxygen is introduced into the substrate, whereas the other is reduced to water. The oxidized substrate and water are released, regenerating the oxidized ferric P450, which can again initiate the catalytic cycle.

It must be emphasized that other pathways of electron transport in the endoplasmic reticulum can have significant impact on the catalytic activity of the monooxygenase by altering the availability of reducing equivalents. The interested reader is encouraged to consult other sources (7, 133) for a more comprehensive discussion of these pathways.

This catalytic cycle is common to cytochromes P450-dependent monooxygenase activity associated with xenobiotic metabolism in a variety of organs and among different species; however, certain of these monooxygenases, especially the more specific forms associated with anabolic and catabolic metabolism, have different mediators of electron transport. For example, the adrenal cortex mitochondria systems use a non-heme iron protein in addition to the P450 reductase in the electron transport chain, as does the monooxygenase in certain microorganisms (137, 147).

The P450 system is not totally independent, and its activity is affected by a number of factors. One of these factors is the availability of reducing equivalents. The monooxygenase is primarily dependent on NADPH, as previously discussed, and possibly, to a lesser extent, on NADH. NADPH is generated from the pentose-phosphate shunt, isocitrate dehydrogenase, and the malate enzyme. Under most conditions, these pathways provide saturating levels of NADPH; however, certain conditions can stress the ability of the cell to provide NADPH, and it may become rate limiting. Under conditions of high monooxygenase activity, starvation may reduce the activity toward certain substrates due to reduced levels of NADPH. It is generally believed that the decreased activity due to limiting NADH is an unlikely condition. A discussion of these and other factors that regulate monooxygenase activity can be found in the (171).

An additional factor that influences monooxygenase activity is the endoplasmic reticulum membrane. The asymmetric nature of the protein components of the system in respect to the membrane surface, coupled with the disproportionality of the concentrations of the components (i.e., a 1-to-15–20 ratio between the flavoprotein and P450), indicates an interesting topology and interaction between the components. The membrane topology of the P450 system has been a topic of research for a number of years. The interaction between the protein components of the system and the interaction of these components with the lipid matrix of the membrane are important in the overall reactions of this system. P450 appears to be anchored into the membrane of the endoplasmic reticulum by an anchor peptide at the NH2-terminal end of the protein with the anchor peptide transversing the membrane. The active site, including the heme, is on the cytoplasmic side of the membrane. The active site portion is rich in alpha helix content, globular in nature, and not associated with membrane lipids. The area around the active site may be associated with the cytosolic surface of the membrane, providing a somewhat rigid

character.
P450 appears to exist as multicomponent complexes of six P450 molecules clustered around a single P450 reductase. The NH_2-terminal regions on the opposite side

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_83.html[2010/10/28 18:31:14]

of the membrane may interact to anchor this complex together. This allows for a catalytic advantage because of the close association of the components. This organization implies that each reductase would be capable of sequentially reducing several P450s. P450 may form a transient complex with the reductase that has an extremely short, non-rate-limiting half-life (10, 64).

Isozyme Heterogeneity and Substrate Specificity of Cytochrome P450

For many years, P450's apparent lack of substrate specificity intrigued investigators. It appeared that one of the major features of substrate specificity was lipid solubility. There appeared to be few other structural restraints for substrates. Intensive research on the nature of the hemoproteins has revealed that much of this apparent lack of substrate specificity results from the existence of multiple families and multiple subfamilies of P450 isozymes.

As the array of individual isozymes grew in number, nomenclature became a problem. It was sometimes difficult for investigators to know what exact P450 they were working with because of inconsistencies in nomenclature. This led to attempts to develop a systematic nomenclature for the isozymes. P450 nomenclature has evolved from identifications based on spectra peaks to speciesdependent nomenclature based on isolated and semipurified P450s to the current system, which is based on amino acid sequences that result from specific gene sequences (124). P450 are now placed in families, which are further divided into subfamilies. Names are based on the root CYP derived from cytochrome P450. The CYP is followed by a number identifying the gene family to which it belongs, such as CYP1, CYP2, CYP3, etc. The number for the gene family is followed by a letter denoting the subfamily to which the P450 belongs, such as CYP1A and CYP2A. The subfamilies are further defined by the addition of a number identifying the gene, such as CYP1A1 and CYP1A2. Thus, P450 nomenclature is based on genetic relationships defined by protein and gene sequences. All P450s within a single family must exhibit a protein sequence similarity greater than 40%. P450s within the same subfamilies have sequence similarities greater than 55% within the same species. Subfamilies have sequence similarity that may be somewhat less than 55% when comparing species that are more distantly related. Members of subfamilies within a species appear to be located on a specific chromosome, and different subfamilies within a gene family may be clustered on the same chromosome. As is generally found in biology, there are exceptions to the classification system resulting from P450s that do not fit the usual patterns. Although this nomenclature provides infor mation on genetic and evolutionary relationships, it provides little information about substrate specificities and the reactions catalyzed by the different P450s. In fact, more is known about the protein and gene sequences of many P450s than about their specific roles in metabolism. With the advent of new methodologies, such as polymerase chain reaction (PCR) techniques, our ability to sequence specific P450s has outgrown our ability to define their specific roles in the metabolism of xenobiotics and endogenous compounds.

Different species may contain a CYP gene or protein that appears to be highly related; these are termed *orthologous genes*, or *orthologs*. Orthologs are believed to have evolved from a single gene that existed before the two species diverged from a single species. Although these genes and their proteins may contain a high degree of sequence homology, it is not necessarily true that they share a catalytic similarity, or vice versa. A small change in an important amino acid sequence can result in a large change in the activity of a P450. Humans and rats have the CYP2 family and the CYP2D subfamily. The rat subfamily contains five genes, one of which is CYP2D1. This P450 has catalytic activity toward debrisoquine metabolism. The human P450 that has the highest catalytic activity toward debrisoquine is CYP2D6, which makes up less than 5% of the complement of P450 in the liver (Figure 3.3). Because these rat and human P450s have similar substrate specificity, it might be assumed they have a high degree of sequence similarity. This was found not to be true. Therefore, even though these two isozymes have similar catalytic activity, they may have been derived from different ancestral genes. Sequence orthologs do not always predict similar catalytic activities. This is important for toxicologists who extrapolate toxicity from animal models to humans, as noted later. It also indicates that such information is important when toxicologists do interspecies extrapolation of toxicity, such as from mice to rats.

The section that follows provides a brief description of the major P450 families involved in xenobiotic metabolism. Those families predominately involved in metabolism of endogenous substrates have been excluded. For a more complete discussion of the P450 families, the reader is referred to the excellent reviews in (73, 159).

CYP1 Family

The CYP1 family contains two subfamilies of P450s: CYP1A and CYP1B. CYP1A is much better characterized than the CYP1B subfamily.

CYP1A Subfamily. The CYP1A subfamily contains CYP1A1 and CYP1A2, which appear to occur in all mammals. These two P450s may have been derived from a common ancestor approximately 120 million years ago.

< previous page page_84 next page >

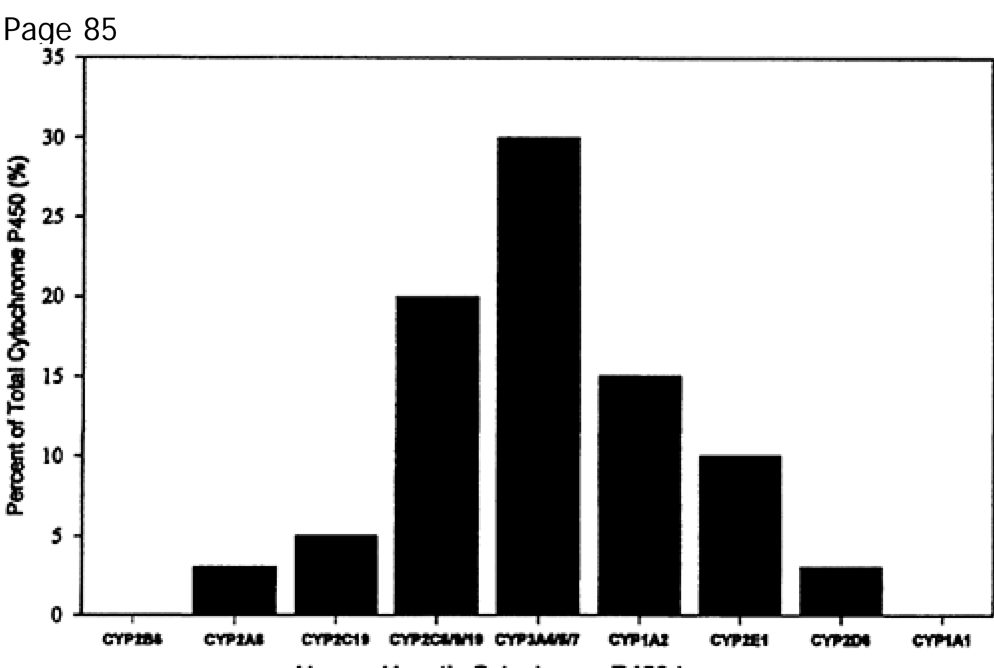

FIG. 3.3. Estimated percentage of distribution of P450 enzymes in human liver. Individual humans may demonstrate significant deviations from this average distribution. CYP2B6 and CYP1A1 may be in very low concentrations and appear only after enzyme induction. Modified from Reference 134.

Both P450s are important in the metabolism of environmental xenobiotics. Although these hemoproteins share a number of physiochemical characteristics, such as similar primary structures, they demonstrate different substrate specificities. For example, CY1A1 is highly active in the metabolism of benzo(a)pyrene (Figure 3.4), whereas CYP1A2 is active in the metabolism of acetanilide. These two P450s were first known as P448, and their classical enzyme inducer is 3-methylcholanthrene. Isosafrole is a specific inducer of CYP1A2. Another characteristic of these P450s is that CYP1A2 is mainly a liver enzyme in humans and animals, whereas CYP1A1 occurs in the liver (Figure 3.3) but also in extrahepatic tissues, such as the lung and kidney. For a number of years there has been an interest in the role of CYP1A1 in the metabolic activation of polycyclic hydrocarbons, such as benzo(a)pyrene. Although many of the investigations on the role of CYP1A1 in activation of polycyclic hydrocarbons have been done in animals with induced CYP1A1, polycyclics may be metabolized by other P450s in uninduced animals. Because its concentration in the liver is low, CYP1A1 may be more important in the metabolic activation of polycyclics in extrahepatic tissues, such as the lung. In humans, CYP1A1 demonstrates genetic polymorphism (discussed later). CYP1A2 has been shown to be associated with the mutagenic activation of heterocyclic amines, such as 4-aminobiphenyl and 2-aminonaphthalene. It also 0-dealkylates phenacetin and 4-hydroxlates acetanilide. Humans can show large differences in the activity of this P450, suggesting it also may be polymorphic. CYP1A2 catalyzes the N3-demethylation of caffeine to paraxanthine. This reaction has been used in vivo as a *substrate probe* for CYP1A2 activity.

CYP2 Family

The CYP2 family contains a number of subfamilies important in xenobiotic metabolism, including CYP2A, CYP2B, CYP2C, CYP2D, and CYP2E.

CYP2A. The CYP2A subfamily contains at least 12 members that differ in their substrate specificity, tissue distribution, and response to inducers and inhibitors, and demonstrate species differences. CYP2A1, CYP2A2, and CYP2A3 are rat P450s, Cyp2a4, Cyp2a5, and Cyp2a12 are found in mice, whereas humans have CYP2A6 and CYP2A7. Rat CYP2A1, along with CYP2A2, hydroxylates testosterone, progesterone, and androsteredione. They can also metabolize aminopyrine, benzphetamine, ethylmorphine, aniline, acetanilide, and N-nitrosodimethylamine. CYP2A1 has low activity toward 3-hydroxylation of benzo(a)pyrene, 7-ethoxycoumarin O-deethylation, and does not metabolize 7-ethoxyresorufin. It occurs in liver and testis, but not kidney and lung. In adult rats it predominates in females and appears to be under endocrine control. CYP2A3 appears to be lung specific, and its substrate specificity has not been well characterized. Human CYP2A6 demonstrates coumarin 7-hydroxylase activity but has

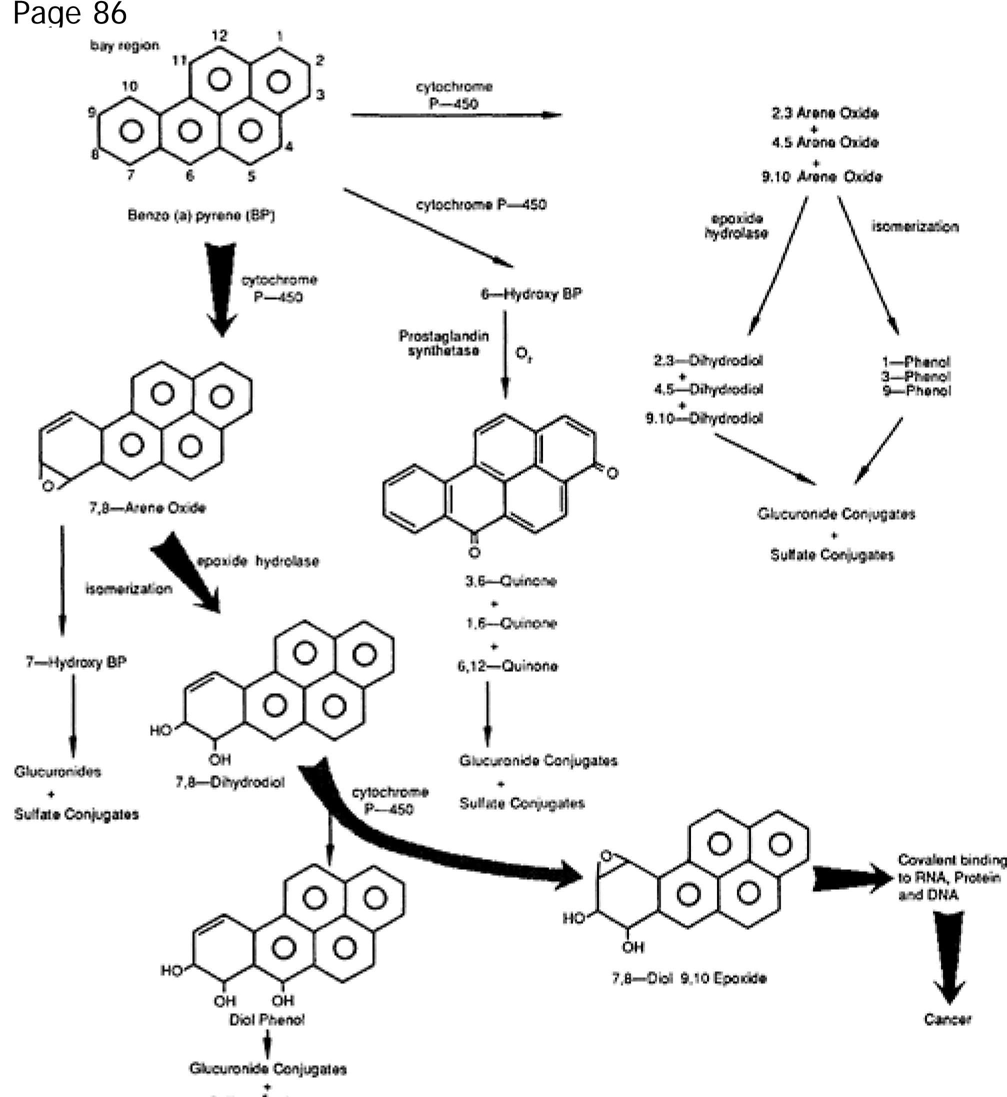

FIG. 3.4. Biotransformation and metabolic activation *(heavy arrows)* of the carcinogen benzo(a)pyrene. (BP).

no activity toward testosterone, in contrast to rat CYP2A1 and CYP2A2. It has no activity toward substrate probes such as 7-ethoxyresorufin, 7-benzyloxyresorufin, ethylmorphine, and testosterone. Although it shows wide variation in activity, there is no evidence that this is a polymorphic P450. Human liver microsomal studies have indicated this P450 may play a role in the metabolic activation of a number of nitrosamines and possibly activation of aflatoxin B1 to its hepatocarcinogenic epoxide.

CYP2B. This subfamily contains P450s, such as rat CYP2B1 and rat CYP2B2, that are highly induced by phenobarbital. Although the rat P450s in the CYP2B subfamily have been studied for a number of years, the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_86.html[2010/10/28 18:31:16]

CYP2B subfamily may have limited importance in humans. The human CYP3A subfamily may be more important in respect to phenobarbital-type induction in humans. Hydroxylation of testosterone at the 16β position is used as a specific substrate probe for this P450 in rats. Other substrates for this subfamily include benzyloxyresorufin, ethoxycoumarin, and pentoxyresorufin. In rats, CYP2B1 has been detected in the lung, adrenal gland, testis, and brain, whereas CYP2B2 occurs in liver and brain. Its role in xenobiotic metabolism has not been thoroughly investigated, although the CYP2B subfamily can metabolically activate xenobiotics, such as bromobenzene, carbon tetrachloride, benzo(a)pyrene, aflatoxin B1, and some nitrosamines in the rat.

CYP2C. Four CYP2C subfamily members have been identified in humans, CYP2C8, CYP2C9, CYP2C18, and CYP2C19. At least eight members of this subfamily have been identified in rats. Rat CYP2C P450s are gender specific, whereas this is not true for humans. In rats, members of this family are expressed in hepatic and extrahepatic tissues. In humans, CYP2C9 and CYP2C8 are present in the small intestine, and CYP2C8 has been detected in skin. Human CYP2C18 catalyzes the 4-hydroxylation, and CYP2C8 catalyzes the 4- and 7-hydroxylation of warfarin, but at a much lower rate. CYP2C8 also hydroxylates benzo(a)pyrene.

CYP2D. Rats have six members in the CYP2D subfamily, whereas three have been identified in humans: CYP2D6, CYP2D7, and CYP2D8. Mice have five CYP2D members, and this subfamily has been identified in other mammals. Human CYP2D6 was the first human P450 shown to be polymorphic, and is discussed later. Many drugs are metabolized by CYP2D6, and the reactions range from aryl hydroxylation to *N*- and *O*-dealkylation.

CYP2E. The CYP2E subfamily is one of particular interest to toxicologists. Currently, CYP2E1 is the only member of this subfamily in rats, mice, and humans. CYP2E1 appears restricted to mammals, and may have evolved more recently than certain other gene families. It is expressed in liver and kidney and occurs at low levels in a number of other tissues. Although it normally represents less than 10% of total P450 in human liver, it is induced by a broad array of its substrates. Its hepatic concentration can vary up to 50% between different humans. Rat and human forms of CYP2E1 share many similarities, including similar substrate specificities. It is known to metabolize more than 70 different chemicals with diverse structures. Structural requirements for CYP2E1 substrates appear limited to small molecules with hydrophobic character. It does not appear to be active in the metabolism of many drugs but does metabolize a wide array of alcohols, aldehydes, alkanes, aromatic hydrocarbons, ethers, fatty acids, halogenated hydrocarbons (including anesthetics), heterocyclics, and ketones. There are no specific substrate probes for CYP2E1, but aniline hydroxylation, p-nitrophenol hydroxylation, and carbon tetrachloride-dependent lipid peroxidation have been used to follow its activity in vitro.

Interest in the role of CYP2E1 as a mediator of toxicity comes from two of its actions. First, it is known to be important in the metabolic activation/detoxication of a number of carcinogens and heptatoxins. Second, it may have an important role in free-radical production and oxidative stress. For instance, it is believed to be involved in the metabolic activation associated with the carcinogenicity of benzene, nitrosamines, and azoxymethane, and the hepatotoxicity of nitrosammes, acetaminophen, halothane, and enflurane.

In respect to free radical production, it is involved in the formation of a reactive hydroxyethyl radical produced during its metabolism of ethanol to acetaldehyde. This hydroxy radical is believed to play a role in ethanol-related liver damage. It also appears to be involved in the production of a trichloroethyl radical produced by chlorine removal during the metabolism of carbon tetrachloride. This radical may initiate membrane lipid peroxidation associated with carbon tetrachloride-induced hepatotoxicity. An additional mechanism by which CYP2E1 could produce reactive radicals is associated with its potential for futile cycling in the absence of substrate. It appears more loosely coupled than some of the other P450s. Oxygen activation during the catalytic cycle in the absence of substrate results in the production of highly reactive hydroxyl radicals, superoxide anions, and hydrogen peroxide. If these reach concentrations that overcome cellular protection mechanisms, they can initiate oxidative stress leading to tissue damage.

P450s are not evenly expressed in the liver but occur in specific zones. The highest concentration of P450 is generally found in a layer surrounding the terminal hepatic venules. This is especially true for induced CYP2E1. Enhanced CYP2E1 activity in the centrilobular region appears related to the centrilobular necrosis produced by hepatotoxins, such as ethanol, carbon tetrachloride, benzene, nitrosamines, and acetaminophen. It may appear that CYP2E1 is predominately involved with metabolic activation; however, this is not necessarily true. As noted before, P450–mediated xenobiotic metabolism is generally associated with production of less toxic metabolites, but in some cases, more toxic

metabolites are produced. CYP2E1 is no exception to this rule and participates in not only metabolic activation, but also detoxication.

CYP3 Family

The CYP3 family of P450s encompasses CYP3A1 and CYP3A2 in rats, Cyp3a-11 and Cyp3a-13 in mice, and

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_87.html[2010/10/28 18:31:17]

CYP3A3, CYP3A4, CYP3A5, and CYP3A7 in humans, along with others from rabbits, dogs, and other species. The CYP3 family contains P450s that are important in the metabolism of many xenobiotics, especially drugs.

CYP3A. This subfamily contains at least four genes in humans. In many cases, it has been difficult to separate the activities of human CYP3A3 and CYP3A4. CYP3A4 is the major form of P450 expressed in human liver. It is also the major P450 expressed in the human gastrointestinal tract. Small amounts are found in several other organs, such as the kidney and skin. CYP3A4 and other members of the CYP3A subfamily are induced by a number of drugs. These isozymes do not demonstrate a high degree of structural selectivity with respect to their substrates. Generally, their substrates are relatively large, highly lipophilic molecules. Over 150 drugs from 38 classes can be metabolized by CYP3A4. They are also capable of metabolically activating carcinogens, such as aflatoxin B1 and benzo(a)pyrene. Because of the large number of drugs metabolized by CYP3A4, it may play a role in a number of drug-drug interactions that may result in adverse effects.

An example of how dietary constituents can affect specific isozymes is provided by the interaction between the consumption of grapefruit juice and CYP3A4. Consumption of grapefruit juice can cause an increase in the oral availability of a number of drugs that are CYP3A4 substrates. This affect appears to be associated with intestinal CYP3A4 more so than hepatic CYP3A4. Increased bioavailability is produced by inhibition of intestinal CYP3A4 activity by 6′,7′-dihydroxyberga-mottin, which is a component of grapefruit juice. This dietary compound is a mechanism-based inhibitor of CYP3A4 that results in the rapid partial loss of CYP3A4 activity (150). Inhibition of metabolism of the CYP3A4 substrates during their intestinal absorption accounts for the higher-than-anticipated plasma concentration of the drugs.

CYP3A5. This P450 may be polymorphically expressed in humans and has been detected in only 25%-30% of adults. It does not appear to have the broad substrate specificity of CYP3A4 and has lower activity.

Other P450s. There are a large number of P450 families and subfamilies not discussed here. Most of these are involved with the metabolism of endogenous substrates or occur in species that are beyond the scope of the topic of this chapter (see (73) for a more complete discussion).

Reactions Catalyzed by the Cytochromes P450-dependent Monooxygenase System

On first inspection, it appears that P450 can catalyze a bewildering number of reactions (Table 3.2); however,

Table 3.2 Major oxidative reactions catalyzed by the P450 monooxygenase system

Aliphatic hydroxylation
Aromatic hydroxylation
Epoxidation
N-Dealkylation
O-Dealkylation
S-Dealkylation
Deamination
Sulfoxidation
N-Oxidation
Oxidative dehalogenation
Desulfuration

on closer inspection, there is a degree of commonality among these reactions. The first area of commonality is that most of the reactions represent oxidations. Second, the reactions convert lipophilic substrates to more hydrophilic products. Third, many of the reactions can be represented as hydroxylations, as pointed out by Mannering (106). For a review of P450 reactions, see (62).

Aliphatic Hydroxylation

Examination of aliphatic hydroxylation reactions is illustrative of several important aspects of monooxygenase activity. The reaction mechanism, which may be common to several other types of monooxygenase metabolism, appears to occur by a hydrogen (or electron) abstraction mechanism. Oxygen activation produces a $[FeO]^{3+}$ at the heme of P450. Hydrogen abstraction from the substrate results in production of the carbon radical. This radical interacts with activated oxygen (through oxygen rebound) to yield hydroxylation. Other reactions, such as O-dealkylation of ethers and carboxylic acid esters, may proceed through this mechanism with decomposition of unstable hydroxylation products. Hydrogen abstraction is site selective, resulting in a nonrandom hydroxylation. The specific hydroxylation site is determined by structure and the specific spacial orientation of the substrate at the active site. Different isozymes of P450 show different degrees of site selectivity. For example, n-hexane

hydroxylation can occur at C-l, C-2, C-3, C-4. P450 isozymes induced by phenobarbital metabolized n-hexane to yield a four- to fivefold increase in the 2-,3-, and 4-hydroxylated metabolites and only a slight increase at the 1 position. On the other hand, benzo(a)pyrene-induced isozymes result in decreased yields of the 1- and 2-hydroxylated products but increased yields of the 3- and 4-hydroxylated products (49). Hydroxylation of aliphatic compounds is generally considered detoxication because of the greater water solubility of the products, but one must be cautioned

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_88.html[2010/10/28 18:31:17]

against overgeneralization, as products that are more toxic could be produced by subsequent metabolism.

Aromatic Oxidation

Aromatic oxidation reaction mechanisms are not completely understood but may occur by several mechanisms. The exact mechanism may be based on a number of factors, such as the steric features of the substrate and the configuration of the active site of the specific P450. Potential mechanisms include direct oxygen insertion into the C-H bond to form an epoxide through radicaloid reactions and/or through intermediates bonded to $(FeO)^{+3}$.

An example of a compound that is hydroxylated by both direct insertion of oxygen at the C-H bond and oxygen addition at the C=C bond is p-chlorobenzene. Both 3- and 4-chlorobenzene oxides are formed by the addition reaction to yield the arene epoxides. These spontaneously rearrange to form the *o*-chlorophenol and *p*-chlorophenol. The occurrence of the *m*-chlorophenol as a metabolite is an example of the direct insertion reaction. The production of arene oxides has been widely studied because of their importance in the formation of epoxide ultimate carcinogens. These epoxides can also be formed in nonaromatic systems, yielding reaction products as illustrated by the metabolism of aflatoxin B1. This mycotoxin is metabolized to a number of hydroxylated products and to the 8,9-epoxide. It is generally agreed that this epoxide is the ultimate carcinogen of aflatoxin B1.

Heteroatom Oxidation

P450 not only oxidizes carbon atoms but also nitrogen and sulfur atoms. A number of nitrogen-containing compounds can be oxidized to stable *N*-oxides. Another hepatic enzyme, flavin monooxygenase (FMO), can also catalyze this reaction. P450 and FMO may form *N*-oxides from the same xenobiotic; however, FMO generally prefers substrates with an electron-deficient nitrogen, whereas P450 prefers an electron-rich nitrogen. P450–mediated *N*-oxidation is possible with primary and secondary aromatic amines to produce hydroxylamines. Sulfoxidation can also be catalyzed by P450 and FMO. Sulfoxidation can produce a sulfoxide (SO) that can be further oxidized to a sulfone (SO_2). The mechanism associated with these reactions is believed to be electron abstraction from the heteroatom by $(FeO)^{3+}$.

Heteroatom Dealkylation

P450-dependent heteroatom dealkylation begins like heteroatom oxidation with electron abstraction from N, S, or O. This is followed by abstraction of H^+ from the carbon attached to the heteroatom. This α-carbon is hydroxylated followed by cleavage of the α-carbon and its rearrangement to an aldehyde or ketone. Sulfur atoms generally are not as readily dealkylated as nitrogen and oxygen atoms.

Ether compounds can also be dealkylated. The O-dealkylation is similar to N-dealkylation and is believed to proceed through the initial oxidation of the carbon adjacent to oxygen (i.e., carbon oxidation). The products of this reaction are again an alcohol and aldehyde, analogous to those produced by N-dealkylation.

Oxidative Deamination, Desulfuration, and Dehalogenation

Primary amines can be deaminated by the elimination of ammonia and the formation of an aldehyde or ketone. In a similar manner, P450 can catalyze desulfuration and dehalogenation, with the heteroatom being replaced with oxygen.

Reduction Reactions

An interesting series of reactions in which P450 may participate under special conditions are reductive reactions. These appear to involve transfer of electrons from Fe^{+2} to the substrate. Examples of such reactions are nitro reduction, azo reduction, arene oxide reduction, and reductive dehalogenation. These reactions generally are studied in vitro under anaerobic conditions in the presence of isolated microsomes and NADPH. Because these reactions require low oxygen tension to progress, their in vivo role (if any) is not well understood. Whether or not these reactions represent simply a curious phenomenon associated with P450 or a viable metabolic pathway is not known. It may be possible that under certain cellular conditions of low oxygen tension these reactions could proceed in vivo.

Induction and Inhibition of Cytochromes P450

Induction

When animals are exposed to certain xenobiotics, their ability to metabolize a variety of xenobiotics is increased. This phenomenon is termed *induction*. Induction produces a transitory resistance to the toxicity of many compounds; however, this may not be the case with compounds that require metabolic activation because their toxicity may increase. The exact toxicological outcome of this increased metabolism will be dependent on the specific xenobiotic and its metabolic pathway. Because the toxicological outcome of a xenobiotic exposure can depend on the balance between those reactions that

represent detoxication and those that represent activation, increases in metabolic capacity may, at times, produce unpredictable results. Induction of P450 has been reviewed in (17).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_89.html[2010/10/28 18:31:18]

One of the initial reports of increased metabolic capacity associated with xenobiotic exposure suggests how induction may provide a survival advantage. In 1954, Brown et al. (19) were studying the metabolism of methylated aminoazo dyes and found that xenobiotics in the animal diets enhanced the P450-dependent demethylation of these compounds. Free-living animals consume a variety of feeds that may contain toxic constituents. If the animal can respond rapidly to these toxic compounds by developing resistance, it can continue to use the feed source and obtain a survival advantage. One mechanism of rapidly developing such resistance is through increased detoxication resulting from stimulation of xenobiotic metabolizing enzyme activity.

Conney (31) published a pivotal review in 1967 that indicated more than 200 chemicals could induce P450–dependent metabolism, and most of these chemicals were monooxygenase substrates. Although the induction of the P450 enzymes has been most intensively investigated, other enzymes of biotransformation can be induced, such as the UDP-glucuronosyltransferases.

The classical definition of enzyme induction requires transcriptional activation at the level of DNA and increased production of mRNA, followed by an increase in the synthesis of the enzyme. The term has taken on a broader definition when used in respect to xenobiotic metabolism. This broader definition includes mechanisms such as mRNA and enzyme stabilization, all of which are associated with xenobiotic "induction." There are a number of "classes" of P450 inducers, which are listed in Table 3.3.

The polycyclic aromatic hydrocarbon class of inducers includes 3-methylcholanthrene, benzo(a)pyrene, and 2, 3,7,8 tetrachlorodibenzo-p-dioxin, and their mechanism of induction in animals has been extensively investigated. These inducers induce CYP1A1, which occurs in the liver and extrahepatic tissues of rats and extrahepatic tissues in humans. The low constitutive hepatic concentrations of CYP1A1 result from suppression of transcription by a nuclear repressor protein. Within the cytoplasm of the hepatocyte, there exists a receptor protein termed the *Ah receptor* that is complexed with heat-shock protein (hsp90). When a polycyclic hydrocarbon-type inducer enters the hepatocyte, it binds and activates the Ah receptor, resulting in release of hsp90. The Ah receptor is phosphorylated and subsequently binds to the Ahr nuclear translocator protein (Arnt), which is also activated by phosphorylation. This complex then moves to the nucleus of the hepatocyte. In the nucleus, this complex binds to a DNA regulatory sequence termed the *xenobiotic responsive element* (XRE). A DNA segment similar to rat XRE has been found in mouse and human cells. The XRE has also been found in genes of other xenobiotic metabolism enzymes, such as glutathione *S*-transferase, aldehyde dehydrogenase, and UDP-glucuronosyltransferase, where it may be involved in regulation of their expression. Binding of the ligand-bound-Ah-Arnt complex to XRE enhances transcription of the CYP1A1 gene, resulting in increased quantities of CYP1A1 mRNA followed by an increase in the hepatic concentration of CYP1A1.

In contrast to the polycyclic hydrocarbon class of inducers, no cytoplasmic receptor has been found for the phenobarbital-type inducers. Phenobarbital and other compounds of diverse structure induce expression of CYP2B1 and CYP2B2 and, to a lessor extent, CYP2A1, CYP2C6, CYP3A1, and CYP3A2. It also increases the quantity of endoplasmic reticulum in hepatocytes, increases total microsomal protein, and increases NADPH-cytochrome P450 reductase as well as other xenobiotic metabolizing enzymes, such as UDPGglucuronosyltransferase and epoxide hydrolase. Its induction of P450s is at the transcription level and is believed to be associated with the removal of a repressor

Table 3.3 Inducers of P450

Class of Inducer	Primary Example	Other Examples	Examples of Induced P450s
Polycyclic hydrocarbon type	3-Methylcholanthrene	Benzo(a)pyrene, β-naphthoflavone, TCDD, chlorpromazine, isosafrole, ketoconazole	CYP1A1, CYP1A2
Phenobarbital type	Phenobarbital	Phenytoin, griseofulvin, chlorpromazine, ketoconazole, dieldrin, butylated hydroxy-toluene	CYP2A1, CYP2B1, CYP2B2, CYP2C6, CYP3A2
Ethanol type	Ethanol	Acetone, heptane	CYP2E1
Glucocorticoid type	Dexamethasone	Pregnenolone-16a-carbonitrile, spironolactone, clotrimazole, prednisolone, methylprenisolone, rifampicin	CYP3A1, CYP3A2, CYP3A4
Clofibrate type	Clofibrate		CYP4

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_90.html[2010/10/28 18:31:18]

protein from an enhancer region of the DNA, allowing an increase in transcription. Compounds in the phenobarbital inducer class, such as terpenes, organochlorine pesticides, and polychlorinated biphenyls, may act through a common pathway of induction (51).

CYP2E1 induction has been studied in detail in the rat and represents an interesting situation where induction is controlled at the transcription, mRNA stabilization, translation, and enzyme stabilization levels. In addition, diet and pathophysiological conditions can produce induction of this P450. CYP2E1 is induced by the ethanol-type inducers. Although not true for all P450s, the CYP2E1 inducers generally are substrates for the isozyme. In many cases, the regulation of expression of CYP2E1 is controlled by stabilization of CYP2E1 mRNA and stabilization of the enzyme apoprotein, along with possible increased efficiency of translation. Cycloheximide, which blocks translation, blocked the increase in CYP2E1 apoprotein when mRNA was unchanged, indicating the increase in apoprotein was related to increased translation. Actinomycin D, which blocks transcription, did not block the apoprotein increase, indicating it was not transcription related. Many of the CYP2E1 inducers act by post-translational stabilization, including acetone, low ethanol doses, pyridine, and pyrazole. With these inducers, CYP2E1 concentration increases, whereas there is no change in mRNA. This indicates that CYP2E1 degradation decreases while synthesis remains constant, with the net result being increased CYP2E1.

Nutritional factors and disease conditions can also result in increased activity of CYP2E1. High-fat diets and starvation produce an induction of CYP2E1, as does insulin-dependent diabetes and obesity. One common factor in all of these conditions is increased plasma ketone body concentrations. Whether or not this induction is produced by increased ketone bodies, including acetone, or by other factors is currently under investigation.

The glucocorticoid-type inducers, such as dexamethasone and pregnenolone-16α-carbonitrile, induce CYP3A1 and CYP3A2. Induction is associated with transcription activation and mRNA stabilization. The exact mechanism of induction is unknown and its relationship to the glucocorticoid receptor, if any, is uncertain. CYP3A isozymes are involved in the metabolism of a number of drugs, and induction could effect drug-drug interactions.

Clofibrate-type inducers induce the CYP4A subfamily, that is, in most part, associated with metabolism of endogenous compounds. They also cause hepatocyte peroxisome proliferation in rodents. Many compounds that cause peroxisome proliferation in rodent liver are also hepatocarcinogens; however, humans are resistant to peroxisome proliferation, and these compounds do not appear to be a hepatocarcinogenic risk to humans. The low concentrations of CYP4A in human liver and its limited number of xenobiotic substrates, reduce its role in drug-drug interactions in humans. Induction by compounds such as clofibrate appears associated with a peroxisome proliferator-activated receptor (PPAR) involved in activation of transcription and resulting apoprotein synthesis.

Inhibition

Just as induction of xenobiotic metabolism can have important toxicological ramifications, inhibition of the ability to metabolize a xenobiotic can result in profound changes in its toxicity. Inhibition of a compound's metabolism can result in a higher plasma concentration than predicted and unexpected toxicity. During multiple drug treatment, unexpected adverse effects can be produced through drug-drug interactions where one drug inhibits the metabolism of another, resulting in higher than expected plasma concentrations.

Four mechanisms are generally associated with inhibition of P450-mediated detoxication. First, two xenobiotics may be substrates for the same P450 isozyme and will compete for the active site of the enzyme. This is an example of competitive inhibition. A second mechanism of competitive inhibition is the binding of a xenobiotic to the active site of a P450, although it is not a substrate for that P450. The presence of the nonsubstrate at the active site blocks the binding of the true substrate, inhibiting its metabolism. A third mechanism of inhibition involves the metabolism of a xenobiotic to a product that has a higher affinity for the active site than the parent compound. The active site is then occupied and additional substrate cannot bind. This essentially makes the enzyme inactive and is an example of noncompetitive inhibition. The fourth mechanism is another example of noncompetitive inhibition resulting from the production of a highly reactive metabolite that binds (often covalently) to the heme or apoprotein of P450, destroying its activity. This type of inhibitor is termed a *mechanism-based inhibitor* or a *suicide substrate*.

Other, less common mechanisms can result in inhibition of P450-mediated xenobiotic metabolism, including compounds that may modify protein or heme synthesis or degradation, those that may uncouple electron transport to P450, those that may interfere with cofactor availability, and those that may directly inhibit NADPH P450 reductase activity. Just as some substrates may demonstrate a higher

affinity for specific P450s and others may not, inhibitors may show a narrow or broad range of affinity for a specific P450. Inhibitors have been useful tools in determining mechanisms associated with xenobiotic metabolism and in attempts to predict specific drug-drug interactions. Induction and inhibition

of human cytochromes P450 have been recently reviewed in (135).
Species, Strain, and Gender Differences in Monooxygenase Activity
The activities of cytochromes P450 play a central role in the expression of the toxicity of the majority of xenobiotics. Knowledge of the rates at which a xenobiotic is metabolized and the chemical and biological nature of its metabolites assist not only in understanding its toxicity, but also its mechanism of action. This provides essential information to enable toxicologists to predict its toxicity. One factor that complicates extrapolation of toxicity between species is the quantitative and qualitative differences in how species metabolize xenobiotics. Generally, the basic reactions and major metabolites of a xenobiotic are similar between species; however, subtle differences in metabolism can lead to major differences in susceptibility to the toxicity of a xenobiotic.
A variety of mechanisms can be associated with differences between species in their response to a xenobiotic, including (1) adsorption, (2) distribution, (3) organ differences in metabolic capacity, (4) qualitative and quantitative differences in P450 isozymes and other xenobiotic metabolizing enzymes, (5) excretion, and (6) insensitivity of either the target organ or biochemical target site. Although all of these factors may be more or less important in understanding species differences in the susceptibility to the xenobiotic, it appears that the dominant factor is xenobiotic metabolism.
Mechanisms that may account for species differences include (1) lack of a metabolic pathway or a genetic "defect" in a particular metabolic pathway, (2) differences in the Km and Vmax of specific enzymes, (3) the existence of different isozymes and differences in the ratios of specific isozymes of important enzymes, such as P450, and (4) differences in the ratio of activities of separate enzyme systems that act together to metabolize a specific xenobiotic.
The lack of a specific pathway or a defect in a pathway will make a species or strain susceptible to xenobiotics that are detoxicated via that pathway. Conversely, when the xenobiotic is metabolically activated by that pathway, the species will be resistant. Although there does not appear to be a mammalian example of the lack of the monooxygenase system, examples exist for other enzymes, such as the lack of glucuronidation in cats. A more common explanation of species difference is the variation in the activity (Km, Vmax) and substrate specificity of isozymes associated with xenobiotic metabolism. At low doses or environmental exposures, these differences will be expressed in detoxication and species susceptibility. Caution needs to be used in both the design and interpretation of studies to investigate species differences. As mentioned, doses below enzyme saturation may not reveal species differences. Care must be used when investigating these differences in vitro, as this activity may not mimic in vivo activity.
When one metabolite represents a metabolically activated form and another a detoxicated form, the ratio of these metabolites can dictate a species susceptibility to a xenobiotic. This type of species difference is most commonly encountered when the P450-dependent monooxygenase acts in coordination with another pathway. Species may differ in either the initial monooxygenase functionalization reaction or in the activity of the secondary pathway. This is illustrated by the metabolic activation of benzo(a)pyrene (BP) (see Figure 3.4) in rats and mice. The metabolic activation of BP requires initial epoxidation by the P450-dependent monooxygenase at the 7,8 position, followed by hydration of the epoxide by epoxide hydrolase to yield the 7,8-diol. This diol is then epoxidated by the monooxygenase to yield the ultimate carcinogen of BP, the 7,8-dihydrodiol 9,10-oxide. When mouse hepatic microsomes were used for metabolic activation in the Ames assay for mutagenicity, BP was highly mutagenic, indicating a high degree of metabolic activation; however, when rat hepatic microsomes were employed in the same assay, only slight mutagenicity was evident. This indicates a significantly lower ability for the rats to metabolically activate BP in vitro (127). Although mice do metabolize BP to a greater extent than rats, rats have six- to sevenfold more epoxide hydrolase activity. Further studies (126, 127) indicated that both species have adequate monooxygenase to metabolically activate BP and that higher epoxide hydrolase activity in the rat may have been responsible for the lower mutagenicity. Therefore, the species differences in the secondary pathway, epoxide hydrolase, may have controlled the mutagenicity, as opposed to differences in the monooxygenase activity.
Just as species demonstrate differences in metabolism that alters toxicity, different strains of the same species may demonstrate differences in metabolism. For instance, if a different strain of mouse had been used in the studies described above, the data may have been different. It is important to recognize these strain differences when designing toxicological studies. The mechanisms associated with strain differences may be diverse. As with any genetically controlled activity, differences in metabolism are not unusual. Laboratory animals are generally bred in distinct groups, and without extensive outbreeding strain differences can develop quite rapidly. In the wild, such strain differences would be less likely, but

individual differences may be greater. Other factors, such as diet, environment, etc., may result in what appears to be strain differences.

Species differences in metabolism and, consequently, susceptibility lead to an important concept in toxicology,

that of selective toxicity. Ideally, a pesticide should be toxic only to the organism against which it is directed. This concept of selective toxicity has resulted in efforts to develop selective pesticides. For these activities to be fruitful, it is important that species differences in metabolism are understood and this information is used.

For the toxicologist, the species differences of major importance are those between humans and those species used in toxicological testing. Without an understanding of these species differences, it will be difficult to extrapolate toxicological studies performed with animals to humans. Studies of species differences in animals are difficult to design and interpret, and those involving humans are even more complex. This complexity results from the large differences in xenobiotic biotransformation found in humans. Many factors contribute to these individual differences in metabolism, including the following: (1) humans are free-living and have few restraints to reproductive diversity, diminishing the development of small genetic pools that result in genetically less diverse, more homogeneous control of metabolism; (2) environmental factors, such as diet, nutrition, xenobiotic exposure, etc., are diverse among humans; and (3) humans generally have more control and probably more interest in consumption of varied non-nutritive materials, such as alcohol, drugs, etc. These, as well as other factors, result in a large diversity in susceptibility to xenobiotic exposure. This is, in part, why such large safety factors are employed in risk or hazard assessments of xenobiotics to which humans may be exposed. These safety factors are used to attempt to protect the vast majority of individuals at risk. For further discussions of species differences, the reader is directed to the articles by Walker and Oesch (182) and by Caldwell (22). A discussion of intraindividual and interindividual differences can be found in the monograph by Vesell and Penno (178). For detailed reviews of P450 in a number of species, including plants, see (149).

Gender differences in xenobiotic metabolism may be an important factor in gender-dependent differences in toxicity. The best example of gender differences in xenobiotic metabolism, especially cytochrome P450-mediated metabolism, is the rat. Because the rat is commonly used in toxicological safety assessments, it is important to realize the gender differences in this species and understand how it relates to the extrapolation of rat data to humans.

Generally, male rats have a higher capacity to metabolize xenobiotics than females. This difference is, in most part, related to the cytochromes P450. Although females have 10%–30% less total P450 than males, this difference is not high enough to explain the 2- 20-fold difference seen in metabolism. Much of the differential seen between males and females can be explained by differences in P450 isozymes between the sexes. For instance, males express CYP2C11 whereas females do not. Isozymes that predominate in males are CYP2A1, CYP2A2, and CYP3A2. Adult females also have predominant P450s, such as CYP2C12, which occurs in juvenile and older males but not in young adult males. These differences are under hormonal control and can be altered by procedures such as castration and administration of sex hormones. They also are developmentally controlled, and the stage of life at which these procedures are done can influence their outcome. Neonatal castration of male rats results in different expression of P450 when they become adults. The adult expression of P450s can actually be "imprinted" during the neonatal period. Although sex hormones play an important role in the expression of P450 in rats, other hormones, including growth hormone, thyroxine, insulin, and somatostatin, may play important roles.

These differences between male and female rats also show an age dependency. As male rats age, their P450 isozyme profiles begin to appear more like females. Toxicologists using rats as a model in safety assessments need to be cognizant of these gender- and age-dependent changes. The toxicity data from young rats, generally used in toxicity studies, may not reflect the toxicity seen in old rats. During chronic toxicity and carcinogenicity studies, the response of rats to the toxicity of a test material may change as the study progresses. This is especially true of carcinogenicity studies that begin with in utero exposure. Early developmental changes in P450 in animals and humans may be important in responses to teratogens and embryotoxic compounds (112).

If gender differences in xenobiotic metabolism in rats can complicate toxicity assessments, what about other species, including humans? Rats have been the most intensively investigated species in regard to gender differences; however, studies with other species suggest that they generally do not demonstrate such large gender differences. Mice, another species important in toxicology studies, generally do not show the exaggerated gender differences in xenobiotic metabolism seen in rats. Gender differences in mice seem to be dependent on the specific strain of mouse investigated. Where gender differences do exist in mice, it is generally the female that has the higher metabolic capacity, but the differences are not as great as that seen in rats.

Other species used in toxicological investigations, such as dogs, appear to demonstrate some gender differences in the expression of P450 isozymes, but, again, they are not as exaggerated as in rats. Although there are few reported studies, monkeys have not been reported to demonstrate significant gender differences in xenobiotic metabolism.

Humans have not been shown to demonstrate gender-dependent differences in the expression of P450 isozymes. Although there can be significant differences

between human males and females in xenobiotic biodisposition, these appear to be more based on anatomical and physiological differences that affect absorption, distribution, and excretion. There can be large differences between individual humans based on life-style factors and exposure to environmental chemicals, food, and drugs; however, there do not appear to be inherent gender differences in the expression of P450.

This raises the question as to how species, such as rats, can be used to predict toxicity in humans. With care and knowledge of the differences between rats and humans, the rat can serve as a model for human toxicity. This has been shown through decades of use. For instance, rats and humans share similarities between the CYP isozyme subfamilies CYP1A1, CYP1A2, and CYP2E1, and these subfamilies are not expressed in a highly gender-dependent manner in rats. Xenobiotics that are substrates for these isozymes may be metabolized in a similar manner in rats and humans. Gender-dependent differences in xenobiotic metabolism are but one of the reasons toxicologists must use both sexes in the safety assessment of chemicals. Gender differences in xenobiotic metabolism have recently been reviewed (120).

Pharmacogenetics, Human Polymorphism of P450 Isozymes, and Their Toxicological Significance

Pharmacogenetics is the study of the hereditary basis of the observed differences in response (both therapeutic and adverse) to drugs by individuals and populations. The term can be expanded to include not only drugs but also dietary and environmental chemicals. This field has seen a large expansion over the last decade, as the understanding of the genetics, genetic regulation, and interindividual variations in P450 and other xenobiotic metabolism enzymes has increased. New methodologies from molecular biology and refinement of other methodologies to study genetic differences in individuals and populations have spurred interest in the pharmacogenetics of xenobiotic metabolism.

Many studies of the adverse effects of chemicals in animals and humans have indicated there are highly significant differences between animal strains, individual animals, and especially differences in individual humans and different human population groups. These genetic *polymorphisms* can result in unexpected drug and environmental toxicities and complicate safety assessments and the extrapolation of data from animal studies to humans. As discussed later, this has led to recommendations that the specific family and subfamily of P450 that metabolizes a specific drug candidate be determined during early drug discovery efforts. This could avoid unexpected interactions and suggest potential adverse effects before additional developmental efforts with a drug or other chemical product are undertaken.

Several human P450s have been shown to be polymorphically expressed, including CYP1A1, CYP2A6, CYP2C9, CYP2C19, CYP2D6, and CYP2E1. The chromosomal locations of these P450 genes have been identified and the genetic basis for the altered P450 activity is becoming understood. For instance, several alleles in the CYP2D6 family are known to contain specific nucleotide deletions that result in inactive genes and a lack of production of the CYP2D6 protein (34). Individuals homozygous for these gene variations will be “poor metabolizers” of CYP2D6 substrates. In contrast, some individuals have multiple copies of the CYP2D6 gene, possibly due to gene duplication (80). These individuals have enhanced capability to metabolize CYP2D6 substrates and are “ultra-rapid metabolizers” (9). A chemical whose detoxification depends on CYP2D6 would be more toxic than expected in the poor metabolizers, but less toxic than expected in the ultra-rapid metabolizers. In contrast, a chemical that is metabolically activated would be less toxic in poor metabolizers and more toxic in ultra-rapid metabolizers. To predict toxicity, it is obvious that not only must the role of metabolism in the toxicity of a compound be known, but also the potential genotype of exposed individuals.

Major advances have been made in determining the genotypes of individuals in respect to P450 isozymes. These range from the in vivo administration of probe drugs and determination of their metabolites as probes of metabolic capability and P450 genotype to the tools of modern molecular biology. For instance, the CYP2D6 genotype of individuals and populations can be probed using polymerase chain reaction (PCR) technology, followed by restriction endonuclease digestion, as well as other techniques (159). Genotyping studies have shown that the most common CYP2D6 mutations occur in about 7% of Caucasians and less than 1% of Asians.

CYP2D6 represents one of the first P450 polymorphisms discovered and one of the most extensively studied from the aspects of genetics, biochemistry, and clinical significance. It also is an excellent example of how all of these factors come into play to define a P450’s role as a determinate of toxicity. Smith and his colleagues were among the first to suggest that the high incidence of side effects associated with debrisoquine, an antihypertensive, might be due to genetic differences in debrisoquine metabolism (103). The early studies led to the knowledge that debrisoquine was metabolized to its 4-

hydroxy metabolite by CYP2D6. Investigations of the substrate specificity of this P450 have indicated that its preferred substrates are basic arylalkylamines with an ionized nitrogen at physiological pH. The site of

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_94.html[2010/10/28 18:31:21]

oxidation is generally on or near a planar aromatic system 5–7 A from the basic nitrogen (160). A proposed strong ion pairing between the substrate nitrogen and an aspartic acid in the active site of the P450 suggest it would have a high affinity for its substrates. This is supported by its low Km and Ki, compared to other P450s.

Although the requirements for a compound to be a substrate for CYP2D6 appear stringent, it has been shown to metabolize over 30 prescribed and overthe-counter drugs, including members of a variety of drug classes such as β-adrenergic blocking agents, antiarrhythmics, and antidepressants, among others. From this listing, it is obvious that CYP2D6 polymorphism is of clinical significance. In addition, it has been linked with increased risk of cancer in several organs, Parkinson's disease, and dopamine neurotransmission.

Regulatory and Product Development Aspects of Xenobiotic Metabolism

International regulatory agencies require some information about the metabolism of drugs and other chemicals that fall under their jurisdiction. The amount of data required will depend on the use of the chemical, its potential exposure to humans, and the potential role of metabolism in its efficacy and toxicity. Early information on the metabolism of drugs is becoming essential for the selection of drug candidates for further development. With the development of combinatorial synthetic chemistry and high-throughput pharmacological screening, the number of potential drug candidates that need to be rapidly screened for their potential metabolism has increased dramatically. This is leading to the development of rapid methods to predict metabolism and potential drug-drug interactions. Data are needed from in vitro and in vivo animal models that will be used in safety assessments to allow the toxicologist to design appropriate studies during the preclinical phase of a safety assessment. Data are also needed concerning the potential human metabolism of the drug candidate to allow the toxicologist to extrapolate animal safety data to humans. In the recent past, it was difficult to obtain in vitro data from human tissues. With the current knowledge of the human P450 isozymes and the commercial availability of human hepatic preparations and cells that express human P450s, it is possible to obtain data concerning human metabolism of drug candidates.

The U.S. Food and Drug Administration (FDA) has recently released a guidance document concerning in vitro drug metabolism and drug-drug interaction studies during the drug development process (173). This document stresses the importance of obtaining infor mation on a drug candidate's metabolism during the early stages of development. This information is important in predicting potential individual differences based on polymorphic expression of xenobiotic metabolism enzymes and in predicting drug-drug interactions. The guidance document is based on the following general observations:

1. The concentrations of a drug or its active metabolite circulating in the body determine the extent of its desirable and/or adverse effects.
2. A major determinant of a drug's concentration is clearance, and metabolism is a major determinant of clearance.
3. Drugs that are not substantially metabolized may impact the metabolism of other drugs.
4. Large differences in blood concentrations can occur because of polymorphic metabolism. Drug-drug interactions can also produce large changes in the blood concentration of a drug.
5. Major advances have been made in availability of human tissue and recombinant enzymes for in vitro studies of drug metabolism.

The guidance document suggests that the goals of in vitro metabolism and interaction studies should be (1) to identify major metabolic pathways and the specific isozymes involved, and (2) to explore and extrapolate the effects of the drug candidate on the metabolism of other drugs and the effect of other drugs on the candidate's metabolism. To accomplish these goals, the FDA suggests starting from human hepatic microsomes, now commercially available, then moving to expression systems that express specific human P450s, which are also commercially available. They note it is possible to move to hepatocytes and precision-cut liver slices but realize there are technical difficulties with these preparations.

Co-incubation of the drug candidate with substrate probes with known metabolic pathways can be used to determine its effects on their metabolism. In addition, assessment of the drug candidates' metabolism by CYP3A4 may provide information on intestinal metabolism that can affect drug bioavailability. Parallel studies using preparations from animal models can aid the toxicologist in choice of species for the toxicological studies. The document points out that in vitro studies currently cannot replace in vivo studies but can give direction for the proper design of in vivo studies. For instance, if the drug candidate is not metabolized by CYP2D6, then it will not be important to study the impact of the slow metabolizer phenotype on potential adverse effects. If the drug candidate is not a substrate for CYP3A4, then there

is less concern that inhibition of CYP3A4 by drugs such as ketoconazole and erythromycin or

< previous page page_95 next page >

induction by rifampin and anticonvulsants could cause problems.

Role of the Cytochrome P450-dependent Monooxygenase in Toxicity

The toxicity of any agent is dependent on its concentration at its target site. This is a function of many factors, including the route of exposure, the pharmacokinetics of the xenobiotic, the excretion of both the parent compound and its metabolites, and the sensitivity of the target site. The ability of the organism to clear the xenobiotic through excretion will have a profound influence on the concentration at the target site. Directly associated with the ability to clear many xenobiotics is the ability to metabolize the xenobiotic to more water-soluble metabolites.

Without doubt, the P450-dependent monooxygenase plays a pivotal role in the metabolism of xenobiotics. It is the prime metabolic route for the majority of xenobiotics, acting either directly in detoxication or indirectly by priming the xenobiotic for further metabolism through functionalization, as illustrated in other sections of this chapter.

The original interest in the P450 system was associated with its ability to metabolize drugs and decrease both their toxicity and duration of action. It soon became evident that, in certain cases, this enzyme system converted certain drugs from pharmacologically inactive forms to active forms. Examples of the metabolic activation of toxicants, such as the in vivo conversion of the inactive insecticide parathion to its active form, paraoxon, were soon encountered. It was also discovered that this enzyme system could activate stable molecules such as benzo(a)pyrene to highly reactive metabolites capable of damaging cellular macromolecules, as shown in Figure 3.4. Further studies have indicated that metabolic activation plays an important role in the toxicity of a number of xenobiotics.

Studies undertaken to understand the biochemistry of P450 played a large role in the development of the modern fields of biochemical and molecular toxicology. Currently, much effort is placed on the determination of the balance between metabolite activation, detoxication, and detoxication of activated metabolites. This is providing new insight for the toxicologist in understanding the toxicity of xenobiotics. Studies on the active sites of P450 and other xenobiotic metabolism enzymes, and the factors that influence their activity and their expression, are bringing toxicologists closer to being able to predict potential toxicity with more accuracy. These efforts are also aiding toxicologists in the difficult task of predicting human toxicity from studies done with cellular and animal models.

Other Enzymes Associated with Oxidative Metabolism

Microsomal Flavin-containing Monooxygenase

Since 1960, it has been apparent that a microsomal monooxygenase other than P450 could catalyze the oxygenation of nucleophilic nitrogen, sulfur, and phosphorus compounds. Purification to homogeneity indicated it was an NADPH-dependent, flavin-containing monooxygenase that does not contain P450. This monooxygenase (EC 1.14.13.8) has been referred to as amine oxidase, Ziegler enzyme, dimethylaniline monooxygenase, and flavin-containing monooxygenase. This enzyme may be a good example of proteins involved in normal anabolic and catabolic metabolism being recruited for xenobiotic metabolism. The flavin prosthetic group that is characteristic of these enzymes is especially versatile at carrying out redox functions.

The catalytic cycle for the flavin-containing monooxygenase is shown in Figure 3.5. NADPH reduces the FAD of the enzyme, and the oxidized NADP+ remains bound. Oxygen then binds to yield FAD peroxide followed by substrate binding. An oxygen atom from the peroxide is transferred to the substrate leaving the hydroxyflavin. The final and rate-limiting step of the cycle is the dehydration to regenerate FAD, yield water, and release the bound NADP+. NADH can substitute for NADPH, but with lower affinity and activity.

There are at least five isoforms of the flavin-containing monooxygenase, designated as FMO1-FMO5, whose genes are expressed across several species and tissues. These forms have different substrate specificities and are probably related to the species-dependent toxicity

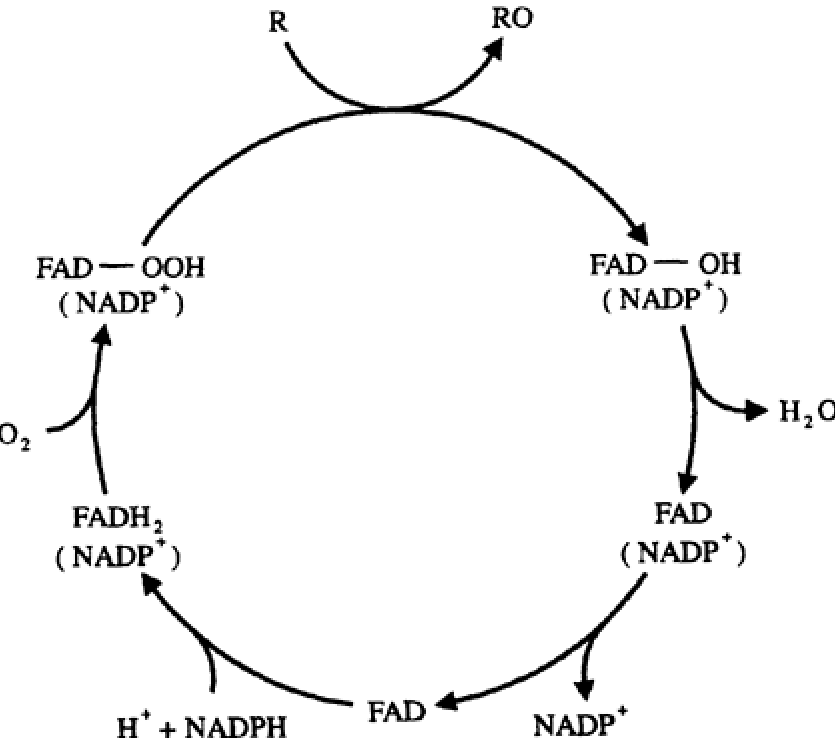

FIG. 3.5. Catalytic cycle of the flavin-containing monooxygenase. Adapted from References 194 and 195.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_96.html[2010/10/28 18:31:22]

of certain substrates, such as the pyrrolizidine alkaloids. Humans, rats, and mice have relatively high activity of FMO1 in kidney. Humans and mice have low activity for this form in the liver, whereas the rat has high activity. Humans and mice have high activity of FMO3 in the liver, whereas the rat has low activity. No FMO3 activity has been detected in human kidney but rat and mouse kidney show high activity. In mice, only females express FMO3 and have two- to threefold higher activity of FMO1 compared to males. FMO5 shows no gender differences. Male rats have higher total FMO than females, and two- to threefold more FMO1 than females, but no differences are seen in FMO3 (27). Humans can show considerable individual differences, but no gender differences have been detected. This illustrates the species, gender, and tissue differences that can be encountered with this monooxygenase and emphasizes the importance of choosing an appropriate animal model for toxicological studies of compounds that are potential substrates for this enzyme.

This microsomal enzyme catalyzes the oxidative attack on the nucleophilic nitrogen and sulfur heteroatom of a variety of xenobiotics (195) (See Table 3.4). It was once believed that oxidations of basic aliphatic and tertiary aromatic amines were carried out by the flavin-containing monooxygenase while primary aromatic amines and the acidic nitrogens of amides were catalyzed by P450, whereas secondary amines were oxidized by both enzyme systems. More recent studies with the purified enzymes have demonstrated that there is no clear division between the types of substrates preferred by the two enzymes. Therefore, the metabolism of each nitrogen-containing xenobiotic must be considered on an individual basis. The thermal instability of the flavin monooxygenase in the absence of NADPH (above 35°C) has provided a tool to separate the activity of this enzyme in vitro from that of P450; however, defining the relative contribution of the flavin monooxygenase and P450 to the metabolism of many xenobiotics is difficult because some inhibitors of P450, such as SKF-525A, are substrates for the flavin monooxygenases. More selective inhibitors of P450, such as N-benzylimidazole and aminobentotriazole, are a better choice for distinguishing these two enzymes (195). Antibodies to specific P450 isozymes can be used to inhibit P450 and determine the role of the flavin-containing monooxygenase.

Many nitrogen- and sulfur-containing xenobiotics are metabolized by this phase I enzyme, as seen in Table 3.4. *N*-oxidation of nucleophilic tertiary amines yields *N*-oxides. Primary and secondary amines are oxidized to hydroxylamines. In addition, primary amines can be oxidized to oximes and secondary amines to nitrones. Thiols, thioethers, and other xenobiotics containing sulfur can be oxidized to sulfur oxides. The flavincontaining monooxygenase has a relatively broad substrate specificity, but individual isozymes demonstrate some specificity. Broad substrate specificity and its occurrence in several tissues indicate that it can be a major determinant in oxidative xenobiotic metabolism.

Amine Oxidases

Amine oxidases can play a significant role in the metabolism of specific xenobiotics (167). Monoamine oxidase (MAO) (EC 1.4.3.4) and related amine oxidases catalyze the oxidative deamination of endogenous amines. They can also be involved in the metabolism of primary, secondary, and tertiary xenobiotic amines. Two of the amine oxidases (MAO and semicarbazide-sensitive amine oxidase) will be used as examples of amine oxidases.

Most tissues express two forms of the mitochondrial enzyme MAO, termed MAO-A and MAO-B, each expressed by a separate gene. MAO is a flavoprotein capable of oxidative deamination of primary, secondary, and tertiary amines. Metabolism of primary amines yields an aldehyde and ammonia, whereas secondary amines yield an aldehyde and a primary amine. The aldehyde products may be further metabolized by other enzymes to carboxylic acids or alcohols. Unlike the monooxygenases, the oxygen used in the reaction is derived from water. During the oxidation, the FAD prosthetic group is reduced (FAD→FADH2) then reoxidized by oxygen with the production of hydrogen peroxide.

A well-publicized example of an MAO-related toxicity was initiated by individuals attempting to synthesize a narcotic related to demerol. Instead of the intended product, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) resulted from the synthesis. Individuals who self-administered MPTP demonstrated Parkinson's disease-like symptoms. This was related to neuro-cytotoxicity in dopaminergic neurons produced by brain MAO-B metabolism of MPTP to l-methyl-4-phenyl-2, 3-dihydropyridine (MPDP+), which oxidizes to the neurotoxic l-methyl-4-phenylpyridine (MPP+). The cytotoxicity of MPP+ results from its inhibition of mitochondrial respiration.

A number of amine drugs have been shown to be substrates for MAO. Some of these act as pro-drugs and require MAO metabolism to produce the active form; others have their activities limited by MAO metabolism. MAO-A and MAO-B have different substrate specificities, but there can be overlap in specificity.

Semicarbazide-sensitive amine oxidases (SSAO) (EC 1.4.3.6), like monoamine oxidase, catalyzes the oxidative deamination of endogenous amines, but also can metabolize xenobiotic amines (102, 167). The SSAO do not contain a flavin but do contain copper. They demonstrate a more limited activity than MAO by only catalyzing deamination of primary aliphatic and aro-

Page 98

Table 3.4 Functional groups oxidized by flavin-containing monooxygenase

Functional group	Compound class	Example
	Sulfur Oxidation	
$RSH \rightarrow RSSR$	Thiols	Cystamine→cysteamine
$RSSR \rightarrow RS(=O)SR$	Disulfides	
$RSR \rightarrow RS(=O)R \rightarrow RS(=O)_2R$	Sulfides	Cimetidine, aldicarb
$-N-C(SH)-NH \rightarrow -N-C(=S{=}O)-NH_2 \rightarrow -N-C(SO_2H)=NH$	Thiocarbamides	
$R-C(S)-NH_2 \rightarrow R-C(=S{=}O)-NH_2 \rightarrow R-C(SO_2H)=NH_2$	Thioamides	Thioacetamide, thiobenzamide
$(-N)(=N-H)SH \rightarrow (-N{=})(=N-H)SOH \rightarrow (-N{=})(=N-H)SO_2H$	Mercaptopurines and pyrimidines	
	Nitrogen Oxidation	
Acrylic $R-N(R_1)(R_2) \rightarrow R-N(OH)(R_1)-R_2$ *Cyclic* $R-(ring)N-CH_3 \rightarrow R-(ring)N(\rightarrow O)-CH_3$	Tertiary amines	Chloropromazine, cocaine, fluphenazine, nicotine
$R-NH-R_1 \rightarrow R-N(OH)-R_1 \rightarrow R=N(\rightarrow O)-R_1$	Secondary amines	Desipramine, *N*-methylaniline
$R-N(NH_2)-R_1 \rightarrow R+N(OH)(R_1)-NH_2$	Hydrazines	Dimethylthydrazine, procarbazine, benzylthydrazine

$$\text{Ar}-\text{NH}-\text{R} \rightarrow \text{Ar}-\text{N(OH)}-\text{R}$$

N-Alkylarylamines 2-Acetylaminofluorene

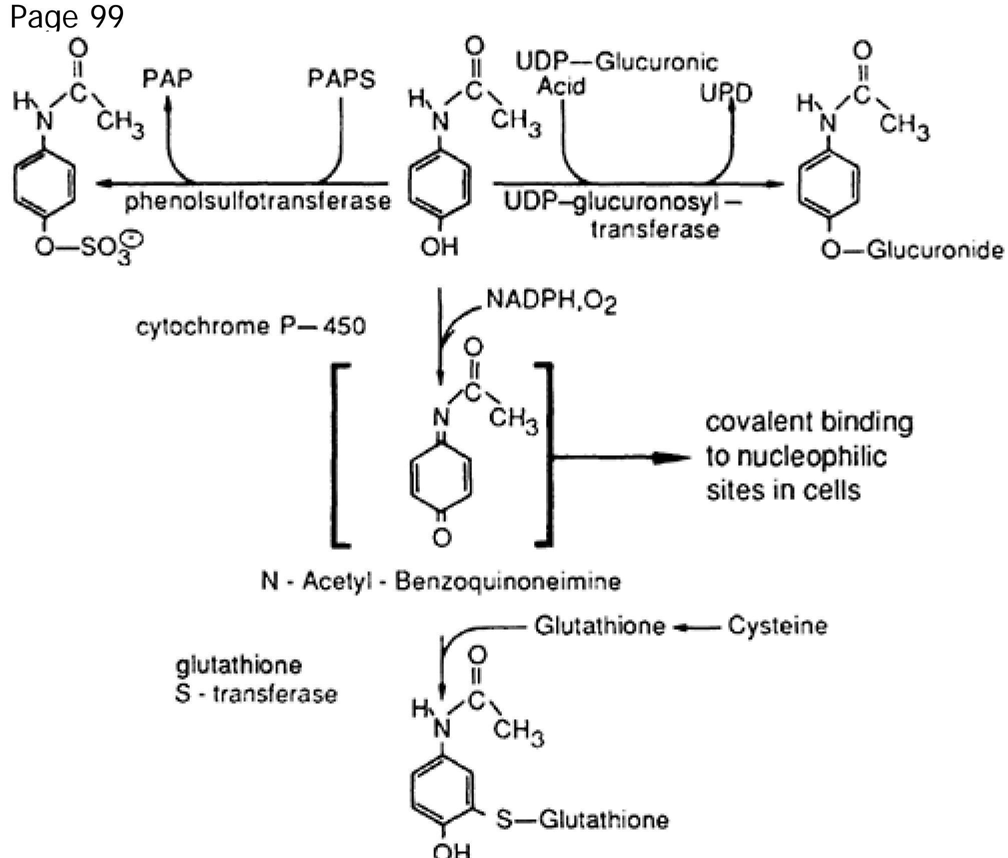

FIG. 3.6. Biotransformation of the analgesic acetaminophen.

matic monoamines. They are sensitive to inhibition by semicarbazide but insensitive to the classic MAO inhibitors. The products of their reaction are an aldehyde, ammonia, and hydrogen peroxide. They occur in most species, including bacteria, fungi, plants, and animals. In animals, they occur in plasma and bound to tissues. Although they can metabolize several endogenous substrates (191), their exact physiological role is currently unknown. There are considerable species differences with SSAO. For instance, rats have relatively low concentrations of plasma SSAO compared to humans. SSAO can metabolize certain xenobiotics to more toxic metabolites. 3-Aminopropene has been used in the manufacture of pharmaceuticals and in rubber vulcanization. Chronic exposure to this compound can produce lesions similar to acute myocardial necrosis and atherosclerosis. SSAO appears to metabolize 3-aminopropene to 2-propenal (acrolein), which alkylates glutathione S-transferase and allows excessive peroxidative damage (66). Damage occurs in the heart and aortic tissue, which have high SSAO activity (30).

Co-oxidation of Xenobiotics by Prostaglandin Synthase H

Pathways other than the monooxygenases may be involved in xenobiotic oxidation. Marnett and Reed (107) demonstrated that prostaglandin H synthetase, an enzyme system responsible for prostaglandin biosynthesis, was capable of oxidizing benzo(a)pyrene to quinones. Two catalytic activities co-purify with the synthase: fatty acid cyclooxygenase and prostaglandin hydroperoxidase. The cyclooxygenase catalyzes arachidonic acid oxidation to prostaglandin G2, and the hydroperoxidase reduces the hydroperoxidase (–OOH) to the corresponding alcohol in prostaglandin H2, as shown in Figure 3.7. Oxidation of xenobiotics results from a one-electron pathway involving an oxidizing agent produced during the hydroperoxidase-catalyzed reduction of prostaglandin G2 to the hydroxy endoperoxide, prostaglandin H2. Prostaglandin synthetase is a major source of alkyl hydroperoxides produced during normal metabolism (108). Most tissues possess prostaglandin synthetase activity and are capable of oxidizing certain xenobiotics, even if the tissue is low in P450 content. In fact, acetaminophen, which is activated to a reactive intermediate by P450 (Figure 3.6), can be activated by prostaglandin synthetase in the medulla of the kidney (Figure 3.7). This tissue is low in P450 activity, but in the presence of arachidonic acid, the medulla activates acetaminophen to a reactive intermediate that covalently binds to tissue macromolecules (14). Other compounds that undergo co-oxidation include aminopyrine, benzphetamine, oxyphenbutazone, benzidine, and benzo(a)pyrene.

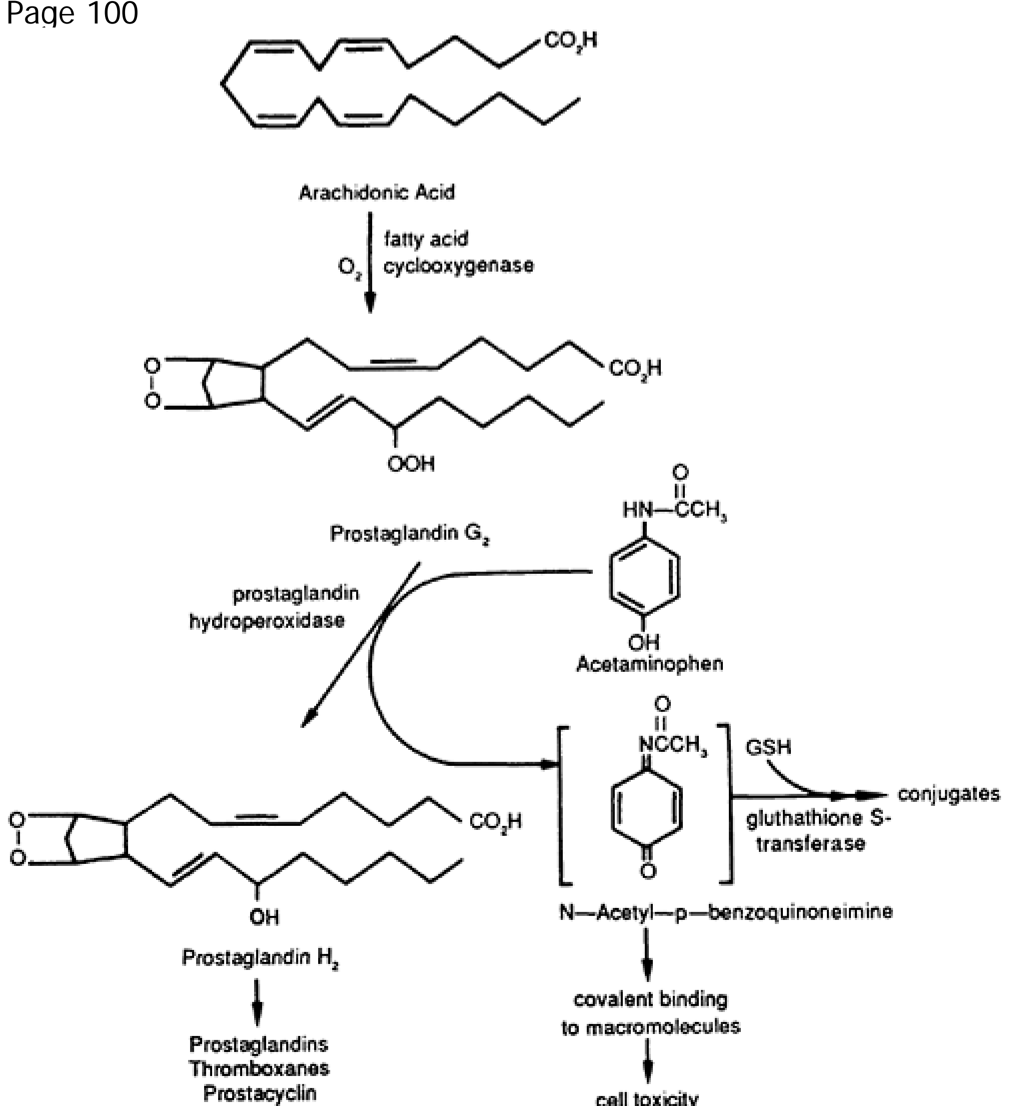

FIG. 3.7. Co-oxidation of acetaminophen by prostaglandin endoperoxide synthetase.

The bladder also possesses high prostaglandin synthetase activity. Mattammal et al. (109) proposed that several structurally diverse renal and bladder carcinogens are metabolically activated by prostaglandin synthetase. For example, the bladder carcinogen 2-amino-4-(5-nitro-2-furyl)thiazole is believed to be activated by prostaglandin synthetase co-oxidation in bladder transitional epithelium to metabolites capable of covalently modifying RNA and DNA. Feeding aspirin to rats can inhibit the bladder lesion induced by 5-nitrofuran, the ultimate carcinogen. This suggests that prostaglandin synthetase is involved in the metabolic activation, as aspirin is a specific inhibitor of prostaglandin synthetase.

Use of the analgesic p-phenetidine has declined because of reports of kidney damage in man following prolonged use of the drug. Andersson et al. (5) proposed a mechanism by which phenetidine is activated by prostaglandin synthetase in the kidney. The primary amine nitrogen of phenetidine undergoes a one-electron oxidation similar to that shown in Figure 3.7 for acetaminophen. This leads to hydrogen abstraction yielding a reactive nitrenium radical. This radical is postulated based on its rate of reaction with reduced glutathione. Benzene can be hydroxylated to phenol in the liver by P450, and the phenol can be further oxidized to hydroquinone. The phenol and hydroquinone can enter the blood stream and be distributed to other tissues. In the bone marrow, the phenol stimulates prostaglandin synthetase peroxidative activation of hydroquinone to reactive metabolites that form adducts with nucleophiles, such as protein and DNA. This is believed to result in the bone marrow suppression seen with chronic exposure to benzene. Phenolic compounds may be converted to reactive phenoxyl radicals by the one-electron oxidative process. Other peroxidases, such as lactoperoxidase and myeloperoxidase, may be involved in xenobiotic metabolism.

BIOCHEMICAL CONJUGATIONS

Mammals can synthesize xenobiotic conjugates that are more polar and readily excreted, compared with the parent compound. Conjugate synthesis is finely controlled through various feedback pathways. Two major reactants are required for conjugate synthesis: a xenobiotic with the appropriate functional group and a cosubstrate that can be conjugated with the xenobiotic. If the xenobiotic does not have a functional group amenable to conjugation, such as a hydroxyl group, it may be oxidized (functionalized) by cytochromes P450. The oxidized product and the cosubstrate must be simultaneously available for conjugation. Both functions must be tightly integrated for rapid excretion of the xenobiotic. Although the forthcoming sections will discuss each conjugating system as a separate entity, it must be emphasized that in vivo metabolism is integrated. Examples showing the integration of the conjugating systems with related pathways will be described.

Glucuronidation: Uridine Diphosphoglucuronosyltransferases

P450s are the principal phase I oxidative enzymes. Similarly, uridine diphospho(UDP)glucuronosyltransferases (also known as UDP-glycosyltransferases) are the principal phase II enzymes. Glucuronosyltranferases can use monooxygenase products to form glucuronides; however, it is not a necessity for substrates of the glucuronosyltransferase to be monooxygenase products. Significant numbers of xenobiotics and certain endobiotics possess the necessary functional groups for glucuronidation and do not require functionalization. These enzymes belong to a superfamily of related genes, and over 30 glucuronosyltransferases have been purified or cloned and expressed. Whereas the multienzyme complex of the P450 monooxygenase is termed a *system* because the enzymes are closely linked, the multiple enzymes of glucuronidation are not linked, but are interdependent. The general reaction mechanism of the conjugating enzymes involves the activation of an endogenous molecule. Subsequent reaction of this activated form of the endogenous molecule with the xenobiotic produces the conjugate. Activation may occur in a different cellular compartment than conjugation, as is the case with glucuronidation. Activation of glucose occurs in the cytosol, whereas conjugation occurs in the lumen of the endoplasmic reticulum. UDP-glucuronosyltransferases occur in several tissues, but their highest activity is found in the liver. Other tissues containing these enzymes include kidney, intestine, lung, skin, adrenals, and spleen. Extrahepatic glucuronosyltransferases may be differentially expressed and demonstrate different isoforms compared to the liver (123, 165).

Although the products of P450 are more water soluble than their parent compounds, some still possess considerable lipophilicity. Subsequent conjugation produces metabolites with higher water solubility. These metabolites can generally be readily excreted in the bile or urine. Transport proteins can recognize the glucuronic acid moiety of the glucuronide and aid in excretion from the liver and kidney. An additional method by which glucuronidation produces less toxic metabolites is via the addition of a bulky moiety to the xenobiotic. This can result in both the shielding of reactive portions of the xenobiotic and in the blocking of reactions between the xenobiotic and the site responsible for the toxicological sequelae. In some cases, the product of glucuronidation has more biological activity than the parent compound, and conjugation can be considered metabolic activation, although examples are far fewer than with P450 oxidation.

Glucuronides are either secreted by the liver into the bile, and consequently found in the feces, or by the kidney into the urine. The excretion route is generally dependent upon the molecular weight of the xenobiotic. The rat excretes glucuronides of xenobiotics with molecular weights greater than about 250–300 in the bile and those with lower molecular weights in the urine. Higher molecular weight xenobiotics, such as morphine, chloramphenicol, and endogenous steroids, are excreted in bile and enter the intestine. Bililary excretion can result in enterohepatic circulation, which can cause prolonged plasma half-lives for some compounds. The intestine contains β-glucuronidase, from the intestinal microflora, that catalyzes the hydrolysis of glucuronides. This releases the xenobiotic in the intestine, where it can be absorbed into the blood. The xenobiotic can then be taken up by the liver, where it is reconjugated and excreted into the bile, where the cycle is again initiated. This can cause prolonged exposure to target organs, such as the liver, and result in unanticipated toxicity.

History of the discovery of glucuronidation and the glucuronosyltransferases is interesting, and the reader is directed to Williams' classic book on detoxication mechanisms (189) and the comprehensive discussions of this enzyme (40, 170).

Nomenclature for UDP-Glucuronosyltransferase Gene Superfamily

Nomenclature for the UDP-glucuronosyltransferases has progressed similar to that for the P450 superfamily. It has been proposed that each gene be identified by the root symbol UGT for *U*DP-glucuronosyltransferase.

D—Glucose → ∝—D—Glucose—1—phosphate

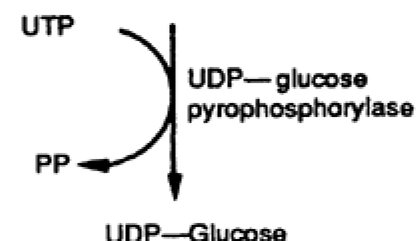

FIG. 3.8. Glucuronidation of phenol. An example of the pathway leading to production of glucuronic acid conjugates.

The gene family is identified by a number and a letter is added to designate the subfamily (UGT2B) followed by a number to identify the gene (UGT2B1). This system, as with the P450 nomenclature, is an attempt to provide isoforms with a name that is not only specific but reflects the evolutionary divergence of the genes. As new discoveries are being made, the nomenclature for these enzymes is evolving.

Biochemistry of Glucuronidation

Glucuronidation (illustrated in Figure 3.8) requires the availability of three reactants:

1. UDP-α-D-glucuronic acid (UDPGA), generated in the cytoplasm.
2. UDP-glucuronosyltransferase (UDPGT, EC 2.4.1.17), bound to the endoplasmic reticulum.
3. Substrate with the requisite functional group and some hydrophobic character.

Maximal enzyme activity is dependent on optimal concentrations of these reactants at the membrane site of catalysis.

As seen in Figure 3.8, D-glucose is the original precursor of UDPGA. During anabolic metabolism, D-glucose is converted to α-D-glucose-1-phosphate. This compound serves as substrate for UDP-glucose pyrophosphorylase (EC 2.7.7.9), which catalyzes its reaction with uridine triphosphate to yield the high-energy phosphate containing UDP-D-glucose and pyrophosphate. UDP-D-glucose then reacts with nicotine adenine dinucleotide (NAD) catalyzed by UDP-glucose

dehydrogenase (EC 1.1.1.22) to yield UDP-D-glucuronic acid, which completes glucose activation. This compound is termed the *glycone,* indicating its source. The xenobiotic that is conjugated is termed the *aglycone*. Glucose activation occurs within the cytoplasm, whereas glucuronidation of the aglycone occurs at the endoplasmic reticulum. Because UDP-D-glucose is also used in glycogen synthesis, it generally is available in the cell. This is not true for all conjugation reactions, and may be one of the reasons that glucuronidation is a major conjugation pathway.

The topology of UDP-glucuronosyltransferases is important for understanding substrate specificity and the need to disrupt microsomes with detergents or other means before assaying these enzymes in vitro. It is believed that large interlaboratory variation of in vitro glucuronidation data comes from variation in detergent-released latency. UDP-glucuronosyltransferases are oriented in the endoplasmic reticulum in such a way that the majority of the protein protrudes into the lumen of the endoplasmic reticulum. The intraluminal portion of the protein possesses the UDP-glucuronic acid-binding domain as well as the xenobiotic or endobiotic (endogenous substrates) binding domain. This means that UDP-glucuronic acid must pass through the membrane, possibly by carrier mediation, and that the substrate must also pass through the membrane (63). Molecular biology studies indicate that the C-terminal half of the protein is highly conserved among different UDP-glucuronosyltransferases, whereas the N-terminal region is highly variable. The C-terminal half of the protein contains the transmembrane sequences that anchor the enzyme within the membrane and the short portion of the C terminus that protrudes from the outside surface of the endoplasmic reticulum into the cytoplasm. The C-terminal half of the enzyme may contain a UDPglucuronic acid binding site. The broad substrate specificity is believed to come from variation in the primary sequence of the N-terminal region where the substrate-binding domain resides (110).

UDP-glucuronic acid and the aglycone (xenobiotic or endobiotic) must be present for the conjugation reaction to be initiated. The number of xenobiotics that have been shown to be substrates for UDPGTs is large and continues to grow (113). The major functional groups forming glucuronides are (a) hydroxyl, (b) carboxyl, (c) amino, and (d) sulfhydryl. The substituents to which these functional groups are attached can be quite variable (see Table 3.5). Similar to the substrate requirements for monooxygenases of the endoplasmic reticulum, the aglycone must be somewhat lipid soluble to be a substrate for the UDPGTs. This requirement reflects the need for the xenobiotic to penetrate the endoplasmic reticulum to gain access to the active site. All of the endobiotics associated with normal metabolism and homeostasis that are substrates for the UDPGTs are lipid soluble and include bilirubin, catechols, such as 3-O-methyladrenaline, serotonin, and 17-hydroxy-containing steroids.

As noted earlier, UDP-glucuronosyltransferases constitute a multigene family, divided into subfamilies, consisting of a number of genes, all but one of which encode for an individual UDPGT isozyme. Evidence accumulated from differential induction and developmental studies, enzyme purification, immunochemical analysis, and the cloning of UDPGT cDNAs suggests the existence of at least 12 different UDPGT isozymes in the rat. Rat isozymes are divided into two gene families. The UGT1 family contains isozymes that appear related to a single gene, and each member of the UGT2 family is related to a unique gene. Some of the UGTI family are inducible by 3-methylcholanthrene and others are inducible by phenobarbital. Two members of the UGT2 family are inducible by phenobarbital.

A similar approach has been applied to human UDPGTs, and the heterogeneity of the enzyme in humans is now recognized. Compared to the rat, the characterization of the isozymes in humans is less complete. The expression of human liver UDPGT cDNAs in tissue culture is providing useful information on the substrate specificity of individual isozymes. Site-directed mutagenesis is proving useful to determine which amino acid sequences are modifying substrate specificity among these isozymes. Human isozymes are also divided into UGT1, which contains at least six isozymes from a single gene, similar to the rat. The human UGT2B family contains at least six isozymes from unique genes.

Reactions Catalyzed by the UDP-glucuronosyltransferases

As with many of the enzymes of detoxication, the glucuronosyltransferases have a low order of substrate specificity. This lack of substrate specificity makes them ideally suitable as detoxication enzymes. Whether or not they evolved as detoxication enzymes or represent enzymes of normal metabolism whose lack of specificity make them suitable for detoxication is open to debate. Of interest in this respect is that they occur only in higher organisms. Glucuronosyltransferases have been found in all mammals, birds, and reptiles that have been investigated, although their specific activities toward specific substrates may vary among different species and strains. Unlike the monooxygenase, they have not been found in bacteria and less developed species. This fact, among others, lends support to Dutton's hypothesis that these transferases evolved to metabolize endogenous compounds, such as bilirubin, catecholamines, and steroids, and not as detoxication enzymes (39).

Table 3.5 Functional groups forming glucuronides

Functional group	Compound class	Example
Hydroxyl → *O*-glucuronide	Alcohols	
—C—OH → —C—O—Glucuronic acid	Aliphatic	Trichlorethanol
	Alicyclic	Hexobarbital
	Benzylic	Methylphenylcarbinol
N—OH → N—O—Glucuronic acid	Phenolic	Phenol
	Enols	4-Hydroxycoumarin
	Hydroxyamines	*N*-hydroxy-2-acetylaminofluorene
Carboxyl → *O*-glucuronide	Carboxylic acids	
	Aliphatic	2-Ethylhexanoic acid
C(=O)—OH → C(=O)—O—Glucuronic acid		
	Aromatic	Benzoic acid
Amine → *N*-glucuronide	Arylalkyl	Phenylacetic acid
N-glucuronic acid	Heterocyclic	Nicotinic acid
—O—C(=O)—N(H)-glucuronic acid		
(R_3)—N^+—glucuronic acid		
	Aromatic	Aniline
R—SO_2—N(H)—glucuronic acid	Carbamate	Meprobamate
	Aliphatic tertiary	Tripelennamine cotinine
	Amine	
	Sulfonamide	Sulfadimethoxine
Sulfhydryl→S-glucuronide		
O—*S*—glucuronic acid	Heterocyclic	Sulfisoxazole
C—*S*—glucuronic acid	Arylthiol	Thiophenol
Carbon→C—glucuronide		
C—glucuronic acid		
	Dithiocarbamic acid	
	1,3-Dicarbonyl system	Phenylbutazone

Modified from Reference 81.

Table 3.5 illustrates the functional groups, generally nucleophilic heteroatoms, that form glucuronides, and examples of the reactions. The glucuronides formed from these functional groups have different properties. Stability is among the most important with respect to detoxication. Breakdown of the glucuronide can lead to reformation of the parent compound, and in certain cases the production of highly reactive electrophilic species. These reactive species may be responsible for the production of acute and chronic toxicity by covalent binding to nucleophilic sites on tissue macromolecules.

Among the most commonly encountered glucuronides are those involving linkage of glucuronic acid and

the xenobiotic through an oxygen atom. These Oglucuronides may form with a number of chemical classes including, aryl, alkyl, and acyl compounds, as illustrated in Table 3.5.
The alkyl-O-glucuronides are ether-linked glucuronides that can form from a variety of primary, secondary, and tertiary alcohols. Although generally stable at physiological conditions, they can be hydrolyzed under acidic conditions.
The enolic glucuronides are formed from aglycones without a free hydroxyl group. Glucuronides are formed from the enolized keto group. These conjugates lack the stability of the ether glucuronides and are susceptible

to both acid and alkaline hydrolysis. They are more stable at neutral and alkaline pH than in acid conditions. Ester glucuronides can be produced from a variety of carboxylic acids, including primary, secondary and tertiary aliphatic acids and both aryl and heterocyclic compounds. They generally are stable in acidic conditions but are susceptible to alkaline hydrolysis.

The chemical properties of *N*-glucuronides are different from those of *O*-glucuronides. One of the most important of these is their lack of stability. They are especially unstable at pH below neutrality. The instability of these compounds may have important biological consequences; examples are discussed in more detail later. Quanternary ammonium N-glucuronides are formed by *N*-glucuronidation of cyclic and acyclic tertiary amines. These charged metabolites can be major metabolites of certain xenobiotics in higher primates while not being found in other animal models, such as the rat.

The *S*-glucuronides are not as commonly encountered as the *O*-glucuronides, but they represent important detoxication pathways for thiolic compounds. Their stability is similar to that of the Oglucuronides.

The *C*-glucuronides represent recently recognized conjugates, and only a few examples are known, such as phenylbutazone. Generally, they appear to be formed by the transferase, but other possible mechanisms of formation have been suggested.

Role of UDP-glucuronosyltransferases in Detoxication and Metabolic Activation

The foregoing discussion indicates that the UDP-glucuronosyltransferases play a critical role in the metabolism and detoxication of xenobiotics. Some substrates require functionalization by the monooxygenase before metabolism by the transferase, whereas others can be directly conjugated. The conjugates are more water soluble than the parent xenobiotic, and some readily form salts. Addition of the glycone may enable some of the conjugates to be more readily excreted through carrier-mediated mechanisms. Mechanisms other than increased excretion rates may also be important. The addition of the relatively bulky glycone may hide or hinder the biological reactivity of particular functional groups on the xenobiotic. In addition, binding of the toxicant to particular receptors responsible for toxicity may be blocked. Overall, these mechanisms represent an efficient system for detoxication. On the other hand, glucuronidation of certain compounds represents a metabolic activation where the product is more toxic than the parent compound.

Aromatic amines are among the most studied examples of the role glucuronidation plays in metabolic activation of carcinogens. These glucuronides transport the proximate carcinogen to the target site, where it decomposes to the species that react with cellular macromolecules producing the biochemical lesion responsible for generating the pathological lesion.

Several of the arylamines are potent bladder carcinogens, including 4-aminobiphenyl, 1-naphthylamine, and benzidine. Metabolic activation of these carcinogens to the ultimate carcinogen appears similar and requires the action of UDP-glucuronosyltransferase. Metabolic activation begins with P450-dependent activation of the arylamine to the proximate carcinogen, an *N*-hydroxyarylamine. Other specific ring hydroxylated forms may be produced and may represent more stable products. The unstable *N*-hydroxyarylamines are then converted to stable N-glucuronides. These *N*-glucuro-nides are transported to the bladder. In the bladder, the *N*-glucuronides are subject to *β*-glucuronidase activity, which splits off the glycone. They are also subject to hydrolysis in acidic urine producing the *N*-hydro-xyarylamine. The *N*-hydroxyarylamine spontaneously converts to the electrophilic arylnitrenium ion as illustrated in Figure 3.9.

The electrophilic arylnitrenium ion can then react with nucleophilic centers on macromolecules of the bladder epithelium, especially DNA, to initiate tumor formation. The concentration of the glucuronide in the bladder, in combination with the time the glucuronide remains in

FIG. 3.9. Metabolic activation of aromatic amines via glucuronidation.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_105.html[2010/10/28 18:40:46]

the bladder, can modify the potential for tumor formation. Glucuronides may function in this manner with a number of carcinogens and be important in explaining why certain target organs are susceptible to a specific carcinogen and others are not susceptible. In the above example, glucuronidation may protect the liver but make the bladder, the target organ, susceptible.

Glucuronidation has also been implicated in adverse drug reactions of certain carboxylic drugs, which resulted in a toxic immunological response. It is believed that a reactive glucuronide covalently binds to cellular proteins that act as haptens, producing an anaphylactic reaction.

Stable expression of cloned UDP-glucuronosyltransferases in tissue culture cell lines is providing a powerful new tool for understanding their role in the biotransformation of xenobiotics (21).

Species, Gender, and Genetic Differences in UDP-glucuronosyltransferase Activity

Studies of species, strain, and gender differences in glucuronidation are complicated by a number of factors. Activity may be affected by age, hormonal status, environmental exposure to xenobiotics in the diet and other sources, and by nutrition status. Factors associated with the methodology to determine differences in glucuronidation also play a role, including substrate, assay method, method of freeing latent activity, and the method of isolating the preparation employed to measure activity. This has led to a number of reports of differences in activity that could be artifactual. However, the large number of reports concerning differences in glucuronidation among species, strains, and the sexes indicate that certain of these differences are real and may have a genetic basis.

As mentioned previously, lower animals, including prokaryotes and invertebrates, do not produce glucuronides. Fish and reptiles do demonstrate glucuronidation of xenobiotics, but vary dramatically in activity, which is generally 10-fold or more lower than mammalian activity. Birds have glucuronidation ability similar to that of mammals.

Differences among mammalian species in their ability to glucuronidate a xenobiotic may be quite large; however, as mentioned, in some cases this could be artifactual. The guinea pig generally has higher activity than most other laboratory species. This higher activity may be associated with less latent enzyme activity, as its UDPG-glucuronosyltransferases can be activated by much gentler methods than other species. Cats are well known for their extremely low transferase activity. Although capable of forming glucuronides with endogenous compounds, they form only low levels or no glucuronides with xenobiotics.

Glucuronidation of amines is divided into two groups: nonquaternary N-conjugates and quaternary N-conjugates. There does not appear to be major species differences with the nonquaternary N-conjugate group, sulfonamides, arylamines, and cyclic and heterocyclic amines, although quantitative differences do exist. Quaternary glucuronidation occurs in primates, including humans, but not in other species. In humans, quaternary ammonium-linked glucuronides of aliphatic amines appear to be produced by UGT1A3 and UGT1A4 (28, 61).

A well-known example of a strain difference is the almost complete lack of bilirubin glucuronidation in the Gunn rat. This rat strain also has low activity toward a number of xenobiotic substrates, but normal activity toward others. There is a genetic component to this, with the low activity being autosomally recessive. The mutation in the Gunn rat responsible for its lack of bilirubin conjugation occurs in the UGT1 family and affects this entire group of isozymes. A frameshift mutation occurs because of a deleted guanine that results in a TGA stop codon occurring sooner than normal. This mutation results in a protein missing 115 amino acids that constitute a hydrophobic region associated with insertion of the protein into the membrane. Lack of insertion negates the activity of this enzyme form and results in degradation of the incomplete protein. The genes in the UGT2 family are normally expressed in the Gunn rat.

Similar defects occur in humans and are known as *unconjugated hyperbilirubinemias*. Gilbert's syndrome is a milder form of the disease that occurs in 2%–5% of the population. This large prevalence in the population makes it an important human genetic deficiency when considering interindividual variation in xenobiotic metabolism. These patients are characterized by mild, chronic, unconjugated hyperbilirubinemia that produces jaundice and an impaired ability to metabolize menthol. Decreased clearance of several drugs, including tolbutamide, rifamycin, josamycin, and paracetamol, has been observed. Crigler-Najjar syndrome is a familial form of severe unconjugated hyperbilirubinemia. Infants often developed severe neurological damage from bilirubin encephalopathy (kernicterus). Patients are divided into two types. Type I is more severe (unconjugated bilirubin >20 mg/dl) and not responsive to barbiturate or glutethimide therapy. Type II patients respond to induction by phenobarbital, which suggests a fundamental difference from type I in the molecular basis of the genetic defect. Type I results from mutations in the UGT1 family that produces a loss of bilirubin conjugation (29), whereas

less severe mutations occur in type II that produce a decrease, but not a loss, of activity.
Gender differences appear hormonally related (166) and can be substrate dependent. Although it is sometimes stated that males have higher glucuronidation activity

than females, this is substrate dependent, and no general classification should be made. Like monooxygenase activity, activity may be sensitive to imprinting or programming during the neonatal period. As with species and strain differences, care must be taken when extrapolating data obtained with one substrate to other substrates.

Glucuronidation of estradiol and estrone is higher in female rats than male rats (193). Paracetamol, oxazepam, and diflunisal are cleared 30%-50% faster in males, due primarily to enhanced glucuronidation.

Induction of the Glucuronosyltransferases

UDP-glucuronosyltransferases are inducible enzymes, much like cytochrome P450. They are inducible by some of the same inducers. Evidence of a true induction process involving *de novo* protein synthesis and increases in mRNA has been observed for induction of the UDP-glucuronosyltransferases by phenobarbital. Most inducers of CYP1A, CYP2B, CYP3A, and CYP4A can induce these transferases. Rat UGT1A6 and UGT1A7 and human UGT1A6 and UGT1A9 are polycyclic hydrocarbon-inducible transferases. Induction appears mediated by the Ah receptor. Rat UGT1A7 and human UGT1A9 have high activity toward the phenolic and diphenolic metabolites of polycyclics, such as benzo(a)pyrene (11). Few specific inducers of the transferases that do not also induce the monooxygenase are known. For example, trans-stilbene oxide and ethoxyquin appear to only induce the transferases, but more studies are needed to determine if this is a true induction. Induction of the transferases modifies the toxicity of xenobiotics in a manner similar to induction of P450, as previously discussed.

Sulfation: Sulfotransferases

As early as 1815, it was recognized that mammals excrete organic sulfates in their urine (68). The discovery that these organic sulfates were esters produced in the mammalian body by conjugation of endogenous organic compounds with inorganic sulfate came about 50 years later (16). The sulfate conjugates were believed to be ethers formed between the organic aryl group and the inorganic sulfate group. Therefore, they called the urinary fraction containing these metabolites *ethereal sulfates;* however, these metabolites are actually esters of sulfuric acid, and the term ethereal sulfate is only of historical significance (121).

Sulfation, or more appropriately, sulfonation, of xenobiotics and endobiotics is catalyzed by a set of enzymes called *sulfotransferases* (EC 2.8.2). These enzymes belong to a multigene family and occur in prokaryotes, plants, and animals. Some of the enzymes are membrane bound and others occur in the cytosol. The membrane-bound sulfotransferases are found in the Golgi membranes and are involved in the sulfation of endogenous compounds, such as glycosaminoglycans, glycoproteins, and proteins, and peptides secreted by the Golgi apparatus; they are not involved in xenobiotic metabolism. The soluble sulfotransferases can also sulfate endogenous compounds, such as steroids and thyroid hormones, and are involved in the metabolism of xenobiotics. For the most part, sulfation of xenobiotics results in metabolites that are less toxic than the parent compound; however, the sulfotransferases, like many xenobiotic metabolism enzymes, can produce metabolically activated products that have mutagenic and carcinogenic potential.

Until recently, the sulfotransferases have not been as intensely investigated as some of the other xenobiotic metabolism enzymes. Currently there is renewed interest in these enzymes based, in part, on attempts to understand their role in metabolic activation. Utilization of the tools of molecular biology has provided new insight into their roles in metabolism and has revealed the complexity of their gene family (38, 139). The ability to sequence the sulfotransferases and identify new isoforms of these enzymes has progressed faster than our understanding of their individual roles in xenobiotic metabolism. The availability of expression systems that express single and multiple sulfotransferases is providing toxicologists a powerful tool to investigate their roles in xenobiotic metabolism.

Biochemistry of Sulfation

A limiting factor in the sulfation of xenobiotics by the sulfotransferases is the availability of 3-phosphoadenosine 5′-phosphosulfate (PAPS) (reviewed in (85)). As illustrated in Figure 3.10, PAPS is synthesized in a two-step process. The first step is formation of adenosine 5′-phosphosulfate (APS) catalyzed by ATP-sulfurylase. Although the synthesis of APS from sulfate and ATP is not energetically favored, the rapid hydrolysis of pyrophosphate and the rapid utilization of APS as a substrate for APS-kinase drives the reaction toward APS synthesis. APS-kinase catalyzes synthesis of PAPS from APS and ATP. This enzyme is tightly coupled with the ATP-sulfurylase, which results in the rapid utilization of APS.

Tissue concentration of PAPS is relatively low (4–80 ng/g tissue), compared to UDPGA, the active form of glucuronic acid used in glucuronidation (200 nmol/g liver). During active sulfation, PAPS becomes

rapidly depleted. For example, the sulfotransferase has a high affinity of acetaminophen, which forms a sulfate con

ATP + $SO_4^{=}$ → (ATP—sulfurylase) Adenosine 5'—phosphosulfate (APS) + Pyrophosphate (PPi)

APS + ATP → (APS—kinase) 3'—Phosphoadenosine 5'—phosphosulfate (PAPS) + ADP

2ATP + SO_4^{2-} → ADP + PAPS + PPi

Overall Stoichiometry

FIG. 3.10. Reactions catalyzing the formation of PAPS from inorganic sulfate and ATP.

jugate. (See Figure 3.6). At low doses, rats excrete the sulfated acetaminophen as a major urinary metabolite. As the dose of acetaminophen is increased, the sulfate metabolite does not increase, whereas the glucuronide of acetaminophen increases dramatically; this is believed to be due to the limited availability of PAPS. The limitation in the synthesis of PAPS is sulfate. The major sources of sulfate include diet and degradation of sulfur amino acids (methionine and cysteine). These sources are inadequate to maintain sulfate concentrations for PAPS synthesis during rapid sulfotransferase activity. In the mouse, sulfation appears more limited by sulfotransferase activity than by PAPS and sulfate.

Reactions Catalyzed by Sulfotransferases

As mentioned, sulfotransferases esterify a variety of endogenous substrates, including steroids, carbohydrates, and proteins. Sulfation also plays a role in the disposition of hormones. Sulfation directs lipophilic compounds, such as the steroidal hormones, to more polar environments, including the active sites of enzymes and to body fluids. For example, sulfation enhances the elimination of steroids from the adrenal gland (116). Sulfation also facilitates deiodination of thyroid hormone and is a rate-limiting step in one of the elimination pathways of thyroid hormone (179).

Xenobiotic conjugation with sulfate (Figure 3.11) is an important route for conversion of lipophilic xenobiotics to more readily excreted polar metabolites (Table 3.6) (79, 151). Sulfation of xenobiotics with an aliphatic or aromatic hydroxyl group readily occurs. For example, phenol is excreted as its sulfate conjugate (Figure 3.12). Often it is necessary for phase I metabolism to functionalize a xenobiotic with a hydroxyl group before it can be sulfated. For example, toluene is oxidized to benzyl alcohol before conjugation with sulfate (Figure 3.12).

Role of Sulfotransferases in Detoxication and Metabolic Activation

Alcohols, phenols, aliphatic and aromatic amines, and aromatic hydroxyamines and hydroxyamides can be

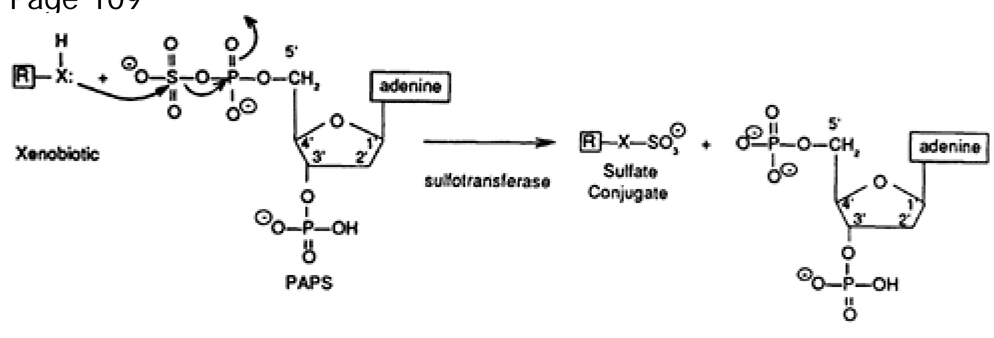

FIG. 3.11. Synthesis of a sulfate conjugate from a model xenobiotic by sulfotransferase.

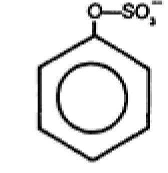
Table 3.6 Sulfotransferases involved in the metabolism of xenobiotics

EC No.	Name	Example substrates
2.8.2.1	Arylsulfotransferase	2-naphthol, phenol, substituted phenols, serotonin, acetaminophen
2.8.2.2	Alcohol sulfotransferase (also called hydrosteroid sulfotransferase)	Primary and secondary aliphatic alcohols, nonaromatic hydroxysteroids
2.8.2.4	Estrone sulfotransferase	Estrone and other aromatic hydroxysteroids
2.8.2.9	Tyrosine ester sulfotransferase	Tyrosine methyl ester, 2-cyanoethyl-Nhydroxythioacetamide
2.8.2.14	Bile salt sufotransferase	Conjugated and unconjugated bile acids



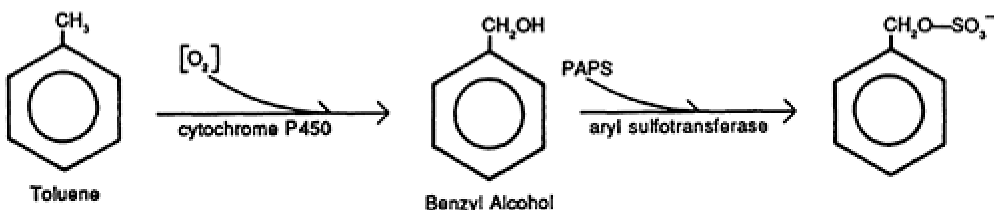


FIG. 3.12. Sulfotransferase-catalyzed sulfation of phenol and toluene.

sulfated. These same groups can form glucuronides. At low doses, sulfation may play an important role in detoxication of xenobiotics; however, as acetaminophen demonstrates, at high doses glucuronidation becomes more important because of sulfate limitations. Secondary effects may be produced by sulfation lowering sulfate availability for the sulfation of endogenous substrates. Sulfotransferases can be involved in the conversion of pro-drugs to their active forms. For instance, minoxidil is sulfoconjugated to its active form, which is more active as an antihypertensive and hair-growth stimulate than the parent drug.

Sulfotransferases can be involved in the metabolic activation of a number of mutagens and carcinogens. One of the best known examples is the metabolic activation of the carcinogen 2-acetylaminofluorene (illustrated in Figure 3.13). *N*-hydroxylation of the amide nitrogen by monooxygenases is followed by sulfation of the *N*-hydroxy group. The sulfate ester is unstable and decomposes to an electrophilic nitrenium ion-carbonium resonance ion that can form covalent adducts at nucleophilic sites on macromolecules. Support for the hypothesis that the sulfate conjugate of 2-AAF is the reactive metabolite comes from studies indicating factors that modulate sulfotransferase activity also modulate 2-AAF carcinogenicity. Male rats have higher sulfotransferase activity and develop more 2-AAF-induced tumors than females. Reduction of sulfotransferase activity in male rats by castration, hypophysectomy, thyroidectomy, or steroid hormones

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_110.html[2010/10/28 18:40:49]

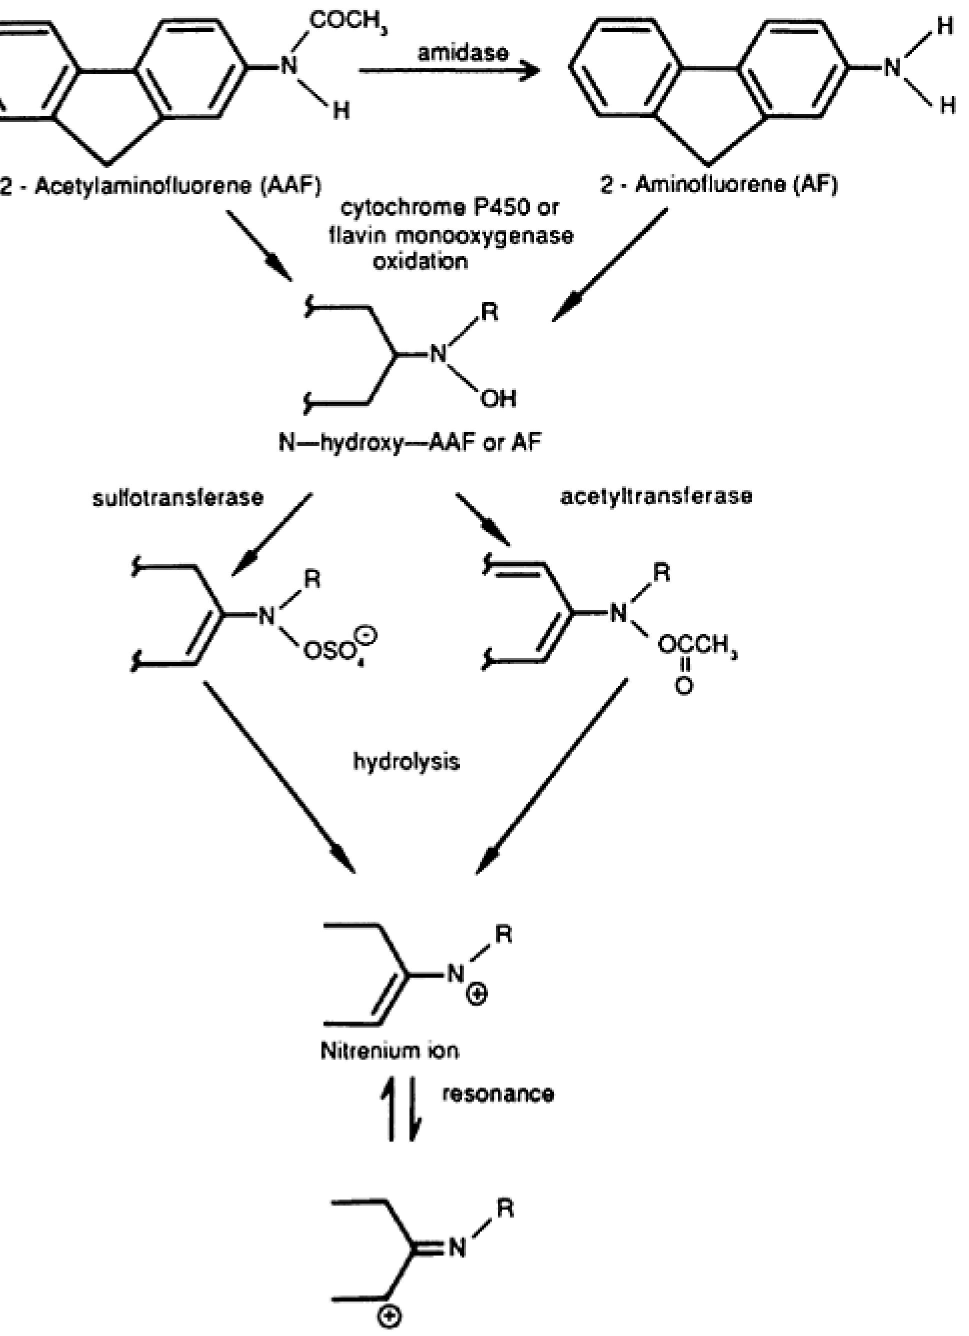

FIG. 3.13. Metabolic activation of 2-acetylaminofluorene to a reactive metabolite capable of covalent modification of macromolecules.

reduces 2-AAF covalent adducts. These results are consistent with the hypothesis that sulfation of 2-AAF is required for covalent modification of DNA. This mechanism is at least partially responsible for the activation of several other xenobiotics, including aromatic amines, mono- and dinitrotoluene, *N*-hydroxyphenacetin, I′-hy-droxysafrole, *N*3-hydroxyxanthine, and other N-hydroxyarylamides (122). Secondary nitroalkanes, such as 2-nitrobutane and 3-nitropentane, can be metabolically activated by aryl sulfotransferase to mutagens and hepatocarcinogens. Primary nitroalkanes, such as 1-butane and 1-nitropentane, are not activated by aryl sulfotransferase (46).

Sulfotransferases can metabolically activate certain products of CYP1A1 metabolism of polycyclic hydrocarbons. For example, 9-hydroxymethylbenzo(a)pyrene (*see* Figure 3.4) can be sulfated to yield a highly reactive sulfate ester that is heterolytically cleaved to produce an electrophilic cation that damages DNA, RNA, and protein. In addition, 6-hydroxymethylbenzo(a)pyrene can be activated to the carcinogenic 6-sulfooxymethylbenzo(a)pyrene by rat and mouse sulfotransferase (47). Other examples include 5-hydroxymethylchrysene and 7,12-dihydroxymethyl benz(a)anthracene (184). The potential for sulfotransferases to metabolically activate xenobiotics has resulted in the development of new assay systems for genotoxicity. For instance, Glatt's laboratory (55, 56) has developed *Salmonella* strains that express rat and human sulfotransferase activity for use in Ames assays. They have also developed Chinese hamster V79-derived cells that express rat sulfotransferase activity.

Sulfotransferase Isoforms, Genetics, and Species Differences

Sulfotransferases belong to a multigene family that produces a number of distinct enzymes that have different, but overlapping, substrate specificities. Some of these enzymes demonstrate species and even tissue specificity in their expression. It is expected that more detailed analysis will identify additional sulfotransferases.

The nomenclature used to describe these enzymes is still evolving, and there is no universal naming system, as yet. Weinshilboum et al. (186) have divided 30 of the known cDNA sequences into three families that have at least a 45% amino acid sequence identity, then into subfamilies with at least 60% homology. Two of the families are expressed in animals and one in plants. The two animal families represent phenol-sulfotransferases and hydroxysteroid sulfotransferases, and the phenol-sulfotransferase are divided into the phenol group and estrogen group. The phenol group contains three human genes, two mouse genes, and one rat gene. The estrogen group contains one human gene, two rat genes, and one mouse gene. The hydroxysteroid family contains one human gene, three rat genes, and three mouse genes. Undoubtedly, more genes will be discovered and the classification system refined; however, this classification demonstrates the diversity of genes in the sulfotransferase family.

Amino acid sequence data indicate that four regions of sulfotransferases have been highly conserved among species. One region, near the carboxy terminus of the proteins, is believed to be the PAPS binding site. A critical lysine may be involved in stabilization of an intermediate form during catalysis.

Humans demonstrate sulfotransferase genetic polymorphisms, which help explain some of the differences between individuals in response to specific xenobiotics. Because sulfotransferases do not appear to be as sensitive to xenobiotic induction of their activity, exposure to xenobiotics may not be as important as with some of the other xenobiotic metabolizing enzymes in producing individual variations in metabolism.

Sulfation occurs in most species, including mammals, birds, reptiles, amphibians, fish, and invertebrates. The most notable exception to this is the low sulfotransferase activity in the pig. Members of the cat family are deficient in glucuronyltransferase activity but have high sulfotransferase activity. This balance of glucuronyltransferase and sulfotransferase must always be kept in mind when evaluating the activity of either enzyme system. A deficiency in one pathway can shift metabolism, as similar functional groups are conjugated by the two enzyme systems. In addition, sulfation appears to have high affinity but low capacity for phenols, whereas glucuronidation has low affinity and high capacity for these substrates.

A large part of our understanding of sulfotransferases comes from study of purified rat enzymes. There are at least six different phenol sulfotransferases and seven different forms of rat liver steroid/bile acid sulfotransferases. By contrast, only three distinct isozymes of cytosolic sulfotransferase have been isolated: two phenol-sulfotransferases and one bile acid sulfotransferase. The two phenol sulfotransferases have been referred to as the monoamine-sulfating form and the phenol-sulfating form. Dopamine, epinephrine, and levodopa are substrates for the monoamine form, and 4-nitrophenol, minoxidil, and acetaminophen are substrates for the phenol form (45).

There is wide species variation in sulfation of two model substrates: isoprenalin and harmol. For example, the activity toward isoprenalin in mouse liver is 10 times that in monkey liver. Sulfation of acetaminophen is limited by PAPS availability in rats. In mice, acetaminophen sulfation is limited by

lower sulfotransferase activity. Although mice have lower PAPS synthetic capability than

< previous page page_111 next page >

rats, lower sulfotransferase activity is the major limiting factor in mice (98). The activity of acetaminophen sulfotransferase and 17 α-ethinylestradiol sulfotransferase in hepatic preparations from monkeys, dogs, and humans were compared. Rhesus and cynomolgus monkeys and dogs had higher activity acetaminophen sulfotransferase than humans (152).

Four cytosolic sulfotransferases, distinguished by their substrate specificity, have been found in human tissues. Dehydroepiandrosterone or hydroxsteroid sulfotransferases appear to be involved in sulfation of steroids and may be important in regulating their activity and in bile acid sulfation and excretion. Estrogen sulfotransferase is involved in the inactivation of estrogens in target tissue. Other sulfotransferases can also sulfate estrogen, but with lower activity. This transferase does not appear to play an important role in xenobiotic metabolism.

The other two cytosolic sulfotransferases belong to the phenol sulfotransferase group and are involved in xenobiotic metabolism. Phenol-sulfotransferases (PST) are found in a number of tissues, and their discovery in blood platelets has provided an important source for their study. They are divided into two groups: P-PST and M-PST. P-PST sulfates phenols, such as p-nitrophenol and α-naphthol, and aromatic amines, such as 2-naphthylamine. M-PST sulfates monoamine neurotransmitters. Again, substrate specificity overlaps as demonstrated by acetaminophen, which can be sulfated by both sulfotransferases. As mentioned, nomenclature for the sulfotransferases is currently under development and can cause confusion. Some investigators use the term *aryl sulfotransferase* for a gene family that includes sulfotransferases found in rats, humans, and mice that have a 70% sequence homology and catalyze the sulfation of dopamine, p-nitrophenol, estradiol, and other phenols.

Factors Modifying Metabolism

Sulfotransferases are not induced by the classical inducers, phenobarbital and 3-methylcholanthrene, and these compounds may actually suppress their expression (146). Several inhibitors of sulfotransferase have been discovered and exploited experimentally to study these enzymes. Pentachlorophenol and 2,6-dichloro-4-nitrophenol are potent sulfotransferase inhibitors. Only 0.2 μM pentachlorophenol is required for 50% inhibition of 2-dichloro-4-nitrophenol sulfation by purified arylsulfotransferase (77). Pentachlorophenol and 2,6-dichloro-4-nitrophenol are effective inhibitors because the *ortho*- and *para*-aromatic ring positions are substituted with electron-withdrawing groups. This effect is consistent with the mechanism whereby the sulfotransferases facilitate electrophilic attack of the hydroxyl oxygen by the sulfur (Figure 3.11).

Gender Differences

There are major gender differences in the sulfate conjugation of steroid hormones. For example, female rats have fivefold higher activity for cortisol metabolism than do male rats (154). This gender difference in cortisol metabolism is apparently due more to suppression of sulfotransferase by male hormone levels than to stimulation by the ovaries (153, 155). Three steroid sulfotransferases have been isolated from rat liver, and it is the relative amounts of these isozymes that account for the large gender difference. Aryl sulfotransferase concentrations in the livers of male rats were higher than in females. In contrast, hydroxysteroid sulfotransferase concentration was higher in the liver of female rats compared to males (26).

Lower sulfotransferase activity observed in neonatal rats has been attributed to sexual immaturity because as gonads develop, sulfotransferase activity increases. Newborn infants, who characteristically exhibit pronounced immaturity in glucuronidation, have a fully developed phenol sulfotransferase activity. For example, newborns excrete acetaminophen as a sulfate conjugate, whereas adults primarily excrete it as a glucuronide conjugate. Chloramphenicol is extremely toxic in neonates because it is a poor substrate for sulfotransferase and is primarily cleared by glucuronidation in adults.

Glutathione S-transferases

A family of cytosolic enzymes known as *glutathione S-transferases* is capable of conjugating relatively hydrophobic electrophilic molecules with the nucleophile-reduced glutathione (Figure 3.14) (24). These enzymes are found in highest concentrations in the liver, kidney, intestines, and lung, but they occur in most tissues. Glutathione conjugates have higher molecular weights and are more water soluble and more likely to be excreted in urine and bile than are the parent compounds. Conjugation with glutathione makes it unlikely the xenobiotic will react with toxicological targets.

Glutathione *S*-transferases involved in xenobiotic metabolism are cytosolic proteins that catalyze the conjugation of glutathione with a substrate bearing an electrophilic atom (74). The transferases facilitate the nucleophilic attack of glutathione thiolate ion (GS−) on the electron-deficient atom of a relatively hydrophobic electrophilic xenobiotic. There is little specificity in the active site for the xenobiotic other than it must possess hydrophobic character. Substrates for the glutathione *S*-transferases can react with

glutathione nonenzymati

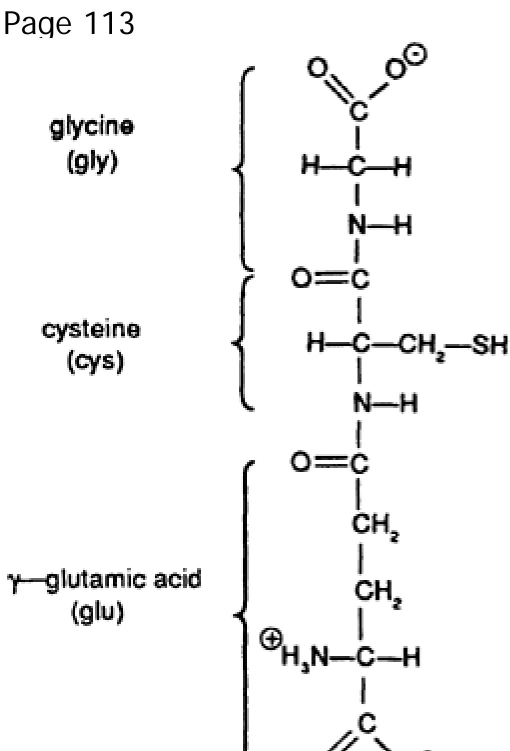

FIG. 3.14. Structure of reduced glutathione (MW 307).

cally but at slower rates than the enzyme-catalyzed reaction.

In addition to catalyzing the conjugation of xenobiotics with glutathione, glutathione *S*-transferases are capable of binding the chemical on the enzyme surface. This binding may or may not inhibit the catalytic activity of the enzyme, but it prevents the xenobiotic from interacting with other critical cellular sites, such as proteins and nucleic acids. A glutathione *S*-transferase possessing this property has been called *ligandin* (161, 162). Glutathione *S*-transferases can form covalent bonds between reactive xenobiotics and the enzyme's active site. Binding inactivates the enzyme but also inactivates the reactive xenobiotic and represents an additional detoxication mechanism (76). This process is called *suicide inactivation* and is seen with other detoxication enzymes, such as P450.

Because of these three activities of the glutathione *S*-transferases, the enzymes have been called "a triple threat in detoxification" by Jakoby and Keen (76). Glutathione and the glutathione S-transferases can detoxify a broad spectrum of compounds that the organism either may encounter in its environment or generate during normal cellular metabolism. Although not highly efficient in its reactions (operates at relatively high concentrations of the xenobiotic), glutathione S-transferases are capable of catalyzing or reacting with a number of reactive chemical functional groups. Any lack of efficiency is made up by the high cellular concentration of glutathione and glutathione *S*-transferase. Liver glutathione concentrations are high (10 mM) and glutathione S-transferases can represent as much as 10% of the total hepatocellular proteins (2); however, it is possible for glutathione conjugation to become capacity limited at high doses of xenobiotics. Glutathione utilization can be faster than its synthesis, resulting in decreased conjugation and increased toxicity.

Bromobenzene metabolism is an example of a compound whose glutathione conjugate protects the liver from the toxicity of its P450-generated epoxide. At doses that deplete the cytosolic store of glutathione, the epoxide produces severe hepatotoxicity. Another example is acetaminophen. It is a very safe drug, but at extremely high doses, where glutathione is depleted by reaction with its activated metabolite, *N*-acetyl-benzoquinoneimine (see Figure 3.6), it produces hepatic necrosis.

Glutathione *S*-transferase enzymes are dimers of two protein subunits. They may exist as homodimers, where each subunit is identical, or as heterodimers, where the subunits are expressed by different genes. These transferases are inducible by the classical P450 inducers phenobarbital and 3-methylcholanthrene. The region of the gene that controls the expression of some of these transferases contains the xenobiotic-responsive element (XRE) previously discussed for P450 induction. In the case of the transferases that are heterodimers, the expression of each subunit may be independently regulated. Different glutathione *S*-transferases have substrate preferences but not a high order of substrate

specificity. Substrate selectivity of these enzymes can be based on small changes in the primary structure of the enzymes. For instance, a glutathione *S*-transferase of the P-class contains a tyrosine at a site important for selectivity, whereas a transferase of the A-class contains a valine. When the tyrosine of the P-class enzyme is replaced with a valine, its substrate selectively is changed toward that of the A-class (125).

Biochemistry of Glutathione S-transferases

Although the urinary metabolites of glutathione conjugation, mercapturic acids, were first described in the 19th century (16), it was not until the 1950s that glutathione (Figure 3.14) was identified as the source of the cysteine in the mercapturic acid (189). Glutathione is synthesized in the cytosol of most cells by the gamma-glutamyl cycle, a series of six, tightly controlled, enzyme-catalyzed reactions (Figure 3.15). The three amino acids that comprise glutathione—cysteine, glycine, and glutamic acid—can enter the cycle from several biochemical pathways, although the cycle depicts them arising from glutathione. Some xenobiotics contain sufficiently electrophilic groups to react directly with glutathione, whereas others must first undergo phase I metabolism. Most xenobiotics react with glutathione through the catalytic activity of

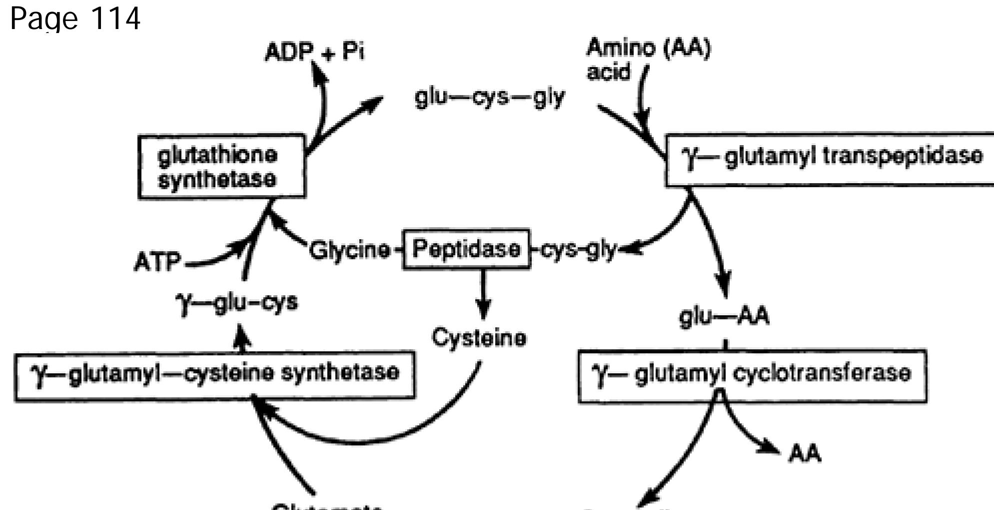

FIG. 3.15. The γ-glutamyl cycle responsible for the biosynthesis of reduced glutathione.

the glutathione S-transferases. Glutathione *S*-transferase reactions fall into four broad categories, as depicted in Figure 3.16: reaction with (1) electrophilic carbon, (2) nitrogen, (3) sulfur, and (4) oxygen (50, 65, 75).

Reaction with Electrophilic Carbon

The reactions of glutathione with electrophilic carbon can be divided into three types, as shown in Figure 3.16: (a) displacement reactions, (b) opening of strained rings, and (c) addition to activated double bonds.

(a) *Displacement of leaving groups such as halides, sulfates, sulfonates, phosphates, and nitro groups from saturated carbon or heteroatoms.* Displacement is facilitated if the saturated carbon atom is allylic or benzylic. Displacement of halide or nitro groups on aromatic rings occurs if there are sufficient electron-withdrawing groups that predispose the ring system toward nucleophilic substitution. The rate of formation of a carbanion intermediate of the aromatic ring governs the overall rate of the reaction. Functional groups that withdraw electrons stabilize the carbanion and

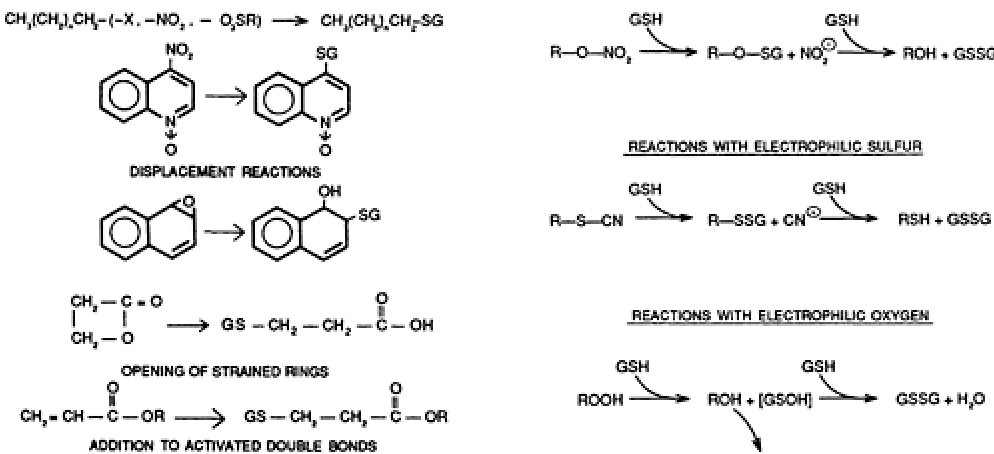

FIG. 3.16. Examples of the reactions catalyzed by the glutathione S-transferases.

FIG. 3.17. Putative reaction mechanisms for the glutathione *S*-transferase-catalyzed nucleophilic attack of the glutathione thiolate anion on electrophilic xenobiotics where X represents a halogen and R and A represents the listed substituents.

are considered "good leaving groups." Those that donate electrons to the ring deactivate the ring, making displacement of the leaving group by glutathione less likely (Figure 3.16).

(b) *Opening of strained rings, such as epoxides and 4-membered lactones.* As shown in Figure 3.16, the 1,2-epoxide of naphthalene is opened, resulting in a 1-napthol conjugate of glutathione. These reactions can be stereoselective. Epoxide products of P450 are detoxified by this reaction and are an example of a phase II conjugation of a phase I activated metabolite.

(c) *Addition to activated double bonds via Michael addition.* The glutathione thiolate anion will also attack *β*-unsaturated xenobiotics due to the partial positive charge on the *β*-carbon, as shown in Figure 3.17 (addition reaction). Figure 3.22 illustrates the addition of glutathione to the β-carbon of an acrylate ester.

Reaction with Electrophilic Nitrogen

The reaction sequence and overall stoichiometry for the reaction of organic nitrate esters with glutathione is shown in Figure 3.16. This reaction was once attributed to a glutathione reductase but is now known to be catalyzed by glutathione *S*-transferases. The transferases catalyze the removal of nitrite from the ester, generating an R-O-S conjugate with glutathione. The vasodilators, nitroglycerin and erythrityl tetranitrate, are two organic nitrate ester substrates for this reaction. As seen in Figure 3.16, the alcohol-glutathione conjugate can react nonenzymatically with another reduced glutathione molecule. This yields an alcohol and oxidized glutathione.

Reaction with Electrophilic Sulfur

Alkyl and aryl thiocyanates are substrates for glutathione S-transferase catalyzed conjugations, as shown in Figure 3.16. Products of this nucleophilic attack of the thiolate ion on the sulfur of the xenobiotic result in a mixed disulfide and hydrogen cyanide. The mixed disulfide can react nonenzymatically with another molecule of glutathione to yield a thiol of the xenobiotic (RSH) and oxidized glutathione (GSSG).

Reaction with Electrophilic Oxygen

Figure 3.16 illustrates how glutathione reacts with organic hydroperoxides in a two-step sequence. The first step is catalyzed by glutathione *S*-transferase and forms an alcohol or phenol and a glutathione sulfenic acid intermediate (G-SOH). Another glutathione reacts nonenzymatically with the sulfenic acid to form oxidized glutathione and water. An example of reaction with endogenous hydroperoxides is the conversion of hydroperoxy-PGF2α to PGFa. Cumene hydroperoxide is metabolized as rapidly by purified glutathione *S*-transferases as the classical transferase substrate probe 1-chloro-2,4-dinitrobenzene.

Glutathione S-transferases Nomenclature

The glutathione *S*-transferases were originally named by their substrate specificity, such as S-epoxide trans

ferase and *S*-alkyltransferase. When purification techniques and homogeneous preparations of the transferases became available, it was found that the transferases had overlapping substrate specificity. Nomenclature based on substrate specificity was no longer appropriate. They were then termed based on their elution from carboxymethylcellulose columns used to purify them (78). As the various enzyme subunits were cloned and sequenced, the older nomenclature was inappropriate. A nomenclature that is being used by many investigators is based on the four major classes of cytosolic enzymes (alpha, mu, pi, and theta) and their subunit classifications. A glutathione *S*-transferase in class Alpha with identical class 1 subunits would be GSTAI-1. A heterodimer transferase from the Mu class with class 1 and 2 subunits would be GSTM1-2.

Mercapturic Acid Formation

Mercapturic acids are *N*-acetylated, *S*-substituted, cysteine conjugates that arise from conjugation of a xenobiotic with glutathione (15).

The glutathione conjugates formed in the liver and other tissues as shown in pathway 1 of Figure 3.18 are polar and partition into the aqueous phase of cells and blood. Because 25% of the blood flow passes through the kidney, glutathione conjugates are transported to the kidney via systemic circulation. There, the glutathione conjugate undergoes a series of reactions, shown in pathway 2 of Figure 3.18, which result in mercapturic acid formation.

The initial step in mercapturic acid synthesis is cleavage of glutamic acid from cysteine catalyzed by γ-glutamyltranspeptidase (EC 2.3.2.2). This enzyme is located in the brush border of the proximal tubules in the kidney (187). Evidence that this enzyme is involved in glutathione degradation comes from observations of pronounced glutathionemia and glutathionuria (high levels of glutathione in blood and urine, respectively) in patients who lack detectable γ-glutamyltranspeptidase. This enzyme not only hydrolyzes the glutathione moiety, but also transfers the γ-glutamyl group to a variety of amino acids and dipeptides. These two reactions have been shown to proceed at equivalent rates under physiological conditions (190).

Next, the glycine group is cleaved from the resulting cysteinylglycine conjugate by aminopeptidase M yielding the *S*-substituted cysteine conjugate of the xenobiotic. The cysteine conjugate is a substrate for N-acetyltransferase that acetylates the free amino group of cysteine to yield the mercapturic acid, which is excreted in the urine (pathway 3, Figure 3.18). These two enzymes, γ-glutamyltransferase and aminopeptidase M, are also responsible for the normal turnover of glutathione in mammalian cells previously shown in Figure 3.15.

Role of Glutathione S-transferase in Detoxication

Free reactive electrophilic intermediates of xenobiotics can produce damage to important cellular constituents. Reduced glutathione and the glutathione *S*-transferases protect cells from this damage by capturing the reactive electrophiles before they can react at nucleophilic sites critical to cell viability.

The metabolism of acetaminophen, an analgesic that at high doses can produce hepatic necrosis, serves as an example of this protective system. A large body of work has shown that one of the principal ways in which acetaminophen produces its hepatotoxicity is via the reactive intermediate, N-acetyl-p-benzoquinone imine, as shown in Figure 3.6. This intermediate is an electrophile that reacts readily with the nucleophile glutathione. As long as the amount of glutathione present at the site of activation of acetaminophen is sufficient to bind the reactive intermediate, no toxicity ensues; however, as demonstrated in the classic study by Mitchell (115), when glutathione is depleted by pretreatment with diethyl maleate, the benzoquinone imine covalently binds to tissue proteins resulting in tissue necrosis. Mitchell (115) was among the first to propose that glutathione plays a fundamental role in protecting tissues against electrophilic attack by xenobiotics.

Since these early studies demonstrating the protective role of glutathione, many compounds have been shown to form conjugates with glutathione. For a comprehensive review of these reactions, see (25, 87).

Factors Affecting Metabolism

Glutathione *S*-transferases have been found in most species, including reptiles, birds, insects, amphibians, and plants. Factors that influence the availability of reduced glutathione drastically alter the effectiveness of glutathione *S*-transferases. As was discussed previously, the toxicity of acetaminophen is modulated by the availability of reduced glutathione. Most xenobiotics that are highly reactive nonenzymatically with glutathione can deplete glutathione. Other mechanisms can also lower glutathione availability. For example, certain individuals have genetic defects in the γ-glutamyl cycle, resulting in low tissue concentrations of glutathione. These individuals generally are anemic due to the lack of glutathione and the resulting loss of protection from oxidative damage to erythrocytes (111).

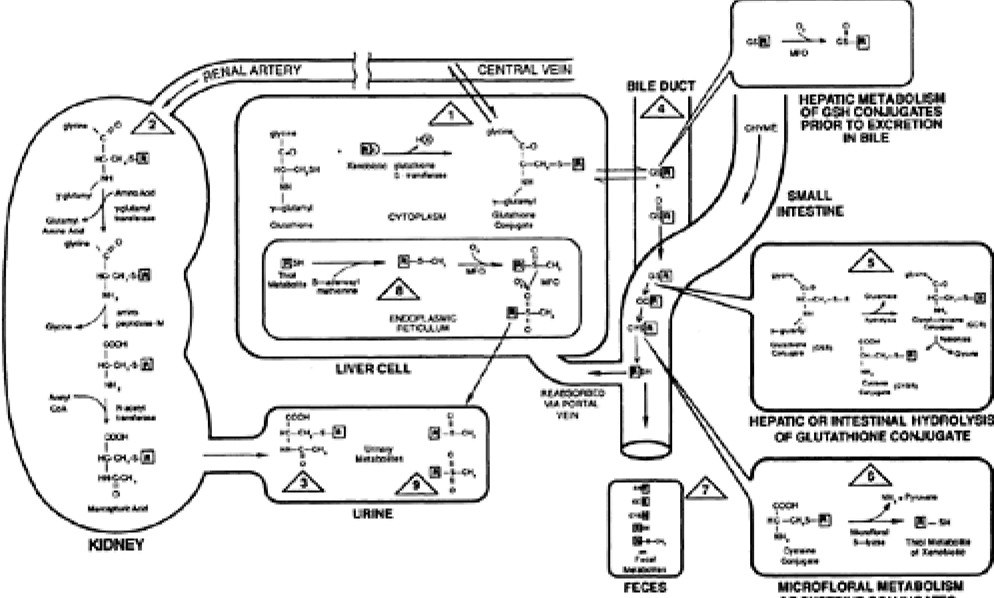

FIG. 3.18 Integration of glutathione conjugate disposition in mammals. Pathway numbers referred to in the text as shown in the triangles.

Cysteine is the limiting factor for synthesis of glutathione via the cycle shown in Figure 3.15. Nutritional factors that limit sulfur amino acid availability decrease glutathione *S*-transferase activity by reducing the availability of glutathione (168). Methionine is an essential amino acid that can be used to synthesize cysteine and cystine via the transsulfuration pathway. If diets low in sulfur amino acids are fed, the availability of glutathione for conjugation with reactive intermediates of xenobiotics can be decreased.
Glutathione *S*-transferases are inducible by phenobarbital and 3-methylcholanthrene. Dietary ingredients, such as cruciferous vegetables, specific components of coffee, butylated hydroxyanisole, and organosulfur compounds of allium vegetables, can also induce glutathione *S*-transferases. For example, when cafestol and kahweol, diterpenes found in coffee, were administered to rats for up to 90 days, DNA adducts produced by aflatoxin B1 were inhibited 50%. This appeared related to induction of glutathione *S*-transferase and a decrease in P450 isozymes involved in the metabolic activation of aflatoxin (23). Coffee consumption has been shown to increase salivary concentrations of the glutathione *S*-transferases in humans (163). Induction may be specific for one or more of the transferases and may be tissue specific. Triphenyltinchloride, bromosulfophthalein, cibracon blue, and hematin are selective inhibitors of the transferase isozymes (175).

Polymorphisms of Glutathione S-transferases

Glutathione *S*-transferases exhibit polymorphic expression in humans, especially GSTM1. A proportion of a population will show low GSTM activity, whereas the majority will show normal activity. Because these enzymes play a critical role in protecting the cell from cytotoxic and mutagenic damage, a number of population studies have been done to determine relationships between genotype and disease. Studies have attempted to correlate lung cancer risk and transferase expression with mixed results. A better correlation has been found between transferase genotype and diseases associated with oxidative stress, especially for GSTM1 or GSTT1 polymorphism and colon cancer (53) and esophageal cancer (97). No correlations were found between breast cancer and GSTM1 polymorphism (1). It appears that some of the highest correlations between genotype and cancer susceptibility are those where P450 genotype and transferase genotype are combined for analysis. This, again, emphasizes the close relationship between metabolic activation by phase I enzymes and detoxication of reactive metabolites by phase II enzymes.

Species and Gender Differences

As mentioned earlier, glutathione *S*-transferases have been found in most species investigated. Species differences in the expression, substrate specificity, and activity of these transferases can have a significant role in the toxicity of xenobiotics. For instance, rats are susceptible to the potent hepatocarcinogen aflatoxin B1 (AFB1), whereas mice are extremely resistant. This species difference results from the expression of mGSTA3–3 in mice, which has a high activity toward the P450-generated activated metabolite of AFB1 (the 8,9 epoxide). Although rats express a closely related transferase (rGSTA3–3), it has low activity toward the epoxide. Although these two transferases have equivalent activity toward a probe substrate (l-chloro-2,4-dinitrobeneze), the rat form has 1,000-fold less activity toward the AFB1 epoxide compared to the mouse. This difference in activity between the transferases from the two species appears to be based on differences in as few as six critical amino acids (177).
Hepatic glutathione *S*-transferase activities are low in prepubertal male and female rats. As the rats reach sexual maturity between 30 and 50 days of age, glutathione-conjugating activity toward dichloronitrobenzene is two- to threefold higher in males than in females (91). This difference in glutathione *S*-transferase activity was not related to sex steroids but was dependent on pituitary secretions. Growth hormone may play a role in establishing glutathione *S*-transferase activities (90), as it does with P450. Although growth hormone is important in regulating adult levels of glutathione *S*-transferase in the rat, it appears that other factors also play a role. The student of toxicology should be aware of the multifaceted way that xenobiotics can affect organisms. For example, monosodium glutamate, which produces lesions in the arcuate nucleus of the hypothalamus, can lower the glutathione *S*-transferase activity in male rats. This, in turn, could increase their sensitivity to electrophilic chemicals.
Gender differences in the expression of glutathione *S*-transferase have been suggested to be responsible for the higher susceptibility of female mice to the carcinogenicity of benzo(a)pyrene compared to males. Males express higher mGSTP1–1, mGSTA3–3, mGSTM1–1, and mGSTA4–4 compared to females. At higher doses of benzo(a)pyrene this gender difference is lost, possibly by the higher doses overcoming the protective role of the higher transferase activity in males (156).
Some studies suggest that humans do not demonstrate gender differences in glutathione *S*-transferases. No gender or age differences were seen in GSTM and GSTP activity in human lymphocytes, but an age-dependent decrease in glutathione was detected (176).

Role of Glutathione S-transferases in Metabolic Activation

Glutathione conjugation does not always produce an innocuous and readily excreted metabolite. For example, Elfarra and Anders (41) compiled a list of 1,2-dihaloalkanes and halogenated alkenes whose glutathione or cysteine conjugates were nephrotoxic (Figure 3.19). Glutathione reacts with these 1,2-dihaloalkanes via a glutathione *S*-transferase-catalyzed reaction that yields sulfur mustards. An electrophilic episulfonium ion can be formed from the mustard when the second halogen atom is displaced by a cellular nucleophile. The episulfonium ion intermediate has been implicated in the toxicity of these chemicals. The major DNA adduct resulting from exposure to the carcinogen, 1,2 dibromoethane, was *S*-2-*N*-7-guanylethylglutathione (72). A brief review of this bioactivation pathway is included in (4, 174).

As shown in Figure 3.18, glutathione and cysteine conjugates (GSR and CySR, respectively) formed in the liver (pathway 1) can be excreted in the bile (pathway 4). Glutathione conjugates can be hydrolyzed to cysteine conjugates by pancreatic peptidases in the small intestine (pathway 5). Cysteine conjugates originating from the bile and those formed by hydrolysis of glutathione con-

FIG. 3.19. Halogenated hydrocarbons that form glutathione and cysteine *S*-conjugates that are nephrotoxic. Asterisks indicate the position where the glutathione *S*-transferase-catalyzed displacement (SN2) occurs.

jugates are good substrates for microfloral *β*-lyase (pathway 6). *β*-Lyase, an enzyme found in liver, kidney, and in intestinal microflora, cleaves thioether linkages in cysteine conjugates of xenobiotics (169). The resulting thiol compounds are more hydrophobic than the conjugates and can be readily absorbed in the small intestine. These thiol metabolites return to the liver via the portal circulation and act as substrates for thiol S-methyltransferase that methylates the thiol group (pathway 8). Enterohepatic circulation (pathways 1→4→5→6→8) of glutathione conjugates accounts for some of the unusual sulfur-containing metabolites (pathway 9) that have been found in the urine of animals treated with xenobiotics, such as propachlor (138). A portion of the glutathione-derived sulfur-containing metabolites formed in the small intestine is excreted in the feces (pathway 7 of Figure 3.18).

Reactions of glutathione and cysteinyl conjugates shown in Figure 3.19 are believed to play a role in the nephrotoxicity of several xenobiotics. For example, the cysteinyl conjugate of trichloroethylene, *S*-(l,2-dichlorovinyl)-L-cysteine (DCVC), is a potent nephrotoxin and a *β*-lyase substrate. Inhibition of renal β-lyase with aminooxyacetic acid, an inhibitor of pyridoxyl phosphate-dependent enzymes, protected

against DCVC-induced nephrotoxicity (41).

In general, glutathione conjugate synthesis results in readily excreted polar metabolites; however, in some cases (depicted in Figure 3.18), the residence time of a glutathione conjugate in the body is prolonged. This can result in formation of metabolites that are more reactive than the original, parent xenobiotic, or the glutathione conjugate. If these reactive metabolites interact with critical cellular sites, toxicity can ensue. For a review, see (3, 118).

Glutathione S-Transferases as Markers of Liver Damage

Glutathione *S*-transferases may be valuable as an adjunct to serum aminotransferases for detecting acute liver damage. These transferases constitute as much as 3% of cytosolic protein in the hepatocyte and are uniformly distributed across the liver lobule, compared with aminotransferases, which are located periportal. Their plasma half-life is less than 60 minutes, compared to 48 hours for the alanine aminotransferase. Selective use of these different characteristics between aminotransferases and glutathione *S*-transferases have led to more accurate diagnosis of hepatic damage produced by xenobiotics (67). Recently, it has been suggested that determination of glutathione *S*-transferase be included in toxicology studies, and validated methods for rats and dogs have been developed (84).

Methylation

Methyl conjugation is an important pathway in the metabolism of many neurotransmitters, drugs, and xenobiotics. Methylation of endogenous substrates, such as histamine, amino acids, proteins, carbohydrates, and polyamines, is important in the regulation of normal cellular metabolism and accounts for the presence of this activity in mammalian cells. Only when a xenobiotic fits the requirements for the enzymes involved in these normal reactions does methylation become important in the metabolism of foreign compounds.

Methylation can be achieved by two routes. First and foremost is the methyltransferase-catalyzed methylation that requires *S*-adenosylmethionine (SAM) as a cosubstrate. Most biological methylations require SAM as the methyl donor; however, there are methyl transferases that require SAM as a cosubstrate but vary in other requirements for optimal activity (105). Reactions involving four of these SAM-dependent methyltransferases are shown in Figure 3.20. Two enzymes catalyze nitrogen methylation: aromatic azaheterocycle N-methyltransferase and indolethylamine N-methyltransferase. Oxygen methylation is primarily catalyzed by catechol *O*-methyltransferase and sulfur methylation thiol *S*-methyltransferase. A secondary source of methylation is the N5-methyltetrahydrofolate (5-CH3-THF)catalyzed methylation. This methylation is important in the synthesis of nucleic acids; however, S-CH3-THF is 1000 times less reactive toward soft nucleophiles (shown in Figure 3.20) than SAM, suggesting that it plays a smaller role in xenobiotic metabolism.

Methylation is a major route for nicotine biodisposition in the guinea pig. The enzyme responsible for nicotine methylation is an aromatic azaheterocycle *N*-methyltransferase that normally methylates histamine (Figure 3.20). Guinea pigs are well known for their ability to methylate histamine. They represent a good animal model for studying xenobiotic methylation. Nicotine is an example of a xenobiotic that can be metabolized by an enzyme of normal cellular metabolism. Because nicotine is a weak base, methylation of the pyridyl nitrogen results in charges at both nitrogens at physiologic pH, increasing water solubility and urinary excretion.

Methylation reactions can be stereoselective. For example, the R(+) enantiomer of nicotine is preferentially methylated over the S(−) enantiomer (33). Stereoselective metabolism of xenobiotics can be important in understanding the metabolic basis of toxicity. Because most biotransformation reactions are catalyzed by enzymes, there is always the possibility that the active site will select one orientation around a chiral center over another.

Individual differences in S-methylation activity have been observed, with activity being trimodal. These data suggested that S-methylation is controlled by a single gen etic locus with two alleles, one controlling low activity and one controlling high activity (185). Inherited variations in "methylator" status should be included among those factors responsible for individual variations in the metabolism of thiopurine and catechol xenobiotics.

Amide Synthesis

Amide biosynthesis can take place via two principal routes:

1. Conjugation of a carboxylic acid-containing xenobiotic with the free amino group of an amino acid such as glycine.
2. The acetylation of a xenobiotic containing a primary amine ($-NH_2$).

Amino Acid Conjugation

Xenobiotics that contain a carboxylic acid moiety are susceptible to conjugation with endogenous amino acids. Xenobiotic conjugation occurs in hepatic mitochondria. The free carboxylic acid is activated by reaction with ATP followed by reaction with acetyl coenzyme A (CoA), as shown in reactions 1 and 2 of Figure 3.21. For example, the carboxylic acid of benzoic acid is activated to a thioester CoA intermediate that reacts with the primary amine of glycine to form the amide, hippuric acid.

Glycine has historical significance in xenobiotic conjugation because it is one of the earliest reactions attributed to xenobiotic metabolism. Keller (83), in 1842, administered benzoic acid to himself and then isolated and characterized the major metabolite, hippuric acid, a glycine conjugate. This reaction has been used as a liver function test in humans. The liver is the principal site of glycine conjugation. Amino acids other than glycine can be used for conjugating aromatic and heterocyclic carboxylic acids. For example, arginine is used by arachnids, glutamine by chimpanzees, and ornithine by certain birds.

Acetylation

Acetylation, catalyzed by *N*-acetyltransferases, is the principal pathway of amide formation for primary aromatic amines, endogenous primary aliphatic amines, anutrient amino acids, hydrazines, hydrazides, and sulfonamides. The activated acetyl group is derived from acetyl-CoA. Mercapturic acid formation in the kidney is an example of acetylation that has been presented. In this reaction, the primary amine

group of the cysteine conjugate of the xenobiotic is acetylated to form the mercapturic acid. This is an exception to the rule that aliphatic primary amines generally are not good substrates

Sulfanilamide (SO_2NH_2, NH_2) + CH_3—C(=O)—S—CoA (Acetyl CoA) → N^4—Acetylsulfanilamide (SO_2NH_2, NH—C(=O)—CH_3) + HS—CoA

FIG. 3.21. Series of reactions leading to amide formation from either a xenobiotic containing a carboxylic functional group (RCOOH) or a primary amine group (R′NH2).

for the N-acetyltransferases. It is worth noting that the use of the -uric suffix to denote an acidic metabolite was once common. Mercapturic acids, hippuric acid, and salicyluric acid all share this common suffix that is probably derived from the fact that these were acids. Uric acid had similar characteristics and all were isolated from urine.

The N-acetyltransferases are cytosolic enzymes that occur in many tissues. Some species, including humans, express two independently regulated transferases, NAT1 and NAT2, whereas other species express three. NAT1 and NAT2 are similar proteins but have different substrate specificities, although there is some overlap. NAT2 is primarily a liver and intestinal enzyme, whereas NAT1 is expressed in a number of organs. The *N*-acetyltransferases are important in the metabolic disposition of drugs and can also be involved in the metabolic activation of xenobiotics (e.g., aromatic amines).

Human Amide Synthesis Polymorphism

The main route of metabolism of isoniazid (1-isonicotinyl hydrazide) in humans is conjugation with acetyl-CoA to form the amide metabolite (106). Isoniazid is eliminated much faster from the body once it is acetylated. With the widespread use of isoniazid to control tuberculosis, it became obvious that there were major differences in the rates at which individuals eliminated the drug (44). Careful studies of hundreds of patients showed that there were two distinct populations: the fast and the slow acetylators. Slow acetylators inherited the trait as a homozygous recessive allele.

NAT polymorphisms have been reported in several species. Although it is possible that NAT1 may be polymorphic, NAT2 has received the most interest. Slow acetylation is associated with mutations, in the NAT2 gene. Not all slow acetylators show identical mutations, and there is a spectrum of activity in the slow acetylator phenotype. Some mutations affect enzyme activity, whereas others decrease the stability of the enzyme. A number of population studies have been done to determine if the NAT polymorphism alters susceptibility to carcinogens. In some studies, no differences have been reported, whereas in others, associations have been suggested (18). The number of enzymes involved in carcinogen biodisposition and the polymorphisms associated with some of these enzymes makes the task of identifying specific polymorphisms associated with increased cancer risk difficult. As more is learned about the complex interactions of these enzymes, populationbased studies will provide valuable information.

HYDROLYSIS

Many xenobiotics and their phase I metabolites contain either a carboxyl ester, an amide bond, or an epoxide that mask hydrophilic functional groups, such as alcohols, carboxylic acids, and amines. The rate at which an organism can hydrolyze these bonds and unmask these function groups can influence their toxicity. In fact, pesticides and therapeutic drugs have been synthesized with intent to modulate the bioavailability of the active species by affecting the rate of hydrolysis of the parent compound. Hydrolysis normally competes with other detoxication reactions. An example of competition is demonstrated by the metabolism of acrylate esters (Figure 3.22). Most acrylate esters either react with glutathione via a glutathione *S*-transferase-catalyzed pathway or are hydrolyzed by B-esterases to acrylic acid and the corresponding alcohol (Figure 3.22).

Epoxide Hydrolase

Organisms may be exposed to epoxides in the environment, or, they may be produced during the oxidative metabolism of specific xenobiotics from their environment. Epoxides generally are reactive electrophilic compounds due to the highly strained oxirane ring (Figure 3.23). Excess strain energy can be released by ring opening in the presence of nucleophiles. Ring opening may follow either a SN1-type mechanism with the formation of an intermediate with carbonium ion character or an SN2 mechanism with bond formation with the attacking nucleophile. The latter case has important toxicological consequences when the nucleophile is on a critical tissue macromolecule, such as DNA, because it results in covalent modification of the macromolecule. Modification of DNA results in a biochemical lesion that may be the precursor to a number of pathological lesions, including cancer. Reaction of the epoxide with cellular nucleophiles, such as proteins, could also lead to other mechanisms producing acute or subchronic toxicity.

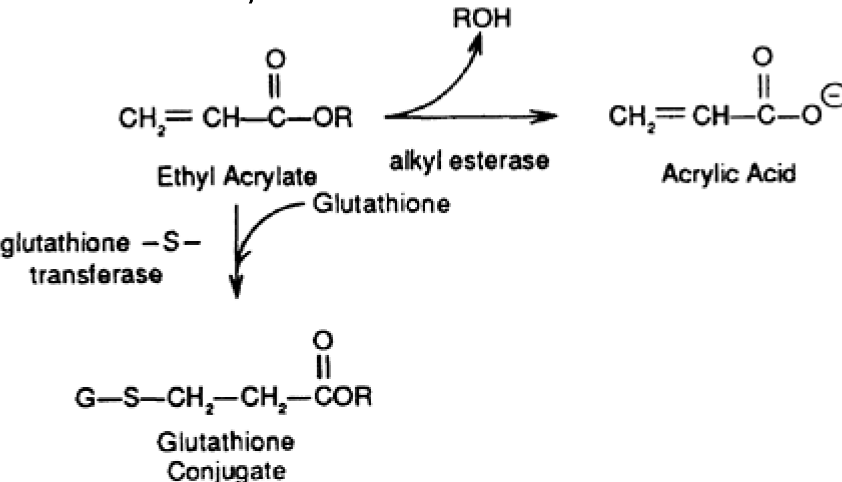

FIG. 3.22. Routes of disposition of ethyl acrylate.

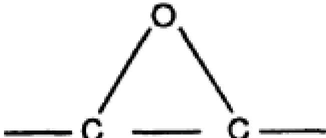

FIG. 3.23. An example of a strained epoxide oxirane ring.

The chemical reactivity and, consequently, the biological activity of epoxides are influenced by the constituents attached to the oxirane ring carbons. Epoxides with asymmetric carbon atoms can exhibit optical activity and exist as enantiomers in a racemic mixture. Reaction of epoxides with nucleophiles with an asymmetrical center will produce diastereoisomers with different spatial orientations around the carbon center. Production of diastereoisomers is important in biological activity in respect to both reaction at critical biochemical sites and subsequent metabolism. For instance, one isomer may react more efficiently at the toxigenic site and be a poor substrate for subsequent metabolism when compared to another isomer.

Although not always the case, the epoxides that are formed in vivo appear to be more toxicologically important than those that occur in the environment. Highly reactive epoxides would most likely interact with nucleophilic sites in the environment, such as proteins in food, and not be absorbed in their active form. Epoxides formed in vivo are produced close to their sites of action and require only diffusion or short transport to their target. Epoxides most frequently formed in vivo represent alkene and arene

oxides produced by P450. Their efficient detoxication is important to cellular survival.
Detoxication of epoxides may follow several routes:
(1) Spontaneous decomposition.
(2) Nonenzymatic reaction with glutathione.
(3) Reaction with glutathione catalyzed by glutathione transferase.
(4) Hydration by epoxide hydrolase.
(5) Minor mechanisms such as a P450 hydrolysis.
Nonenzymatic and enzymatic conjugations with glutathione have been previously discussed.
A major route for biodisposition of epoxides is hydration catalyzed by epoxide hydrolase. This enzyme was previously referred to as epoxide hydrase and epoxide hydratase, and readers will sometimes encounter these terms still in use. This microsomal enzyme catalyzes the biotransformation of arene oxides and aliphatic epoxides to vicina (Latin: *vicinalis*, neighboring) dihydrodiols. In most cases, this enzymatic pathway results in less reactive diol metabolites that are more readily excreted from the organism, either as the diol or as a glucuronide or sulfate conjugate of the diol.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_123.html[2010/10/28 18:40:57]

Epoxide hydrolases occur as membrane-bound proteins located in the endoplasmic reticulum and as a soluble enzyme in the cytosol of most mammalian cells. The mechanism of the soluble and microsomal epoxide hydrolase-catalyzed reaction appears to be a nucleophilic attack by an amino acid at the active site, possibly asparagine, on the epoxide to form an α-hydroxy-acyl-enzyme intermediate. Water hydrolysis of the acyl-enzyme occurs at the carbonyl carbon of the ester bond yielding the active enzyme and diol (12, 172). This stereoselective attack usually results in the diols having a transconfiguration. Hydrolysis of the ester is the rate-limiting step in catalysis.
Membrane-bound epoxide hydrolase has a 20 amino acid sequence at the N-terminal end that anchors it to the membrane. The active site of the enzyme occurs outside of the membrane. Unlike P450, if the anchor sequence of the protein is not present, the enzyme retains a portion of its catalytic activity (48).
Epoxide hydrolase has been found in a variety of tissues, including liver, kidney, lung, skin, intestine, colon, testis, ovary, spleen, thymus, heart, and brain. The activity of liver microsomal enzyme is relatively low in newborn rats and increases during neonatal development until adult males have about twice the activity of females. This sexual dimorphism is remarkably similar to that seen in the rat for P450. In contrast, the renal epoxide hydrolase of male and female rats does not demonstrate age-dependent changes or gender differences. Human hepatic microsomal epoxide hydrolase activities increase during gestation, but there does not appear to be a gender difference in humans (129).
Humans demonstrate considerable variation in epoxide hydrolase activity. This, in part, is associated with the inducibility of epoxide hydrolase and environmental exposures and life-style differences among individuals. In addition, there is evidence that there are genetic polymorphisms with the enzymes that result from amino acid sequence differences. These human polymorphisms may not result in significantly altered enzyme activity nor post-transcriptional regulation (93), although more work is needed in this area. Polymorphic expression of epoxide hydrolase has been related to specific human diseases (92, 158).
The activity of this enzyme is induced by the classical inducers of cytochromes P450. Although *trans*-stibene oxide has been shown to be an inducer of epoxide hydrolase, no specific inducer of epoxide hydrolase has been reported. Two widely used inhibitors of epoxide hydrolase are trichloropropane oxide and cyclohexene oxide.
Because of its localization in the endoplasmic reticulum, microsomal epoxide hydrolase is ideally situated to catalyze the detoxication of lipophilic epoxides formed by P450; however, it can also be involved in meta bolic activation. One example of metabolic activation is the biotransformation of benzo(a)pyrene to the ultimate mutagen benzo(a)pyrene trans-7, 8-dihydrodiol-9–10-oxide, which is shown in Figure 3.4 and described under metabolic oxidations. These diol epoxides are poor substrates for further metabolism by epoxide hydrolase and, as shown in Figure 3.4 react with critical cellular macromolecules.
An immunologically distinct epoxide hydrolase has also been identified in the cytosol of some species. This enzyme may play a role in hydrolysis of more water-soluble epoxides that partition out of the endoplasmic reticulum. As discussed earlier, this enzyme completes with glutathione transferases for cytosolic epoxides. The activity of the cytosolic epoxide hydrolase appears to be highest in mice and rabbits and relatively low in rats.

Esterases and Amidases

Hydrolysis of xenobiotics containing ester linkages and amide bonds is catalyzed by a group of enzymes with broad substrate specificity. In general, these enzymes perform endogenous functions and appear to metabolize xenobiotics that have structural similarities to endogenous substrates.
The reactions carried out by this diverse group of enzymes are illustrated in Figure 3.24. Specificity of carboxylesterases depends on the nature of the R groups rather than on the atom (*O*, *N*, or *S*) adjacent to the carbonyl carbon (69). The esterases have been broadly grouped into three categories based on their reactivity with organophosphorous compounds (181). Those esterases preferring carboxylesters with aryl groups in the R position and that can use organophosphate esters as substrates are classified as A-esterases (Table 3.7). Those esterases preferring esters with alkyl groups in

FIG. 3.24. Reactions catalyzed by esterases and amidases.

Page 125

Table 3.7 Classification of esterases by how they interact with organophosphates and substrate specificity

Esterase	Interaction with organophosphates	Substrates	Examples
A-esterases (arylesterases)	Substrates	$R-C_6H_4-C(=O)-O-R'$ Aromatic Esters	Organophosphate and carbamate insecticides
B-esterases (carboxyltesterases including cholinesterases)	Inhibitors	$R-CH_2-C(=O)-O-R'$ Aliphatic Esters	Acetylcholine, acrylate esters, succinylcholine, propanidid
C-esterases (acetylesterases)	No interaction	$CH_3-C(=O)-O-R'$ Acetate Esters	*p*-Nitrophenyl acetate, *n*-propylchloroacetate

the R position and that are inhibited by organophosphate esters are classified as B-esterases. Another group of esterases that prefer acetate esters and do not interact with organophosphates are referred to as C-esterases. This classification has been devised to help organize this multifarious group of enzymes. It also has some practical value in toxicology. The mechanism of organophosphate and carbamate insecticide toxicity is inhibition of acetylcholinesterase, a B-type esterase. Organophosphate insecticides, such as malathion, are detoxified in mammals by A-esterase hydrolysis. Many insects have lower levels of A-esterases than mammals. The selective toxicity of malathion in birds and insects can be explained by the low activity of A-esterases compared to mammals (182).

MICROFLORA METABOLISM

Xenobiotic metabolism by microorganisms can be divided into reactions occurring in the environment and reactions occurring inside the body (141). Metabolism of chemicals by microorganisms in the environment has become familiar through the use of microorganisms to degrade chemical spills (164). The in vivo metabolism of chemicals by microorganisms is not as familiar. Mammals are colonized by microorganisms (only those animals raised in a germ-free environment (gnotobiotic) are microbe-free). The metabolic reactions carried out by these microorganisms are dependent on the substrate and environment in which they are growing. Microbes growing in an aerobic environment are capable of cleavage of aromatic nuclei and can use these xenobiotics as sole carbon sources for biosynthetic reactions and growth. Microbes growing in an anaerobic environment are more likely to carry out reductive metabolism. The hallmark of metabolism by organisms colonizing the intestinal tract of mammals is reduction (Table 3.8).

Because the majority of microbes that colonize various surfaces of the mammalian body reside in the intestinal tract, most of this discussion will center around intestinal microflora metabolism. The intestinal microflora can alter xenobiotic bioavailability by metabolizing the parent compound to a metabolite that may be absorbed to a greater or lesser extent. Intestinal microflora can also metabolize products of xenobiotic biotransformation that are secreted into the intestine either directly from the blood or via the bile, saliva, or by swallowing respiratory tract mucus. Metabolism of secreted metabolites is a common mechanism by which microflora influence xenobiotic toxicity.

Xenobiotic Biotransformation by Microbes Colonizing Mammals

The intestinal tract of mammals contains a variety of microorganisms. The location, total number, and species diversity of microflora vary among mammals. Microflora can range from ruminants that have evolved to be dependent on microflora metabolism for energy needs to monogastric mammals, such as humans, that have great

Table 3.8 Types of metabolic reactions carried out by intestinal bacteria

Reaction	Representative Substrate
Hydrolysis	
Glucuronides	Estradiol-3-glucuronide
Glycosides	Cycasin
Sulfamates	Cyclamate, amygdalin
Amides	Methotrexate
Esters	Acetydigoxin
Nitrates	Pentaerythritol trinitrte
Dehydroxylation	
C-Hydroxy groups	Bile Acids
N-Hydroxy groups	N-Hydroxyfluorenylacetamide
Decarboxylation	Amino acids
N-Demethylation	Biochanin A
Deamination	Amino acids
Dehydrogenase	Cholesterol, bile acids
Dehalogenation	DDT
Reduction	
Nitro groups	*p*-Nitrobenzoic acid
Double bonds	Unsatrated fatty acids
Azo groups	Food dyes
Aldehydes	Benzaldehydes
Alcohols	Benzyl alchols
N-Oxides	4-Nitroquinoline-1-oxide
Other Reactions	
Nitrosamine formation	Dimethylnitrosarnine
Aromatization	Quinic acid
Acetylation	Histamine
Esterification	Gallic acid

numbers of bacteria only in the large intestine. Because of this variation in location within the intestinal tract, the types of microorganisms present, and hence the types of microflora metabolism, vary with the mammalian species being studied.

Another factor that relates to the location of the microflora is the disposition of the xenobiotic and its microflora metabolites. Chemicals metabolized by microflora located in the stomach will be distributed differently than chemicals metabolized in the large intestine.

The majority of mammals have a gradient of microflora that increases in numbers and species diversity along the intestinal tract from the foregut to the hindgut. Most research on microflora metabolism has focused on microorganisms that colonize the large intestine of humans, as most of the research in toxicology is directed toward understanding the toxicity of chemicals in humans. In vivo and in vitro models have been developed for studying human colonic flora (145).

Role of Diet and Other Factors in Modulating Microflora Metabolism

The microflora colonizing the digestive tract of mammals play a major role in the digestion of plant cell wall constituents that are indigestible by mammalian enzymes. These dietary fibers provide energy substrates that support the large bacterial populations in the gut. These energy sources also influence the microflora metabolism of xenobiotics. Certain types of dietary fiber, such as the fermentable carbohydrate pectin, can influence the toxicity of xenobiotics that require microflora metabolic activation by increasing the number of anaerobic bacteria colonizing the large intestine (35). This diet-induced elevation in the number of bacteria increases the total metabolic capacity of the large intestine for metabolizing xenobiotics. For reviews of this topic, see (143, 144).

Examples of Xenobiotics Whose Toxicity is Dependent on Microflora Metabolism

Nitroaromatics

A body of literature has now accumulated indicating that the toxicity of many nitroaromatic compounds is dependent on microflora metabolism. One of the most studied nitroaromatics is 2,6-dinitrotoluene (DNT), which is hepatocarcinogenic in male rats (94). DNT is metabolized to the 2,6-dinitrobenzylalcohol glucuronide conjugate that is preferentially excreted in the bile of male rats (99) (Figure 3.25). The glucuronide conjugate is hydrolyzed by gut microflora β-glucuronidase, and one or both of the nitro groups are reduced by microflora nitroreductase to a reduced aglycone. The resulting aminobenzyl

alcohol is relatively nonpolar and reabsorbed in the intestine, where it returns to the liver via the portal circulation. In the liver, the aglycone is activated to the putative proximate carcinogen by N-hydroxylation of the amine functional group followed by sulfation of the N-hydroxy group (82). Evidence that intestinal microflora were required for the activation of DNT was provided by studies indicating the genotoxicity of DNT in hepatocytes isolated from rats treated with DNT was dependent on the presence of bacteria in the intestinal tract (114). Rats raised in a germ-free environment showed minimal levels of genotoxicity. Additional evidence emphasizing the role of microflora in the metabolic activation of DNT was the observation that DNT was not genotoxic when tested in vitro in isolated hepatocytes (114). These results indicated that liver metabolism was not sufficient to activate the molecule to the ultimate carcinogen. The genotoxicity of DNT to liver cells only occurred when the compound was

Page 127

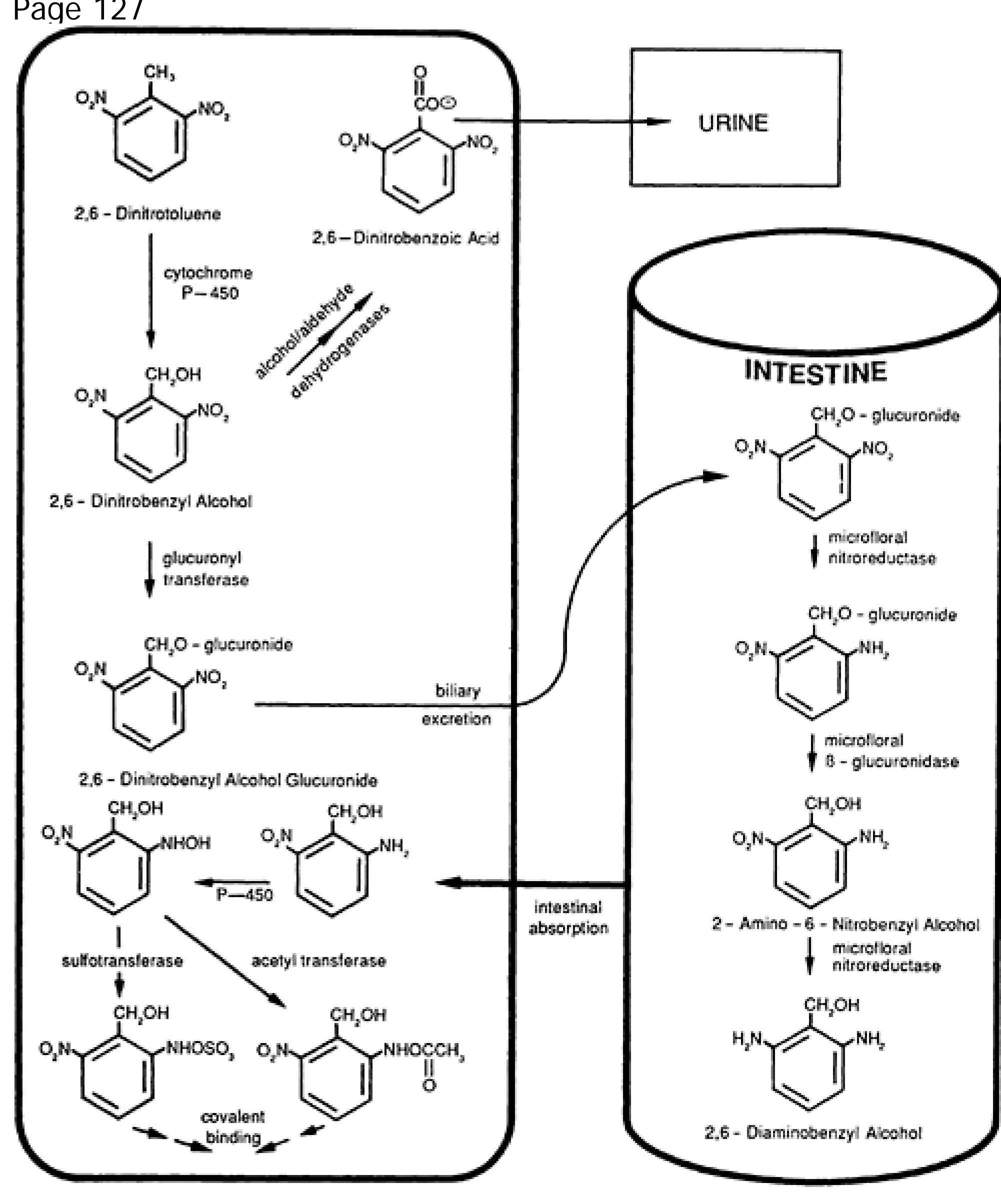

FIG. 3.25. Putative route of disposition of 2,6-dinitrotoluene.

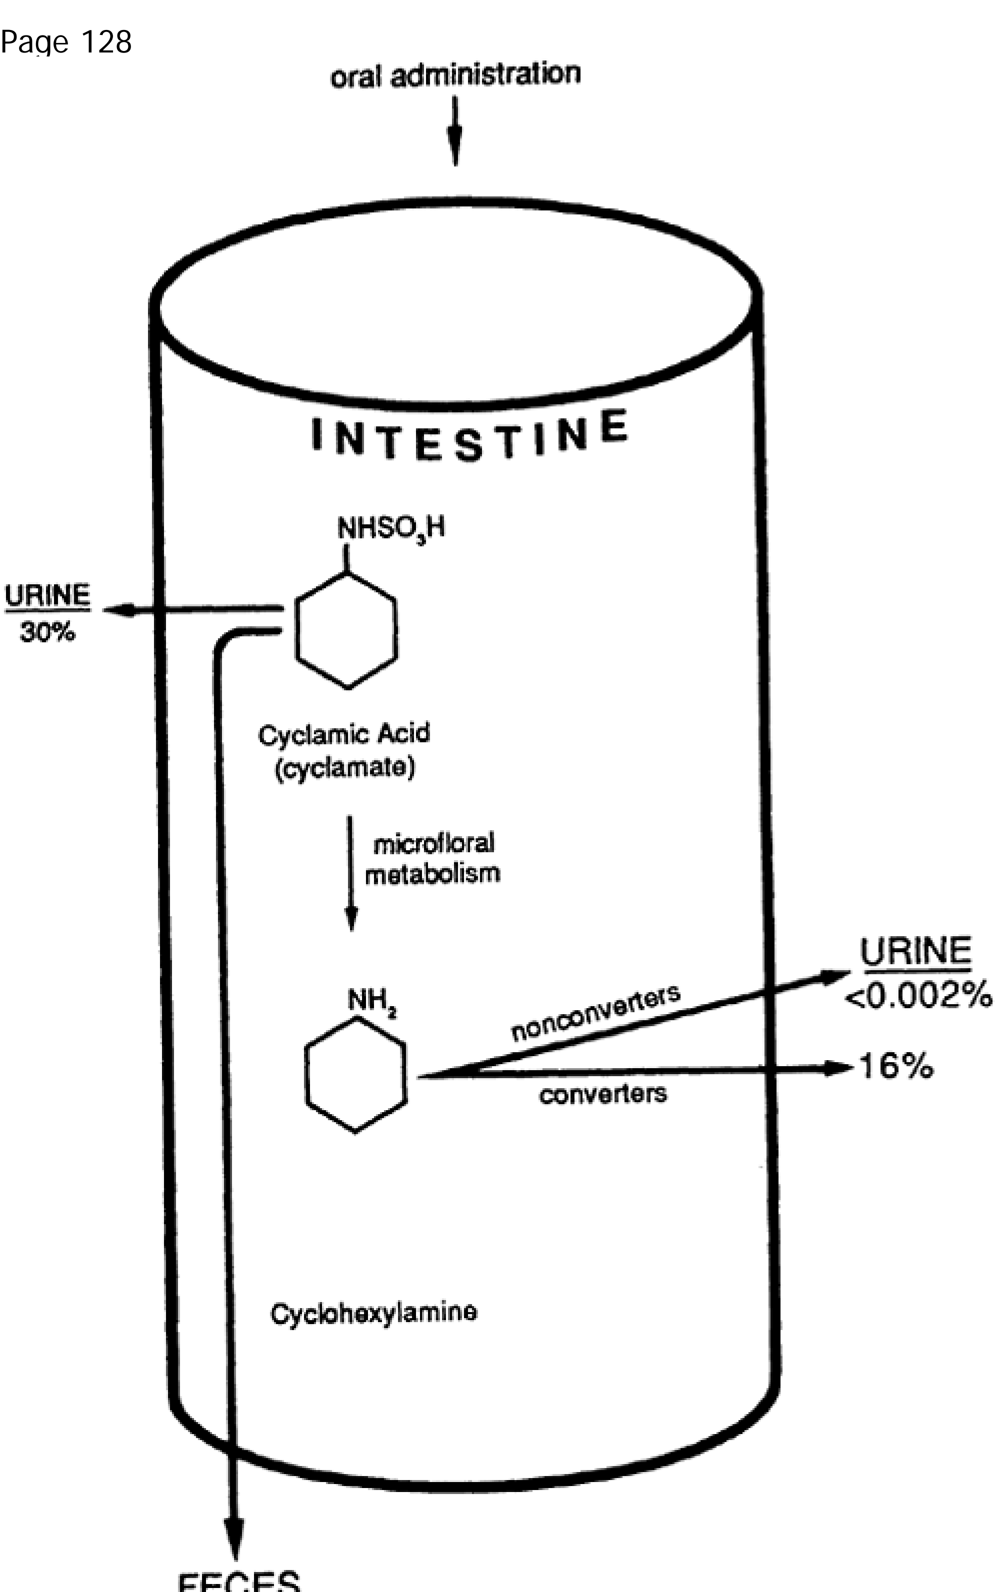

FIG. 3.26. Metabolic degradation of cyclamic acid by intestinal microflora.
administered to the animal and allowed to undergo enterohepatic circulation involving intestinal microflora.

The level of DNT-derived radioactivity covalently bound to DNA, RNA, and protein isolated from the livers of rats treated with DNT was also dependent on the presence of intestinal microflora (99). Dietary treatments that increased the microbial metabolic capacity of the rat's large intestine also increased the covalent binding of DNT-derived radioactivity to hepatic macromolecules (35).

The importance of complementary in vitro short-term toxicity test with suitable in vivo test for predicting a chemical's toxicity is well illustrated by this example, where the toxicity of DNT was dependent on the disposition within the host rather than metabolic activation within a single organ.

Cyclamate

The sodium and calcium salts of cyclamic acid (cyclohexylsulfamic acid) were used as an artificial

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_128.html[2010/10/28 18:41:00]

sweetening agent until 1969 in the United States, when it was removed from the market because a metabolite, cyclohexylamine, was suspected of being a bladder carcinogen.

Most of the hydrolysis of cyclamate to cyclohexylamine takes place in the gut by the microflora, as shown in Figure 3.26 (142). Cyclohexylamine is more lipophilic than the parent acid and is readily absorbed from the intestine and excreted in the urine. Minor urinary metabolites include cyclohexanol and trans-cyclohexane-1,2-diol.

Although only trace amounts of the cyclohexylamine could be detected in humans administered cyclamate, chronic exposure to the acid increased the capacity to produce this metabolite (104). It was found that certain individuals possessed a greater capacity to metabolize cyclamate to cyclohexylamine; these individuals were called converters. Thus, cyclamate is a good example of how prior exposure to a xenobiotic can alter the disposition of the xenobiotic. For additional reading on intestinal microflora xenobiotic metabolism, see (57, 148).

INTEGRATION OF METABOLIC PATHWAYS

To understand a complex system, it is necessary to reduce it to its basic components and study each component separately. After achieving an understanding of the components, it is important to integrate them back into the whole. Xenobiotic metabolism is a complex system. Now that the reader has examined each component of the system in detail, let us examine how they act in concert to protect an organism from toxic injury. Specific examples of integrated biotransformations will be presented.

Bromobenzene

Bromobenzene, an industrial solvent, produces centrilobular necrosis in the rat liver. Bromobenzene's hepatotoxicity results from metabolic activation of the parent compound via epoxidation (Figure 3.27) catalyzed by P450. Bromobenzene-3,4-epoxide is stable enough to

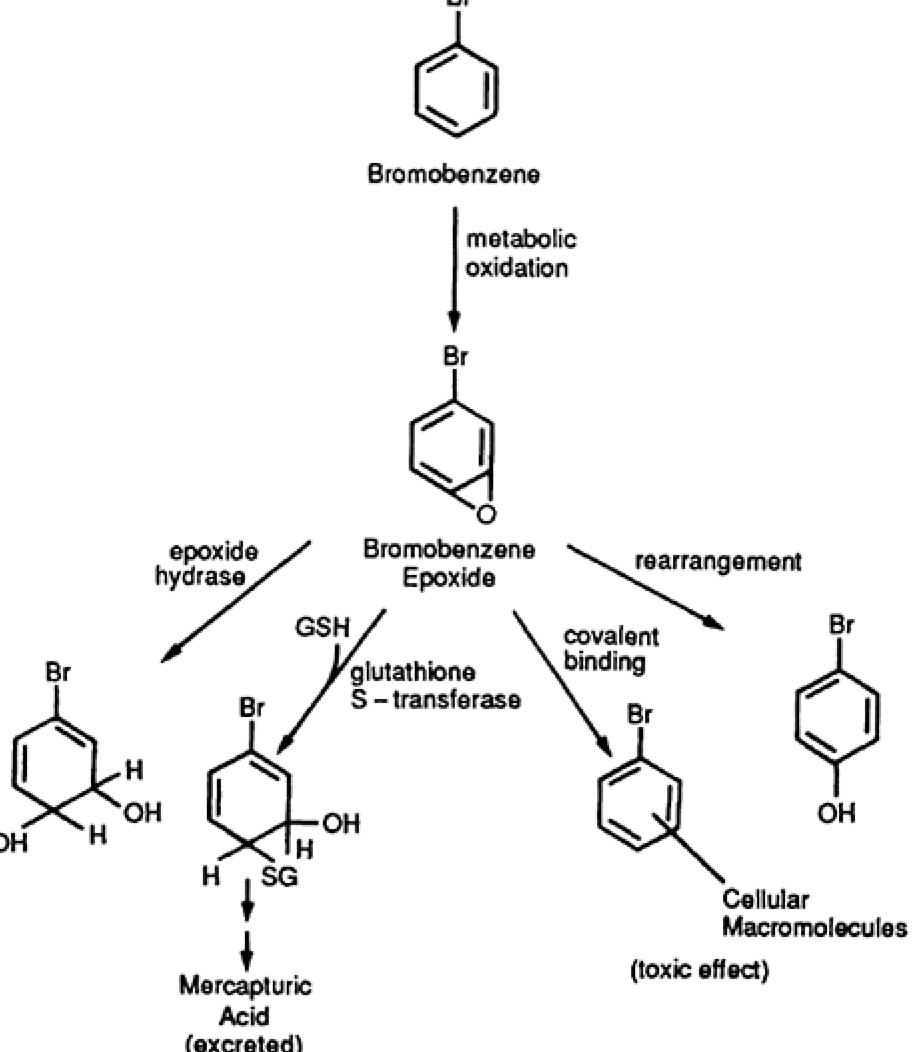

FIG. 3.27. Routes of disposition of bromobenzene. From Reference 93.

diffuse from its site of formation in the endoplasmic reticulum. It can then follow several biodisposition routes, depending on a variety of factors. The epoxide is a substrate for epoxide hydrolase, which would catalyze its hydration to the diol (Figure 3.27). It is also a substrate for glutathione *S*-transferase, which catalyzes thioether formation. The glutathione conjugate is processed by the kidney into its corresponding mercapturic acid, which is excreted in the urine (Figure 3.18). The epoxide can also undergo spontaneous rearrangement to form *p*-bromophenol. This metabolite can cycle through oxidation by P450. If the phase II reactions do not trap the reactive epoxide metabolite formed from the phase I metabolism of bromobenzene, the electrophilic carbon of the epoxide will react nonenzymatically with nucleophilic sites on cellular macromolecules. The ability of electrophilic metabolites to react covalently with critical cellular macromolecules is responsible for many chemical-induced toxicities, including chemical carcinogenicity. The delicate balance between detoxication and metabolic activation determines whether a chemical will be toxic to an organism and in what tissue. Toxic doses of bromobenzene produce centrilobular hepatic necrosis, whereas benzo[a]pyrene, which is activated via a similar mechanism, produces carcinogenicity. Many xenobiotics that are activated to mutagens and are tumorigenic are also cytotoxic.

Multiple Pathways for Xenobiotic Activation

Three different pathways in which chemicals can be nephrotoxic have been presented: oxidation by P450, formation of an episulfonium ion of a cysteine conjugate, and oxidation by prostaglandin synthetase. Very often, the toxicity of a xenobiotic results from more than one route of activation, even within the same organ. For example, acetaminophen has been associated with analgesic nephropathy. Acetaminophen can be activated by P450 and prostaglandin synthetase to a reactive metabolite capable of binding to macromolecules. The realization that a pathway other than the wellcharacterized P450 route was involved occurred through observations that acetaminophen was covalently bound in the inner medulla of the rabbit kidney, a site nearly devoid of P450 activity (117); however, large in vivo doses of acetaminophen produce only damage in the kidney cortex because prostaglandin synthetase is inhibited by these large doses. The P450 pathway is not inhibited and is responsible for the cortical damage. Aspirin and indomethacin are very specific inhibitors of prostaglandin synthetase. Analgesic preparations containing aspirin and one of the analgesics known to be activated by prostaglandin synthetase would probably show considerably less toxicity to the medullary tissue of the kidney. This gradient of oxidation pathways across the kidney, with the cortex possessing higher P450 activity than prostaglandin synthetase, the outer medulla being intermediate, and the inner medulla possessing far greater prostaglandin synthetase activity, results in certain xenobiotics being more toxic to one region of the kidney than another (192). These examples stress the importance of understanding the metabolic activation of a toxicant in explaining its mechanism of action.

Another example of competing pathways is acrylate ester metabolism. Many acrylate esters are good substrates for both alkyl esterase and glutathione S-transferase, and can react with glutathione nonenzymatically. Depending on the dose and route of administration of these compounds, these pathways compete for acrylate metabolism. The alkyl esterase hydrolyzes the acrylate ester to acrylic acid, and the corresponding alcohol (Figure 3.22) and glutathione adds to the β-carbon of the acrylate ester. Both pathways are considered detoxication pathways; however, at high doses glutathione can be depleted faster than it can be resynthesized. Elimination of the glutathione pathway can result in saturation of the esterase pathway and an accumulation of the acrylate ester at the site of administration producing tissue damage.

QUESTIONS

1. During the development of a new pesticide, it was decided that the introduction of a hydroxyl group onto the molecule would make the compound more water soluble. This had advantages in making the spraying of the pesticide simpler. An initial study of the plasma concentrations of the nonhydroxylated analogue in rats had been completed in anticipation of beginning a subchronic toxicity study. When the plasma concentrations of the less lipophilic, hydroxylated pesticide were determined, it was found that the plasma concentrations were maintained for a longer period of time than with the nonhydroxylated analogue. How would you explain this finding?
2. As a toxicologist, you have been asked to design a program to assess the potential hazard of a chemical. What type of information concerning its metabolism would you want to have before you design the hazard assessment program? Based on the metabolism information you have requested, how would you choose the species to be used in the hazard assessment program?
3. A cancer chemotherapeutic drug has been shown effective in treating a specific type of cancer; however, the drug is also cytotoxic and produces severe side effects if it is not rapidly metabolized

by cytochromes P450. Therefore, it is important to not treat a patient with doses of the drug that are too high for the patient's capacity to rapidly metabolize it to the less toxic product. What characteristics of the patient should be considered when attempting to choose a dose that will minimize the side effects?

4. A compound is functionalized by the P450 system and then forms sulfate and glucuronide conjugates and a mercapturic acid before being excreted. How may its metabolism be altered as the dose is increased from a No Observable Effect Level (NOEL) to a dose that produces severe toxicity?

5. Many chemical carcinogens are metabolized by routes that represent detoxication and by other routes that represent metabolic activation. What are the various phenomena that may shift the balance between detoxication and metabolic activation?

The term pharmacokinetics is derived from the Greek words *pharmako* (medicine, drug, or poison) and *kinetikos* (motion or movement). Thus, pharmacokinetics is the study of the movement of drugs within the body, that is, the absorption, distribution via the blood, metabolism, and excretion. This term is in contrast to *pharmacodynamics,* which is concerned with the pharmacological actions of the drug within the body, that is, its effects at the site of action/receptor. The word drug is popularly associated with medicines or therapeutic agents, although for certain subjects, for example, drug metabolism, this word has long been applied to any environmental anutrient, that is, drugs, pesticides, environmental contaminants, and plant products. Because the processes concerned with the absorption, distribution, and elimination of therapeutic drugs are nonspecific and shared with other types of anutrients, the principles of pharmacokinetics apply to any environmental anutrient (xenobiotic). It is thus valid to apply the term *pharmacokinetics* to all foreign compounds, although other terms, such as "chemobiokinetics" (32), have been proposed to describe the application of these principles to nontherapeutic substances. *Toxicokinetics* is receiving increasing and even international (122) usage; it has useful connotations with respect to the nonspecific nature of the toxicant and the implicit requirement for kinetic data at toxic doses. However, most of the basic principles were established in relation to therapeutic drugs, and the introductory chapters of many clinical pharmacology textbooks contain much useful basic information.

The term *toxicokinetics* is frequently misused and applied to nonspecific data, such as autoradiography, and radiolabeled excretion and metabolism studies. Toxicokinetics, in the present context, is the application of pharmacokinetic principles to animal toxicity studies and to human toxicity data in order to provide information on exposure to the parent compound and its metabolites, and other aspects such as accumulation during chronic exposure. The incorporation of data from animal studies into risk assessment requires data from related studies in humans at appropriate doses.

The understanding and interpretation of toxicological findings requires information on two key areas: (a)

delivery of the compound to its site of action (toxicokinetics) and (b) the mechanism of action and potency of the chemical at the site of action (toxicodynamics) (Figure 4.1). Such information may assist in understanding the dose-response relationship in animal toxicity studies and its relevance to humans as well as assisting in the identification of potentially at-risk subgroups of

the exposed human population. Risk assessment has traditionally used different approaches for cancer (and other nonthreshold effects), compared with toxicity believed to show a biological threshold. For cancer, and similar effects, the dose-response relationship in animals is extrapolated down to a very low level of risk, or virtually safe dose; toxicokinetics are frequently incorporated into the process by the use of a physiologically based pharmacokinetic model (PBPK). For threshold toxicity, the approach is to estimate a level of human intake without appreciable health effects; the acceptable daily intake (ADI), or tolerable daily intake (TDI), or reference dose (RfD), for human exposure is derived by dividing the intake of animals treated at the no-observed-adverse-effect level (NOAEL) (on a mg/kg basis) by an appropriate safety or uncertainty factor. A safety factor of 100 is usually applied with a 10-fold factor to allow for extrapolation from animals to humans and a 10-fold factor to allow for interindividual differences in the exposed human population (75, 123). A scheme was proposed (76) that would allow appropriate toxicokinetic or mechanistic data to be incorporated into the derivation of a data-derived safety factor by the replacement of part of the relevant 10-fold default factor. The use of such a scheme would produce a more secure basis for the establishment of an ADI/TDI/RfD, while providing a direct return for the investment necessary to produce more than the minimum toxicity database required for regulatory purposes. The greater use of toxicokinetic data in regulatory decisions will provide a more scientific basis for risk assessment, and will encourage the increased generation of such data.

Toxicokinetic studies are important in compound development, and such information is regarded as necessary before proceeding with long-term and carcinogenicity tests (101). If the kinetic evidence indicates tissue accumulation on prolonged dosing, saturation of elimination at subtoxic doses, or the formation of chemically reactive metabolites, chemical analogs without these problems may be selected for development, because these properties mitigate against a high therapeutic index (for drugs) or ADI (for food additives).

Toxicokinetics is concerned with the relationship between the external dose, as usually measured in toxicity studies (e.g., mg/kg body weight per day) and a measure of the internal dose of active compound delivered to the target for toxicity (Figure 4.1), such as the concentration in the general circulation or at the target for toxicity. Frequently the compound administered has to pass many lipid and metabolic barriers prior to reaching the target, as shown in Figure 4.2. An understanding of the extent and nature of these processes may be derived from serial analysis of the concentrations of the chemical in plasma and urine. A knowledge of the concentrations of the parent compound and any metabolites in plasma and tissues, allied to the rate of change on further dosing or cessation of administration, allows logical selection of the animal species most appropriate for toxicity testing, and extrapolation of any toxicity observed in animals to the likely risk for man (2, 17, 29, 65, 75, 76, 122, 123, 124).

Therefore, toxicokinetic studies are designed to produce information on the profile of exposure of the site of toxicity to the active moiety, under the conditions which produce the toxicity, and which are the basis for determining the NOAEL. Important toxicokinetic data relate to:

1. Exposure (or internal dose) in animals based on plasma or blood concentrations of the parent compound or its active metabolite
2. Relationship between the dose given to the animals and exposure
3. Relationship between plasma or blood concentrations and those at the site of toxicity
4. Information on appropriate blood/plasma data after the administration of tracer doses to human volunteers in order to allow extrapolation of animal data to humans

The aim of this chapter is to introduce the underlying principles in both biological and mathematical

terms, and subsequently to describe methods of obtaining suitable samples from certain animal species, primarily the rat. The final section of the chapter covers the analysis of data, with examples to illustrate the type of information and insights that may be obtained using these techniques. In all cases, the examples and data processing described have been restricted to simple analyses of results, in order to illustrate principles. References are provided for further reading, because the analysis of data using computer programs and more complex mathematical models are not covered in this chapter.

In the past, animal and human disposition studies during drug development utilized slightly different approaches, with absorption, distribution, metabolism, and excretion studies (ADME studies) in animals, which were usually based on the fate of the radiolabeled drug,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_138.html[2010/10/28 18:41:06]

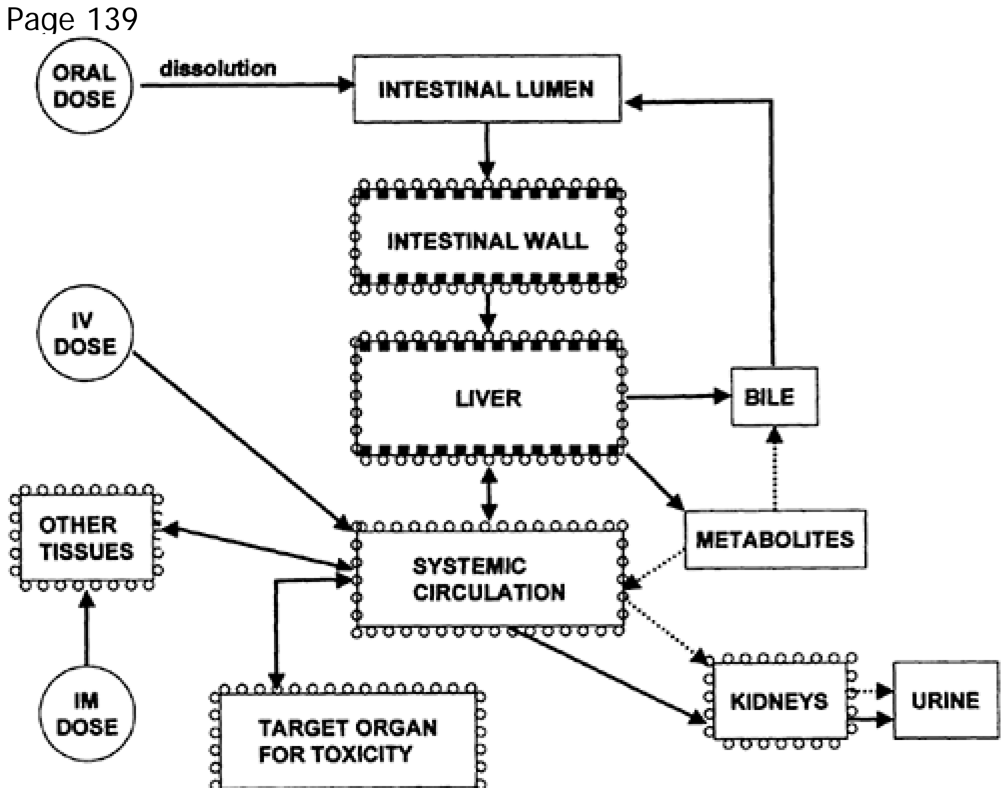

FIG. 4.2. Toxicity in relation to pharmacokinetics. The chemical may be given orally or by injection or inhalation. The concentration at the target organ is in equilibrium with that in the systemic circulation, which is itself in dynamic equilibrium with a large number of other physiological processes tending to increase or decrease that concentration. The transfer from one tissue to another usually involves transfer across a lipid membrane *(open circles)* and frequently entails entering a tissue with high elimination capacity *(solid squares)* such as the liver.

whereas similar radiolabeled studies in humans were frequently supplemented with data on plasma concentration-time curves. The basis for the interpretation of plasma concentration-time curves was the formulation of suitable mathematical models which allowed the derivation of rates of absorption, metabolism, and excretion in humans. It was thus possible, using pharmacokinetic methods, to gain an insight into the rates and extents of processes in humans, which had been shown to occur in animals using serial sacrifice and tissue analysis, and which had been detected in metabolic studies (measurement of urinary metabolites or incubation of the drug with liver microsomes).

However, with the development of automated analytical techniques of high sensitivity and specificity (such as HPLC, LC-MS, and LC-MS-MS), the expansion of laboratories undertaking plasma drug analyses, and the full potential of pharmacokinetics to reveal information on in vivo drug absorption, distribution, and elimination has resulted in these techniques being applied increasingly to toxicology problems in laboratory animals. For therapeutic drugs, the impetus to develop toxicokinetic data in animals has been increased by recent international harmonization initiatives which promote the use of kinetic data in animals and humans to establish maximum dosage levels for toxicity studies. Although there is not acceptance that the top dose for nondrugs can be based on kinetic principles, there is increasing recognition of the value of such data for the interpretation of toxicity studies in which the top dose has been established by tolerability, for example the maximum tolerated dose. Problems of accumulation on repeated dosing and saturation of elimination are particularly pertinent to high-dose animal toxicity studies, and information on these areas can be obtained only from suitably designed in vivo toxicokinetic studies. It must be emphasized at the outset that the key to successful kinetic studies is the development of an assay of high specificity that measures the chemical without interference by its metabolites, and that is of sufficient sensitivity to define the terminal slope accurately (see below).

BIOLOGICAL PRINCIPLES

Certain general principles governing the disposition of therapeutic drugs are applicable to nearly all foreign compounds that are not substrates for normal intermediary

metabolism. These general properties of absorption, distribution, and elimination are valuable concepts, but it should be emphasized that they are not universally applicable, and investigators must be alert for exceptions. Exceptions arise when the foreign compound is structurally similar to an endogenous body constituent, because it may then undergo a specific carrier-mediated uptake process or metabolism. Good examples of compounds showing such characteristics include the antiparkinsonian drug levodopa, the amino acid metabolites of the intense sweetener aspartame, and the purine and pyrimidine base analogs used in cancer chemotherapy and as antiviral agents, many of which not only undergo active uptake into cells but also may be metabolized to phosphorylated products, which accumulate within the cells of the body.

Absorption

Absorption describes the processes involved in the transfer of the drug from the site of administration into the systemic blood circulation. Because most toxicity studies are performed by the oral route, absorption from the gut is of greatest importance, although absorption from other sites is appropriate for certain toxicological studies.

Absorption from the Gut

Significant absorption occurs once the compound has dissolved and is present in the gut lumen as a molecular solution. Slow dissolution and release of drugs from oral sustained-release formulations can be useful for therapeutic drugs that are eliminated very rapidly. Dissolution may be slow and be the rate limiting process, especially when high doses have to be administered as a suspension. Slow dissolution of the compound in the gut lumen can affect the rate of absorption, the peak concentrations, and even the magnitude of acute effects.

The extent of absorption is determined largely by the pH of the gut lumen and the pKa and lipid solubility of the compound. Other biological variables, such as the presence of food, gastric emptying time, intestinal transit time, and the gut microflora, may also play important roles in limiting the rate of absorption and the amount of compound absorbed unchanged. The absorption of chemicals requires passage across lipid membranes (Figure 4.2), which can involve (a) passive diffusion through the membrane, (b) passage through membrane pores, and (c) specialized carrier-mediated processes.

The rate of diffusion of a chemical across a membrane, given by Fick's law, is proportional to the concentration gradient, the membrane surface area, and the permeability coefficient of the compound. The permeability coefficient depends on the diffusivity of the molecule through the membrane, the membrane/aqueous medium partition coefficient, and the thickness of the membrane (21), and thus it is a characteristic for that particular compound and corresponds to a rate constant. Most environmental anutrients are absorbed in the small intestine because of its large surface area. For weak acids and bases, the membrane/aqueous partition coefficient varies with the pH of the medium. For such compounds, the diffusivity and partition coefficient of the ionized molecular species may be regarded as insignificant compared with the uncharged or un-ionized species.

Because it is the uncharged species that readily diffuses across membranes, absorption is faster under conditions in which ionization is suppressed, that is, at low pH for acids and high pH for bases. When the two compartments separated by the lipid membrane are kept at different pH values, the total concentrations in each compartment at equilibrium are different. The extent of ionization of a weak acid may be related to the environmental pH and its p*Ka* by the Henderson-Hasselbalch equation:

$$\mathrm{pH} = \mathrm{pK_a} + \log\frac{[\text{conjugate base}]}{[\text{conjugate acid}]}$$

At equilibrium, the concentrations of the diffusible form (un-ionized) on each side of the membrane are equal, and the concentration of the ionized form is given by the Henderson-Hasselbalch equation (Figure 4.3).

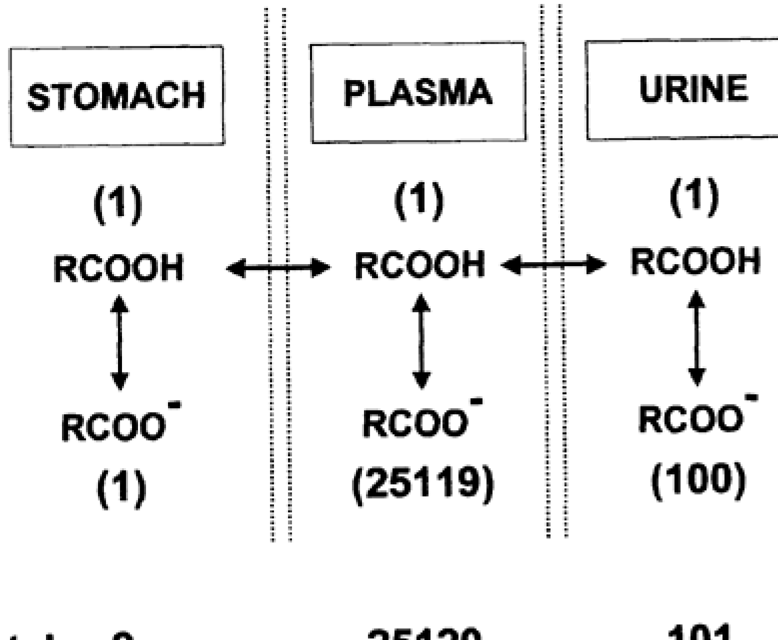

FIG. 4.3. pH partitioning. The numbers give the relative concentration of un-ionized and ionized species in each compartment, as determined by the HendersonHasselbalch equation for a weak acid (p*Ka* 3.0) at the pH of stomach (3.0), plasma (7.4), and urine (5.0). The total concentration is the concentration of compound in each compartment at equilibrium, assuming that the ionized form undergoes negligible diffusion.

It is apparent from Figure 4.3 that weak acids should be absorbed rapidly and extensively in the low pH of the stomach, whereas weak bases should undergo absorption in the intestine and not the stomach. Although this is true for bases, absorption of acids from the stomach is limited, possibly due to the relatively small surface area of the gastric mucosa. Strong organic acids and bases frequently show incomplete absorption from the gut, because they are extensively ionized at all pH values of the gut.

The absorption of foreign compounds by passage through membrane pores, which are about 4 A in diameter, is largely applicable to small water-soluble molecules (<200 Da) (21). Bulk passage of water across the membrane may act as a driving force and carry small molecules with it (66), and this should be borne in mind when studying the absorption kinetics of large doses of sparingly water-soluble compounds. Under such circumstances, the oral administration of high doses in large volumes of hypotonic solution could result in enhanced absorption. This situation is the opposite of the case for compounds undergoing carrier-mediated absorption, because high concentrations may saturate the carrier, and the rate and extent of absorption may be reduced at high doses. Food can also affect carrier-mediated absorption by competition with the natural substrate for the carrier. Examples of foreign compounds undergoing active absorption are rare and usually apply when the chemical resembles a nutrient (e.g., levodopa).

A number of factors may limit the amount of a compound that reaches the systemic circulation as the original or parent compound after oral administration (bioavailability; see later).

1. Extremes of pH, which may affect the stability of the compound. Species differences can then arise between rats (gastric pH 3.8–5.0) and rabbits (gastric pH 3.9) (98) and humans (gastric pH 1–2).
2. Hydrolytic enzymes. The gut is rich in nonspecific proteases and lipases, which may affect foreign compounds.
3. Gut microflora. The gut flora can perform a wide range of largely degradative metabolic reactions on foreign compounds (91), which may reduce the amount available for absorption or result in the formation of potentially toxic metabolites (72). Species differences in gut flora are seen in both types of organism present and their distribution along the gut (98), with larger numbers in the stomach and upper intestine of rats and mice, compared with rabbits, dogs, and humans, in which the upper intestinal tract is almost sterile because of the low gastric pH.
4. Metabolism by the gut wall. The gut wall has the capacity to inactivate metabolically certain compounds prior to their reaching the hepatic portal vein (first-pass effect) (16). The intestinal wall is rich in enzymes catalyzing general hydrolysis and conjugation reactions (such as glucuronidation and sulfation), monoamine oxidase, and some oxidative enzymes, particularly CYP3A4/5.
5. Metabolism by the liver. Many compounds are effectively removed from the hepatic portal vein by a single passage (first-pass effect) (36). The liver is the main site of foreign compound metabolism in the body, and represents the main metabolic barrier to the parent compound reaching the general circulation.
6. Food present in the gut lumen, which may affect the absorption rate, gastric pH, or gut motility.
7. P-Glycoprotein, which is expressed on the luminal surface of the intestinal epithelium, and can act as an efflux pump for compounds entering the enterocyte.

These barriers to the establishment of effective plasma levels of the compound may be associated with suppression of systemic pharmacological and toxic properties (35) and thus render dietary administration an inappropriate route for the toxicity testing of compounds for which exposure of humans is parenteral.

Absorption from the Nasal Cavity

The nasal cavity has various interesting properties as a route of administration. Although it has relatively small surface area, the mucous membrane is highly permeable, so that after nasal administration even quaternary ammonium compounds, which are poorly absorbed from the gut, show blood levels approaching those present following intravenous administration (103). In addition, the nature of this site and its venous drainage directly into the systemic circulation allow increased absorption of compounds extensively metabolized in the gut lumen (e.g., proteins) or in the liver. Local toxicity may be a problem with this route at high doses (103).

Absorption from the Lung

The lung represents a poor barrier to a chemical entering the blood, as it has a large surface area of thin membrane, a limited capacity to metabolize foreign compounds, and an excellent blood supply. The epithelium acts as a limited permeability barrier, allowing only slow absorption of highly water-soluble compounds (106), although the rate may be greater than that from the gastrointestinal tract. The lung is a major site of inactivation of circulating local hormones such as peptides and prostaglandins; however,

for toxicity testing, similar substances would not be likely to be given by this route. Major problems exist with the quantitative analysis of the extent and rate of absorption from the lung, due to poor measurement of the dose given by this route. Par

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_141.html[2010/10/28 18:41:08]

Page 142

ticulate matter is largely trapped by the cilia and passed back to be absorbed in the gut. Volatile compounds are absorbed only partially, and the unabsorbed fraction is eliminated in the expired air and not retained for subsequent absorption, as occurs in the gut (37).

Percutaneous Absorption

The extent of percutaneous absorption is highly dependent on the lipophilicity of the compound, because the stratum corneum of the epidermis acts as an effective barrier (37, 54). This route is important for the therapeutic administration of potent lipophilic drugs which undergo extensive first-pass metabolism (e.g., organic nitrates in angina) and for workers exposed to environmental aerosols and particulates. Studies in animals and humans suggest that the rate-limiting step is the initial penetration of the stratum corneum (40), which may result in very slow absorption and "flip-flop" kinetics (see following).

Distribution

Foreign compounds are distributed largely via the blood, although the lymphatic system may be important in the initial distribution of some very lipid-soluble chemicals given orally. The rate of uptake of a compound by the tissues may be limited by either diffusion rate or perfusion rate.

1. Diffusion rate. If the diffusion of the chemical across membranes is slow, the rate of entry into tissues is limited by this property of the molecule.
2. Perfusion rate. If the diffusion of the chemical across membranes is rapid, the rate of entry is limited by the rate of delivery to the tissue, that is, the perfusion rate.

As a generalization, diffusion rate limitation applies to highly water-soluble compounds, whereas perfusion rate limitation applies to the entry of lipid-soluble compounds into slowly perfused systems, such as adipose tissue. The perfusion rates of the major organ systems of man (Table 4.1) can be readily divided into well and poorly perfused tissues.

The extent to which chemicals leave the blood and enter tissues depends on their relative affinities for each system. Thus compounds highly bound to plasma protein but not to tissue show a relatively high concentration in the plasma, whereas drugs with a high affinity for tissue components such as proteins or fat have a low plasma concentration. However, it should be remembered that it is the *relative* affinity that determines the extent of distribution to tissues. The dye Evans Blue has a high affinity for plasma protein, and its distribution (Table 4.2) is restricted to the plasma volume (3 L in man); the β-blocker propranolol is highly bound to plasma protein (95%), but it also shows a higher affinity for the tissues,

Table 4.1 Relative organ perfusion rates in man[a]

Organ	Percent Body weight[b]	Blood flow[c] (ml/min)	Percent cardiac output[b,c]	Blood flow[b,c] (ml/min/100 g)
Well perfused

a Compounds for which the distribution is restricted to a particular body fluid.

so that relatively low concentrations remain in the plasma after distribution.

The volumes of body fluids and chemicals that distribute in them are given in Table 4.2. However, only rarely do compounds distribute to a single physiologically recognizable volume, and usually some degree of tissue selectivity is observed. Thus, a compound may appear to have dissolved in total body water because the apparent volume of distribution (see below) corresponds to about 60% of body weight, but it may actually show a nonuniform tissue distribution.

Many foreign compounds bind reversibly to plasma proteins, with albumin being of the greatest importance, although acid glycoproteins may be important for certain organic bases (68). Foreign compounds bind at specific sites in a reversible, saturable fashion, and the bound material represents an inactive depot of the chemical. Extensive protein binding lowers the concentration of unbound chemical in the blood, which may increase the concentration gradient and thus the rate of diffusion into blood from the gut (during absorption) or reabsorption from the kidney tubules (during elimination) (56). The dissociation of the chemical-protein complex occurs within milliseconds, and by comparison with tissue perfusion times may be regarded as instantaneous. Thus, for tissues in which the free plasma concentration is lowered rapidly by an active uptake process within the tissue (i.e., liver or kidney), the compound can be effectively stripped from plasma proteins in a single passage. The plasma protein binding of foreign compounds has been reviewed and discussed by several authors (19, 25, 50, 56, 61).

Elimination

There are two main mechanisms by which the circulating levels of a foreign compound may be reduced: metabolism and excretion. *Metabolism* and its toxicological consequences are discussed in an earlier chapter. Certain mathematical implications are discussed later. The principal routes of excretion are via the urine and feces, and in the case of volatile compounds, the expired air.

Excretion via Urine

There are three major processes affecting elimination in the kidney.

Glomerular filtration. The glomerular membrane has pores of 70–80 A. Under the positive hydrostatic conditions in the glomerulus, all molecules smaller than about 20,000 Da are filtered. Thus proteins and protein-bound compounds remain in the plasma, and about 20% of the nonbound chemical is carried with 20% of the plasma water into the glomerular filtrate.

Reabsorption. Because the glomerular filtrate contains many important body constituents (e.g., glucose), there are specific active uptake processes to transport them from urine back into blood. Although not normally substrates for these transport processes, lipid-soluble chemicals diffuse back from the tubule into the blood, especially as the urine becomes more concentrated because of water reabsorption. The pH of the urine is generally lower than that of the plasma, and therefore weak acids are more ionized in plasma, so that pH partitioning (see above) tends to increase the reabsorption of weak acids. The pH of the urine can be altered appreciably by treatment with ammonium chloride (decreases pH) or sodium carbonate (increases pH); the buffered plasma shows little change. It is thus relatively easy to affect the pH partitioning of foreign compounds between tubule contents and plasma, and either increase or decrease the elimination rate. This possibility should be considered when preparing dose solutions, because the use of excess acid or alkali to dissolve the test compound could alter its renal elimination.

Tubular secretion. Foreign compounds may be secreted actively into the renal tubule against a concentration gradient by anion and cation carrier processes. These processes are saturable and of relatively low specificity; many basic or acidic compounds and their metabolites (especially the phase II or conjugation products) are removed by them (26). Organic cation transporters are expressed on the luminal membrane of

the renal tubule and are important in eliminating charged molecules (125). Because the dissociation rate for the chemical-albumin complex is rapid, it is possible for highly protein-bound compounds to be almost completely cleared at a single passage through the kidney.

Excretion via the Gut

The bile is the most important route allowing foreign compounds to move from the general circulation into the gut. The biological aspects of this mechanism have been reviewed (99), and certain pertinent points have emerged. Organic cation transporters on the sinusoidal membrane transfer large polar cations into the hepatocyte and from the hepatocyte in the bile (125). The bile may be regarded as a complementary pathway to the urine, with small molecules being eliminated by the kidney and large molecules in the bile. Thus the bile becomes the principal excretory route for many xenobiotic conjugates. Species differences exist in the molecular weight requirement for significant biliary excretion, which has been estimated as 325±50 Da in the rat, 440±50 Da in the guinea pig, 475±50 Da in the rabbit (43), and about 500 Da in humans. In the rat, small molecules (<350 Da) are not eliminated in the bile and large molecules (>450 Da) are not excreted in the urine, even if the principal excretory mechanism is blocked by ligation of the renal pedicles or bile duct, respectively. Compounds of intermediate molecular weight (350–450 Da) are excreted by both routes, and ligation of one pathway results in increased use of the other (42).

Foreign compounds may also enter the gut by direct diffusion or secretion across the gut wall, elimination in the saliva, pH partitioning of bases into the low pH of the stomach, and elimination in the pancreatic juice. In most cases, these routes are quantitatively of minor importance, although they may play an important role in toxicity by allowing a foreign compound to undergo metabolism by the gastrointestinal flora (30, 72, 74). The toxicological implications of the gut microflora have been reviewed by Scheline (91).

MATHEMATICAL PRINCIPLES

In order to adequately describe the changes in blood or plasma concentrations of foreign compounds, it is necessary to assign a suitable mathematical model that accurately predicts the shape of the plasma concentration-time curve. However, certain aspects are model independent and are considered first, because these considerations are usually constituent parts of the various models. In addition, there has been a marked trend away from multicompartmental mathematical analysis, which offers little apart from mathematical predictability, toward physiologically more relevant model-independent concepts such as clearance (17, 118). Physiologically related parameters such as clearance and bioavailability represent an intermediate stage between mathematical multicompartment models and PBPK models.

Model-Independent Considerations

Biochemical and physiological processes are usually either zero-order or first-order reactions. In zero-order reactions the rate of change in concentration occurs at a fixed amount per time, that is,

$$\frac{dC}{dt} = k$$

where C is concentration, t is time, and k is a constant with units of amount per time, for example, micrograms per minute. In first-order reactions the rate of change in concentration is proportional to the concentration of the chemical available for the reaction, that is,

$$\frac{dC}{dt} = kC$$

where k is a constant that represents a proportional change with time and has units of time^{-1}, for example, min^{-1}.

Most processes (e.g., diffusion, carrier-mediated uptake, metabolism, excretion) are first-order reactions at low concentrations. *Most of the equations given below make this assumption.* Zero-order reactions are particularly important at high concentrations, when enzymes are working at maximum rate and an increase in C cannot result in an increase in rate. This situation produces nonlinear, or saturation, kinetics, which can assume considerable importance in toxicity studies, and is discussed later.

First-order reactions can be described by equations employing exponential functions. In many cases the entry of a foreign compound into the body or into a tissue follows an exponential increase, which may be described mathematically by

$$\text{Uptake} = 1 - e^{-kt} \quad [1]$$

where the uptake is the concentration present at time t divided by the final concentration when all the compound has entered the body or tissue. This equation assumes that there is no elimination process

occurring. The elimination of a compound (by a single mechanism) once it has entered the body or tissue may be described by

$$C=C_0e^{-kt} \quad [2]$$

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_144.html[2010/10/28 18:41:10]

Page 145

where C is the concentration present at time t, and C_0 is the initial concentration. In Eq. (1) and (2), k is the rate constant for that process.

Exponential equations of the type given in Eq. (2) may be solved as

$$\ln C = \ln C_0 - kt$$

or using $\log_{10}$

$$\log C = \log C_0 - \frac{kt}{2.303}$$

which represents an equation of the generalized form

$$y = C + mx$$

where m and C are constants, and x and y are variables. In such cases, a plot of x against y gives a straight line graph with a slope of m and an intercept of C. Thus for toxicokinetics, a graph of $\ln C$ against time gives a slope of $-k$ and an intercept of $\ln C_0$. If such a graph is drawn using log-linear graph paper, the slope must be calculated by taking the $\log_{10}$ of the concentration terms and dividing by the time (see below), and the slope will be $-k/2.303$.

Frequently, the equation necessary to describe the kinetics of a compound in the body requires the use of two exponential rate terms, that is, absorption into a single compartment plus elimination, or elimination from a two-compartment system (see below). In such cases the early time points in the concentration-time curve are influenced by both rates. However, provided the rate constants are sufficiently dissimilar, eventually the influence of the component with the higher rate becomes negligible, whereas the smaller rate constant still affects the concentration. Thus the terminal phase of the concentration-time curve is determined by the process with the smaller rate constant, and the earlier phase by the sum of both processes. This process allows both rate constants to be determined by the procedure known as the method of residuals or stripping (see below).

Tissue Extraction

Removal of a compound from the blood by a tissue is schematized in Figure 4.4. On constant infusion, the rate of entry into the tissue may be regarded as equivalent to a first-order absorption rate (78):

$$\text{Uptake} = 1 - e^{-kt} \quad [1]$$

where uptake=the fractional uptake=$C_t/C_{equilibrium}$.

In *perfusion limited uptake*, the value k is related to the flow rate *(Q)* as follows (Figure 4.4):

$$\text{Fractional uptake} = 1 - e^{-(Q/PV_t)t} \quad [3]$$

(Q/V_t is the volume-adjusted flow rate and P is the par

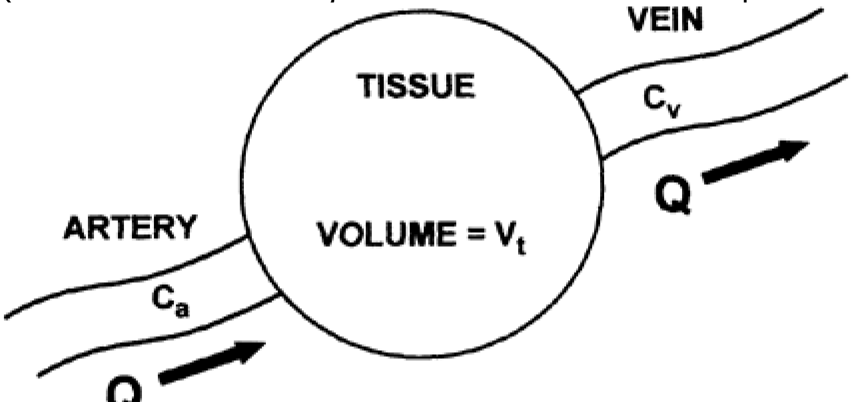

FIG. 4.4. Tissue uptake of foreign compounds. Q is the blood flow, C_a is the arterial concentration, C_v is the venous concentration, C_t is the concentration in tissue, and V_t is the volume of tissue. We define the following parameters: rate of delivery of drug=QC_a, rate of outflow of drug=QC_v, and rate of uptake=QC_a-QC_v. The units for these rates are mass time^{-1} (i.e., μg min^{-1}, etc.). Thus

$$\text{Extraction ratio } (E) = \frac{\text{rate of uptake}}{\text{rate of delivery}} = \frac{QC_a - QC_v}{QC_a} = \frac{C_a - C_v}{C_a}$$

$$\text{Partition ratio } (P) = \frac{\text{Concentration in tissue}}{\text{Concentration in blood supply}} = \frac{C_t}{C_a}$$

These relationships are an essential part of PBPK models.
tition ratio). The uptake half-time may be derived as described below for Eq. (19):

$$t_{1/2}(\text{uptake}) = \frac{0.693}{k} = \frac{0.693PV_t}{Q} = \frac{0.693P}{Q/V_t} \quad [4]$$

For *diffusion-limited uptake,* the value *k* is related to the diffusion rate constant and thus is not readily measurable.

Plasma Protein Binding

The extent of protein binding may be represented by an equilibrium reaction:

$$P^r + C_u \rightleftharpoons C_b$$

where *Pr* is the free protein, *Cu* is the unbound compound, and *Cb* is the compound-protein complex. The equilibrium constant *K* is given by

$$K = \frac{[C_b]}{[P^r][C_u]} = \frac{[\text{product}]}{[\text{reactants}]} \quad [5]$$

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_145.html[2010/10/28 18:41:10]

The fraction unbound a is given by

$$\alpha = \frac{C_u}{C_u + C_b} = \frac{C_u}{C_p} \quad [6]$$

where Cp is total plasma concentration. Scatchard plots of r/Cu against r (where is the moles of drug bound per mole of protein and Cu is the free drug concentration in moles) can be used to derive the number of binding sites and their association or affinity constants (25). Normally, for the binding of organic compounds to albumin, two or more binding sites are revealed. This approach is valuable for detailed studies on binding to and displacement from albumin, but it could yield multiple binding sites if applied to a complex protein mixture, such as plasma, containing different proteins at different concentrations.

Because it is the unbound compound in plasma that undergoes equilibration with the unbound compound in tissues (Figure 4.5), adequate information may be obtained from a knowledge of α, or of the percentage bound. Detailed knowledge is not required for pharmacokinetic analysis of the plasma data because the plasma concentrations used to calculate kinetic parameters are usually the total concentrations $(Cu+Cb)$. (When the nonbound concentration is used this has to be specified in the description of the parameters, e.g. clearance [nonprotein bound]; in the absence of such a description it is assumed that the total plasma concentration has been used). Because plasma protein binding is a saturable process (see later), in vitro binding studies should be performed over a range of concentrations.

Clearance

Clearance (CL) is defined as the ratio:

$$\mathrm{CL} = \frac{\text{Rate of elimination}}{\text{Plasma concentration}}$$

and may be regarded as the volume of plasma or blood that is cleared of compound in unit time by the route under consideration. The units are volume $time^{-1}$, for example, usually ml min^{-1} because if rate is μg min^{-1} and plasma concentration is μg ml^{-1} the plasma clearance will be ml min^{-1}.

Renal Clearance

The renal clearance (CLR) is given by

$$\mathrm{CL}_R = \frac{\text{rate of elimination in urine}}{\text{plasma concentration}} = \frac{C_u \times F_u}{C_p} \quad [7]$$

where Cu is the urine concentration, Fu is the urine flow (volume in unit time), and Cp is the plasma concentration at the midpoint of the urine collection period. The con

LIPID MEMBRANE

$$Cp_b \underset{}{\overset{K_{ap}}{\rightleftarrows}} Cp_u \leftrightarrow Ct_u \overset{K_{at}}{\rightleftarrows} Ct_b$$

Plasma Tissue

FIG. 4.5. Protein binding and tissue distribution. Cp is the plasma concentration, Ct is the tissue concentration, u=unbound, b=bound, Kap is the association constant for plasma protein binding. At equilibrium, $Cpu=Ctu$; and the relative distribution between plasma and tissue is determined by the values of Kap and Kat.

centration in urine is dependent on a number of variables, which are now described.

Glomerular filtration. The rate of filtration is given by

$$\mathrm{GFR} \times Cpu = \mathrm{GFR} \times Cp \times \alpha \quad [8]$$

where GFR is the glomerular filtration rate, Cpu is the unbound concentration in plasma, Cp is the total

plasma concentration, and a is the fraction unbound. Thus compounds binding extensively to plasma proteins show limited clearance by glomerular filtration. The protein binding equilibrium is not disturbed in the glomerulus because after loss of 20% free drug and 20% water, *C*pu is unaltered, whereas the concentrations of both free protein and drug-protein complex increase by 20%, that is,

Before filtration

$$K_{ap} = \frac{[\text{complex}]}{[C_{pu}][P^r]}$$

After filtration

$$K_{ap} = \frac{1.2\,[\text{complex}]}{[C_{pu}]\,1.2[P^r]}$$

where *Kap* is the protein-binding association constant. Thus, the chemical–protein complex does not dissociate in the glomerulus. The complex dissociates to give more free compound when the plasma is diluted by water reabsorbed in the distal parts of the renal tubule. Under such circumstances, about 99% of the plasma water is reabsorbed, so that the concentrations of the protein and complex return to almost their initial levels, whereas the concentration of unbound compound is diluted to about 80% of its former level, that is, after reabsorption:

$$K_{ap} \neq \frac{[\text{complex}]}{0.8[C_{pu}][P^r]}$$

Therefore the complex dissociates to restore the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_146.html[2010/10/28 18:41:11]

equilibrium. The glomerular filtration rate is about 130 ml min^{-1} in men and 120 ml min^{-1} in women, or approximately 2 ml $min^{-1}kg^{-1}$, which is lower than that of the Wistar rat (3.4 ml $min^{-1}kg^{-1}$) (100).

Reabsorption. Reabsorption from the renal tubule back into the blood is variable and dependent on the lipid solubility of the compound, the pH of the urine, and the extent of concentration of the urine (i.e., water reabsorption). Mathematical quantitation is impracticable, but an indication of the extent of reabsorption may be obtained (see below). In certain instances the administered foreign compound may be a substrate for carrier mediated reabsorption, in which case the renal elimination is dose dependent and is greater at high doses when this reuptake is saturated. Such a saturable reuptake process is obviously ideal for maintaining a constant low body load of an essential compound, for example, glucose or riboflavin, which might show adverse effects at high body concentrations.

Tubular secretion. Saturable carrier-mediated processes are present in the proximal part of the tubule. They show a relatively low substrate specificity, and the extent of their involvement for a particular compound is dependent on the affinity between the compound and the carrier protein. The extent of clearance by these active processes may be regarded as analogous to hepatic clearance, which is another active, saturable process. The specificities of the carriers have been studied extensively (26, 116, 125) and structural requirements such as

$$\begin{array}{c} \mathrm{R-\underset{\displaystyle O}{\overset{}{\underset{\|}{C}}}-\underset{\displaystyle H}{\underset{|}{N}}-(CHR')_n-COOH} \end{array}$$

have been proposed. Saturation of secretion causes a decreased elimination at high doses.

All three processes described above can alter, simultaneously and independently, the value of C_u for any given value of C_p. The final renal clearance may be regarded as a composite expression:

$$\text{Renal excretion} = \text{glomerular filtration} - \text{reabsorption} + \text{tubular secretion}$$

$$\text{Rate of excretion} = \text{GFR}\, C_p\alpha - \text{rate of reabsorption} + \text{rate of tubular secretion}$$

The values of GFR, C_p, and α can be determined experimentally. Measurement of inulin clearance (or creatinine clearance in man) determines the GFR, because this compound does not undergo significant reabsorption, tubular secretion, or protein binding; thus for inulin:

$$\text{Rate of renal excretion} = \text{GFR}\, C_p$$

and because

$$CL_R = \frac{\text{rate of excretion}}{C_p}$$

$$CL_R = \text{GFR}$$

The extent of reabsorption and secretion of a compound may be inferred from a comparison of its renal clearance with the value of GFR×α.

$CL_R < \text{GFR} \times \alpha$ Reabsorption must be occurring and is greater than secretion (which may or may not be present).

$CL_R = \text{GFR} \times \alpha$ Reabsorption, which may or may not be present, is negated by an equal rate of secretion.

$CL_R > \text{GFR} \times \alpha$ Tubular secretion must be occurring and is greater than reabsorption (which may or may not be present).

The mathematical implications of the renal elimination process have been the subject of a number of reviews (31, 115).

Hepatic Clearance

The clearance of a compound by the liver may be regarded as dependent on the rate of delivery to the organ (blood flow) and the efficiency of removal from the blood (extraction ratio; see Figure 4.4). Thus

$$CL_H = QE \qquad [9]$$

where CL_H is the hepatic (metabolic) clearance, Q is the hepatic blood flow, and E is the extraction ratio. This simple relationship has been verified experimentally for a number of compounds. However, it is complicated by the finding that the variables Q and E are not independent, because for certain compounds an increase in blood flow decreases the extraction efficiency. This finding led Rowland et al. (87) to propose the following relationship, known as the *perfusion limited model:*

$$CL_H = Q\left(\frac{\alpha \times CL_{int}}{Q + \alpha CL_{int}}\right) \qquad [10]$$

where α is the fraction unbound in plasma, CLint is the intrinsic metabolic clearance by the hepatocytes from the cell water, and *Q* is the blood flow (as plasma).

If the metabolic clearance (CLint) is high, the value in parentheses in Eq. (10), which is equivalent to the term *E* in Eq. (9), approaches unity; under these circumstances the hepatic clearance approximates to the hepatic blood flow and becomes dependent on the blood flow. However, if the metabolic clearance is low, $Q+\alpha$CLint approximates to *Q*, and therefore the extraction ratio *(E)* decreases with an increase in blood flow and the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_147.html[2010/10/28 18:41:12]

hepatic clearance remains relatively constant. These equations adequately explain the effects of changes in perfusion rate on the extraction ratio and clearance of compounds that show a range of extraction ratios. In addition, comparison of the hepatic clearance (calculated by measurement of *Q* and *E*) with "nonrenal" clearance (calculated as plasma clearance minus renal clearance) can indicate the role of extrahepatic tissues in the elimination of the compound.

Further analysis of this equation (see ref. 117 for discussion) indicates that

$$\mathrm{CL_{int}} = \frac{V_{max}}{K_m + C_{pu}} \qquad [11]$$

where V_{max} and K_m are Michaelis-Menton constants for the enzyme metabolizing the foreign compound, and C_{pu} is the hepatic venous concentration of unbound compound. If C_{pu} is low and is much less than the K_m for the enzyme (i.e., well below saturation levels), this term may be ignored and

$$\mathrm{CL_{int}} = \frac{V_{max}}{K_m} = \text{constant}$$

When the value of C_{pu} approaches or exceeds K_m, the substrate concentration is sufficient to saturate the enzyme, and the kinetics are grossly altered and become nonlinear. This situation is a distinct possibility in high-dose toxicity testing and is discussed later in more detail. The concepts given above are important for the use of V_{max} and K_m values in interspecies comparisons. V_{max}/K_m is taken as a measure of enzyme activity; species differences in clearance will relate to differences in this measure of enzyme activity for low clearance compounds, but will relate to liver blood flow for high clearance compounds (irrespective of differences in V_{max}/K_m). This possible source of error in extrapolation across species is avoided when both the enzyme activity and organ blood flows are part of a PBPK model (see below).

Biliary Clearance

The clearance via the bile CL_B is given, by analogy with renal clearance, as

$$\mathrm{CL}_B = \frac{\text{rate of elimination in bile}}{C_p} = \frac{C_B \times F_B}{C_p} \qquad [12]$$

where C_B is the concentration in bile and F_B is the volume of bile in unit time (bile flow).

Plasma Clearance

Plasma clearance (CL) may be defined as

$$\mathrm{CL} = \frac{\text{rate of elimination from plasma}}{C_p}$$

The plasma clearance is the sum of the various contributory clearance processes:

$$\mathrm{CL} = \mathrm{CL}_R + \mathrm{CL_H} + \mathrm{CL}_B + \text{etc.} \qquad [13]$$

Plasma clearance, which is one of the most valuable toxicokinetic constants, is determined from the plasma concentration-time curve and is discussed in detail later. It may be used to derive other model-independent variables, for example, mean residence time, which are given later under Statistical Moment Analysis.

Physiologically Based Pharmacokinetic Models

In recent years models have been developed which are based on the principles discussed above, that is, organ blood flow, tissue extraction, and rates of metabolism and excretion. These models are derived from the physiology of the test animal and are discussed in detail in Chapter 5. PBPK models have been applied successfully to a number of compounds and have been particularly successful for organic solvents, e.g., benzene (108). This approach represents a powerful method, capable of dealing with saturation of metabolism and valuable for the extrapolation of animal data to humans (69, 57, 113). However, its ability to predict concentrations is dependent on the precision of the parameter estimates used and the model chosen (9). Therefore, PBPK modeling should be considered as one of three possible approaches to the analysis and interpretation of toxicokinetic data:

1. Simple physiologically related concepts, such as bioavailability and clearance (this chapter)
2. Compartmental analysis, which gives mathematical precision but does not directly reflect organ concentration (this chapter)
3. PBPK modeling, which allows the prediction of target organ concentrations (Chapter 5)

Compartmented Systems: Modeling

In order to describe plasma concentration-time curves mathematically, an appropriate predictive model

has to be fitted to the data. The correlation between the actual data and the concentration-time curve generated using the model shows the suitability of the model in describing the experimental results. Thus considering the data presented in Figure 4.6 and Table 4.3, it is apparent that the same model cannot describe the properties of both compounds, although in both cases the initial and final plasma measurements were the same. The differences in the plasma concentration-time profiles originate in the number of rates at which the compound may leave and enter the plasma.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_148.html[2010/10/28 18:41:12]

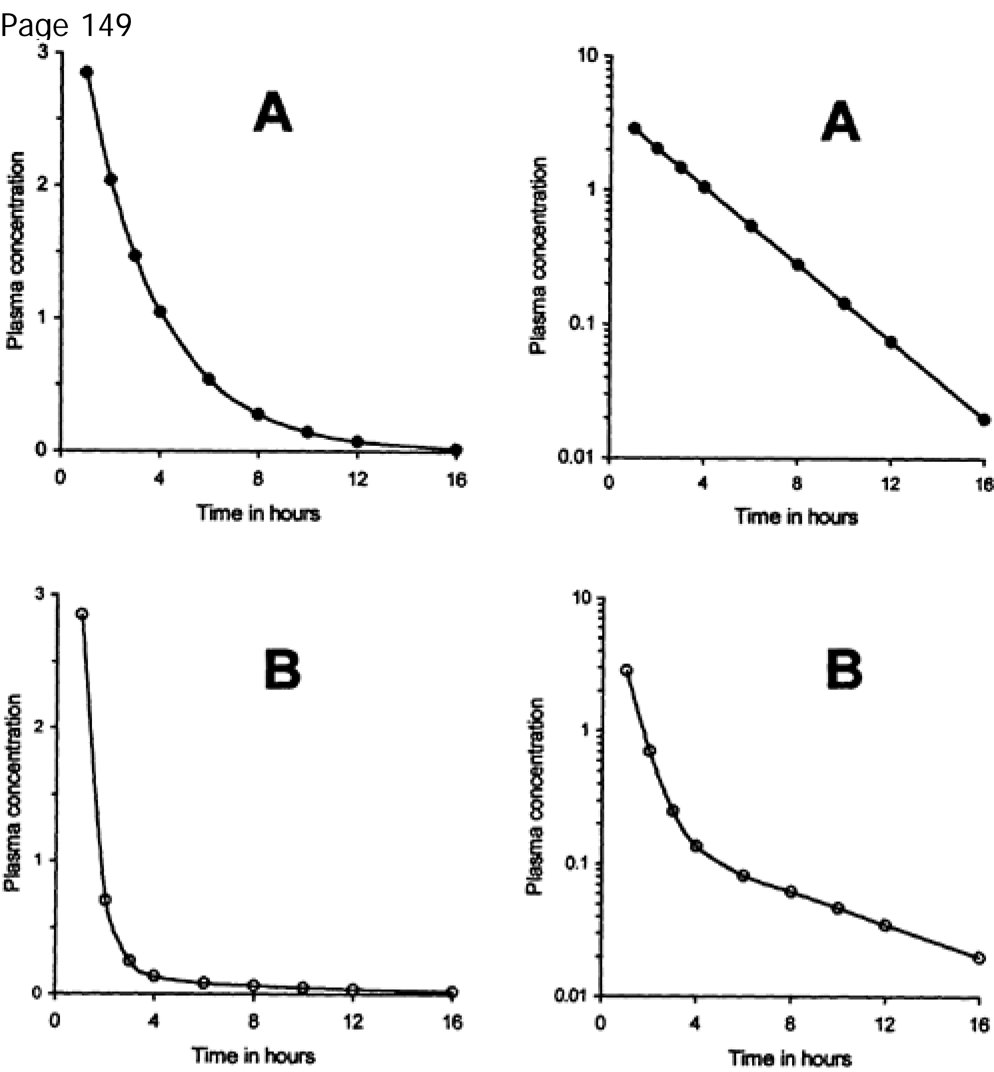

FIG. 4.6. Plasma concentration-time data for two compounds; results are plotted in linear and semilogarithmic forms. The data used to generate the curves are given in Table 4.3.

If the tissues show instantaneous equilibration with plasma, the compound leaves the plasma by a single process (Scheme 4.1A), an elimination process with a simple exponential decrease. Alternatively, the compound may leave the plasma to enter "other tissues" at measurable rates, as well as undergoing elimination from the plasma. Under such circumstances, the "other tissues" may be adequately described mathematically by a second compartment in addition to the plasma (or the central compartment) (Scheme 4.1B). In some cases, two or more additional compartments are required. It is important to realize that these "other tissues" share only one criterion, that is, their associated rate constants, and that biologically diverse tissues may be part of the same compartment. In addition, elimination may occur from compartments other than the central compartment (Schemes 4.1C-G). In most cases the processes of elim

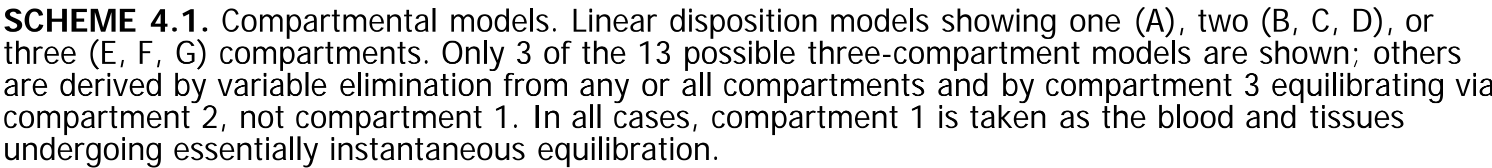


SCHEME 4.1. Compartmental models. Linear disposition models showing one (A), two (B, C, D), or three (E, F, G) compartments. Only 3 of the 13 possible three-compartment models are shown; others are derived by variable elimination from any or all compartments and by compartment 3 equilibrating via compartment 2, not compartment 1. In all cases, compartment 1 is taken as the blood and tissues undergoing essentially instantaneous equilibration.

ination and distribution of foreign compounds are by first-order reactions, that is, the rate of the reaction is proportional to the amount of substrate available for the reaction.

Wagner (111) reviewed compartmental models and showed that 17 linear models existed to describe one-, two, and three-compartment systems, that is, models in which the plasma concentration-time curve could be resolved into a number of linear components (see below). However, if the input into the model was noninstantaneous, additional models would be generated. Wagner (111) concluded that there were 760 possible pharmacokinetic models comprising up to three distribution compartments and two input compartments, but that in many cases and for many calculations a knowledge of the best-fit model was not necessary. Because the aim of this chapter is to provide an introduction to toxicokinetics (i.e., samples needed, data handling, and the type of information that can be obtained), only simple models are discussed in detail. Readers are referred to standard texts on pharmacokinetics if the plasma data are not fitted by the simple models discussed here. However, the two models selected show widespread applicability, and an understanding of the principles underlying these simple models is essential, if the data generated by computer analysis of more complex models are to have any meaning. In addition, more complex models contain greater numbers of variables, and blood sampling must be increased to define the rate constants accurately.

Texts recommended for further reading include those by Rescigno and Segre (78), a mathematical approach with few drug illustrations; Gibaldi and Perrier (36), a classic text, which is a mathematical approach that is well explained and illustrated using actual experimental data; Rowland and Tozer (85), a well-written, readable text with many excellent illustrations and study problems at the end of each section; Wagner (112), an approach similar to that of Gibaldi and Perrier but with a useful "biological" introductory chapter and expanded sections on dosage regimen calculations, pharmacological response, and automated pharmacokinetic analysis. Additional useful sources for background reading include Benet et al. (8), a collection of papers from a symposium to honor S.Riegelman; Rowland and Tucker (86), which has useful sections on interspecies scaling and timeand dose-dependent kinetics; and Yacobi et al. (124), which relates to drug development. A particularly valuable book has been published recently by Gabrielsson and Weiner (28), which gives a clear account of different models in relation to the use of WinNonlin, and provides excellent explanations of the basics of data fitting. All volumes provide references, either at the end of each chapter or for each illustration.

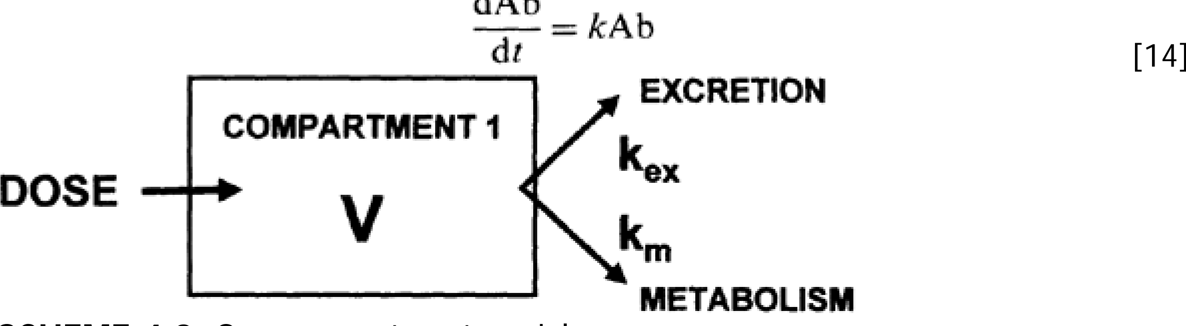
One-Compartment Open Model

Intravenous Bolus Dose

The compound is dissolved in and evenly distributed within a single compartment of volume *V*. Elimination of the compound, by both excretion and metabolism, is by first-order processes, and changes in plasma concentration are reflected in similar and simultaneous decreases in the tissue concentrations, because all tissues represent part of the single compartment (Schemes 4.1A and 4.2). In Scheme 4.2, *V* is the volume of distribution, k_{ex} is the excretion rate constant, and k_m is the metabolism rate constant. The plasma concentration-time curve for a one-compartment system is given

in Figure 4.7, the data are presented in Table 4.4. In mathematical terms, such a system may be described adequately by a simple first-order equation, where the rate of removal of a compound from the body (e.g., in milligrams per hour) is proportional to the body load (e.g., in milligrams):

$$\frac{\mathrm{dAb}}{\mathrm{d}t} = k\mathrm{Ab} \qquad [14]$$



SCHEME 4.2. One-compartment model.

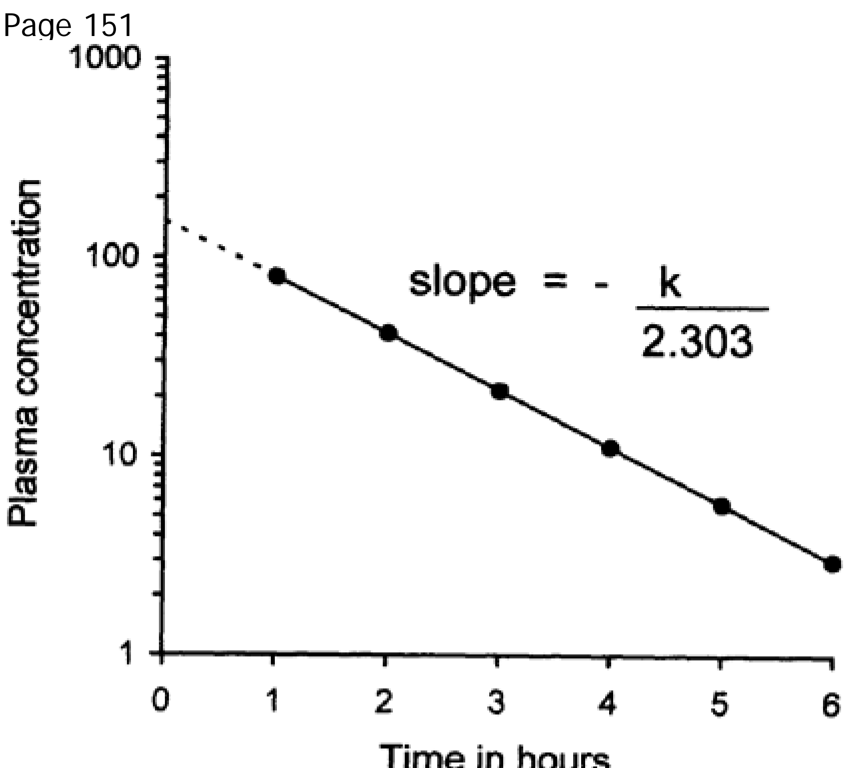


FIG. 4.7. Plasma concentration-time curve after a bolus intravenous dose for a one-compartment system. The data are given in Table 4.4.

Table 4.4 Data used for Figure 4.7*a*

Time (h)	C_p (μg ml^{-1})	ln C_p

6	3.0	1.099	V=324 ml Kg^{-1}

a The plasma concentrations were obtained after an intravenous bolus dose of 50 mg/kg.

where Ab is the amount of compound in the body, and k is the elimination rate constant (k equals $[k_{ex}+k_m]$). A solution to this equation to give the amount remaining in the body at time t after injection is given by

$$Ab_t = Ab_0 e^{-kt} \quad [15]$$

where Ab_t is the amount of compound at time t, and Ab_0 is the amount at time zero.

Assuming uniform distribution within a single compartment, the concentration in the plasma *(Cp)* may be related to Ab by the *apparent volume of distribution (V)*. This volume may be regarded as the volume of plasma in which the body burden (body load) would have to be dissolved, in order to give the plasma concentration measured. For a chemical that is lipid soluble or that readily binds to tissue components, the plasma concentration represents a small fraction of the total amount in the body, and thus the compound appears to have been dissolved in a large volume of plasma (see below):

$$C_p = \frac{Ab}{V} \quad [16]$$

where C_p is the plasma concentration and V is the apparent volume of distribution. Thus Eq. (15) may be rewritten in its more usual form,

$$C_{pt} = C_{p0} e^{-kt} \quad [17]$$

where C_{pt} is the plasma concentration at time t, and C_{p0} is the concentration at time zero. For such a system, we can define the following parameters.

Apparent volume of distribution. The apparent volume of distribution *(V)* is the apparent volume into which the dose would have been dissolved to give the initial plasma concentration, C_{p0}, that is,

$$V = \frac{\text{Ab}}{C_p} = \frac{\text{dose}}{C_{p0}} \qquad [18]$$

The units are in liters, milliliters, liters per kilogram, or milliliters per kilogram.

Elimination rate constant. The elimination rate constant *(k)* represents the fractional loss of compound from the body per unit time, that is,

$$k = \frac{\text{amount of chemical eliminated in unit time}}{\text{amount of chemical in the body}} = \frac{(\text{dAb}/\text{d}t)}{\text{Ab}}$$

Equation (17) may be rewritten as

either $\ln C_{pt} = \ln C_{p0} - kt$

or $$\log C_{pt} = \log C_{p0} - \frac{kt}{2.303}$$

Thus a graph of ln C_p against time has a slope of $-k$ and an intercept of ln C_{p0}; a graph of log C_p against time has a slope of $-k/2.303$ and an intercept of log C_{p0} (Figure 4.7). The units of k are h^{-1} or min^{-1}. Thus if the elimination rate constant is determined as 0.4 h^{-1}, it means that 40% of the body load is removed each hour. The value of k is the summation of component elimination rate constants (e.g., k_{ex}, k_m).

Elimination half-life. The elimination half-life ($t_{1/2}$) is the time taken for the amount in the body (Ab) or the plasma concentration (Ab/V) to decrease to one-half. Thus after one half-life, C_p in Eq. (17) equals $C_{p0}/2$, that is,

$$\frac{C_{p0}}{2} = C_{p0}e^{-kt_{1/2}} \qquad \text{or} \qquad \frac{1}{2} = e^{-kt_{1/2}}$$

Page 152

Therefore,

$$\ln 0.5 = -kt_{1/2} \qquad \text{or} \qquad -0.693 = -kt_{1/2}$$

$$t_{1/2} = \frac{0.693}{k} \qquad [19]$$

where the units are hours or minutes.

Plasma clearance. Plasma clearance (CL) is the amount of chemical eliminated in unit time related to the plasma concentration and may be regarded as the volume of blood that is cleared of chemical in unit time. CL is a constant for first-order reactions. In many respects, this measurement is a better reflection of the inherent capacity of the tissues to eliminate the compound than is the half-life or elimination rate constant:

$$\mathrm{CL} = \frac{\text{rate of elimination}}{\text{plasma concentration}}$$

$$\mathrm{CL} = \frac{(\mathrm{dAb}/\mathrm{d}t)}{C_p} \qquad [20]$$

Substituting from Eq. (14),

$$\mathrm{CL} = \frac{k\mathrm{Ab}}{C_p}$$

The amount in the body at any time (Ab) is given by Eq. (16); therefore

$$\mathrm{CL} = \frac{kC_pV}{C_p} = kV \qquad [21]$$

where the units are in L h^{-1}, L min^{-1}, ml h^{-1}, or ml min^{-1}. Rearranging Eq. (21),

$$k = \frac{\mathrm{CL}}{V}$$

This equation shows clearly that the elimination rate constant *(k)* is derived from two independent variables that can be related to physiological processes: the *clearance*, which reflects the capacity of the organs of elimination to remove the compound from the plasma, and the *apparent volume of distribution*, which reflects the proportion of the total body burden that is circulated to the organs of elimination. Plasma clearance may depend on the rate of the active process in the organs of elimination or on the plasma flow to the principal organ(s) of elimination.

Clearance may also be obtained without knowing the value of *V*. Rearranging Eq. (20),

$$\frac{\mathrm{dAb}}{\mathrm{d}t} = \mathrm{CL} \times C_p$$

or in time d*t*, the amount lost $\mathrm{dAb} = \mathrm{CL} \times C_p \times \mathrm{d}t$. Integrating between time=0 and infinity (∞) the total dose will have been eliminated, so that dAb=Dose,

$$\mathrm{Dose} = \mathrm{CL} \int_0^{\infty} C_p \mathrm{d}t$$

$$\mathrm{Dose} = \mathrm{CL} \times \mathrm{AUC}$$

$$\mathrm{CL} = \mathrm{Dose}/\mathrm{AUC} \qquad [22]$$

where AUC is the area under the plasma concentration-time curve extrapolated to infinity. For Eq. (22) to be valid, the dose has to be fully available to the organs of elimination (i.e. intravenous dosage) and the AUC has to be extrapolated to infinity.

This relationship can also be used to calculate *V;* substituting CL from Eq. (21) into Eq. (22):

$$V = \frac{\mathrm{dose}}{\mathrm{AUC} \times k} \qquad [23]$$

The value of Eqs. (22) and (23) is that both the clearance and the apparent volume of distribution can be derived from infusion or parenteral administration, where the determination of *V* using Eq. (18) is not possible, because the total dose is not present in the central compartment at *t*=0. These equations may

also be applied to oral administration, providing that allowance is made for incomplete absorption of the dose. This method of calculating CL is also applicable to multicompartment linear systems with elimination from the central compartment.

Information Obtainable from Urinary Data

From Eq. (7), we obtain

$$\text{Rate of urinary excretion} = CL_R \times C_p$$

where CL_R is the renal clearance. Thus

$$CL_R \times C_p = k_R \times V \times C_p = k_R \times Ab$$

from Eqs. (21) and (18), where k_R is the renal excretion rate constant. However, Ab at any time=dose $\times e^{-kt}$. Therefore

$$\text{Rate of urinary excretion} = k_R \times \text{dose} \times e^{-kt} \quad [24]$$

or

$$\log(\text{rate of urinary excretion}) = (\log k_R \times \text{dose}) - \frac{kt}{2.303} \quad [25]$$

A plot of rate of urinary excretion (amount excreted per time interval) against time gives a straight line on log-linear graph paper, the slope of which is $-k/2.303$, and the intercept is log k_R dose. It is important to note that the slope of this graph gives the overall elimination rate constant, not the specific urinary elimination rate

constant. In other words, the decrease in the amount appearing in the urine mirrors the overall decrease in the plasma concentration. It is not possible to obtain information regarding other kinetic parameters (such as CL_R or V) without sampling the central (blood) compartment. The value of k_R may be derived from the values of renal clearance

$$CL_R = \frac{C_u \times F_u}{C_p} \quad [7]$$

and the apparent volume of distribution, V, when $CL_R = k_R \times V$.

The above approach is subject to considerable fluctuation in the excretion rate due to factors such as incomplete bladder emptying. To overcome this problem, the rate constant can be derived more reliably from the amount remaining to be excreted, using the *sigma-minus* method. This method is based on the equation below, which is derived from integration of Eq. 24:

$$A_{ex} = \frac{k_R \times \text{dose}}{k}[1 - e^{-kt}] \quad [26]$$

where A_{ex} is the total amount excreted up to time t. At infinite time, $(1-e^{-kt})$ equals unity. Therefore

$$A_{ex}^{\infty} = \frac{k_R \times \text{dose}}{k}$$

where A_{ex}^{∞} is the cumulative total amount excreted in urine up to time infinity. Substituting back into Eq. (26)

$$A_{ex} = A_{ex}^{\infty}[1 - e^{-kt}]$$

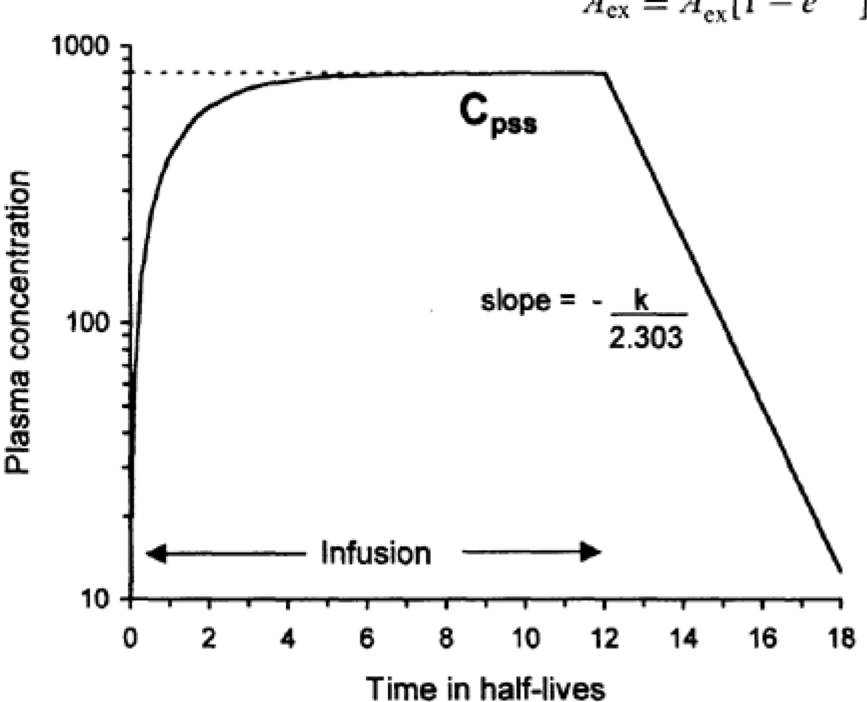

FIG. 4.8. Plasma concentration–time curve for constant intravenous infusion into a single-compartment system. The foreign compound was infused at a constant rate from time =0 to time=12 half-lives when the infusion was stopped.

or

$$A_{ex}^{\infty} - A_{ex} = A_{ex}^{\infty} e^{-kt} \quad [27]$$

The left-hand side of Eq. (27) is equivalent to the amount finally excreted minus the amount excreted up to that time (ΔA_{ex}). Taking logs,

$$\log \Delta A_{ex} = \log A_{ex}^{\infty} - \frac{kt}{2.303} \quad [28]$$

A semilog plot of ΔA_{ex} against time gives a straight line of slope $-k/2.303$. An example of this method is described below under Data Handling.

By analogy with Eq. (22), CL_R may be calculated from the total amount excreted and the plasma AUC

$$CL_R = \frac{A_{ex}}{AUC}$$

where A_{ex} and AUC refer to the same time interval.

Constant Intravenous Infusion

During infusion the plasma concentration (C_p) rises to reach a plateau or steady-state concentration (C_{pss}) at which time the rate of infusion equals the rate of elimination. By analogy with Eq. (1)

$$\frac{C_p}{C_{pss}} = (1 - e^{-kt})$$

or

$$C_p = C_{pss}(1 - e^{-kt}) \quad [29]$$

The various kinetic parameters may be derived from the plasma concentration-time curve for infusion (as given in Figure 4.8).

Decrease at end of infusion. The slope equals $-k$ because on cessation of entry into the single compartment, $C_p = C_{p0} e^{-kt}$. The same slope would be obtained if the infusion was stopped at any stage during the infusion.

Plateau level (C_{pss}). At steady state, the rate of infusion (R) equals the rate of elimination:

$$R = CL \times C_{pss}$$

or

$$CL = \frac{R}{C_{pss}} = V \times k$$

Increase to plateau. Rearranging Eq. (29),

$$C_{pss} - C_p = C_{pss} e^{-kt}$$

Therefore, a plot of ln ($C_{pss} - C_p$) against time gives a straight line with a slope equal to k. The time taken to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_153.html[2010/10/28 18:41:16]

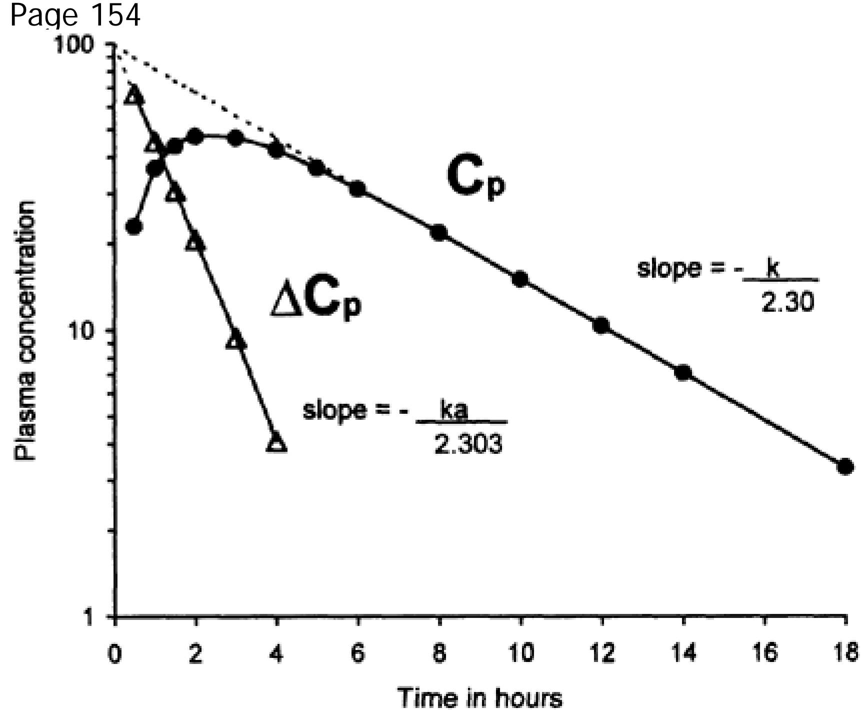

FIG. 4.9. Use of the method of residuals to calculate the absorption rate constant for a one-compartment system. The dose was given at time 0, and plasma levels *(Cp)* were measured at intervals. The linear terminal phase was extrapolated to yield the values corresponding to the measurement times. The difference values (*Cp* extrapolated −*Cp* measured) are plotted (Δ*Cp*) to yield a line of slope −*ka*/2.303 or −*k*/2.303; see text. The data are given in Table 4.5.

reach the plateau is therefore similar to the time taken to eliminate the compound after infusion, or about 97% of the final level within five half-lives.

Area under the curve. Both CL and *V* may be derived using Eqs. (22) and (23).

Oral Administration

Absorption frequently obeys first-order kinetics (80), but may involve a lag time due to delayed gastric emptying. The plasma concentration-time profile may thus resemble Figure 4.9 (see also Table 4.5), and the various pharmacokinetic parameters are related by the equation:

$$C_p = \frac{F \times \text{dose} \times k_a(e^{-kt} - e^{-k_a t})}{V(k_a - k)} \qquad [30]$$

where *F* is the fraction of the dose absorbed and *ka* is the absorption rate constant.

Decrease after peak. The decrease after the peak concentration is determined by the slower of the two processes (absorption or elimination), but it is usually elimination, and the slope is equal to −*k*. (Note that for a polar compound showing slow absorption and rapid elimination, this decrease is equivalent to −*ka*, a situation described by Gibaldi and Perrier (36) as "flip-flop" kinetics [see Figure 4.10]).

Peak plasma concentration. The peak plasma concentration is determined by the relative rates *ka* and *k*. This may be of toxicological importance, especially for acute effects when the extent of toxicity is frequently related to the peak concentration rather than to the area under

Table 4.5 Data used for Figure 4.9

Time (h)	*Cp*	In *Cp*	In *Cp*ex	*Cp*ex	Δ*Cp*	In Δ*Cp*	
0.5	23.0		4.501	90.1	67.1	4.206	
1	36.5		4.406	82.0	45.5	3.818	
1.5	43.9		4.312	74.6	30.7	3.424	
2	47.2		4.218	67.9	20.7	3.030	
3	46.8		4.029	56.2	9.4	2.241	$ka=0.797\ h^{-1}$

4	42.4		3.840	46.5	4.1	1.411
5	36.7		3.652	38.5	1.8	
6	31.1		3.463	31.9	0.8	
8	21.8	3.082				
10	15.0	2.708				
12	10.3	2.332				
14	7.1	1.960	k=0.1887 h−1			
18	3.3	1.194				

Note: The 5- and 6-h points are not included in the residuals analysis, as an error of 3% in the original value of C*p* would translate into an error of 61 and 117%, respectively, for the Δ*Cp* value.
In *Cp*ex=Data generated by linear regression analysis of the terminal phase of In *Cp* against time.
*Cp*ex=Antilogs.
Δ*Cp*=The values *(Cp*ex−*Cp)* used to draw the residuals line.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_154.html[2010/10/28 18:41:17]

Page 155

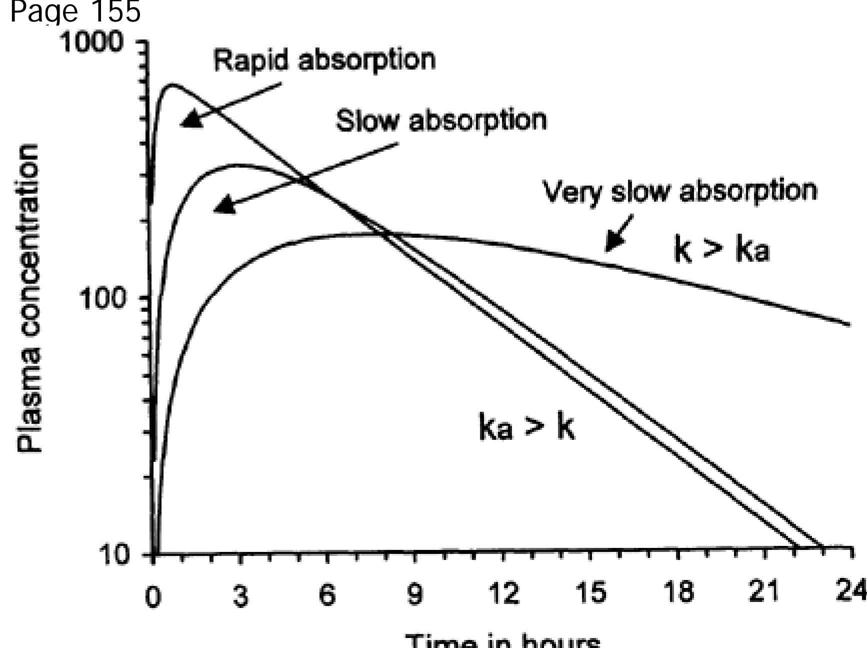

FIG. 4.10. The effect of absorption rate on the shape of the plasma concentration-time curve.

the curve. An increase in the absorption rate may be as important toxicologically therefore as a decrease in elimination rate.

Area under the curve. Both CL and *V* may be derived using Eqs. (22) and (23), providing that the dose used in the calculation is adjusted for the fraction absorbed *(F)*, that is,

$$\mathrm{CL} = \frac{\mathrm{dose} \times F}{\mathrm{AUC}}$$

It is common to see CLoral calculated as (dose/AUC) in the absence of any information on *F*. Such a term is meaningless physiologically; if the value of F is unknown, oral AUC data should be compared as such. Intravenous data are necessary to relate a nonlinear change in AUC at high oral doses to either altered CL or *F*.

The value of *F* may be determined by comparison of oral with intravenous dosing, because CL remains constant.

$$CL = \frac{\mathrm{dose}_o \times F}{\mathrm{AUC}_o} = \frac{\mathrm{dose}_{\mathrm{iv}}}{\mathrm{AUC}_{\mathrm{iv}}}$$

$$F = \frac{\mathrm{dose}_{\mathrm{iv}} \times \mathrm{AUC}_o}{\mathrm{AUC}_{\mathrm{iv}} \times \mathrm{dose}_o} \quad [31]$$

where *o* relates to oral and iv relates to intravenous dosing. These relationships are valid only if the AUC/dose ratio is constant: if not, the value of either *F* or CL must alter with an increase in dose, suggesting saturation of absorption or elimination (see below).

Alternatively, the fraction *F* may be derived from the cumulative urinary excretion:

$$\mathrm{F} = \frac{A^{\infty}_{\mathrm{exo}}}{A^{\infty}_{\mathrm{exiv}}} \times \frac{\mathrm{dose}_{\mathrm{iv}}}{\mathrm{dose}_o} \quad [32]$$

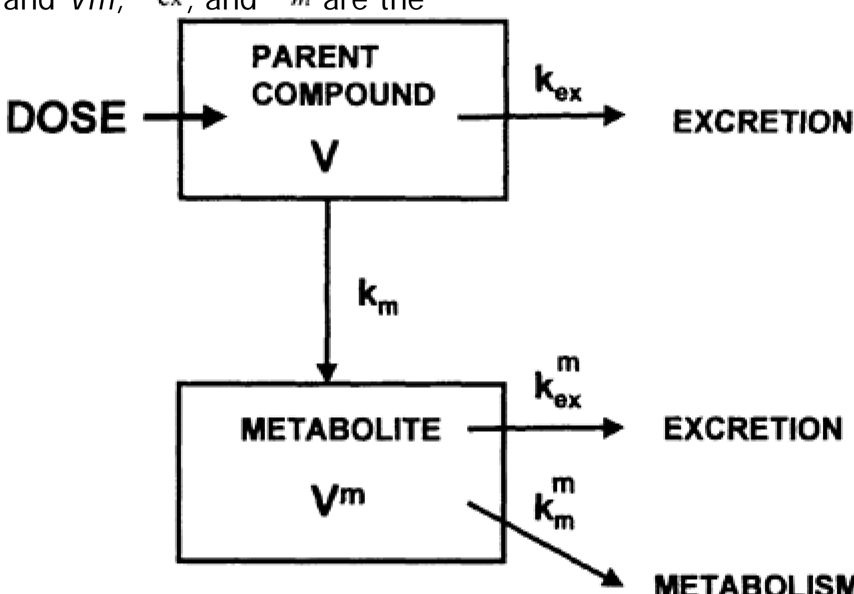
Increase to peak. The increase to peak is determined by the more rapid of the two processes, that is, usually absorption. Measurement of the absorption rate constant must make allowance for the excretion occurring throughout the postdosing period; the method of residuals is used (see Gibaldi and Perrier (36) for the mathematical basis of this method). The method is illustrated and explained in Figure 4.9 and Table 4.5. In cases where absorption is slow, the rate of increase may be determined by the elimination rate constant. Thus the value of *ka* can be assigned to the increase to peak only after demonstration that the value of *k* for the decrease is similar to that seen after intravenous dosing.

Metabolite Kinetics

As discussed elsewhere, the biotransformation of xenobiotics usually results in detoxication but is sometimes associated with the formation of a toxic metabolite. Measurement of the rate of metabolism

in vivo can provide much useful information on detoxication or bioactivation processes. In most cases, the rate of metabolite formation is governed by in vivo enzyme kinetics, which are first-order only over a limited substrate concentration range. Saturation of metabolism is discussed in more detail below, and the following analysis relates to metabolite formation under first-order reaction conditions, when CL depends on enzyme activity rather than liver blood flow.

The measurements that are available for analysis of metabolite kinetics include plasma levels of unchanged drug *(Cp)* and metabolite (C_p^m). The simple system given earlier, for the parent compound (Scheme 4.2) can be extended into Scheme 4.3, where *V, k*ex, and *km* are, respectively, the apparent volume of distribution, excretion rate constant, and metabolism rate constants for the parent compound, and *Vm*, k_{ex}^m, and k_m^m are the



SCHEME 4.3. One-compartment model with metabolite formation.

same parameters for the metabolite. The time course for the metabolite is given by

$$\frac{dM}{dt} = k_m \mathrm{Ab} - k^m M$$

where Ab and *M* are the amount of parent compound and metabolite in the body, respectively, and *km* is the overall elimination rate constant for the metabolite, that is, $k^m = k^m_{ex} + k^m_m$. This equation may be solved to yield

$$C^m_p = \frac{k_m \mathrm{dose}(e^{-k_m t} - e^{-kt})}{V^m(k - k^m)} \quad [33]$$

where C^m_p is the plasma concentration of the metabolite at time=*t*.

In many cases the overall elimination rate of the metabolite *(km)* is greater than the overall elimination rate of the parent compound *(k)* (for example in the case of the formation of a more polar metabolite). In such cases the term $e^{-k^m t}$ approaches zero before *e−kt*, and thus at late time points Eq. (33) may be rewritten and solved omitting e^{-k^m} when it becomes

$$\log C^m_p = \log \frac{k_m \times \mathrm{dose}}{V^m(k^m - k)} - \frac{kt}{2.303} \quad [34]$$

Thus the log plasma concentration of the metabolite-time curve has a terminal slope similar to that of the parent compound (i.e., *k*/2.303) (Figure 4.11). In this case the rate of elimination of the metabolite is limited by the elimination of the parent drug, and the metabolite/drug ratio remains constant during the elimination phase (Figure 4.11).

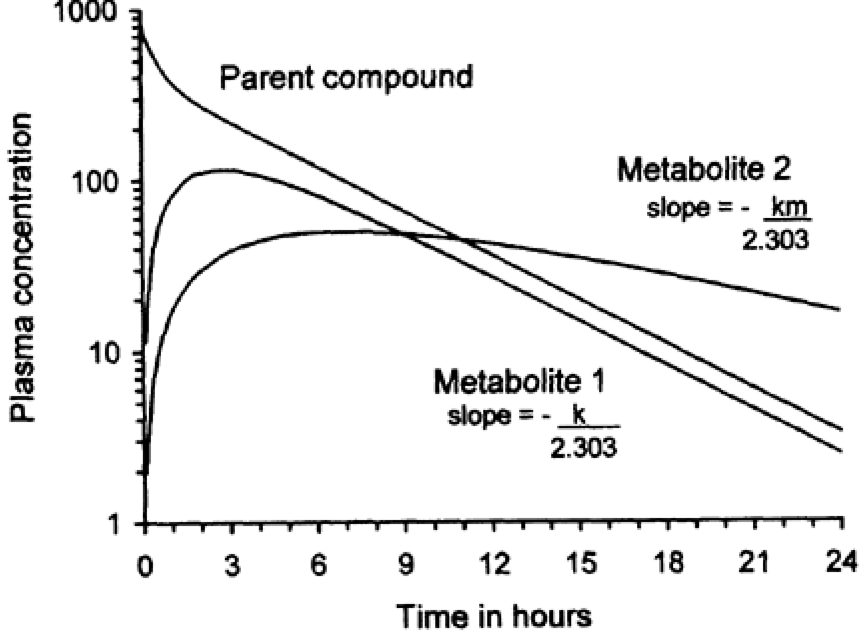


FIG. 4.11. Plasma concentration-time curves for parent compound and metabolites after intravenous dosing. The parent compound was given as an intravenous bolus dose at time=0.

In those cases where the elimination rate of the metabolite *(km)* is less than that of the parent compound *(k)*, the term *e−kt* approaches zero before $e^{-k^m t}$, and thus Eq. (33) may be written

$$\log C^m_p = \log \frac{k_m \times \mathrm{dose}}{V^m(k - k^m)} - \frac{k^m t}{2.303} \quad [35]$$

and a plot of log plasma concentration of the metabolite-time curve has a slope of −*km*/2.303. In this case, the ratio metabolite/drug increases during the elimination phase (Figure 4.11). The latter case is of particular interest to toxicologists because on repeated exposure the concentrations of metabolite at steady state may exceed those of the parent compound.

The overall elimination rate constants may also be derived from urinary metabolite levels as described above for the parent compound, although again the derived rate may be either *k* or *km* and the identity

can be determined only by measuring k and k_m separately after administration of both the parent compound and the metabolite. However, if metabolite kinetics are based solely on urinary excretion data, the formation of more lipid-soluble metabolites may be missed. For example, the active thioether metabolite of sulfinpyrazone is a major circulating metabolite of which negligible amounts are excreted in the urine (102).

Two-Compartment Open Model

Mathematically and physiologically, it is often more appropriate to regard the body as representing a simple two-compartment open system in which the distribution to certain peripheral tissues is not an instantaneous process. In such a system the chemical initially enters a central compartment (the plasma and those tissues for which distribution is instantaneous) and is subsequently distributed to a second, peripheral compartment. Elimination occurs from the central compartment, so that chemical in the peripheral compartment must transfer back to the central compartment in order to be eliminated (Scheme 4.1B or Scheme 4.4). In Scheme 4.4, k_{12} and k_{21} are the rate constants for transfer from compartment 1 to 2 and from 2 to 1, respectively, and k_{10} is the elimination rate from the central compartment.

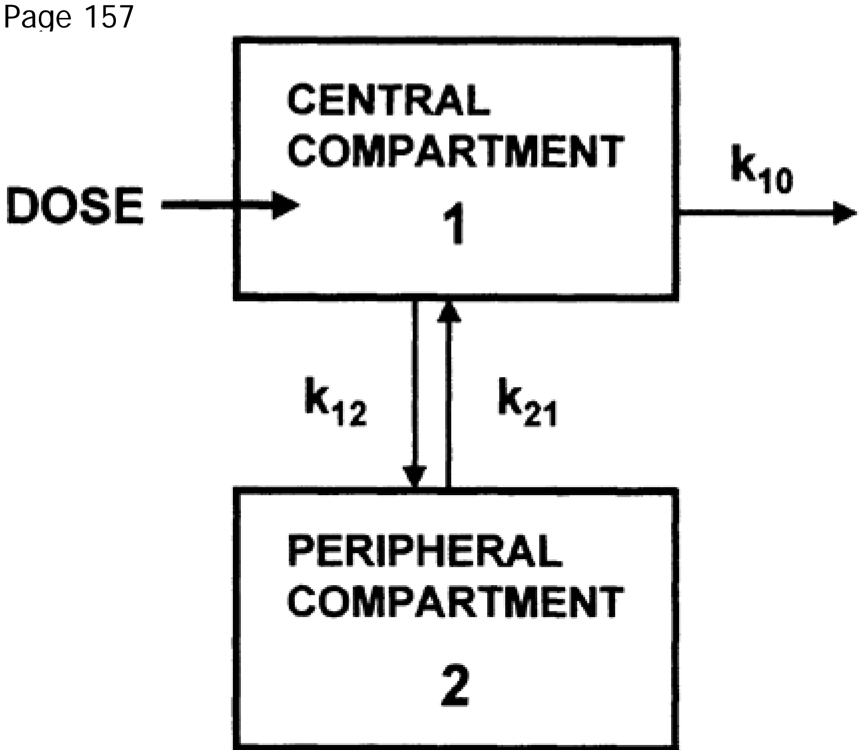
Intravenous Bolus Dose

After a single intravenous bolus dose into a twocompartment system, the plasma concentration *(Cp)* at time t may be described by

$$Cp = Ae^{-\alpha t} + Be^{-\beta t} \qquad [36]$$

where A and B may be regarded as analogous to Cp_0 for each compartment, and $A+B=Cp_0$; α and β correspond

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_156.html[2010/10/28 18:41:18]



SCHEME 4.4. Two-compartment model.

to hybrid rate constants, each influenced by all the individual distribution, redistribution, and elimination rate constants, that is, $k12$, $k21$, and $k10$ (36). The shape of a typical plasma concentration-time curve following a bolus intravenous dose is given in Figure 4.12 (see also Table 4.6) with the plasma data and the method of derivation of the various constants. As with the determination of absorption rate constants discussed above, the method of residuals or line stripping is used to separate α and β. In the terminal phase, $Ae-\alpha t$ approaches zero, and the data are described by $Cp=Be-\beta t$. For example, using the data in Table 4.6,

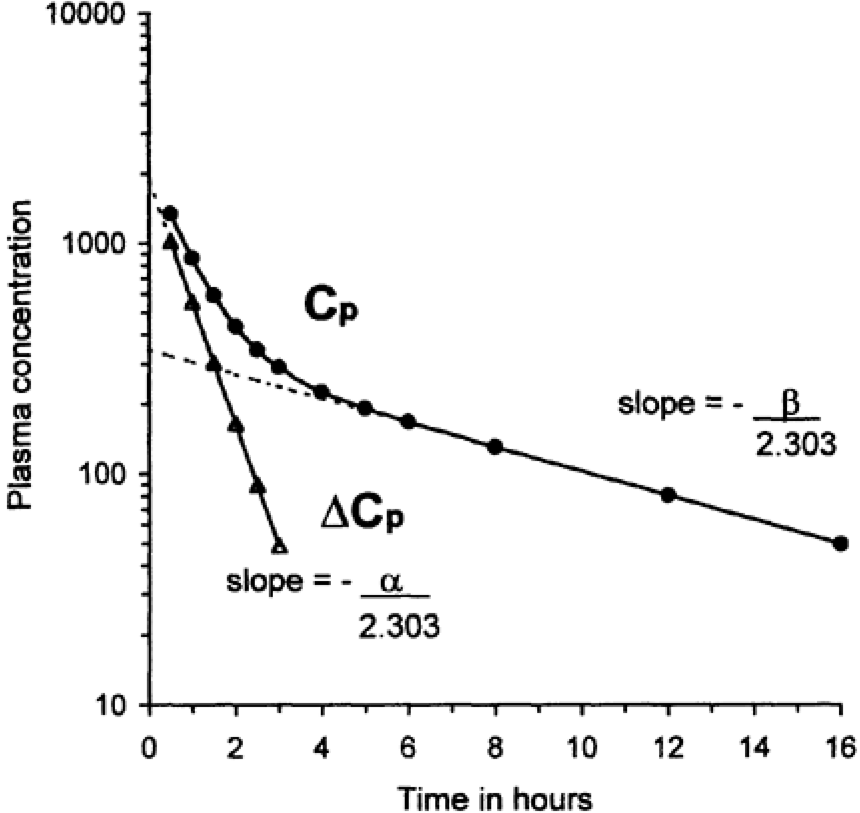


FIG. 4.12. Plasma concentration-time curve for two-compartment system. The data are given in Table 4.6.

when $t=8$ h, $Be^{-\beta t}=346e^{-0.121\times 8}=131$ μg/ml, whereas $Ae^{-\alpha t}=1875e^{-1.214\times 8}=0.1$ μg/ml; therefore, the contribution of the latter term is negligible. The terminal phase after 8 h is therefore extrapolated back to time 0 when the intercept is equal to B and the slope of log Cp against time is $\beta/2.303$. As described in Table 4.6, the values of B and β may also be derived by least-squares linear

Page 158

regression analysis of the terminal phase, after graphical analysis to determine the point at which linearity commences.

At early time points, the difference between the actual *Cp* values and the concentrations derived by backextrapolation of the $Be^{-\beta t}$ line are due to the contribution from $Ae^{-\alpha t}$. The values of *A* and *α* may be similarly derived by calculated linear regression or graphical analysis of the residuals or Δ*Cp* (*Cp*actual−*Cp*extrapolation). In the analysis of the residuals (Table 4.6), the Δ*Cp* values for 4 and 5 h were not included, as these values represent only about 5% or less of the original value of *Cp* and thus are subject to large inaccuracies (up to +100%) owing to the errors inherent in all methods of analysis of foreign compounds in biological fluids.

Thus the plasma concentration-time curve in Figure 4.12 may be represented by the equation:

$$Cp = 1875e^{-1.214t} + 346e^{-0.1210t}$$

The rate constants *α* and *β* are composite rate constants, from which it is possible to derive k_{12}, k_{21}, and k_{10} given in Scheme 4.4 using the following equations (see refs. 36 and 112 for derivations):

$$C_{p0} = A + B$$

$$\alpha + \beta = k_{12} + k_{21} + k_{10}$$

$$V_1 = \frac{\text{dose}}{A + B} \quad [37]$$

where V_1 is the volume of the central compartment, and

$$k_{21} = \frac{A\beta + B\alpha}{A + B} \quad [38]$$

$$k_{10} = \frac{\alpha\beta}{k_{21}} \quad [39]$$

$$k_{12} = \alpha + \beta - k_{21} - k_{10} \quad [40]$$

For the example given in Figure 4.10,

$$k_{21} = \frac{(1875 \times 0.1210) + (346 \times 1.214)}{(1875 + 346)} = 0.291$$

$$k_{10} = \frac{(1.214 \times 0.1210)}{0.291} = 0.505$$

$$k_{12} = 1.214 + 0.1210 - 0.291 - 0.505 = 0.539$$

It is important to note that k_{10} (0.505) and *β* (0.121) do not relate to the same process, because k_{10} refers to the elimination from the central compartment, whereas *β* refers to the overall elimination from the body (and is slower due to transfer out of tissues as well as elimination from the central compartment). The relation between *β* and k_{10} is given by Eq. (40), which may be rewritten as

$$\beta = k_{10} + k_{21} + k_{12} - \alpha$$

which clearly shows that *β* is a hybrid rate constant. It is, however, a valuable constant and can be used to derive the terminal half-life (0.693/*β*).

As with the one-compartment system, an intravenous bolus allows derivation of most pertinent pharmacokinetic parameters:

1. *A, B, α,* and *β* may be derived from plasma data (see above).
2. k_{10}, k_{12}, k_{21}, and V_1 may be derived by manipulation of *α, β,* etc. (see above).
3. *α, β,* k_{10}, k_{12}, and k_{21} may be derived from urine by plotting the excretion rate against time. In this case, the intercept values of excretion rate $(A'+B')$ do not equate to $A+B$, and thus V_1 cannot be deduced. However, k_{10}, k_{12}, and k_{21} can be obtained from Eqs. (38–40) by substitution of *A* and *B* by *A′* and *B′*. The renal elimination rate constant (k_R) is given by

$$k_R = \frac{A' + B'}{\text{dose}}$$

4. *α, β,* k_{10}, k_{12}, and k_{21}, may be derived from urine by the sigma-minus method, where log $(A_{ex}^{\infty} - A_{ex})$ [see Eq. (27)] is plotted against time. Again *α* and *β* may be derived by the method of residuals; k_{10}, k_{12}, and k_{21} can be calculated from from *α* and *β* and the intercepts (*A″* and *B″*) by substitution in Eqs. (38–40). The renal elimination rate constant (k_R) is given by

$$k_R = \frac{A_{\text{ex}}^{\infty}}{\text{dose}} \times k_{10}$$

5. The renal elimination constant, k_R, may be derived also from the renal clearance

$$CL_R = \frac{C_u \times F_u}{C_p}$$

and the value of V_1 as $CL_R = k_R V_1$.

6. The amount in the peripheral compartment may be calculated from the following equation (which is similar to Eq. (30) for absorption into a single compartment):

$$C_2 = \frac{\text{dose} \times k_{12}(e^{-\beta t} - e^{-\alpha t})}{V_2(\alpha - \beta)} \qquad [41]$$

where C_2 and V_2 are respectively the concentrations in, and volume of, the peripheral or deep compartment.

During the terminal phase of the concentration-time curve, $e^{-\alpha t}$ approaches zero and therefore Eq. (41) may be simplified as

$$C_2 = \frac{\text{dose} \times k_{12} \times e^{-\beta t}}{V_2(\alpha - \beta)}$$

Therefore, a graph of log C_2 against time has a slope of $-\beta/2.303$. Thus the terminal rate of decrease in the peripheral compartment of a two-compartment system is identical to the decrease in the central compartment.

In absolute terms, the calculation of C_2 is not particularly valuable, because the peripheral tissues comprising the deep compartment are not homogeneous, and the compound may not show a uniform concentration. Thus C_2 should not be regarded as the effective drug concentration, even if the target organ lies within the deep compartment. Rather, the concentration in the target organ should be measured, from which subsequent concentrations may be calculated using β defined from the central compartment.

A further useful kinetic parameter (V_β), which relates the total amount of chemical in the body to the plasma concentration, is given by the equation

$$V_\beta \times \beta = V_1 \times k_{10} = \frac{\text{dose}}{\text{AUC}} = \text{CL}$$

Just as β is a hybrid term reflecting overall elimination from the body, so V_β is a composite but valuable function.

$$V_\beta = \frac{\text{dose}}{\text{AUC} \times \beta}$$

Intravenous Infusion

The shape of the plasma concentration-time curve on intravenous infusion into a two-compartment open system is similar to that given in Figure 4.8, but with a biphasic increase at the start of the infusion and a biphasic decrease at the end. The kinetic parameters may be derived from the graph similarly to the one-compartment model, as follows.

Increase to plateau. The increase to plateau follows a complex exponential function with 90 and 99% of the steady-state concentration being reached after four and seven half-lives, respectively.

Plateau level (C_{pss}). At steady state, the rate of infusion *(R)* equals the rate of elimination. Therefore

$$\frac{R}{C_{pss}} = \text{CL} = V_1 \times k_{10} = V_\beta \times \beta$$

Decrease after plateau. The decrease after plateau follows the equation:

$$C_p = A^* e^{-\alpha t^*} + B^* e^{-\beta t^*}$$

where A^* and B^* are the intercepts by back extrapolation to the end of the infusion of the α and β slopes (determined as described for Figure 4.12) and t^*=time since cessation of infusion.

In many cases, two-compartment characteristics seen after a bolus dose are obscured in postinfusion data, because much of the distribution phase will have occurred during the infusion, so that the duration of the α phase may be reduced.

Area under the curve. The AUC can be used to derive the plasma clearance using Eq. (22).

Oral Administration

Assuming first-order absorption into compartment 1, the plasma concentration at time t is given by

$$C_p = A^{\ddagger} e^{-\alpha t} + B^{\ddagger} e^{-\beta t} + C^{\ddagger} e^{-k_a t}$$

Graphical analysis by a semilogarithmic plot of log C_p against time may reveal three separate phases, from which α, β, and k_a should be measurable using the method of residuals. However, in practice the value of k_a is frequently similar to a, and compounds that require a two-compartment model after intravenous administration appear to fit first-order absorption into a one-compartment model following oral dosing (18). Thus analysis is not possible without reference to intravenous data to determine which rate constant refers to the absorption rate. An example of linear regression analysis to obtain the three rate constants was given by Wagner (112). An alternative method (deconvolution method) may be used that derives the absorption rate constant by a comparison of plasma concentrations for intravenous and oral administration, and does not require fitting the data to a particular one-, two-, or three-compartment model. This method (36, 112) does, however, require analysis of the plasma concentrations at the same time points after both oral and intravenous dosing. Various methods of

calculating the absorption rate are discussed in Gibaldi and Perrier (36).

The absorption rate is likely to be of greatest importance in acute toxicity studies, whereas the bioavailability *(F)* may be more significant in chronic studies; the latter may be measured using model-independent equations [Eq. (31) or (32)]. However, absorption from the gastrointestinal tract is complex, as it involves physiologically different membranes at differing luminal pH values. Thus the process may involve more than one first-order rate, or a zero-order component, or both; an alternate approach to compartmental analysis and a valuable measure is the mean absorption time (see below).

Metabolite Kinetics

Frequently, metabolites of foreign compounds fit a two-compartment open model, in which case a second

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_159.html[2010/10/28 18:41:21]

compartment for the metabolite is in equilibrium with the central metabolite compartment, as well as a second compartment for the parent compound (see Scheme 4.3). The equation describing these four compartments requires four exponential terms, but often the concentration-time curve for the metabolite appears as a bi-exponential decrease. The slow terminal phase of the metabolite is given by either β for the parent compound, or the terminal rate for the metabolite (see earlier); the faster rate is a composite of the other three rate constants.

Multiple Dosing: Chronic Administration

On multiple dosing or continuous intake, the plasma levels increase over a period of four to five half-lives to establish a plateau concentration similar to that seen with intravenous infusion (Figure 4.8). The average plateau level is subject to variations around a mean as material is eliminated between "doses." In oral toxicity studies, these "doses" may represent either repeated single-gavage doses or the feeding habits of the animals if the test compound is incorporated into the diet and fed ad libitum. On cessation of chronic intake, the rate of decrease in blood levels is usually but not always similar to that seen after a single dose (22).

One-compartment Open Model

The time taken to reach plateau plasma levels is four to five times the half-time of the terminal phase of the plasma concentration-time curve. The average plateau level is given (by analogy with intravenous infusion) as

$$C_{p\,\text{mean}} = \frac{\text{dose} \times F}{V \times k \times T} \qquad [42]$$

where F is the fraction absorbed, T is the dose interval, and k is the elimination rate constant. However, it is important to realize that this equation is appropriate only if the terminal phase following oral administration is due to elimination. When the compound exhibits slow absorption and rapid elimination, the decrease in plasma levels is determined by the slower absorption rate *(ka)*. An alternative equation can be derived from the fact that at steady state the rate of input ($F \times \text{dose}/T$) is balanced by the rate of elimination ($Cp\text{mean} \times \text{CL}$); therefore

$$C_{p\,\text{mean}} = \frac{\text{dose} \times F}{T \times \text{CL}}$$

The fluctuations around the mean plateau level depend on the dosing interval in relation to the terminal elimination rate. Thus compounds with a short half-life show much larger fluctuations, as more of the chemical is eliminated between each dose. In the case of compounds with a short half-life (2–3 h), single daily dosing gives plasma levels approaching zero prior to each dose. Interdose fluctuations may be reduced and blunted by slow absorption. The equations relating to these processes were detailed by Gibaldi and Perrier (36) and Wagner (112). In summary, at steady state after repeated intravenous doses, the minima and maxima are given by

$$C_{p\,\text{minimum}} = \frac{\text{dose}}{V}\left(\frac{e^{-kT}}{1-e^{-kT}}\right) \qquad [43]$$

$$C_{p\,\text{maximum}} = \frac{\text{dose}}{V}\left(\frac{1}{1-e^{-kT}}\right) \qquad [44]$$

When absorption from the gut occurs as a first-order process, the fluctuations in the steady-state concentration-time curve can be described by the following equation:

$$C_p = \frac{F \times \text{dose} \times k_a}{V(k_a - k)} \times \left[\left(\frac{1}{1-e^{-kT}}\right)e^{-kt} - \left(\frac{1}{1-e^{-k_aT}}\right)e^{-kt}\right] \qquad [45]$$

where Cp is the concentration at time t and T is the dose interval. The similarity between this equation and Eq. (30) for absorption of a single dose is apparent.

The value of the mean plasma concentration at steady state (Cpmean) may be calculated without knowledge of F, V, ka, or k by measuring the area under the plasma concentration-time curve for a single oral dose, as

$$\text{AUC}_{\text{oral}} = \frac{\text{dose} \times F}{V \times k} = \frac{\text{dose} \times F}{\text{CL}} \qquad [23]$$

where AUCoral is the area under the plasma concentration-time curve between $t=0$ and $t=\infty$ for a single oral dose. Substituting into Eq. (42),

$$C_{\text{mean}} = \frac{\text{AUC}_{\text{oral}}}{T}$$

[46]

It is important to realize, however, that substitution of Eq. (23) into Eq. (42) assumes that the AUC is directly proportional to the dose, that is, that dose-dependent kinetics are absent and that CL does not alter during chronic administration of the compound. The latter possibility may be assessed by comparison of the $\text{AUC}_{0-\infty}$ for a single dose, with the AUC for a dose interval at steady state, that is, AUC_{0-T} for chronic administration,

$$\begin{aligned} \text{CL} &= \frac{\text{dose (single)} \times F}{\text{AUC}_{0-\infty}} \\ &= \frac{\text{dose (chronic)} \times F}{C_{p\,\text{mean}} \times T} \\ &= \frac{\text{dose (chronic)} \times F}{\text{AUC}_{0-T}} \end{aligned}$$

If $\text{AUC}_{0-T}(\text{chronic}) < \text{AUC}_{0-\infty}(\text{single})$, either induction

of metabolism or decreased bioavailability is indicated; conversely if AUC_{0-T}(chronic)>$AUC_{0-\infty}$ (single), then inhibition or saturation of metabolism is suggested.

The extent of accumulation on repeated intake may be measured by the average amount in the body at steady state (Abmean), divided by the amount in the body after a single dose (Ab), that is,

$$\text{extent of accumulation} = \frac{Ab_{\text{mean}}}{Ab} = \frac{Ab_{\text{mean}}}{\text{dose} \times F}$$

The amount in the body at the plateau is given by Eq. (42):

$$Ab_{\text{mean}} = VC_{p\,\text{mean}} = \frac{F \times \text{dose}}{k \times T}$$

Therefore

$$\text{Extent of accumulation} = \frac{1}{k \times T} = \frac{1}{0.693/t_{1/2} \times T} = \frac{1.44 \times t_{1/2}}{T}$$

Two-compartment Open Model

The equations giving the plasma concentration at time *t* at steady state into a two-compartment system with first-order absorption are considerably more complex than those for the one-compartment system. However, the simplified equation [Eq. (42)] applies in the form

$$C_{p\,\text{mean}} = \frac{\text{dose} \times F}{V_1 \times k_{10} \times T} = \frac{\text{dose} \times F}{V_\beta \times \beta \times T}$$

and the value of $C_p$mean may still be derived from Eq. (46):

$$C_{p\,\text{mean}} = \frac{\text{AUC}_{\text{oral}}}{T} = \frac{\text{dose} \times F}{\text{CL} \times T}$$

In addition, the relationship between the AUC between $t=0$ and $t=\infty$ for a single dose and the AUC for a dose interval at steady state applies on the condition that neither CL or *F* changes on chronic intake (see above); a difference between these AUC estimates indicates changes in CL or *F* during chronic treatment.

Statistical Moment Analysis

In recent years both clinical pharmacokinetic and animal toxicokinetic studies have moved away from compartmental analyses, because they involve multiple variables, which require numerous properly timed blood samples to characterize them adequately. Also, curve fitting is dependent on the terminal slope, which is frequently measured using plasma concentrations that approach the limit of detection of the assay method, that is, are the weakest data. In contrast, terms such as clearance are measured from dose and AUC, the latter being determined largely from the highest and most accurately measured concentrations. Such "time-averaged" parameters may be extended to "time-related" parameters by the use of statistical moment theory, which allows assessment of additional useful kinetic parameters such as *mean residence time* (MRT). The plasma concentration-time curve may be regarded as a statistical distribution curve for which the zero and first moments are the AUC and MRT respectively:

$$\text{AUC} = \int_0^\infty C_p \text{d}t$$

$$\text{MRT} = \frac{\text{AUMC}}{\text{AUC}} \quad [48]$$

where AUMC is the area under the first moment of concentration time curve, that is, $\int_0^\infty t \times C_p \text{dt}$.

The AUC and AUMC may be calculated using the trapezoid rule, which is illustrated under Data Handling (see Table 4.17). The AUC from the last data point to infinity can be calculated as $C_p$last/β. The AUMC from the last data point to infinity has to be calculated as

$$\frac{t_{\text{last}} \times C_{p\,\text{last}}}{\beta} + \frac{C_{p\,\text{last}}}{\beta^2}$$

Clearly any inaccuracy in the value of *β* affects the extrapolation of AUMC to infinity more than the extrapolation of AUC. This situation is shown in the data given in Table 4.17, where the extrapolated area is 17% of the AUMC, but only 3% of the AUC.

In the same way that the AUC can be related to CL, *k* and ***V*, *β*** and *Vβ*, etc., so the AUMC can be used to derive additional useful parameters.

Intravenous Administration

Following an intravenous bolus dose, the MRT can be calculated by Eq. (48) as illustrated in Table 4.17. The *apparent volume of distribution at steady state (V*ss*)* may be regarded as the volume of plasma in which the compound appears to be dissolved and that has to be "removed" from the body, that is, the product of clearance (ml min−1) and MRT (min):

$$V_{ss} = \mathrm{CL} \times \mathrm{MRT} = \frac{\mathrm{dose}}{\mathrm{AUC}} \times \frac{\mathrm{AUMC}}{\mathrm{AUC}} = \frac{\mathrm{dose} \times \mathrm{AUMC}}{\mathrm{AUC}^2} \qquad [49]$$

Attempts to separate the MRT, which refers to the whole body, into central and peripheral components (110) may prove to be of value, but are dependent on the data fitting a two-compartment model.

If the compound is too toxic to be given as an instantaneous bolus, the MRT can be calculated from the AUMC determined following an intravenous infusion

using the equation:

$$\mathrm{MRT}_{\mathrm{infusion}} = \mathrm{MRT} + \frac{T}{2} \qquad [50]$$

where $\mathrm{MRT}_{\mathrm{infusion}}$ is calculated from the AUMC and AUC by Eq. (48) from the infusion data, and *T* is the infusion time.

V_{ss} cannot be derived directly from the AUMC and AUC data from infusions, because the AUMC value contains a component due to the infusion time. The following equation therefore applies,

$$V_{ss} = \frac{\text{infused dose} \times \mathrm{AUMC}}{\mathrm{AUC}^2} - \frac{\text{infused dose} \times T}{2 \times \mathrm{AUC}} \qquad [51]$$

In the same way that CL may be related to *V* by the rate constant *k* [Eq. (21)], so it may be related to V_{ss} by the first-order rate constant k_{ss} (7, 36).

$$\mathrm{CL} = k_{ss} V_{ss} = \frac{V_{ss}}{\mathrm{MRT}}$$

Therefore k_{ss} is equivalent to 1/MRT; for a two-compartment system k_{ss} is intermediate between α and β. The half-life derived from k_{ss} ($0.693/k_{ss}$ or $0.693\times\mathrm{MRT}$) is therefore a composite half-life, and may be regarded as the "effective" half-life. This is shown in the data analyzed later (Table 4.17) where the half-life derived from MRT ($0.693\times25=17$ min) is intermediate between that calculated from α ($0.693/0.0705=10$ min) and β ($0.693/0.0240=34$ min).

Oral Administration

A major strength of the statistical moment theory is its ability to derive meaningful data following oral administration, because it is both more reliable and easier to use than most other methods (18) and does not rely on assumptions about a first-order or zero-order process. The most useful parameter is the *mean absorption time* (MAT), which is the difference between the mean residence times following oral and intravenous dosing:

$$\mathrm{MAT} = \mathrm{MRT}_{\mathrm{oral}} - \mathrm{MRT}_{\mathrm{iv}} \qquad [52]$$

The MAT may be used to derive apparent first-order rate constants and half-lives:

$$k_a = \frac{1}{\mathrm{MAT}}$$

$$\text{Absorption } t_{1/2} = 0.693 \times \mathrm{MAT}$$

Alternatively, if absorption appears to be zero order, by analogy with Eq. (50):

$$\mathrm{MAT} = \frac{T_{\mathrm{abs}}}{2}$$

where T_{abs} is the duration of the absorption process.

The measurement of MAT is generally applied to absorption from a solution. If a sparingly soluble compound is given,

$$\mathrm{MRT}_{\mathrm{oral}} = \mathrm{MRT}_{\mathrm{iv}} + \mathrm{MAT} + \mathrm{MDT}$$

where MDT is the mean dissolution time.

The statistical moment theory is therefore a valuable technique for comparisons on the influence of dosage formulations on absorption (18, 79).

Chronic Administration

As discussed previously, the increase to steady state for multicompartment models is complex. AUC data may be used, in the absence of compartmental analysis, to derive the proportion of steady state reached at any time after dosing. The proportion of steady state is equal to the AUC to that time (AUC_{0-t}) calculated as a proportion of the total AUC extrapolated to infinity ($\mathrm{AUC}_{0-\infty}$), that is,

$$\%\ \text{steady state} = 100 \times \frac{\mathrm{AUC}_{0-t}}{\mathrm{AUC}_{0-\infty}}$$

There is, however, a significant complication in the use of statistical moments for the analysis of steady-state data because, unlike AUC data, $\mathrm{AUMC}_{0-\infty}$ for a single dose does not equal AUMC_{0-T} during regular dosing (6). A simple way to overcome this difficulty is to apply a method of residuals to the steady-state plasma concentration prior to the regular dose (C_{min}). Assuming that this level decreases by a single first-order rate (β) determined from the terminal phase of the interdose period (or the terminal phase following a single dose), the contribution of this residue to each subsequent sample can be calculated as $C_{min}e^{-\beta t}$, where *t* is the time of that particular sample after C_{min}. The calculated

residue is then subtracted from the measured value at each time to derive pseudo-single-dose data $(C - C_{min} e^{-\beta t})$ that can be used to calculate AUMC.

Dose-Dependent or Nonlinear Kinetics

Whereas simple diffusion obeys first-order kinetics at all concentrations, many of the other processes fundamental to toxicokinetics involve an interaction between the foreign chemical and a specific site on a protein (examples being active transport across the gut, plasma and tissue protein binding, metabolism, and renal tubular secretion). These processes have a finite capacity for interaction between the chemical and the protein; thus at high concentrations of chemical, all the specific sites on the protein may be occupied. Addition of further chemical cannot result in further interaction between the chemical and protein, and the concentration of free compound increases rapidly. Depending on the nature of the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_162.html[2010/10/28 18:41:23]

protein-chemical interaction, there are a number of possible consequences, which are summarized in Table 4.7. This table represents a considerable simplification because the effect of saturation at one site may affect another protein-chemical interaction. For example, saturation of renal tubular secretion gives increased AUC/dose and elevated plasma concentrations. However, the resultant high concentrations may saturate plasma protein binding, resulting in an increase in free drug and increased glomerular filtration and/or hepatic clearance. Thus the decreased elimination in the renal tubule may be overcome to some extent by increased elimination elsewhere.

Almost all of the processes listed in Table 4.7 may be described by a Michaelis-Menten equation of the type introduced into Eq. (11), that is,

$$-\frac{dC}{dt}=\frac{V_{max}\times C}{K_m+C} \quad [53]$$

where *V*max is the theoretical maximum rate of the reaction and *Km* is the Michaelis constant (which reflects the concentration giving 50% saturation of the protein).

At low concentrations $C \ll K_m$, and *Km*+C approximates to *Km* so that

$$-\frac{dC}{dt}=\frac{V_{max}\times C}{K_m}$$

and *Vmax/Km* is equivalent to the first-order rate constant *k*.

At higher concentrations $C \gg K_m$, and *Km*+C approximates to *C* so that

$$-\frac{dC}{dt}=\frac{V_{max}\times C}{C}=V_{max}$$

and thus the elimination is a zero-order reaction. The shape of the plasma concentration-time curve for a hypothetical compound showing saturation kinetics is given in Figure 4.13, which clearly shows that although low doses are indistinguishable from first-order elimination, the decrease at high plasma concentrations shows zero-order and then first-order reaction components.

It is important to note that the terminal slope and terminal half-life are derived from low plasma concentrations, and do not provide evidence of dose dependence. However, the plasma clearance, which is derived from AUC data and which reflects the capacity of the organs of elimination to remove the chemical from plasma, provides the best evidence of saturation. This is shown clearly by derivation of the appropriate rate constants, etc., for the example given in Figure 4.13 and Table 4.8, which shows a fivefold change in CL; it also illustrates the power of the statistical moment approach, which shows a fourfold increase in MRT. The value of *k* (0.0485) approximates to *Vmax/Km* (0.050).

Table 4.7 Consequences of saturation of chemical-protein interactions

Site	Interaction	Possible consequences of saturation at high dose
Absorption	Active uptake	Reduced plasma levels and AUC after oral but not IV doses.
	First-pass metabolism	Increased plasma levels and AUC after oral but not IV doses.
Distribution	Plasma protein	Increased volume of distribution; increased glomerular filtration; increased hepatic clearance if extraction ratio is low.
	Tissue protein	Decreased volume of distribution; a graph of *Ct/Cp* against *Cp* will be nonlinear.
Metabolism	Metabolizing enzyme (saturation by substrate, depletion of cofactors, product inhibition)	Decreased clearance; AUC/dose ratio increases for parent compound, whereas AUC of metabolite/dose ratio may decrease for both oral and IV doses; enzymes with high *Km* values may handle a larger proportion of the dose.
Excretion	Renal tubular secretion	Decreased renal clearance; AUC/dose ratio increases for oral and IV doses; nonrenal routes of elimination become of more importance; total excretion in urine per dose may decrease depending on the availability of other routes of elimination.
	Renal tubular reabsorption (rare)	Opposite of effects for saturation of renal tubular secretion.
	Biliary excretion	Decreased biliary clearance; decreased enterohepatic recirculation; renal route may become more important; AUC/dose ratio increases for oral and IV doses.

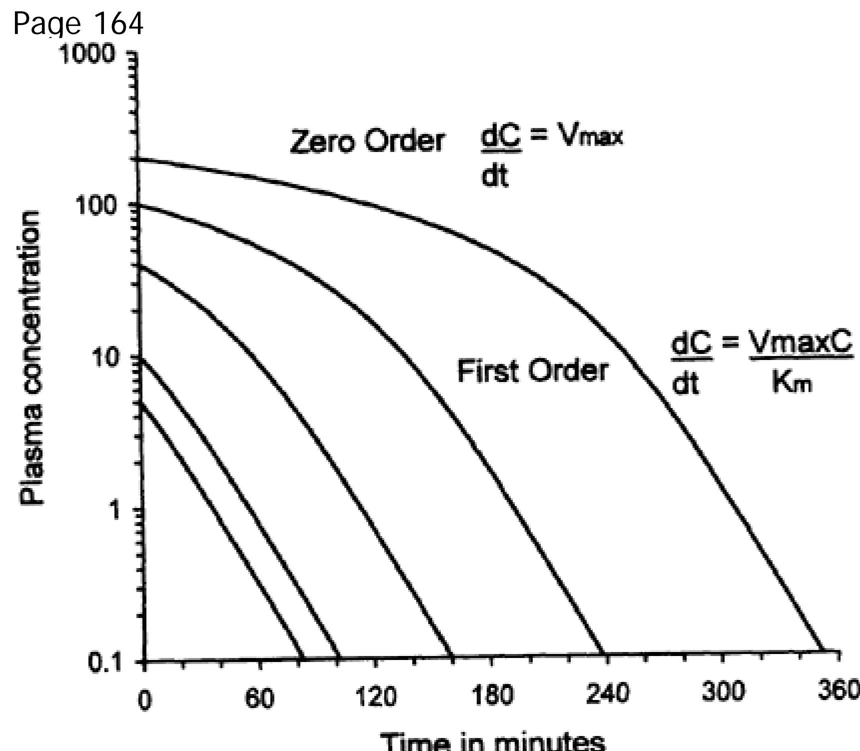

FIG. 4.13. Plasma concentration-time curve for a compound showing saturation kinetics. The data were generated using an apparent V_{max} of 1 μg/min and a K_m of 20 μg/ml for initial concentrations of 5, 10, 40, 100, and 200 μg/ml. Data points were obtained using a derivative of Eq. (53), $V_{max}(t - t_0) = C_{p0} - K_m \ln(C_{p0}/C_p)$.

An increased understanding of saturation kinetics can be obtained by the determination of K_m and V_{max} from in vivo data. The value of K_m which reflects the plasma concentration necessary to give 50% saturation of the active process, is particularly useful for interpreting toxicity dose-response relationships. These constants can be determined following a single intravenous bolus dose using various equations, provided that the elimination is by a single saturable process (see below). The simplest method, applicable to a one-compartment model, is by calculation directly from the plasma concentration-time curve using the equations

$$\ln C_p = \ln C_{p0e} - \frac{V_{max} \times t}{K_m}$$

and

$$K_m = \frac{C_{p0a}}{\ln(C_{p0e}/C_{p0a})}$$

where C_{p0e} is the value of C_p at t=0 derived by back extrapolation of the terminal linear phase, and C_{p0a} is the actual concentration measured at t=0. A plot of ln C_p against time has a terminal "first-order" slope of V_{max}/K_m.

Applying these equations to the data in Figure 4.13 for the highest dose gives values of 0.0486 for the slope, 200 for C_{p0a}, and 2,701,271 for C_{p0e}. Thus

$$K_m = \frac{200}{\ln(2,701,271/200)} = 21\ \mu g\ ml^{-1}$$

and

$$V_{max} = 0.0486 \times 21 = 1.0\ \mu g\ min^{-1}$$

Alternative equations for the calculation of K_m and V_{max} require calculation of the rate of change of concentration from one sample to the next ($\Delta C_p/\Delta t$) as well as the plasma concentration at the midpoint (C_{pm}).

Table 4.8 Pharmacokinetic parameters derived from data showing saturation kinetics: Figure 4.13

Parameter	Curve 1	Curve 2	Curve 3	Curve 4	Curve 5
Dose (mg/kg)	5	10	40	100	200

C_p0 (μg ml^{-1})	5	10	40	100	200
k (min^{-1})[a]	0.0486	0.0486	0.0486	0.0485	0.0486
Half-life (min)[a]	14.3	14.3	14.3	14.3	14.3
AUC (μg ml^{-1} min)[b]	115	254	1614	7020	24,027
AUMC (μg ml^{-1} min^2)[b]	2437	5702	50,682	355,788	2,002,493
CL (ml min^{-1} kg^{-1})[c]	43.5	39.4	24.8	14.2	8.3
MRT (min)[d]	21.2	22.4	31.4	50.7	83.3

The parameters were calculated assuming a one-compartment model with a volume of distribution of 1 L/kg, which is not dose-dependent.

[a]Derived from data between 2.0 and 0.1 μg/ml for each dose.

[b]Calculated by the trapezoid rule with extrapolation to infinity. (See Table 4.17 for a worked example.)

[c]CL=dose/AUC [Eq. (22)].

[d]MRT=AUMC/AUC [Eq. (48)].

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_164.html[2010/10/28 18:41:24]

Lineweaver-Burk plot

$$\frac{1}{\Delta C_p/\Delta t}=\frac{K_m}{V_{\max}\times C_{pm}}+\frac{1}{V_{\max}}$$

Therefore a plot of 1/(Δ*Cp*/Δ*t*) against 1/*Cpm* has a slope of *Km/V*max and an intercept of 1/*V*max.

Hanes-Woolf plot

$$\frac{C_{pm}}{\Delta C_p/\Delta t}=\frac{K_m}{V_{\max}}+\frac{C_{pm}}{V_{\max}}$$

Therefore a plot of *Cpm*/(Δ*Cp*/Δ*t*) against *Cpm* has a slope of 1/*V*max and an intercept of *Km/V*max.

Woolf-Augustinsson-Hofstee plot

$$\frac{\Delta C_p}{\Delta t}=V_{\max}-\frac{(\Delta C_p/\Delta t)K_m}{C_{pm}}$$

Therefore a plot of (Δ*Cp*/Δ*t*) against (Δ*Cp*/Δ*t*)/*Cpm* has a slope of −*Km* and an intercept of *V*max.
When the data for the highest dose in Figure 4.13 are analyzed by these techniques (Table 4.9) the following values are obtained (Figure 4.14):

Lineweaver-Burk plot

$$x\text{-intercept}=-\frac{1}{K_m}=-0.0537;\qquad K_m=18.6\,\mu\text{g ml}^{-1}$$

$$y\text{-intercept}=\frac{1}{V_{\max}}=1.04;\qquad V_{\max}=0.96\,\mu\text{g min}^{-1}$$

$$\text{Slope}=\frac{V_{\max}}{K_m}=0.0517;\qquad \frac{0.96}{18.6}=0.0516$$

Hanes-Woolf plot

$$\text{Slope}=\frac{1}{V_{\max}}=0.999;\qquad V_{\max}=1.001\,\mu\text{g min}^{-1}$$

$$\text{Intercept}=\frac{K_m}{V_{\max}}=19.85;\qquad K_m=19.9\,\mu\text{g ml}^{-1}$$

Woolf-Augustinsson-Hofstee plot

Slope=−*Km*=−20.3; Km=20.3 μgml−1

Intercept=*V*max=1.005; *V*max=1.005 μg min−1

The values of *V*max and *Km* may be derived from plateau levels on intravenous infusion, providing that elimination is essentially by a saturable process only, because at

Table 4.9 Calculation of *Km* and *V*max from plasma concentration time data

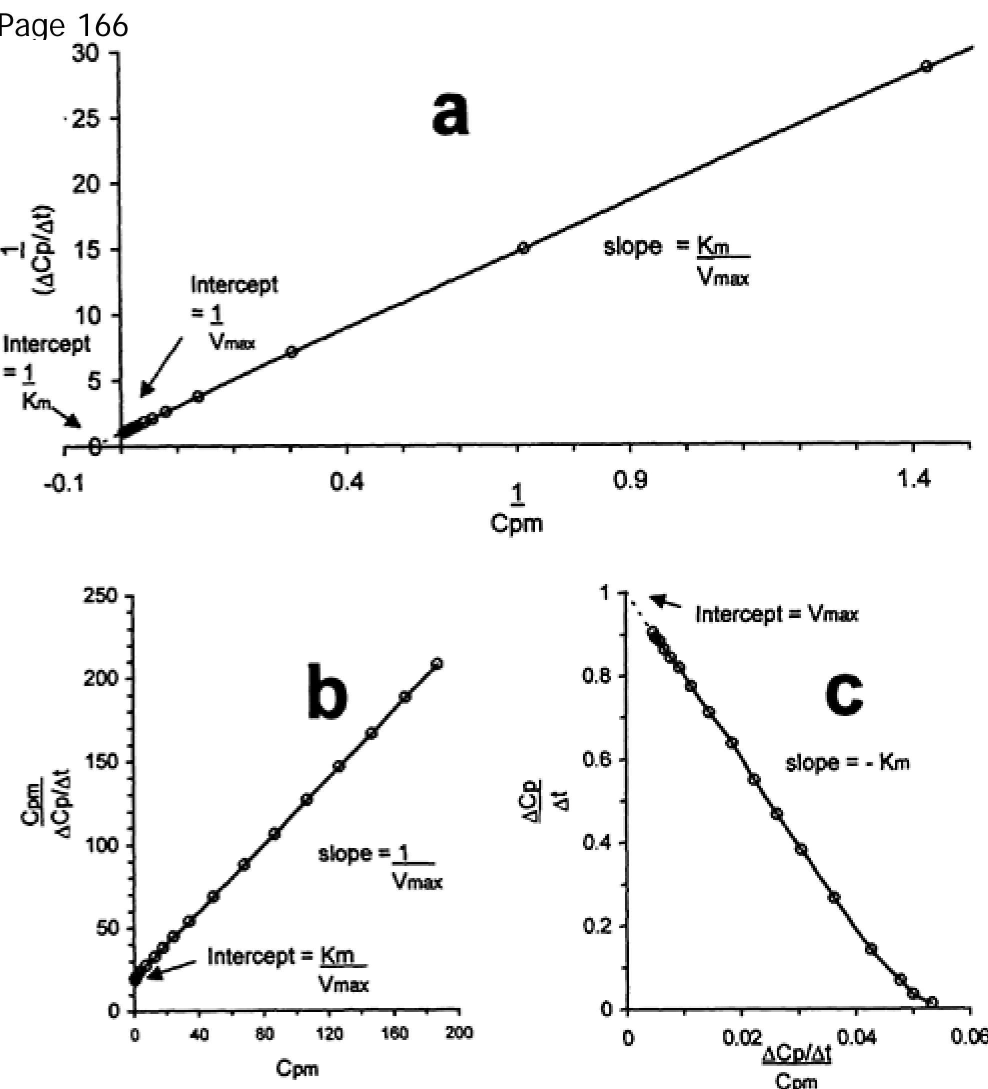

FIG. 4.14. Analysis of the maximum dose given in Figure 4.13 to derive *Km* and *V*max using the data in Table 4.9 and the methods of (a) Lineweaver-Burk, (b) Hanes-Woolf, and (c) Woolf-Augustinssohn-Hofstee.

steady state the rate of input=rate of elimination:

$$R = \frac{V_{\max} \times C_{pss}}{K_m + C_{pss}}$$

where *R* is the rate of infusion, or

$$R = V_{\max} - \left(K_m \times \frac{R}{C_{pss}}\right)$$

Thus a plot of *R* for different rates of infusion against *R*/*Cp*ss gives a straight line with a slope of *Km* and an intercept of *V*max on the *R* axis.

Frequently, the rate of elimination can be described by a combination of saturable and nonsaturable processes

when

$$-\frac{dC}{dt} = \frac{V_{\max} \times C}{(K_m + C)} + k'C$$

where *k′* is the rate constant for the nonsaturable process: *k′* may be replaced by CL′/*V* where CL′ is the clearance by the nonsaturable process; for example for glomerular filtration the value (GFR×*a*/*V*) may be substituted for *k′*.

Of greatest importance for toxicology is the clear demonstration of saturation at high doses, an estimation of the plasma concentration above which first-order kinetics cease to apply, and the plasma

concentrations present in animals showing overt toxicity. Wagner (112) proposed five tests for the establishment of saturation or nonlinear kinetics.

1. Graphs of Cp/dose against time should be superimposable for linear kinetics at different doses. Although considerable scatter is seen, an overall trend to increased or decreased levels at higher doses should be apparent for nonlinear systems.
2. Administer different intravenous doses and estimate $Cp0$ by fitting only the first two or three early time points to the equation $\ln Cp = \ln Cp0 - kt$. Graphs of $Cp/Cp0$ against time should be superimposable if linear kinetics apply.
3. Fit each set of concentration-time data to a linear model and derive the appropriate kinetic parameters (CL, V, k, $k12$, $k21$, $V1$, etc.). A dose-dependent change in a parameter indicates nonlinearity or saturation kinetics (which will invalidate some of the derived parameters, e.g., k).
4. If Michaelis–Menten kinetics apply, the percentage metabolized by that pathway decreases with an increase in dose (provided other elimination routes are available), the value of AUC/dose is not constant, and plots of log Cp or ln Cp against time curve downward, as shown in Figure 4.13.
5. Measure the tissue and unbound plasma concentrations over a range of doses. A graph of tissue concentration against unbound concentration in plasma should be a straight line for a linear tissue extraction. Saturation of tissue binding is shown by the tissue concentration having a smaller increase at higher concentrations.

A consequence of nonlinear kinetics is that the time to reach steady state is also dose dependent. In simple terms, this is because the "effective half-life," which can be calculated by $0.693 \times \text{MRT}$, increases with an increase in dose (e.g., Table 4.8) so that the time to steady state (four to five half-lives) must also increase. This situation should be borne in mind when planning short-term studies. The importance of nonlinear kinetics in toxicology is discussed in greater detail after Data Handling.

PRACTICAL METHODS

General information on techniques may be obtained from the texts by Waynforth (114) and Cocchetto and Bjornsson (20). Waynforth described practical methods ranging from how to hold the animal for injection to such specialist techniques as renal transplantation. The other work, which contains 501 references, is an extensive and invaluable literature review of methods for the collection of body fluids. A number of modifications applicable to other species are given below.

The methods for dosing, blood sampling, urine collection, etc., described below are largely related to the rat, as it is the species most commonly used in toxicological studies.

Administration Techniques

Oral Dosing

Because a number of lipid and metabolic barriers separate the lumen of the gastrointestinal tract from the systemic circulation (Figure 4.2), the plasma levels of test compounds usually increase gradually after oral administration to reach a maximum. Therefore it is possible to give higher doses by this route than by intravenous injection, and this technique is aided by the capacity of the stomach to hold a large volume of liquid. For toxicokinetic studies, the oral route can provide valuable information on elimination and clearance values, provided that the extent of absorption of the parent compound (F) is known. The latter may be determined by measuring either the area under the plasma concentration-time curve or the total amount of the test substance excreted in the urine unchanged after both oral and intravenous administration at low doses. The fraction absorbed is given by Eq. (31), and this value can then be used to calculate the clearance as described in the derivative of Eq. (22). The possibility of saturation of absorption may be determined by plotting the value Cp/dose against time for doses up to and including those producing overt toxicity.

Rats, guinea pigs, and mice may be dosed orally using a syringe fitted with a suitable intubation needle; in rabbits, a polyethylene cannula is passed into the stomach while the jaws are held open by a gag. Certain precautions should be taken to prevent artifacts. For example, it is important that the test chemical is completely dissolved, because if the chemical is given as a suspension, the apparent absorption rate must include a component due to dissolution of the chemical. If this factor is rate limiting, the measured absorption rate reflects the dissolution rate and is not related to the biological availability of the chemical. The ideal vehicle for dissolution is water or a small volume of a water-miscible solvent such as ethanol, propylene glycol (propane-1,2-diol), or dimethylsulfoxide, although for very lipid-soluble compounds, it may be necessary to give the dose in corn oil or as an emulsion. Excess acids or bases should not be used to dissolve the test compound, and the pH of the dose solution should be near pH 7, because pH partitioning in either the gut or the renal tubule could be affected, which could alter the measured absorption or elimination rate constants. If a water-miscible organic solvent is used to dissolve the chemical, water should be added to reduce the dehydrating effect of the solvent within the gut lumen. The volume of water or solvent/water used to dissolve the chemical

should be kept low, because excess quantities may distend the stomach and cause rapid gastric emptying. In addition, large volumes of water may carry the chemical through membrane pores and increase the absorption rate. If dose-dependent absorption is

suspected, the different doses should be given in the same volume of solution. The maximum volume of aqueous solution that can be administered without the possibility of gross interference with absorption is approximately 5–10 ml/kg. Larger volumes may be given, although nonlinear kinetics seen under such circumstances may be due to solvent-induced alteration of intestinal function.

The use of water-immiscible solvents such as corn oil, which are sometimes used for gavage doses, should be avoided if possible, because mobilization from the vehicle may be rate limiting. However, such a vehicle would obviously be appropriate if it was the method of administration used in toxicity studies, because it would give information on the rate of absorption and bioavailability under the conditions of the toxicity study.

The rate of absorption can have a major effect on the toxicokinetic profile, affecting not only the time to maximum concentration and the maximum concentration but also the total amount entering the systemic circulation by saturating hepatic uptake and first-pass metabolism. The hepatotoxicity of oral carbon tetrachloride is markedly higher after a bolus dose compared with gastric infusion (89).

When toxicity studies are performed by mixing the compound into the animals' diet, it is important to measure the concentration-time curve over a 24-h period at steady state, because both the peak concentration and the AUC may be different from data obtained from bolus gavage studies.

Nasal Administration

Methods have been described for assessing absorption from the nasal cavity based on plasma pharmacokinetics following intranasal and intravenous dosing and by in situ perfusion experiments (45, 103). A technique for inhalation with nose-only exposure has been described for studies in guinea pigs (52).

Rectal Administration

Because a number of therapeutic compounds are given in the form of suppositories, an indication of the bioavailability after rectal administration is sometimes required. Normally, toxicity studies and initial drug formulations of such compounds are performed by the oral route, and the rectal formulation comes late in development and marketing. Animal bioavailability studies late in drug development are of limited value because of the differences between laboratory animals and man in intestinal anatomy and microflora of the colon and rectum. However, in cases where an indication of rectal bioavailability is required, the compound may be introduced into the rectum of the rat using an oral dosing needle to prevent tissue damage. To avoid rapid excretion of the unabsorbed dose, anesthetized animals are used and the dose is retained with an inert plug or bung.

Inhalation

As indicated previously, a major problem associated with determining the kinetics of inhalation concerns the measurement of the extent to which the chemical is absorbed across the lung, rather than passed back into the mouth to be swallowed, exhaled in the expired air, or absorbed across the skin. Comparison of the plasma AUC or the total urinary excretion of unchanged compound, after a period of inhalation with the same parameter after a known intravenous dose, can be used to determine the total dose, entering via the lungs plus gut.

A method used successfully by McKenna et al. (59) to obtain kinetic data involved a 6-h exposure to the vapor of [14*C*]vinylidene chloride in rats, after which the animals were transferred to a metabolism cage. The body load at the time of removal was determined by the total recovery of radioactivity in the expired air, excreta, cage washings, and carcass. This method is appropriate for determining the total dose because the nonspecific measurement of 14C includes parent compound and all metabolites. If the parent compound alone is measured, the inhalation data must be compared to intravenous data in order to measure the extent of exposure after inhalation. The approach of McKenna et al. (59) was capable of revealing differences between fasted and fed animals in their capacity to metabolize vinylidene chloride, which correlated well with the toxicity of this compound. The absorption of most compounds given by inhalation is rapid, although certain compounds, for example the highly polar antiasthmatic drug sodium cromoglycate, may show a measurable first-order absorption across the lungs. It should be remembered that the observed absorption rate after instillation of a micronized powder into the trachea may be that of the formulation, not of the chemical moiety itself.

The metabolism rate constants of inhaled 1,1-dichloroethylene were determined by measurement of the rate of removal of the compound from circulating air in a closed chamber system containing the experimental animal (1). The air was recirculated, with oxygen added to maintain the concentration at 19–21%, and the air was sampled at regular intervals and analyzed for unabsorbed 1,1-dichloroethylene by gas-liquid chromatography. The rate of removal showed two phases: (i) a rapid phase proportional to the mass of the animal and the concentration of chemical, (ii) and a slow phase, which represented

metabolism of the compound. The slow phase showed saturation (Michaelis-Menten) kinetics, and rate constants (Km and Vmax) were derived in terms of the concentration of chemical in the chamber. This approach is interesting as the data are obtained by a noninvasive method. Also, the kinetic constants

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_168.html[2010/10/28 18:41:27]

are derived in terms of vapor or gas concentrations, which are most appropriate when interpreting inhalation studies in relation to human exposure to volatile agents.

Percutaneous Absorption

The percutaneous route is likely to be of increasing importance in drug formulation in the future. Animals may be used as suitable models; however, there may be major species differences related to the presence of hair follicles and the barrier function of the stratum corneum. An added pharmacokinetic advantage to this route is that the fraction absorbed may be measured as described above for the oral route (i.e., AUC data) and also by analysis of the amount remaining at the site of administration. The dermal absorption of vapors can be assessed in rats using a body-only chamber (58). Shaving the hair from the backs of rats can provide a suitable site for in vivo absorption studies (47), although in vitro data provide a suitable model for extrapolation to humans.

Intravenous Injection

The bolus intravenous dose is the most important single technique for deriving information concerning the kinetics of the distribution and elimination of chemicals. As with oral administration, aqueous or aqueous miscible solvents should be used, although the maximum dosage volume is considerably lower, that is, about 2 ml/kg for aqueous and 1 ml/kg for solvent-aqueous mixtures. Ideally, the solution is made isotonic by the addition of sodium chloride, although in practice dissolution of low doses in isotonic saline is adequate.

There are two important parameters to be considered in such studies. First, the data processing assumes that the material was administered instantaneously at time zero. In practice, a rapid injection may produce considerable toxicity, which a slower injection can prevent. Generally, a"bolus" dose, given over a finite period of up to a few minutes, is regarded as instantaneous provided that the total injection time does not represent more than about 5% of the half-life of the most rapid phase of the plasma concentration-time curve. The other parameter to be considered is the true location of the dose, because in kinetic studies it is important that 100% of the dose is intravenous and none ends up in a perivascular site. The following techniques have proved successful.

Rat. The tail and hind paw veins are convenient for dosing but neither is particularly easy to use or gives 100% intravascular dosing repeatedly and routinely without the necessary expertise. The following technique, although more complex, is preferable because it overcomes the problems experienced with the above routes, and the cannula can be used subsequently for sample collection. The animal is anesthetized with ether, and an incision is made through the skin of the neck to the right of the midline. Blunt dissection is used to separate the thin layer of muscle covering the external jugular vein, which is exposed and cleaned. Thread is passed under the vein at both anterior and posterior ends of the exposed section but is not tied off posteriorly. A small incision is made in the vein, and a length of polyethylene cannula tubing, connected to the dosing syringe, is passed into the vein toward the heart for a distance of about 2 cm. The dose solution is injected and the cannula rinsed with isotonic saline. The tubing may then be removed and the vein tied off, or the cannula tubing can be tied in situ for subsequent sampling, providing that the compound is not adsorbed to the cannula (see below). In anesthetized rats, which will not regain consciousness during the study, an alternative site of injection is the femoral vein, which may be exposed by an incision into the ventral surface of the top of the hind leg.

Guinea pig. A modification of the external jugular method described above may be used for the guinea pig. The external jugular vein of an anesthetized animal is exposed but not cleaned of connective tissue. The dose is injected directly using a fine needle (0.5-mm gauge) bent inward through about 45°, which allows the needle to be positioned without undue stretching or movement of the vein. The vein is clamped, above and below the injection site, as the needle is withdrawn. The vein is subsequently ligated and the incision sutured.

Rabbit. It is relatively easy to administer intravenous doses to rabbits, because the vein running around the periphery of the ear lobe can be readily exposed by shaving with a scalpel blade. This vein is of sufficient size and visibility to give reliable intravenous dosing.

Intravenous Infusion

For intravenous infusion studies, the dose must be given via an indwelling cannula, and the external jugular vein is a suitable site in rats. If the infusion period is prolonged, such that recovery from anesthesia is envisaged, the cannula can be run under the skin from the ventral surface of the neck and exteriorized on the dorsal surface behind the ears. If the cannula is then secured on the dorsal surface, the animal is prevented from damaging it during infusion while being permitted a degree of restricted movement. This method of exteriorization is also valuable as a method of long-term sampling (see

below).

The delivery of compound during intravenous infusion must be at a constant but low rate such that the animal is not subjected to excessive hemodilution. To date, the standard method has been to use a high-quality infusion pump. The development of osmotically driven minipumps (Alzet), which can be implanted into the animal and deliver a constant rate as low as 0.5 *μ*l/h for up to 2 weeks, opened up exciting possibilities. Minipumps allow investigations of steady-state plasma and tissue concentrations associated with toxicity, and the

pharmacokinetics under similar steady-state conditions. Such devices have been used to study the renal clearance of 63Ni under steady-state conditions; interestingly, these studies revealed diurnal fluctuations in the steady-state levels, probably due to metabolic changes that were not suspected from earlier studies (94).

Sampling Techniques

Blood (Plasma and Serum)

When considering the frequency, timing, and duration of blood sampling, it is important that an adequate number of samples are taken to define each section of the plasma concentration-time curve (Figure 4.6). It has been suggested that plasma samples be collected during the first four to five half-lives, during which time 93–97% of the compound will have been eliminated (119). However, it is possible that such a restriction may mask a quantitatively minor distribution component, for example a third compartment, capable of significant accumulation on continuous ingestion as part of a toxicity test. Such a compartment could be perfusion- or diffusion-limited distribution to a tissue in which the tissue affinity was high. If such a tissue was the site of toxicity on chronic administration, a single-dose kinetic investigation restricted to four half-lives would have failed to throw any light on the process involved. However, autoradiography following a radiolabeled dose may reveal such a selective distribution; but it must be remembered that this method cannot differentiate between parent compound and metabolites. Thus, as a general guideline, the plasma concentrations should be measured until the limit of detection of the analytical method is reached. Obviously, if the limit of detection allows analysis over a large number of half-lives, less frequent sampling is required during the slow terminal phase, which can be defined adequately by about four samples. Thus a three-compartment system can be accurately analyzed by about 12 samples provided that they are correctly timed. The corollary to this situation is that a relatively insensitive analytical method is incapable of yielding full pharmacokinetic data. Considering the data in Figure 4.6, if the limit of detection for compounds A and B were 0.1 μg/ml, both would appear to be represented adequately by a one-compartment model, with different values of k. Indeed, under these circumstances the plasma concentration of both A and B would fall from 2.85 to 0.10, a decrease of 97%, equivalent to about five half-lives.

Using the methods described below, it is possible to withdraw a significant fraction of the total blood volume (64 ml/kg in the rat), thereby modifying the perfusion of the organs of elimination and corrupting the derived pharmacokinetic data. This problem can be avoided by taking the smallest samples consistent with accurate analysis and the minimum number of samples necessary to define adequately the various phases (i.e., smaller samples at early time points). As a general rule, individual blood samples should be restricted to a maximum of about 0.5 ml/kg body weight, providing the total number of samples is small (i.e., less than 10). This general rule takes no account of the duration of the experiment, which may indicate either smaller or larger sample sizes.

Rat. Various methods have been used successfully to obtain small serial blood samples from anesthetized and conscious rats.

Tail vein. Whole-blood samples (approximately 70 μl) are obtained on cutting the tail vein with a scalpel blade and collecting the blood into heparinized capillary tubes. This method is widely used and was employed by Sauerhoff et al. (90) in their study of the dose-dependent kinetics of 2,4,5-trichlorophenoxyacetic acid. Care must be taken to wash the tail to avoid contamination of late blood samples by the much higher concentrations present in urine and feces. Washing the tail vein with warm water will often remove the blood clot and reinstigate blood flow.

Toe vasculature. Blood samples (up to 500 μl) may be collected by clipping the toenail into the vascular bed and allowing the blood to run into heparinized capillary tubes (41), but this would be more stressful for the animal than the use of the tail vein.

Cardiac puncture. Multiple cardiac sampling is possible but involves more trauma than the above methods, and anesthesia (ether) is essential. However, provided that a fine (0.5-mm) needle is used, it is possible, with practice, to obtain a number of samples without evidence of extravascular blood loss, although this technique is also more stressful than a simple incision into the tail vein.

Orbital sinus. The animal is anesthetized with ether and held down by gentle pressure with thumb and forefinger behind the head. A heparinized capillary tube is inserted into the orbit at the anterior apex and moved to rupture the sinus membrane in the anterior dorsal region at the back of the orbit. A considerable blood flow is obtained, which stops on removal of the tube and the pressure at the back of the neck.

External jugular vein. Methods have been described in which silicon medical grade cannula tubing (Silastic; 0.05 cm i.d., 0.09 cm o.d.) implanted in the external jugular vein has remained patent for

blood sampling for periods up to 2 months (109). The use of silicon tubing is preferred to polyethylene for such long-term studies because it is more flexible for exteriorization on the dorsal

surface and less apt to cause thrombosis.
The tubing is inserted into the vein by either of two methods. First, a suitable size syringe needle shaft is attached, which is passed into the vein and then pushed back out again about 5 mm lower down. The needle shaft is then removed, and the cannula tubing is gently pulled back until it reenters the vein. Alternatively, the end of the cannula is made into a point by a steep diagonal cut and inserted via a small incision in the vein. A shallow diagonal cut (i.e., almost parallel with the longitudinal axis of the tubing) aids insertion but is more prone to obstruction by the vein wall during sampling. Careful positioning of the end of the cannula tubing by gentle maneuvering may be necessary to achieve optimal sampling, which usually involves passing the cannula toward the heart for a distance of about 2 cm. A similar technique has been described (4) in which the cannula is then exteriorized and secured behind the head of the animal. However, under such circumstances a collar may be necessary to prevent the animal damaging the tubing (20).
Common carotid artery. In anesthetized animals in which the external jugular vein is used for infusion, the ipsilateral carotid artery can be used for sampling. The artery lies deep below the sternohyoid muscle and may be reached using blunt dissection. The artery is a robust structure and can be brought to the surface by curved forceps. Cotton ties are placed anterior (×1) and posterior (×2) to the intended site of incision and tied loosely. The artery is then placed under tension by artery forceps attached to the anterior tie and to the posterior tie nearer the heart so as to prevent blood loss during incision. A small incision is made in the artery, and a length of cannula tubing, attached to a saline-filled syringe, is inserted and passed toward the heart, through the first posterior tie. It is tied firmly, and the tension on the second posterior tie is released. The cannula can now be slid through the second posterior tie, which is then tied securely. The anterior tie is now tightened and the artery forceps removed. Blood may be sampled by removing the syringe when the blood pressure is sufficient to expel the saline. The sampling is stopped by clamping the tubing, replacing the syringe, and passing saline back up the tubing. It is important to keep the artery under tension during insertion of the cannula, or significant blood loss may occur. An alternative method of applying tension is to insert a pair of forceps underneath the artery and allow them to open and stretch the artery.
Other species. For experiments performed under anesthesia, a major vein or artery (e.g., jugular, carotid, femoral) can be cannulated. For multiple sampling under temporary ether anesthesia, cardiac puncture has been used successfully for guinea pigs. On the other hand, the orbital sinus is a more appropriate site for the mouse, and the marginal ear vein can be used for the rabbit without anesthesia.
Urine
A knowledge of the urinary excretion rate is necessary for calculating the overall renal clearance of a compound. The bladder causes variable slowing of the output; for compounds with a short half-life, a method of overcoming sporadic urination is necessary. Calculating results by the sigma-minus method, rather than using excretion rate data, reduces the importance of incomplete bladder emptying and the resultant scatter in the data. For compounds with a half-life of many hours, sufficiently frequent samples may be obtained merely by placing the animals in a metabolism cage, which gives adequate separation of urine and feces, and by encouraging reflex urination (20).
Under anesthesia, the effect of the bladder may be overcome by (a) inserting and tying a cannula into the bladder via the urethra or directly across the bladder wall, and emptying and rinsing the bladder with isotonic saline using a syringe; (b) inserting a cannula via the urethra and allowing the urine to be expelled naturally or with the aid of gentle massage (11); or (c) cannulation of both ureters and collection of the urine without it passing through the bladder (77). The third technique was used by the author to analyze the extent of reabsorption of saccharin from the rat urinary bladder, but was found to be technically difficult, because both ureters had to be cannulated with polyethylene tubing stretched to give a suitable taper, and even slight twisting of the ureter effectively blocked the urine flow. This technique is not recommended for routine investigations. However, these studies did reveal that although the intact urinary bladder was relatively impermeable to saccharin (which is highly ionic), manipulation of the bladder with forceps produced a slight increase in permeability, and bladder cannulation (as described above) produced a marked increase in permeability and reabsorption. Thus any damage or irritation caused by the cannula should be kept to a minimum; if a cannula is inserted across the wall into the apex of the bladder, it is essential that the contents be removed and rinsed at frequent intervals, that is, at least every 15 min. Similarly, any palpation used in method (b) above, should not be excessive, or increased reabsorption from the bladder may occur and cause a decreased apparent renal clearance. In addition, cannulae passed via the urethra, which is particularly suitable for female animals, should be positioned carefully such that

they do not enter too far into the bladder lumen and damage the epithelium.

Renal clearance studies may be performed either after single doses or during infusion at steady state (when the clearance can be related to total clearance and plasma concentration). Insights into the extent of reabsorption and tubular secretion can be obtained by measuring the renal clearance of inulin given simultaneously (1–20 μCi of [14C]inulin/kg or 50–100 μCi of [3H]inulin/kg).

Bile

Bile may be collected from a cannula inserted into the common bile duct such that the tip is located at the point of bifurcation near the hilar region of the liver. The common bile duct is found by making an incision through the midline into the anterior part of the body cavity. Slight tension on the proximal part of the duodenum reveals the bile duct running through the pancreatic tissue. The bile duct is cleaned, a thread is placed loosely around it, and cannula tubing is inserted via a small incision and tied in place. Bile flow is usually 0.5–1.0 ml/h in the rat. Bile may be collected by either placing the animal in a restraining cage and collecting from the exteriorized cannula or passing the tubing into a suitable container (sealed plastic sachet) placed subcutaneously. The test chemical is usually given soon after establishing the cannula, because changes in bile composition occur if the bile salts are not allowed to recirculate. A modified technique avoiding the use of animals still under the stress of surgery has been demonstrated by Light et al. (55). With this technique, the bile cannula was exteriorized and joined to a second cannula, which passed back into the body cavity and entered the duodenum via the greater curvature of the stomach. The animals were then left for 4 days, after which constant feed intake and body weight were observed. This method could be useful for studies with chronic dietary intake of the chemical; however, chronic intake for more than 4 days might be necessary after surgery in order to reestablish steady-state intake via the diet, which may be different from that of normal animals.

In animal species that possess a gallbladder (i.e., guinea pig and rabbit), it is necessary to prevent this organ from delaying elimination by ligation around its base so that bile has to pass directly down the cannula.

DATA HANDLING

The type of information that can be obtained from kinetic studies, and its derivation from raw plasma, and urine data are illustrated by results obtained by the author and colleagues. Saccharin is a nonnutritive sweetener which causes an increased incidence of tumors of the urinary bladder in male rats when fed at high dietary concentrations (more than 3%) for two generations (88) or from birth (93). The possibility of nonlinear kinetics at such high doses was investigated using the Charles River CD-derived rat, the same strain used in the cancer bioassays. The study, which has been published elsewhere (105), investigated the concentrations of saccharin in the tissues of animals fed saccharin-containing diets and used the techniques outlined above to investigate details of the disposition of this compound. Previous studies using [14C]saccharin had shown that it was incompletely absorbed from the gut, and eliminated in the urine and feces without undergoing detectable metabolism (73).

On feeding rats with saccharin-containing diets ad libitum for a period of 22 days, significant nonlinearity was apparent in the concentrations of saccharin in the plasma and tissues, with elevated concentrations at high dietary levels (Figure 4.15). The following studies were

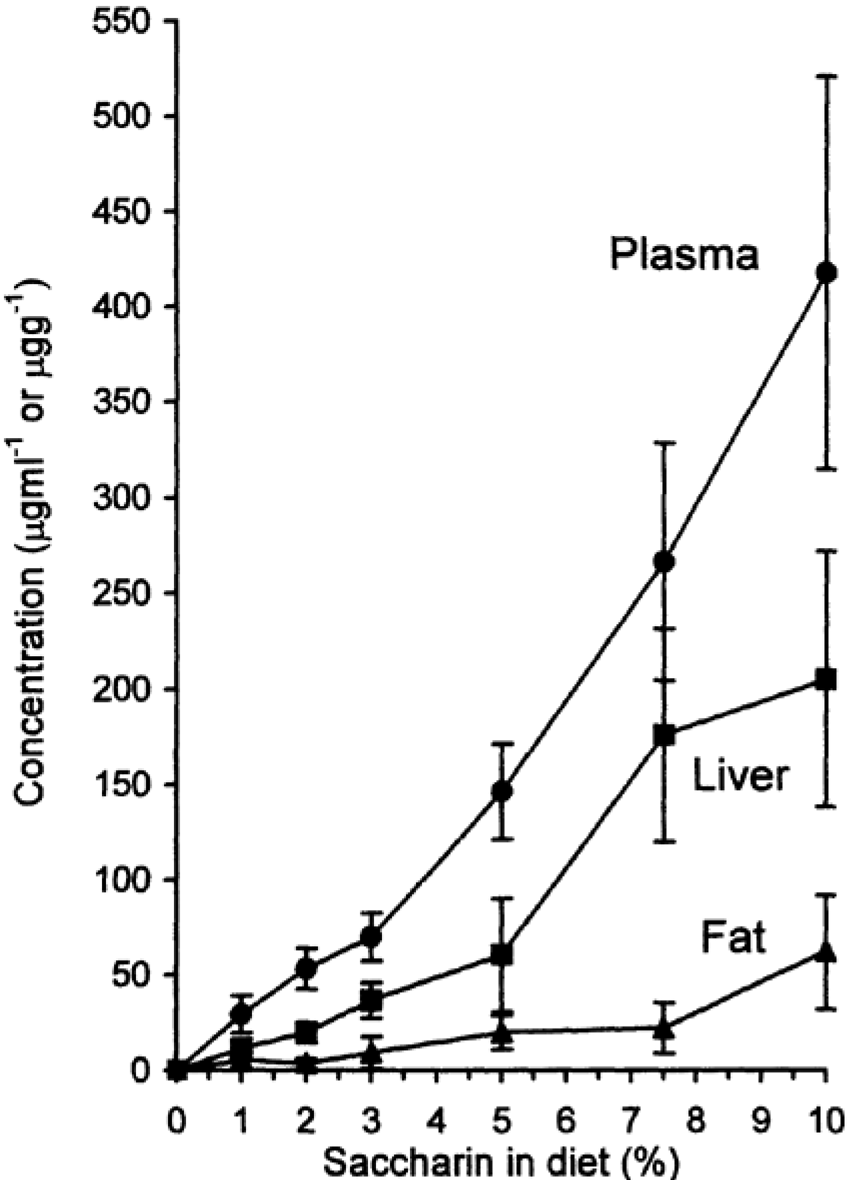

FIG. 4.15. Concentrations of saccharin in the plasma and tissues of rats given saccharin-containing diets. Adult male rats were given saccharin-containing diets ad libitum for 22 days prior to killing at 6 AM. The results are the means with standard deviations represented by vertical bars. From Reference 105.

Table 4.10 Concentrations of saccharin in the plasma and urine of a rat given a single intravenous bolus dose[a]

Plasma		Urine	
Time of sample (min)	Concentration (μg ml^{-1})	Collection period (min)	Amount excreted (μg)
5	184.3	0–5	7518
15	102.0	5–15	6275
30	50.5	15–30	4989
45	24.9	30–45	2580
60	14.1	45–60	1485
75	8.0	60–75	861
90	5.7	75–90	561
105	4.0	90–105	363
120	2.9	105–120	300

[a]The animal (body weight 570 g) was given a single IV bolus dose of saccharin (50 mg/kg) at time 0.

performed in an attempt to investigate the cause of this phenomenon.

Intravenous Bolus Dose: Plasma Analysis

Saccharin is a strong organic acid (p*Ka* about 2) that forms a highly water-soluble sodium salt. 5-[^{3}H]Saccharin was used in these studies, and the concentrations in plasma and urine samples were determined by measuring the total radioactivity present *(because saccharin does not undergo metabolism)*. A range of doses of saccharin were given (1–1000 mg/kg as a single intravenous bolus over a period of 30 s) to anesthetized male rats via a cannula inserted into the jugular vein. The dead volume in the cannula was displaced with saline. Plasma samples were subsequently withdrawn from the same cannula, because saccharin showed no tendency to adhere to the polyethylene tubing used. The bladder was cannulated, emptied, and rinsed at each plasma collection period. The results for an individual animal given 50 mg/kg are presented in Table 4.10.

A graph of plasma concentration against time (Figure 4.16) clearly shows a biphasic decrease, which may be analyzed graphically using the method of residuals as shown in Table 4.11. Alternatively, the β phase can be analyzed by linear regression analysis to yield the extrapolated values, which can then be analyzed by linear regression to give the values of A, B, α, and β as shown in Table 4.11. The data selected for this discussion were for an individual animal that showed a prolonged $\alpha+\beta$ phase. This choice was necessary, as information on the initial $\alpha+\beta$ phase is decreased when urine data are analyzed. For other animals, the $\alpha+\beta$ phase was apparent only during the first 30 min, and linearity occurred between 30–45 and 120 min, so that the corresponding urine data could not be studied adequately by the methods used in Tables 4.13 and 4.14 (see below). Thus, in the animal selected, the data are actually deficient in that the β phase is dependent on only four

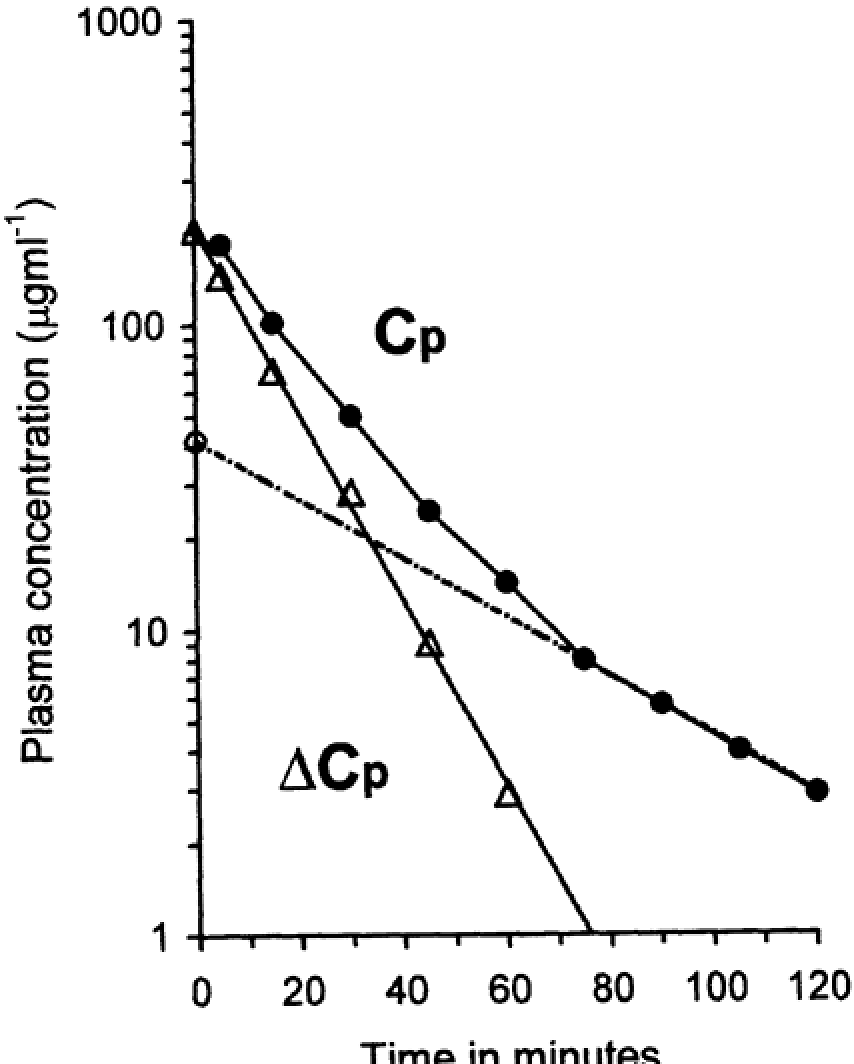

FIG. 4.16. Plasma concentration-time curve after a bolus of saccharin (50 mg/kg IV) into a male rat. The data used are given in Tables 4.10 and 4.11.

points. Thus it is apparent that more reliable results would have been obtained had the sampling period been extended for another 30 min in this animal, such that both the *α* and *β* phases were represented by five or six points. This observation emphasizes an important principle, that is, that the more data points measured, the more reliable are the results (provided that it does not involve removal of too much blood).

Intravenous Bolus Dose: Urine Analysis

The urinary excretion data have been recalculated in Table 4.12 in a form suitable for analysis of the excretion rate against time. A graph of excretion rate against time, using the midpoint of the sample collection period (Figure 4.17 and Table 4.13), shows a biphasic decrease similar to that seen in plasma. Because of the scatter in the points of the terminal *β* phase, it is not clear whether the 52.5-min point should be included in the *β* or the *α*+*β* phase. However, from the plasma curve (Figure 4.16), it seems that the *β* phase started after 60 min, and thus the 52.5-min point was not included in the analysis of *β*. The residuals line (Figure 4.17) was analyzed with the omission of the 2.5-min point, because this value did not fit the line clearly shown by other points (possibly due to high initial renal elimination prior to mixing of the compound within the central compartment). The constants *α* and *β* may be derived from the excretion rate or using the sigma-minus method, which is described by Eq. (28). The total amount finally excreted (Table 4.12) is obtained by extrapolation of the cumulative total (column 5, Table 4.12) to infinity, which may be done either graphically or from the excretion rate data, as shown in Table 4.12. The amount remaining to be excreted (ΔAex) is calculated by subtracting the running total from the final total for each time point (column 6, Table 4.12). A graph of ΔAex against time (Figure 4.18)

Table 4.12 Urinary excretion of saccharin after a single bolus dose of 50 mg/kg

Time of collection*a* (min)	Midpoint (min)	Amount excreted (μg)	Excretion rate (μg min−1)	Cumulative total (μg)	A_{ex}^{∞} −cumulative total (ΔAex) (μg)

75–90	82.5	561	37.4	24,269	1496
90–105	97.5	363	24.2	24,632	1133
105–120	112.5	300	20.0	24,932	833
120–∞	—	833*b*	—	25,765*b*	—

a Raw data from Table 4.10.

b The additional amount excreted from the last data point to infinity can be calculated as the excretion rate (last) divided by the terminal slope. The graph of rate against time (Figure 4.17; Table 4.13) gives a terminal slope of 0.024 min−1; therefore the amount excreted, 120–∞, equals 20.0 µg min−1/0.024 min−1=833 μg.

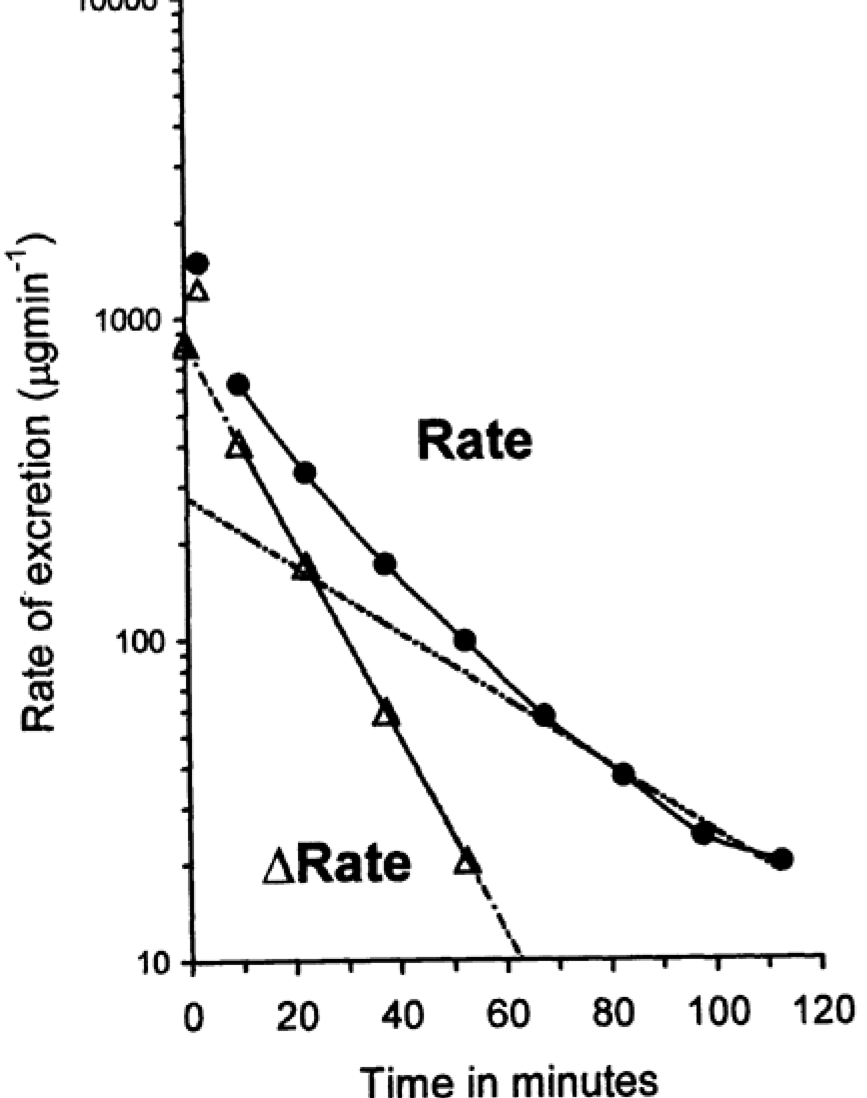

FIG. 4.17. Urinary excretion of saccharin after a single intravenous dose. The results are given as micrograms excreted per minute plotted against the time at the midpoint of the collection period. The data used are given in Table 4.12.

clearly shows a biphasic decrease, although the *β* phase appears to have started slightly earlier, at 60 min. Analysis of this curve by the method of residuals gave values of ***α, β, A″,*** and ***B″*** (Table 4.14).
The renal clearance of the compound can be determined by Eq. (7) using the excretion rate during individual collection periods and the plasma concentrations at the middle of the collection period. These values are given in Table 4.15 and show a clearance of 5.0 ml min^{-1}±10% for seven of the nine time points. The clearance adjusted for body weight was 8.82 ml min^{-1} kg^{-1}. As an alternative to averaging the values derived during the experiment, CL_R may be calculated also from the time-averaged values A_{ex} and AUC (Table 4.15).

Intravenous Bolus Dose: Rate Constants

The values ***α, β, A, B, A′,*** and so on, derived from plasma and urine, are given in Table 4.16. Using the six values for each constant given in the table, it is interesting that the values of *β* (0.0222 ±0.0017 [SD]) and *α* (0.0691 ±0.0023 [SD]) show much less variability (±7.5 and ±3.3%, respectively) than the values of k_{21}, k_{10}, and k_{12} derived by Eqs. (38), (39), and (40) (±12, ±16, and ±19%, respectively).
Another important parameter that can be derived from the raw data is the plasma clearance, which is given by Eq. (22). The AUC may be measured by the trapezoid rule, as shown in Table 4.17. With the linear trapezoid method, the concentrations are joined by straight lines; thus after oral dosing, the area during the increase is underestimated and that after the peak is overestimated, as a result

the errors tend to cancel. After intravenous dosing, however, the AUC for each segment is overestimated, the total extent of which depends on the number of time points available. Such errors may be minimized by applying the trapezoid rule to log-transformed data. These points are shown in Table 4.17, which also illustrates the derivation of the model-independent parameters MRT and *V*ss. Because the terminal half-life (β phase) from plasma was 30.8 min (0.693/0.0225), the duration of the study was the minimum necessary to adequately define the curve. Ideally, the data collection should have been extended for at least another 30 or 60 min in order to give five half-lives, which was borne out by the fact that the β phase was dependent on only four data points. Because the duration of the experiment was four half-lives, a total of about 94% of the dose should have been eliminated, which is in good agreement with that pre dicted from the urinary data, as the urinary clearance, 8.82 ml min−1 kg−1 (Table 4.15), represented 87% of the plasma clearance, and the total urinary recovery in 2 h (24.9 mg) represented 87% of the dose administered (28.5 mg, or 50 mg/kg). The urinary elimination rate constant *kR* may be calculated by a number of methods using the data obtained, and these figures show good agreement (Table 4.17).

It is clear from these results that low doses of saccharin fit a two-compartment open model with a terminal half-life of about 30 min, a plasma clearance of 10.1 ml min−1 kg−1, and a renal clearance of about 8.8 ml min−1 kg−1. The latter value is considerably higher than the glomerular filtration rate in the rat (3.4 ml min−1 kg−1). Because glomerular filtration removes only the nonprotein-bound compound and saccharin is about 80% protein-bound (105), the clearance due to filtration would be only about

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_176.html[2010/10/28 18:41:32]

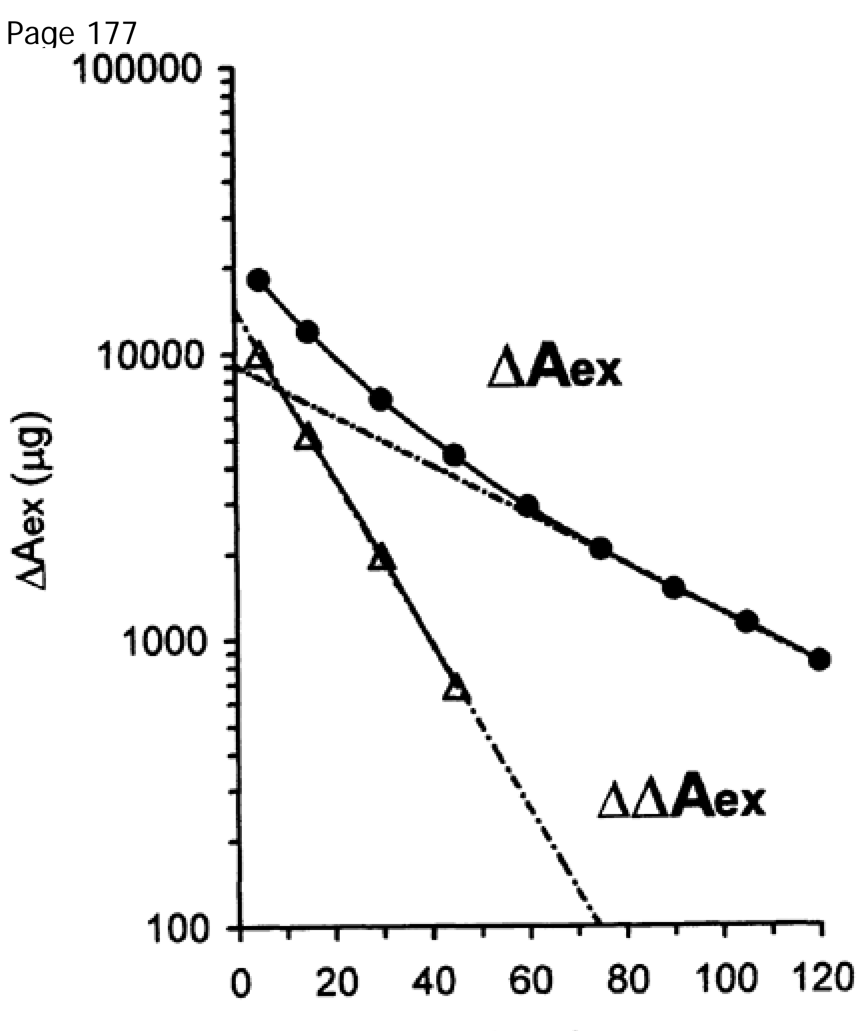

FIG. 4.18. Urinary excretion of saccharin analyzed by the sigma-minus method. The results are the amount remaining to be excreted (Δ*A*ex) plotted against time. The data used are given in Table 4.12.

0.7 ml min−1 kg−1. It is therefore apparent that extensive secretion and negligible reabsorption must be occurring in the renal tubule, and we can conclude that the major route of elimination of saccharin is by renal tubular secretion. Renal tubular secretion is responsible for about 80% [(8.8−0.7)/10.1×100] of total elimination. This finding was confirmed by studies in which the plasma clearance of saccharin was reduced by about 70% by the drug probenecid, which inhibits renal tubular secretion (105).

Because renal tubular secretion is a saturable process, it was possible that the nonlinearity of plasma levels, seen on dietary administration, arose from saturation of this major route of elimination. This possibility was investigated by giving a range of intravenous bolus doses of saccharin (1–1000 mg kg−1) and calculating the plasma clearance. The plasma concentration-time curves for high doses (Figure 4.19) reflected nonlinear kinetics (Figure 4.13) being superimposed on the two-compartment pattern seen at low doses (Figure 4.16). It resulted in high doses appearing to be a simple one-compartment system during the course of the experiment. Obviously, better data would have been obtained if the collection period was extended (105). These data illustrated well that the

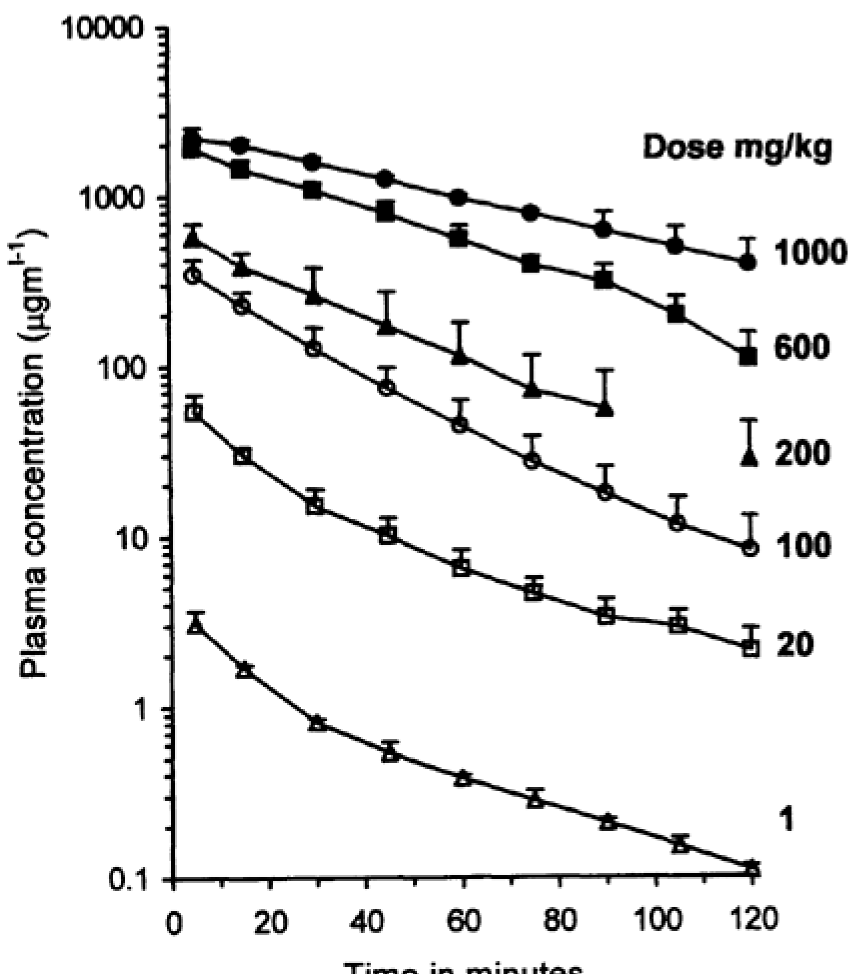

FIG. 4.19. Plasma concentration-time curves for rats given bolus intravenous doses of saccharin. Adult male rats were given [3H]saccharin (1–1000 mg/kg IV) by bolus dose, and plasma levels were measured by liquid scintillation counting. From Reference 105.

terminal half-life, which was derived at low plasma levels, did not show a dose-dependent increase and that the best indication of saturation kinetics was given by plasma clearance, which was decreased at doses of 300 mg kg−1 or more (Figure 4.20). The increased half-life at the highest dose is probably a reflection of the duration of the study rather than a true value.

Intravenous Infusion

Saturation kinetics apparent after single doses of about 300 mg kg−1 (shown by the decreased plasma clearance and altered plasma concentration-time curve) could not be related closely to a particular plasma concentration, because the levels fell from about 500 to 30 μg ml−1 during the 2-h study period. Infusion studies were used to relate altered clearance to a particular plasma level, because at steady state the rate of infusion equals the rate of elimination for a *fixed* plasma concentration. CL can be calculated using Eq. (20),

$$\mathrm{CL} = \frac{\text{rate of infusion}}{C_{pss}}$$

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_177.html[2010/10/28 18:41:33]

(*Note:* 1/*y* weighting is normally used to allow for analytical errors of ±*x*%.)

The rats were anesthetized and infused at a rate of 9.6 μl/min with [3H]saccharin solution in isotonic saline via the jugular vein using a Harvard infusion pump. The infusion rate was selected because it approximates 14 ml/day and is therefore not an excessive fluid intake. Each animal was infused at a constant rate, within the range 50-2000 μg min−1, and the plasma was analyzed every 30 min from 90 min onward until three consecutive samples showed the same concentration (C*p*ss). The clearance for each animal was calculated using the equation given above. A graph of clearance against steady-state plasma concentration (Figure 4.21) shows that the clearance was about 8–12 ml min−1 kg−1 at plasma con300 μg ml−1 (a value similar to that seen after an intracentrations below 200 μg ml−1, whereas the clearance decreased to 4–8 ml min−1 kg−1 at concentrations above venous bolus dose of 600 mg kg−1).

Thus, based on these studies, the renal tubular secretion of saccharin appears to be saturated by doses giving plasma concentrations of 200–300 μg ml−1 or more. This value correlates well with the concentration in the plasma of rats fed a 7.5% saccharin diet, and which was associated with elevated levels in the plasma and most organs (Figure 4.15) (105). [Intravenous infusion in dogs was used to relate serum concentrations of minoxidil at steady state to cardiovascular effects and to cardiac toxicity (60).]

Oral Studies

Because saccharin has a short terminal half-life (30 min), it is possible that there are rapid fluctuations in plasma concentrations during chronic dietary administration. This possibility was investigated by studies on the plasma concentration-time curve for animals maintained on a 5% saccharin diet for an extended period. The diuraal variation showed relatively small changes, with a peak at around 6 AM and a minimum

Page 179

a Data are from Figure 4.16.

b Renal clearance, calculated using Eq. (7). Mean renal clearance=5.03 ml min−1 (per 570 g)=8.82 ml min−1 kg−1. CLR *m*ay be calculated also from *A*ex (Table 4.12) and AUC (Table 4.17) between 0 and 120 min:

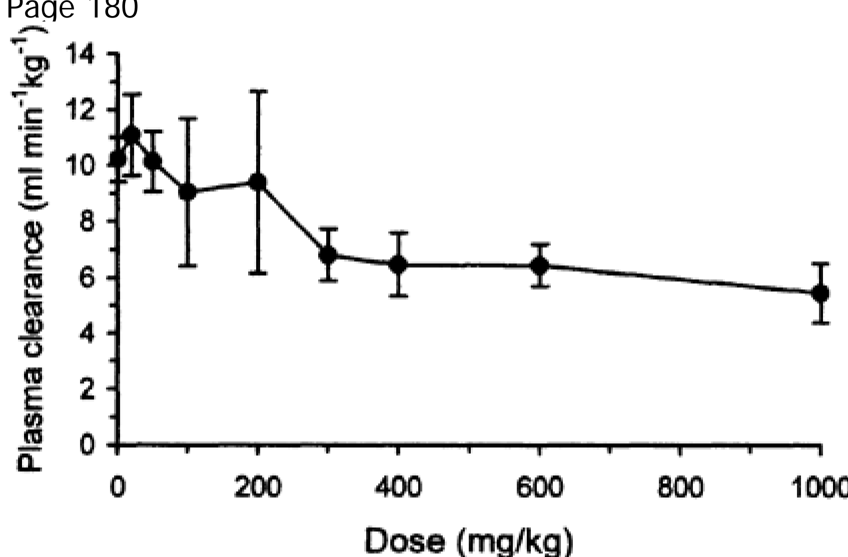
$$CL_R = \frac{A_{ex}}{AUC} = \frac{24,932\,\mu g}{4895\,\mu g\,ml^{-1}\,min} = 5.09\,ml\,min^{-1}$$

at 6 PM. (Figure 4.22). The extent of variation was less than might have been expected from the half-life, and the fact that little saccharin-containmg feed was consumed between 6 AM and 6 PM. It therefore seemed probable that the rate of absorption from the gut was low and blunted any large change in plasma level. The plasma concentration-time curve after oral administration was studied and showed much lower levels than after similar doses given intravenously (Figure 4.23). The peak concentration was at the time of the first sample, followed by a slow and variable decrease. The decrease in concentration was obviously not related to the value of *β*, and thus saccharin is a good example of a compound for which the decrease after oral administration is related to *ka*, and not to *k* or *β* (see Mathematical Principles, above). The decrease was slow and complex, emphasizing that if absorption from the gut is slow, a single rate constant cannot be derived to apply to the many rates occurring simultaneously at different sites within the gastrointestinal tract. The duration of sample collection after oral dosage was inadequate for definition of the ACU0–∞, and thus the bioavailability could not be calculated from these plasma data. The methods for deriving simple absorption rate constants are described above under Mathematical Principles.

In summary, these studies have been used to illustrate the derivation of kinetic data and the insights they can give into the handling of the compound during chronic toxicity studies. The possibility of saturation of one pathway revealing a second pathway of elimination could result in saccharin (which is not metabolized normally) undergoing metabolism in rats fed high-saccharin diets. However, this phenomenon has not been detected for saccharin (104), although Gehring and Young (33) showed that metabolism of 2,4,5-trichlorophenoxyacetic acid was revealed by doses resulting in saturation of renal tubular secretion.

Computation

The use of computer programs to derive kinetic constants from plasma and urinary concentrations can greatly simplify data handling. Because data handling is also optimized, computer usage is the method of choice. There are a number of suitable programs (e.g. BLIN, NONLIN, SIPHAR) available for nonlinear least-squares regression analysis, which is the most appropriate method, and readers are referred to Gibaldi and Perrier (36), Wagner (112), and Gabrielsson and Weiner (28) for further details. The use of such a program would automatically put the best-fit line through the data presented in Figures 4.16–4.18 and would avoid a possibly erroneous decision as to the time at which the a component was exerting an insignificant influence and the line was described by *β* alone. In the analysis of data by computer program, it is common to apply a suitable weight to each data point to ensure the most appropriate fit. The weights that can be applied to the concentration data include (a) all weights equal, which is applicable if the errors in measurement are a constant amount, for example, ±2 μg/ml; (b) weighted by 1/*y*, which is



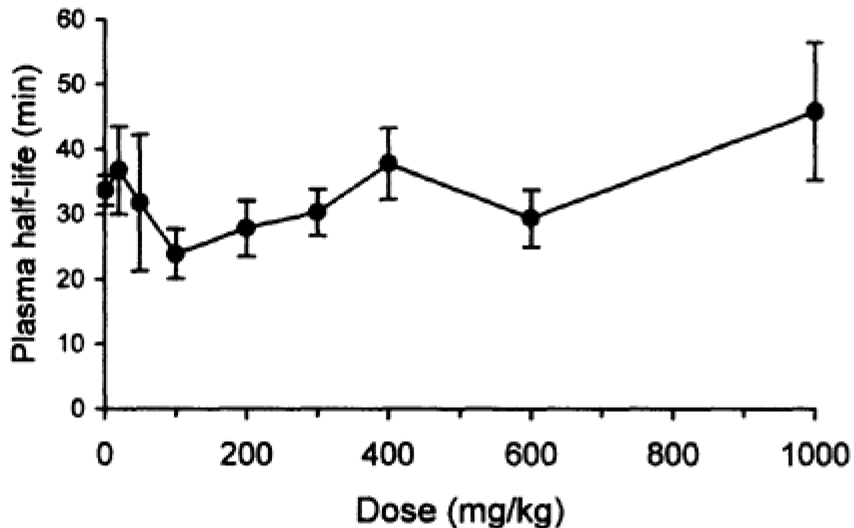


FIG. 4.20. Influence of dose on the plasma clearance and half-life of saccharin in male rats following an intravenous bolus dose. From Reference 105.

applicable if the errors of measurement are a constant proportion, for example ±2%; and (c) weighted by 1/*y*2, which can be used to force the fit through the later time points at the expense of the early higher values. The second option, 1/*y*, closely represents the accuracy of most assay procedures and is used most frequently. It is important with computer fitting of data that some indication of appropriateness of fit is obtained by either a graphical representation or analysis of the deviation between observed and calculated concentrations (error analysis). With the latter approach, a consistent positive or negative deviation is more important than wider but randomly distributed deviations, because it indicates an inadequate fit. Reasons for this situation could be the choice of an inappropriate model to fit to the data or incorrect weighting. Another factor to consider is that although adoption of a more complex model may give a closer fit to the data, the sampling times may be inadequate to provide accurate parameter estimates.

It should be realized that although kinetic constants derived from sophisticated computerized line fitting contain the minimum possible errors due to data handling, any errors in the raw data, due to methodological problems, will still be present. Indeed, the adage "rubbish in, rubbish out" is particularly pertinent to the use of sophisticated data handling to analyze inaccurate or badly designed animal toxicokinetic experiments.

Interpretation of Toxicokinetic Data

There are three principle aims of kinetic studies as applied to toxicology. First, toxicokinetics can provide

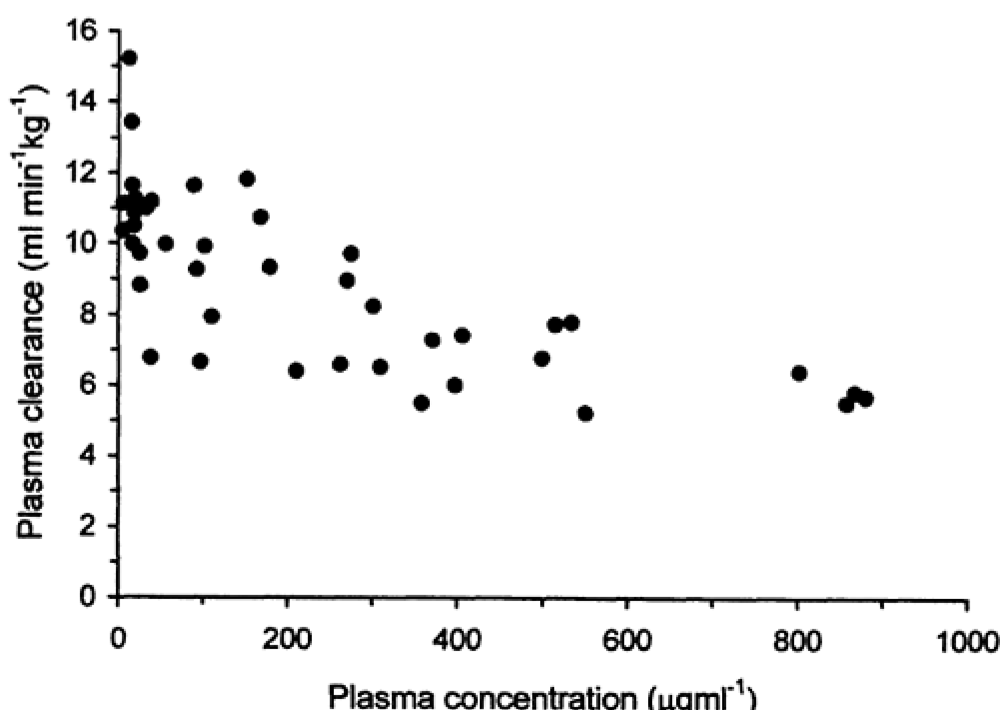

FIG. 4.21. Plasma clearance of saccharin at steady-state plasma concentrations. Adult male rats were given [3H]saccharin in isotonic saline by intravenous infusion (0.0096 ml/min) until a constant plasma 3H concentration was obtained. The plateau saccharin concentration was calculated from the specific activity of the dose solution, and the plasma clearance from the infusion rate and plasma concentration. From Reference 105.

$$k_{10} = \frac{\alpha\beta}{k_{21}}$$

$k12 = \alpha + \beta - k21 - k10$

The constants were derived by graphical analysis or by least-squares linear regression analysis applied to β phase and residuals.

$$\text{Renal excretion} = \frac{25,765}{50,000 \times 0.57} \times 100 = 90.4\% \text{ of dose } (0.57 = \text{body weight in kg})$$

Renal elimination rate constant (kR)

$$k_R = \frac{A' + B'}{\text{dose}} = \frac{277 + 833}{28,500} = 0.039\,\text{min}^{-1}$$

$$k_R = \frac{A_{ex}^{\infty} \times k_{10}}{\text{dose}} = \frac{25,765 \times 0.050}{28,500} = 0.045\,\text{min}^{-1}$$

$$k_R = \frac{CL_R}{V_1} = \frac{8.82}{201} = 0.044\,\text{min}^{-1}$$

$$\text{MRT} = \frac{\text{AUMC}}{\text{AUC}} = \frac{125{,}072}{5024} = 25\,\text{min}$$

$$V_{ss} = \frac{\text{dose} \times \text{AUMC}}{\text{AUC}^2} = \frac{50{,}000 \times 125{,}072}{5024^2} = 248\,\text{ml kg}^{-1}$$

an understanding of the physiological processes that are involved in the fate of the chemical in the body. Second, the relation between dose and toxicokinetics may be the key to either the establishment of appropriate dose levels for chronic studies (101) or the interpretation of such studies. Third, comparative toxicokinetics may be used to assess potential human risks with a more secure basis by reducing the number of unknown variables involved in the extrapolation from animal to humans (see ref. 76).

A good example of the physiological insights that may be obtained is provided by the data on saccharin discussed above. In summary, these data showed that the sweetener is slowly absorbed from the gut. Thus, during chronic feeding of saccharin diets, there are only slight diurnal fluctuations due to the absorption rate producing "flip-flop" kinetics. The absorbed saccharin has a low volume of distribution so that the concentrations in most tissues are similar to or lower than those in plasma. The urinary bladder tissue is part of the central compartment (105). The sweetener is cleared rapidly from plasma, mostly as a result of renal tubular secretion. This process is saturated at the high dietary intakes that are necessary to produce an increase in bladder tumors. Renal tubular secretion is a general mechanism for the elimination of organic acids, and saturation of renal clearance of saccharin at high dietary concentrations is accompanied by decreased renal clearance of indican, a major urinary metabolite of tryptophan (95). Subsequent studies demonstrated that the slow absorption of saccharin from the gut results in altered metabolism of essential nutrients within the gastrointestinal tract (53, 95, 96). Thus the dietary levels necessary throughout life (≥3%) to increase the incidence of bladder tumors in male rats produce profound perturbations of the physiology and biochemistry of the test animal, although these are not directly related to bladder tumor formation. Neither saturation of renal clearance (73) nor altered excretion of amino acid metabolites (81) has been found in humans following doses equivalent to the highest likely human intake.

The relationship between kinetics, dose, and toxicity is probably the single most important contribution that kinetics can make to the field of toxicity testing. Although a few therapeutic chemicals show nonlinear kinetics at the doses normally given to man (notable examples being salicylates, phenytoin [diphenylhydantoin], and ethanol), the plasma levels of foreign chemicals in humans are usually well below those necessary to saturate any protein-mediated reactions. However, in toxicity testing,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_182.html[2010/10/28 18:41:36]

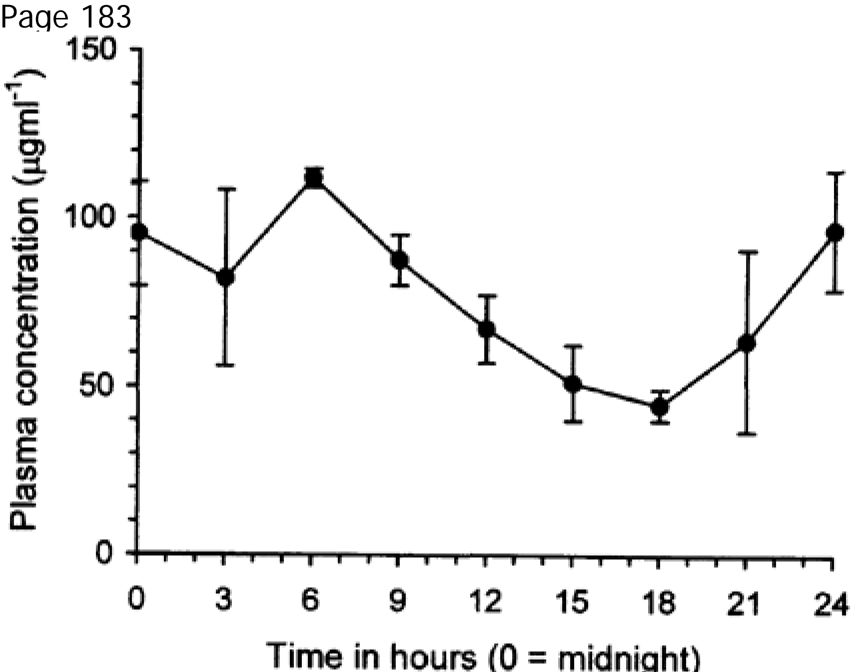

FIG. 4.22. Diurnal variation in the concentration of saccharin in the plasma of rats given a 5% saccharin diet. Adult male rats were given a 5% saccharin (sodium saccharin dihydrate) diet for 66 days ad libitum; plasma samples were collected during a 24-h period and analyzed for saccharin content by HPLC. The results given are the mean concentrations ±*SD* (as sodium saccharin dihydrate) for three animals. From Reference 105.

when the maximum dose tested is designed to show some degree of toxicity, nonlinear kinetics are a distinct possibility and should be fully and carefully investigated. At doses above saturation, the body load of free compound increases steeply with an increase in dose. Under such circumstances, effective tissue concentrations of the chemical will also be considerably higher than predicted by extrapolation from doses showing first-order kinetics. The presence of dose-dependent kinetics may result in an extremely steep dose-response curve for the toxic effect observed. In such circumstances, the nonlinearity in kinetics shown in animal toxicity testing must be taken into account when extrapolating the effects to man.

A possible cause of toxicity associated with large saturating doses of chemicals is that normally minor pathways of metabolism may become of major significance. Thus if a chemical undergoes metabolism by two routes, one with a low *Km* (high affinity) and one with a high *Km* (low affinity), at low doses most chemical in the cell is eliminated by the former route. However, if the levels increase to saturate the high affinity enzyme, any further input will exceed removal and levels will rise such that the low-affinity enzyme will metabolize the excess. (A useful analogy is that of water pouring into a bucket that has two holes in the side at different heights.

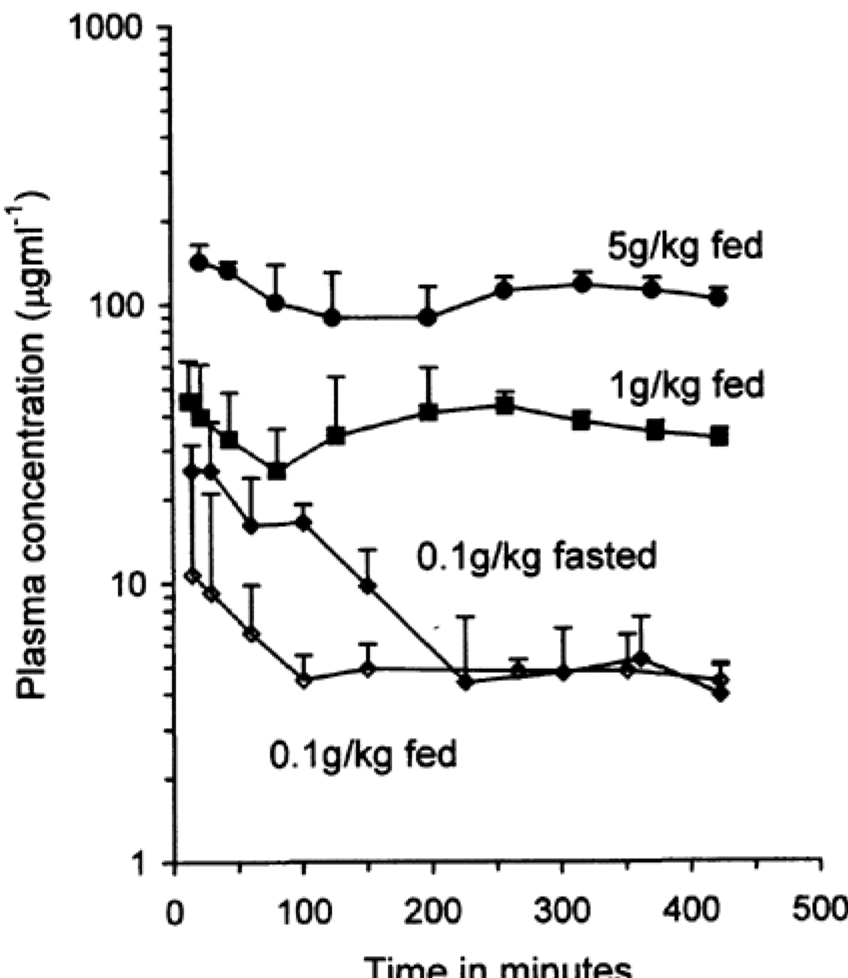

FIG. 4.23. Concentration of saccharin in the plasma of rats given [3H]saccharin orally. Adult male rats were given a single oral dose of [3H]saccharin, and the plasma 3H content was determined by liquid scintillation counting. The saccharin (5, 1, and 0.1 g/kg) was given in aqueous solution (20, 10, and 0.5 ml/kg). The plasma concentration-time curve for 0.1 g/kg was not altered by giving the dose in a large volume (10 ml/kg). The results given are the mean of three animals ±*SD*. From Reference 105.

Little escapes through the upper hole until the rate of input exceeds the rate of removal by the lower hole.)

There have been some notable examples of toxicity occurring largely at saturating doses of foreign chemicals. In a series of papers by Brodie and co-workers (48, 62, 63, 71), it was shown that the hepatotoxicity of paracetamol (acetaminophen) was related to the metabolism of the compound and occurred only at high doses, which were associated with extensive covalent binding of the compound to tissue components. Little binding occurred at low doses or if the metabolism of toxic doses was inhibited by treatment with piperonyl butoxide. The binding at high doses arose from saturation of the capacity of the hepatocytes to protect themselves from the reactive metabolite produced. The protective mechanism was conjugation with glutathione, and saturation of this system at toxic doses was caused by depletion of the available glutathione.

Another example of saturation in toxicology is seen in the studies of Gehring and co-workers on the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) (33, 90). This compound showed a higher toxicity in dogs than in rats because the former species exhibits a longer half-life, reduced renal and increased biliary elimination, and the presence of metabolites. In the rat, embryotoxicity was seen with doses of 100 mg kg^{-1}, and nonlinear kinetics were seen at similar doses due to saturation of elimination by renal tubular secretion. Metabolites of 2,4,5-T were detected in the urine of rats given saturating doses (i.e., 100 or 200 mg kg^{-1}). Saturation of the metabolism of 1,4-dioxane has also been shown at doses associated with toxicity (33). Saturation of biliary excretion of FPL 57787 in the dog has been demonstrated at toxic doses of this antiallergy compound (97).

A good example is also provided by studies on the metabolism and toxicokinetics of cyclohexylamine (82, 83). This compound produces testicular toxicity when given chronically to rats, but not to mice (10). Toxicokinetic studies indicated that the plasma clearance was higher in mice than in rats, and that rats, but not mice, showed evidence of nonlinear kinetics at high doses (84). The steady-state concentrations in the plasma and testes during chronic administration confirmed dose-dependent kinetics in the rat (Figure 4.24), which coincided with the dose-response curve for testicular

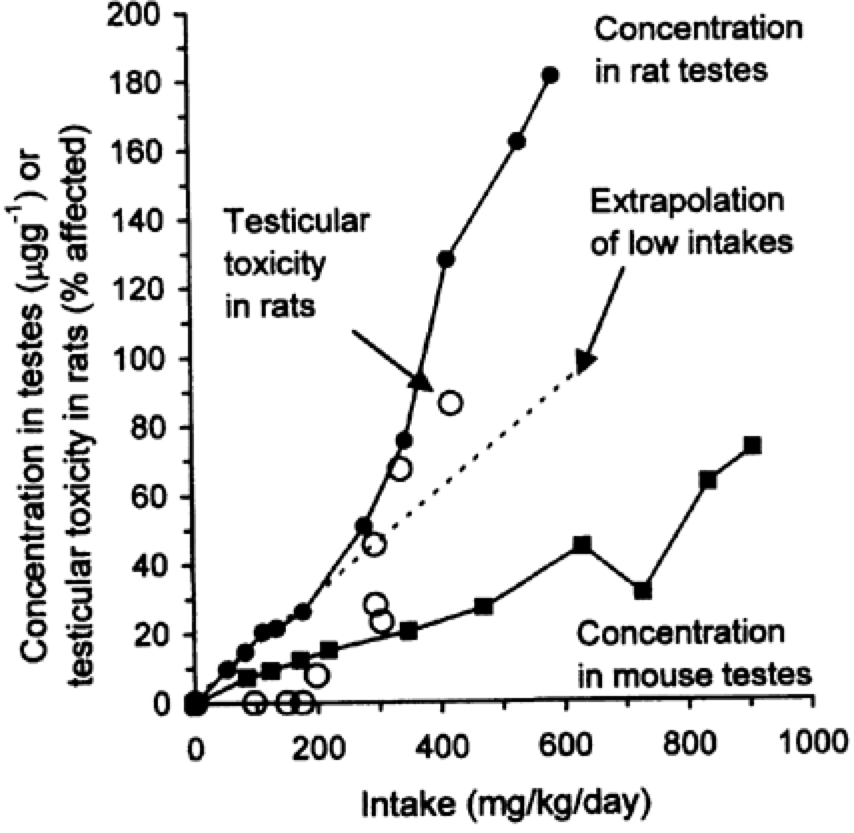

FIG. 4.24. Relation between dose, toxicity, and target organ concentrations of cyclohexylamine during chronic administration; (●) concentration in rat testes; (■) concentration in mouse testes; (○) testicular toxicity in rats. Data from Reference 84.

atrophy in this species (84). These toxicokinetic data thus provide a possible explanation for the steepness of the dose-response curve in the rat and the apparent species difference in sensitivity. Cyclohexylamine is an indirectly acting sympathomimetic amine in rats (12), but it does not increase blood pressure in humans following its formation from cyclamate metabolism (13). The apparent difference in response arises from the different concentration-time profiles when the metabolite is administered orally or when it is formed by the intestinal microflora from cyclamate (13), illustrating further the importance of kinetics in the interpretation of dose-effect relationships.

Finally, toxicokinetic data can be invaluable for the interpretation of animal toxicity with respect to possible human risk. This analysis may be made in the absence or the presence of human pharmacokinetic data. In the absence of human data, extrapolation may be by either physiological or compartmental modeling methods (3). The physiological approach relies on the scale-up between animals and man of such parameters as tissue volume and blood flow (Figure 4.4) and by their relation to body weight. Assuming that the uptake from blood to tissue (extraction ratio) is a function of the

chemical and therefore independent of species, it is possible to derive complex models involving all the major tissues of the body (34). These models may then be scaled up from known animal data to humans based on the known physiological differences. Alternatively and more pragmatically, the plasma kinetics in various species may be fitted by compartmental modeling and then scaled up empirically according to the body mass of the species studied and extrapolated to humans (39, 64).

The most secure comparison is when kinetic data are available in animals and humans, allowing direct analysis of the potential risk. In any such analysis the species difference in basic physiological processes such as cardiac output and relative tissue weight usually result in lower clearances and longer half-lives in humans than in animals (75). Thus comparisons of animals and humans on the basis of plasma levels or AUC values, rather than intake or exposure data expressed per kilogram body weight, result in a decreased apparent safety margin compared with intake data. However, by removing important variables from interspecies comparisons, such an approach provides a more secure basis for the safety assessment (76, 92).

Toxicokinetic data can also be useful in defining the contributions of parent compound and metabolites to toxicity. Retinol (vitamin A) is an animal and human teratogen, which is metabolized to a number of biologically active species such as all-*trans*-retinoic acid, 13-*cis*-retinoic acid, and 9-*cis*-retinoic acid. The principle sources of exposure to retinol (rather than the precursor carotenoids) are from the consumption of animal livers

Table 4.18 The AUC values for retinol and its metabolites in young women after oral doses of 50 mg and 150 mg of retinol given as retinyl palmitate in a supplement or in cooked calf liver

	AUC values in ng ml−1h					
Dose	Retinyl palmitate	Retinol	All-*trans*-retinoic acid	13-*cis*-retinoic acid	All-*trans*-4-oxo-retinoic acid	13-*cis*-4-oxo-retinoic acid
50 mg S	10,400 (5,300)	2070 (1900)	86 (63)	359 (104)	30 (33)	877 (207)
50 mg L	5900 (3,700)	1530 (2490)	6 (5)	243 (70)	11 (15)	492 (145)
150 mg S	18,900 (20,200)	2300 (1180)	170(118)	674 (156)	133 (47)	2385 (563)
150 mg L	14,500 (8,800)	2430 (2090)	23 (11)	596 (131)	120 (84)	1820 (294)

S=Supplement given under fasting conditions.
L=Cooked liver as part of a meal.
The results are the mean (with *SD* in parentheses) for 10 subjects dosed at 4-week intervals (data from ref. 14).

and from vitamin supplements. The evidence for teratogenicity in humans is from case reports of excessive consumption of vitamin supplements; there is little evidence of a risk from liver consumption, despite the fact that this source may give similar or even higher intakes than those causing malformations after excessive supplement consumption. The areas under the plasma concentration-time curve of retinol and its metabolites in young women following oral doses of retinyl palmitate as an oral solution (fasting) and as cooked liver (as part of a meal) (14) are given in Table 4.18. The main difference was the 5–10-fold difference in the AUC of all-*trans*-retinoic acid, which is recognized to be the major teratogenic metabolite. However, 13-*cis*-retinoic acid (isotretoin), also a recognized human teratogen, showed no major difference. Therefore, the key issue for the assessment of human risk was the plasma concentrationresponse relationship for the main metabolites, and whether the teratogenicity of retinol and 13-*cis*-retinoic acid could be explained by their metabolism to all-*trans*-retinoic acid. A subsequent study (107) gave single oral doses of retinol, all-*trans*-retinoic acid and 13-*cis*-retinoic acid to pregnant rats and determined the dose-response relationship (Figure 4.25) and plasma kinetics of the different metabolites for each compound. Both retinol and 13-*cis*-retinoic acid gave measurable levels of all-*trans*-retinoic acid in the plasma. A graph of teratogenic response against the AUC of all-*trans*-retinoic acid for the three compounds (Figure 4.26) shows that whereas the teratogenicity of 13-cis-retinoic acid could be explained on the basis of the circulating all-*trans*-retinoic acid, this was not the case for retinol. Retinol was considerably more potent than would be predicted from the plasma AUC of all-*trans*-retinoic acid after retinol administration, possibly due to local bioactivation within the fetus. Consequently, the

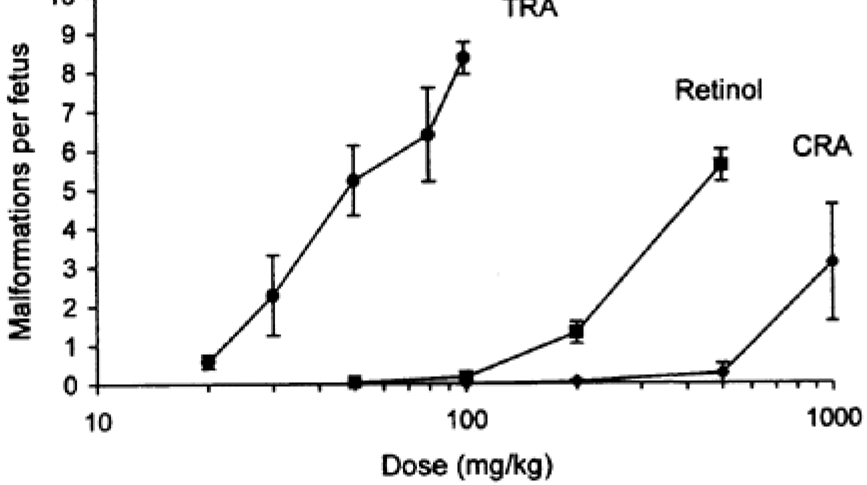

FIG. 4.25. Dose-response relationships for teratogenicity of all-*trans*-retinoic acid (TRA), retinol, and 13-*cis*-retinoic acid (CRA) given as a single oral dose to rats on day 10 of gestation. Data from Reference 107.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_185.html[2010/10/28 18:41:38]

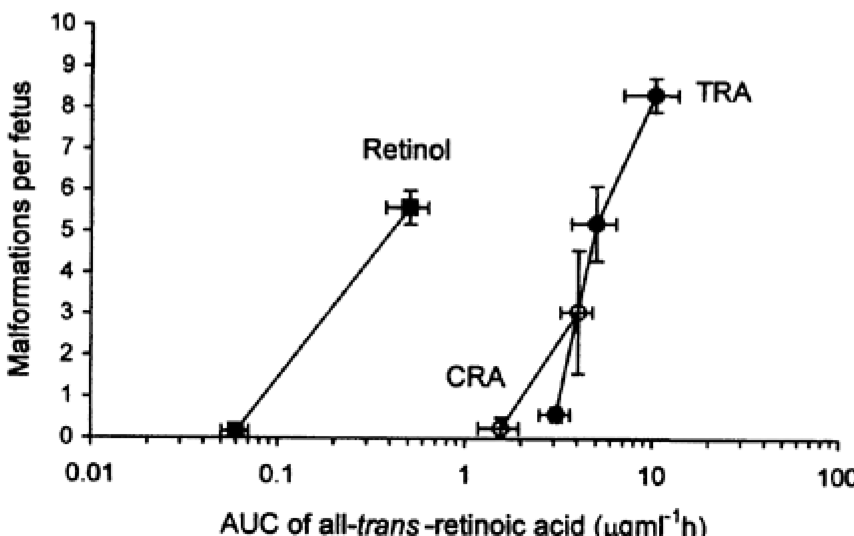

FIG. 4.26. Relationship between AUC of all-*trans*-retinoic acid in maternal plasma and teratogenicity in female rats given all-*trans*-retinoic acid (TRA), retinol, and 13-*cis*-retinoic acid (CRA) on day 10 of gestation. Data from Reference 107.

5–10-fold difference in the AUC of all-*trans*-retinoic acid between liver and supplements (Table 4.18) would not be expected to be translated into a similar difference in teratogenic risk. Using the comparative potency ratios in rats (Figure 4.25) of about 25:3:1 for all-*trans*-retinoic acid, 13-*cis*-retinoic acid, and retinol, and the AUC data in Table 4.18, the doses of 50 and 150 mg as supplements would be expected to be about 2.2 and 1.8 times, respectively, more active than the equivalent doses given in cooked liver. However, this analysis was heavily biased by the AUC and response data for retinol; also, there could be major species differences in local activation of retinol in the fetus and/or vehicle-dependent differences (liver compared with supplements) in the proportions bound to retinol-binding protein (which could alter this conclusion).

The Use and Interpretation of In Vitro Data

In vitro data can provide important qualitative insights into the metabolic fate of the compound, but care must be taken in their quantitative incorporation into risk assessment. There is a wide variety of in vitro systems of increasing cell integrity, that can be used, for example subcellular fractions (such as microsomes), cell homogenates, isolated cells and cell lines, and tissue slices. Each preparation has strengths and weaknesses and these can be exploited to provide useful information (24, 51).

Strengths of In Vitro Systems

Microsomes comprise the smooth endoplasmic reticulum and its associated enzymes, cytochrome P450s and UDP-glucuronyl transferases. The rates of reaction in vitro are determined by the availability of appropriate cofactors, and therefore it is possible to study oxidation by the addition of NADPH in the absence of glucuronidation, which requires UDPGA (and vice versa). This allows the rates of P450-mediated oxidation to be studied directly, because the product of the primary oxidation produced is not lost due to conjugation. An additional major value for such simple systems is that they can be used to generate metabolites for structural analysis.

More complex systems, such as isolated cells and tissue slices, provide a comprehensive picture of the metabolic fate of the compound. All enzyme systems are present, including cytoplasmic and mitochondrial enzymes, and the cell architecture can affect cell uptake and intracellular distribution of the chemical. Perhaps the most integrated in vitro system is the isolated perfused rat liver, which can give excellent correlations with in vivo clearance (23). As a result, these systems can provide infor mation on the relative importance of alternative metabolic pathways.

A major advantage of in vitro systems is that they allow data to be generated on the potential metabolism in humans, without the need for in vivo exposure. This has been particularly valuable for carcinogens, where the generation of in vivo data would be unethical. Identification of the specific isoenzymes of cytochrome P450 involved in metabolism of a compound is important in understanding the potential variability in metabolism within the human population, because of the genetic polymorphism in some of the isoforms, for example CYP2D6. Such information can be generated by in vitro studies in three ways:

1. Comparisons of the rates of metabolism in stored (banked) liver preparations from individuals with characteristic isoenzyme profiles
2. The use of isoenzyme specific inhibitors or inducers (in cell-intact preparations)
3. The use of expression systems in which the DNA for specific isoenzymes is incorporated and expressed by a suitable host, such as a yeast or bacteria (38)

The generation of in vitro data using human tissues allows characterization of species differences both qualitatively and quantitatively by the generation of the appropriate enzyme constants *V*max and *Km*. Such data represent critical components of PBPK models (70) and for the prediction of in vivo clearance (44, 46, 120, 121).

The outline given above should be sufficient to indicate the huge potential for in vitro studies and explain why these methods have been the basis for much of our understanding of pathways of xenobiotic metabolism.

Precautions with In Vitro Systems

A number of limitations need to be remembered when considering in vitro data.

1. Many studies give data on the extent of metabolism at a single high concentration in vitro and therefore represent *V*max, which may be of limited relevance to in vivo concentrations. A full analysis of the enzyme kinetics is necessary to give both *V*max and *Km*.
2. The strengths of simple systems, for example microsomes outlined above, will be weaknesses if the data are overinterpreted in relation to the fate in vivo.
3. Changes in enzyme expression occur in vitro, for example isolated cell lines show a different complement of cytochrome P450 activities to those in the same cells at isolation.

4. Many human data are generated from stored liver samples obtained at postmortem. The in vitro enzyme activity could be affected by both in vivo aspects, such as drugs given in attempts at resuscitation, disease, etc., and ex vivo aspects, such as the period between death and freezing and storage (67).

5. In vitro data may still be misleading, even if all of these aspects are optimum. This occurs when the clearance of drug by an organ is blood flow limited rather than enzyme limited (see earlier). Under these conditions, both interspecies differences and interindividual variability will reflect organ blood flow, rather than *V*max and *Km*. A good example of this is furan (49) for which the rate of oxidation in vitro would greatly exceed delivery via the liver blood flow.

These problems can be avoided if the in vitro data are incorporated into a PBPK model that will allow for organ blood flow, partitioning between blood and tissue, and enzyme kinetics.

The increasing use of in vitro test systems facilitates a quantitative analysis of the dose-toxicity curve and may provide information on mechanisms of action (24, 27). The logical interpretation of such data with respect to human risk requires information on the steady-state concentrations of the active chemical species in the target organ and plasma of the test animal during chronic toxicity testing, combined with knowledge of the toxicokinetics of the chemical in the test animal at toxic doses and in human at the likely exposure level. It must be emphasized that large safety factors have been introduced to protect us from our own ignorance. The increased use of pharmacokinetic data, especially when combined with knowledge of the mechanism of toxicity, will allow the future use of potentially toxic chemicals to be based on scientific principles and understanding (76, 92).

STUDY QUESTIONS

1. A new chemical has been administered to rats and humans by both oral and intravenous routes. Basic toxicokinetic measurements (extrapolated to infinity) are given below.

	Rat	Human
Intravenous		
Dose (mg kg−1)	10	1
AUC (*μ*g ml−1 min)	2000	500
Terminal slope (min−1)	0.0025	0.001
% dose excreted unchanged in urine	1	15
Oral		
Dose (mg kg−1)	100	1
AUC (*μ*g ml−1 min)	8000	490
Terminal slope (min−1)	0.0025	0.001

Calculate appropriate toxicokinetic parameters and suggest biochemical and physiological mechanisms that could explain the species difference.

2. The pharmaceutical company for which you work has synthesized a new antianxiety drug, a basic compound, structurally related to the old drug debrisoquine. The parent drug, the active form, causes enzyme (cytochrome P450) induction and liver enlargement; the hydroxylated metabolite, formed on incubation of the drug with liver microsomes, is inactive. After an oral dose, 40% is excreted in the urine within 24 h as the parent compound, 40% is in urine as an hydroxylated metabolite, and 20% is in feces as the parent drug. After an intravenous dose, 80% is in urine as the parent drug, and 20% is in the urine as the metabolite. What advice would you give the company about the following issues:

a. Is the drug likely to be toxic after oral dosage?

b. Would the oral and intravenous doses associated with toxicity be the same?

c. What are the likely sources of variability in kinetics in young physically healthy adults (20–30 years old)?

d. Would the kinetics be different in the elderly (70–80 years old)?

e. How much would a 50% decrease in liver or kidney function affect the kinetics, and would the toxicity be increased or decreased?

f. How much would a 50% increase in liver or kidney function affect the kinetics, and would the toxicity be increased or decreased?

g. Should the pharmaceutical group develop a slow-release formulation and would this be likely to affect the toxicity?

3. The company you work for has developed a novel opioid for the treatment of intractable pain. The drug is 20 times more potent than morphine in relation to both analgesia and respiratory depression when given to rats by intravenous injection, and binding studies show that it has a high and similar affinity for *μ*-receptors of rats and humans. Initial kinetic studies in humans after a single intravenous

bolus dose of 10 mg gave the following data.

Time after dose (h)	*Plasma concentration (ng/ml)*
0.5	367
1.0	336
2	283
4	200
6	141
10	71
24	6.3

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_187.html[2010/10/28 18:41:39]

The area under the plasma concentration-time curve (AUC) extrapolated to infinity was 2310 ng ml^{-1} h. Urine was collected over the period 2–4 h after dosing and contained a total of 1.85 mg of the parent drug and 0.1 mg of an hydroxy metabolite. The plasma concentration of parent drug at 3 h was 238 ng/ml.
After a single oral dose of 10 mg the maximum plasma concentration occurred at 8 h and was only 48 ng/ml; the blood concentration reached 6 ng/ml by 36 hours. The AUC to infinity was 1155 ng ml^{-1} h.
Plot the intravenous data on graph paper. Calculate appropriate pharmacokinetic parameters to describe the elimination rate, clearance, distribution, and absorption of the drug. Describe the probable overall fate of the drug in the body (e.g., routes of elimination).
Your research director needs the following advice:
i. What extra studies/data could support your description of the fate of the drug?
ii. What route(s) of administration should the company use for its first trials of clinical effect for pain relief?
iii. How should the drug be administered to provide relief of chronic pain?

Hints and Clues

Question 1

a. Calculate clearance (per kg body weight)—why is it different? (See b).
b. Use urinary excretion data to think about pathways of elimination.
c. Use clearance and "terminal slope" (k or *β*—we don't know) to calculate the apparent volume of distribution.
d. Use AUC data to calculate bioavailability.
e. Are terminal rates different after oral dosage? What would it mean if they were?
f. What are the likely causes of differences between species? Could clearance and bioavailability be interrelated? If so, how?
g. Would scaling to body surface area affect the calculations and conclusions? If so, how?

Question 2

a. Use urinary excretion data to interpret the potential for exposure (or not) of the liver to the parent compound. (Obviously the dose will affect the response, but is toxicity possible?)
b. Use urinary excretion data to calculate bioavailability. What processes are giving rise to the low bioavailability?
c. Variability in adults: What are the routes of elimination? What is the relevance of debrisoquine?
d. Consider 50% changes in liver in relation to bioavailability and clearance. Then, consider changes in renal function similarly. Will kidney function affect bioavailability?
e. A slow-release formulation is necessary when a drug has a very short half-life (e.g., 3–4 h or less). There is information on the rate of elimination in the question. What can you conclude about half-life? (*Clue:* Could it be 24 h?)

Question 3

a. You can calculate clearance, apparent volume of distribution, and half-life from the intravenous data. But what route is important for elimination? (*Clue*: Use urine data to calculate renal clearance and compare with plasma clearance.)
b. The extra studies should relate to kinetics. (*Clue*: What studies would we normally have before giving the first dose to humans?)
c. What is happening with the oral data? What is the extent of absorption? Why are blood levels at 36 h higher after oral dosage? (*Clue*: You can calculate the concentration at 36 h after IV dosage using the exponential terms derived from the IV data.)
d. Phase 1 studies (initial human studies) are usually by the oral route. Is this likely to produce analgesia or side effects with this compound?
e. Chronic pain relief requires the maintenance of constant concentrations of the analgesic. Which route would be likely to give this profile? If oral dosage could not give effective plasma levels without unacceptable side effects (such as constipation), how could you give the drug parenterally to provide similar constant concentrations?

Pharmacokinetic modeling deals with the development of mathematical descriptions of the time-course of chemical concentration in biota. The temporal change in the concentration of a chemical in blood and tissues of an exposed organism is the net result of its absorption, distribution, metabolism, and excretion. Two commonly used compartmental pharmacokinetic models are:

(a) data-based, and
(b) physiologically based.

The data-based pharmacokinetic models correspond to mathematical equations that describe the available data on the temporal change in the blood or tissue concentration of a chemical in the animal species of interest (see the chapter by Renwick). This procedure considers the organism as a single homogeneous compartment or as a multi-compartmental system with elimination occurring in specific compartments of the model (106, 276). The number, behavior, and volume of these hypothetical compartments are estimated by the type of equation chosen to describe the data, and not necessarily by the physiological characteristics of the organism in which the blood/tissue concentration data were acquired.

These data-based pharmacokinetic models can be used for interpolation, but they should not be used for extrapolation outside the range of doses, exposure routes, and species used to generate data for constructing these models. To use the data-based models to describe the pharmacokinetic behavior of a chemical administered at various doses by different routes, extensive animal experimentation would be required to generate similar blood-time course data under respective conditions. Even within the same species of animal, the time-dependent nature of critical biological determinants of disposition (e.g., tissue glutathione depletion and resynthesis) cannot easily be included or evaluated with the data-based pharmacokinetic modeling approach. Further, due to the lack of actual anatomical, physiological, and biochemical realism, these data-based compartmental models cannot easily be used in interspecies

extrapolation, particularly to predict pharmacokinetic behavior of chemicals in humans. These various extrapolations, which are essential for the conduct of dose-response assessment of chemicals, can be performed more confidently with a physiologically based pharmacokinetic modeling approach. This chapter presents the basic

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_193.html[2010/10/28 18:41:43]

principles and methods of physiologically based pharmacokinetic (PBPK) modeling as applied to the study of toxicologically important chemicals.

PBPK modeling refers to the development of mathematical descriptions of the uptake and disposition of chemicals based on quantitative interrelations among the critical biological determinants of these processes. These determinants include partition coefficients, rates of biochemical reactions, and physiological characteristics of the animal species. The biological and mechanistic bases of the PBPK models enable them to be used, with limited animal experimentation, for extrapolation of the kinetic behavior of chemicals from high dose to low dose, from one exposure route to another, and from test animal species to people.

The development of PBPK models for volatile and gaseous anesthetics dates back to the research work of Haggard (112) who mathematically described the uptake of inhaled diethyl ether from a physiological perspective. Further developments in PBPK modeling with vapors were contributed by Kety (136) and Riggs (233), who provided mathematical descriptions of the kinetics of chemicals in the body based on parameters such as blood flow rates, tissue volumes, and chemical partitioning into tissues, and by Mapleson (178), who developed PBPK models for inert gases utilizing an electric analog. This electric analog approach was expanded by Fiserova-Bergerova (80) for describing the pharmacokinetic behavior of metabolized vapors and gases relying on numerical integration of mass balance equations. In the pharmaceutics area, PBPK modeling traces back to Teorell's pioneering work in the 1930s (258, 259). Beginning in the early 1960s, scientists trained in chemical engineering also developed PBPK models of various drugs, particularly antineoplastic agents such as methotrexate, 5-fluorouracil, and cisplatin (18, 42, 77). Subsequently, the PBPK modeling approach has found extensive application in toxicology, particularly for conducting various extrapolations essential for the dose-response assessment of chemicals.

The development of PBPK models is initiated in four interconnected steps: model representation, model parameterization, model simulation, and model validation (Figure 5.1). *Model representation* involves the development of conceptual and mathematical descriptions of the relevant compartments of the animal as well as the exposure and metabolic pathways of the chemical. *Model parameterization* involves obtaining independent measures of the mechanistic determinants, such as physiological, physicochemical, and biochemical parameters, which are included in one or more of the PBPK model equations. *Model simulation* involves the prediction of the uptake and disposition of a chemical for defined exposure scenarios, using a numerical integration algorithm, a software program, and a computer. The

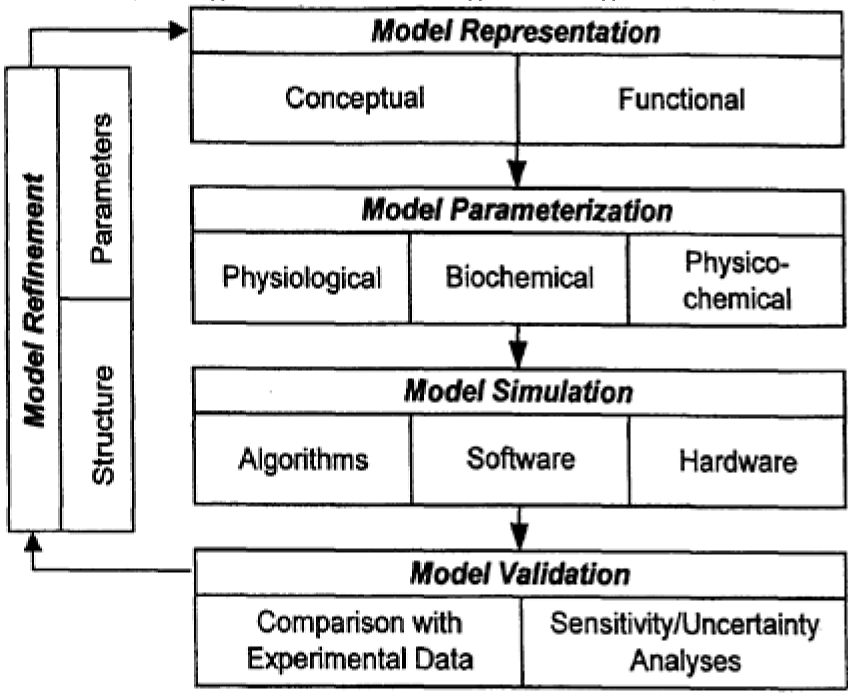

FIG. 5.1. Schematic of the steps involved in the development of physiologically based pharmacokinetic models.

model validation step involves the comparison of the a priori predictions of the PBPK model with experimental data to refute, validate, or refine the model description. PBPK models after appropriate

testing or refinement and validation can be used to conduct extrapolations of the pharmacokinetic behavior of chemicals from one exposure route/scenario to another, from high dose to low dose, and from one species to another.

The PBPK model development for a chemical is preceded by the definition of the problem, which, in toxicology, may often be related to the apparently complex nature of toxicity. Examples of such apparently complex toxic responses include non-linearity in dose-response, sex/species differences in tissue response, differential response of tissues to chemical exposure, qualitatively and/or quantitatively different responses for the same cumulative dose administered by different routes/scenarios, and so on. In these instances, PBPK modeling studies can be utilized to evaluate the pharmacokinetic basis of the apparent complex nature of toxicity induced by the chemical. One of the values of PBPK modeling, in fact, is that accurate description of target tissue dose often resolves behavior that appears complex at the administered dose level.

The problem identification step is followed by the specification of the goal(s) of the PBPK modeling effort. At this stage, the integrated model development process begins with the model representation step.

MODEL REPRESENTATION

Model representation refers to the development of conceptual (i.e., diagrammatic) and mathematical des

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_194.html[2010/10/28 18:41:44]

Page 195

criptions of the relationships among system elements as they relate to system response of interest (e.g., tissue dose).

Conceptual Representation

This step involves the diagrammatic representation of the relevant anatomical and physiological features of the organism, and the uptake and disposition pathways of the chemical. The organism is represented as a network of compartments, each of which is physically, physiologically, and biochemically characterized. The pathways of uptake and disposition of chemicals are indicated by adding arrows to the appropriate compartments in the conceptual representation of the PBPK model. The conceptual representation of the PBPK model for a chemical requires an understanding of the anatomical and physiological characteristics of the test animal species, and the pathways of uptake and disposition of the chemical under study such that both the animal and the chemical can be represented adequately.

Representing the Animal

The diagrammatic representation of the organism (e.g., rat) should correspond to the real system; in other words, it should clearly show how the relevant individual compartments are placed and interconnected in the test organism (Figure 5.2).

In representing the animal system, the organism as a whole in terms of its body weight (e.g., 250 g for a rat) should be accounted for, so the mass balance of chemicals can be accurately maintained. More precisely, maintaining the mass balance in PBPK models requires that the total blood flow (i.e., cardiac output) in the model be equal to the sum of the flows to the tissue compartments of the model. In other words, the tissues that receive the chemical via blood flow need only be represented in the model. Further, it is not necessary to represent these tissues as individual compartments, and they may be lumped together as long as the total flow in the model is accounted for. The simplest conceptual model may consider the organism as a one-compartment system, whereas there is virtually no limit to the number of compartments in larger systems with more detailed representation of events at the cellular/molecular levels.

In addition, the necessity for representing a particular tissue as a separate compartment in a PBPK model is determined by whether its

(a) chemical,
(b) biochemical,
(c) physiological, and/or
(d) anatomical characteristics contribute significantly to the uptake and disposition of the chemical being modeled.

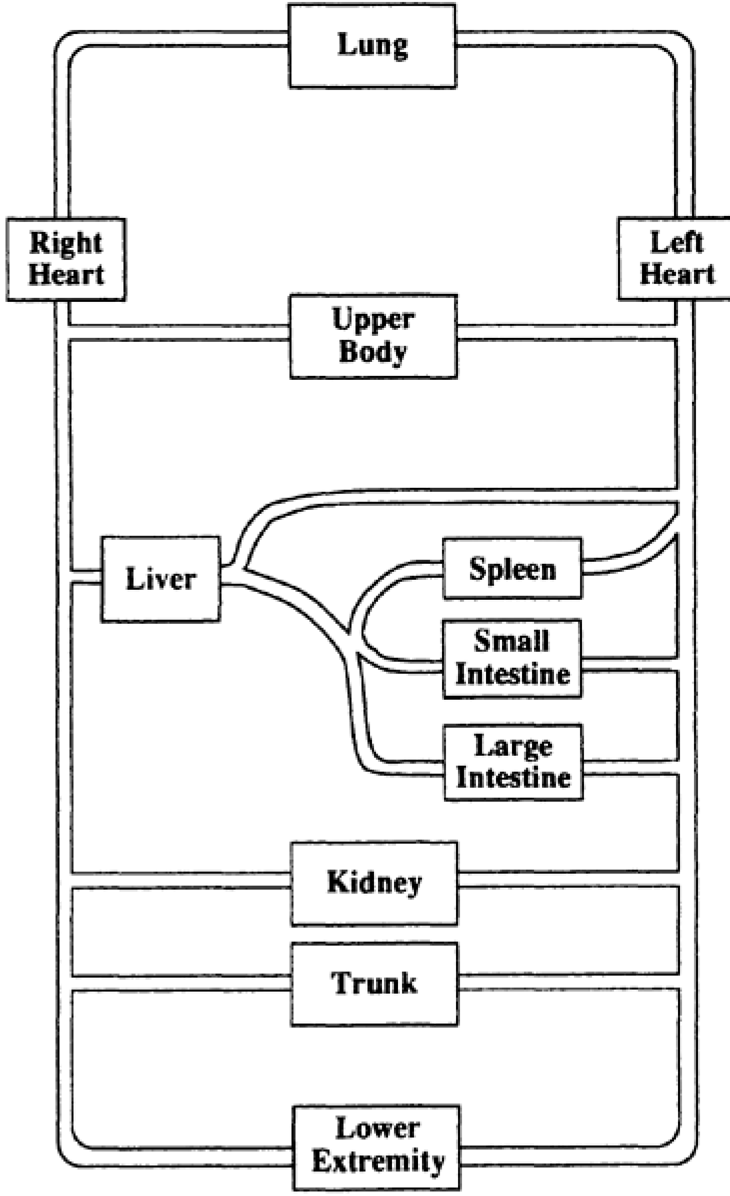

FIG. 5.2 Flow diagram for mammals. Adapted with permission from Reference 17.

The chemical composition of tissues in the present context refers primarily to the water and non-polar lipid contents. These tissue constituents are non-reactive but account for the differential solubility of a chemical among various tissues. In this respect, the adipose tissue is represented as a separate compartment in many PBPK models (Figure 5.3; fat) because of its ability to sequester lipophilic chemicals during exposure and release them after the cessation of exposure. In the case of a hydrophilic chemical, adipose tissue may be combined with the rest of the body since it may not show any particular kinetic behavior that is unique and different from the rest of the body. If other chemical components of the tissue (e.g., chloride levels or pH) are critical determinants of disposition, then individual or groups of tissue compartments defined with this kind of information should be included in the model as necessary.

The biochemical characteristics, in the present context, refer primarily to the binding and metabolizing capacities of the tissues. These properties account primarily for the removal of chemicals from the circulating blood by mechanisms other than chemical partitioning. For

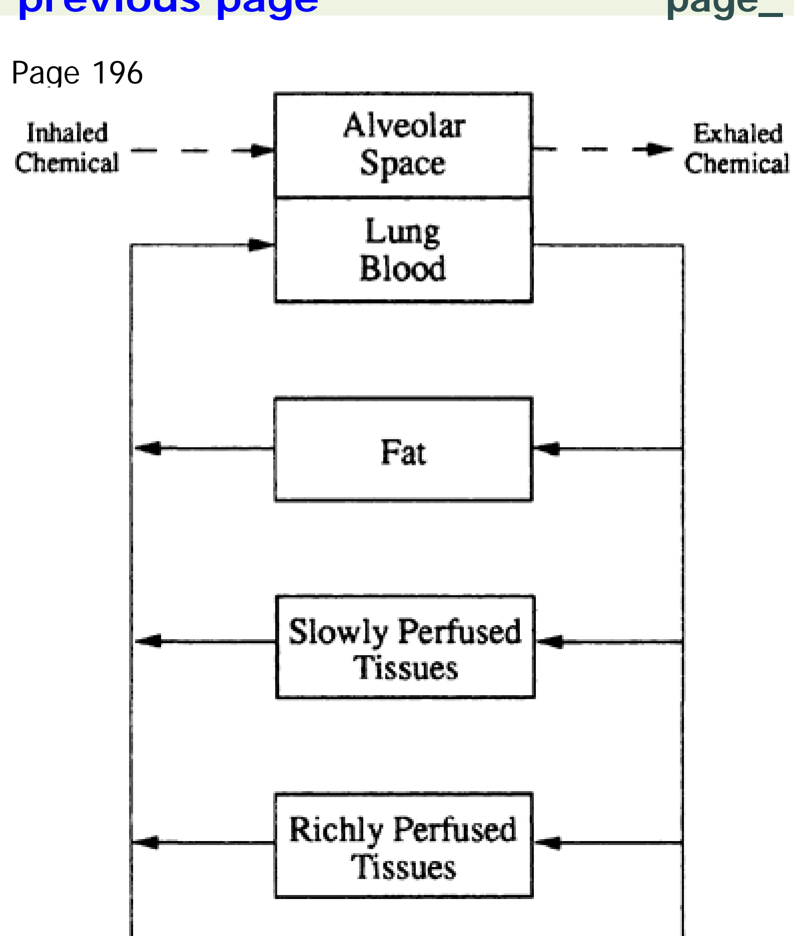

FIG. 5.3. Conceptual representation of a physiologically based pharmacokinetic model for styrene. Adapted with permission from Reference 223.

example, liver is often represented as a compartment in the PBPK models because of its central role in the metabolism of many organic chemicals. Representation of other tissues as separate compartments may be required according to the extent of expression of specific enzyme activities of relevance to the metabolism of the chemical being modeled (e.g., P450 and glutathione S-transferase in lung or kidney, epoxide hydrolase in testis, or myeloperoxidase in bone marrow).

The physiological characteristics refer to breathing rate, cardiac output, glomerular filtration rate, tissue blood flow rates, and so on. These characteristics essentially determine the biodisposition of chemicals. The tissue compartments possessing these properties (i.e., lung, heart, and kidney) or a quantitative description of these physiological processes should be included in the PBPK model. Respiration, urinary excretion, and blood circulation often are represented as quantitative descriptions of the processes themselves. Depending on the proposed use of the model, the tissues involved may be represented individually and characterized for particular aspects. For example, lung is represented as both an uptake and a metabolizing tissue in PBPK models for cer

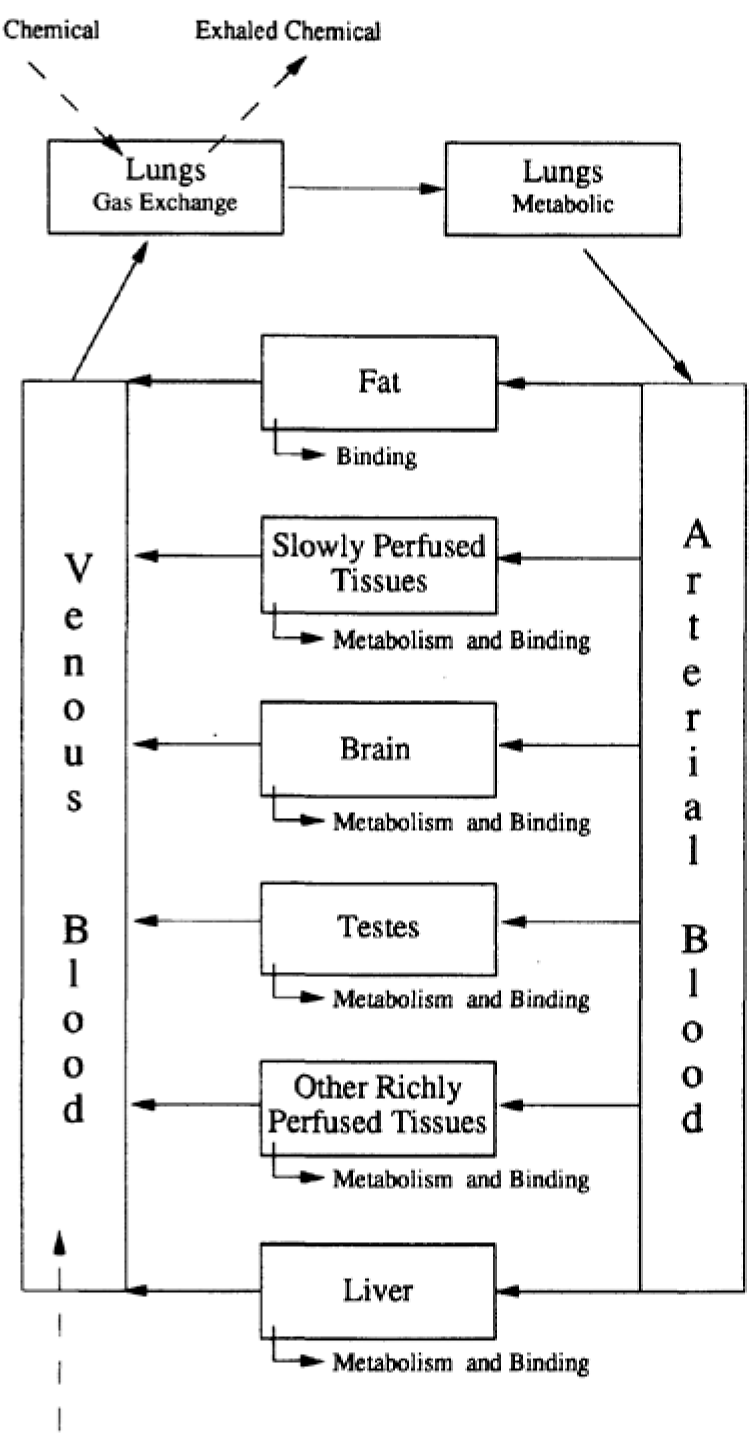

FIG. 5.4. Conceptual representation of a physiologically based pharmacokinetic model for ethylene oxide. Adapted with permission from Reference 151.

tain volatile organics (Figure 5.4), whereas it is not characterized separately in the case of nonvolatile organics which are neither eliminated by exhalation nor metabolized significantly by this tissue (Figure 5.5).

The anatomical location of certain tissues makes them particularly important for the uptake and elimination of chemicals. Lung, skin, and gastrointestinal tract serve as portals of entry for chemicals. According to their relevance and relative importance to the pharmacokinetics of a chemical, they should be included in PBPK descriptions. Target organs are included as separate compartments.

In principle, if the characteristic time constants of tissue disposition (i.e., the product of partition coefficient

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_196.html[2010/10/28 18:41:45]

and volume divided by blood flow rate) are similar for various tissues, they can be lumped together to form a single tissue group. In other words, when the critical determinants of pharmacokinetics do not vary quantitatively among several tissues, the time course of the chemical concentration in these tissues will be similar. That is why fat depots such as perirenal, epididymal, and omental fat are frequently grouped and represented as a single "fat" compartment (Figures 5.3–5.5). If necessary, a fat compartment may be subdivided into two or more groups according to the perfusion rates (e.g., inner and subcutaneous adipose tissues). Another example of this kind involves tissues such as adrenal, kidney, thyroid, brain, lung, heart, testis, and hepatoportal system, which often are pooled into one compartment and referred to as "richly perfused tissues" (Figures 5.3 and 5.5). When the contents of

relevant metabolizing enzymes quantitatively differ among the richly perfused tissues, the individual organs are represented as separate compartments even though the blood flow rate and solubility characteristics are somewhat similar (Figure 5.4). Tissues with poor blood perfusion characteristics (muscle, skin) are frequently grouped as "slowly perfused tissues." Other groupings of tissues based on perfusion characteristics can also be defined, but this has not been done routinely.

Since the skeletal and structural components of the body have only a negligible perfusion and do not play a significant role in the disposition of many organic chemicals, they have not been included in the PBPK model descriptions for these chemicals. When describing certain metals and metalloids stored in bone, inclusion of this compartment is essential.

In PBPK models for organic and inorganic chemicals that are not stored to a significant extent in the skeletal/structural components of the body, approximately 91% of the body weight is represented by the tissue compartments included in the models (100% body weight minus 9% skeletal/structural component weight). In other words, 91% of the body weight is fractionated into the four, five, or nine compartments included in the models presented in Figures 5.3–5.5. In some models, blood is not described as a separate compartment (Figure 5.3 vs. Figure 5.4) even though blood concentrations are calculated. When blood is not described as a separate compartment, its total volume is apportioned among the tissues implicitly or explicitly.

Although PBPK models are mechanistically based and more detailed than the classical data-based pharmacokinetic models, they still represent a significant simplification of the true complexities of the biological systems. Model complexity and the number of compartments should not be equated with accuracy and usefulness of the model description; oftentimes model complexity yields a multitude of parameters to be estimated and greater uncertainty of the model description. Parsimony in PBPK modeling, on the other hand, refers to the choice of a model structure that has minimal but necessary elements that together adequately describe the pharmacokinetics of a chemical.

Representing the Chemical

The pathways of uptake, distribution, metabolism, and excretion of the chemical should also be conceptually represented in the PBPK model. The pathways of uptake are indicated by adding arrows to appropriate model compartments for representing the port of entry for each exposure route of interest (Figures 5.3–5.5). The interconnections among the individual tissue com

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_197.html[2010/10/28 18:41:45]

partments of the conceptual model serve to represent the working hypothesis of the researcher regarding the distribution of the chemical in the organism. With respect to binding and metabolism, the specific pathways in each of the relevant tissue compartments should be identified/hypothesized so changes in parent chemical concentration and the formation and/or tissue distribution of the metabolite(s) can be followed. Even though there is not much uncertainty regarding the mechanistic basis of the absorption and distribution of chemicals, there are larger uncertainties regarding the importance, basis, and magnitude of specific aspects of binding to tissue macromolecules, metabolic pathways, and extra-hepatic metabolism. In such cases, the extent of metabolism or binding by a particular pathway may be included in the model structure and verified by specific model-directed experiments.

Once the tissue compartments of the animal and the pathways of uptake and disposition of a chemical are identified/hypothesized and conceptually represented, mathematical descriptions of pharmacokinetic processes are developed.

Mathematical Representation

This phase of the PBPK modeling process involves the development of mathematical representations of
(a) the quantitative interrelationships among the mechanistic determinants of the functions of each tissue compartment, and
(b) the interrelationships among the individual tissues.

The functional representation of a PBPK model requires a rudimentary knowledge of calculus. A brief review of basic mathematics and differential calculus required for pharmacokinetic modeling has been provided by O'Flaherty (192).

Prior to the development of mathematical descriptions of the various functions of the tissue compartments, it is essential to characterize them physicochemically, physiologically, and biochemically. The symbols and abbreviations that refer to these characteristics, in the mathematical representations of the PBPK models described in this chapter, are provided in Table 5.1.

In PBPK modeling, each tissue compartment is described with a mass balance differential equation (MBDE) that consists of a series of clearance terms as follows:

$$\frac{dA_t}{dt} = Cl_u C_a - Cl_e C_{vt} - Cl_m C_a - Cl_f C_a \qquad (1)$$

Dimensionally, the units for each of the clearance terms is flow per time, that is L/h or ml/min.

Table 5.1 Symbols and abbreviations used in the mathematical representations of PBPK models described in this chapter

Symbol or abbreviation	Description	
A	Amount (mg)	
	Subscripts representing the chemical	
	o	orally absorbed
	bm	bound to macromolecules
	bo	rest of the body
	i	liver
	met	metabolized
	sk	skin
	stom	remaining in the stomach
C	Concentration (mg/liter or mmol/liter)	
	Subscripts representing the chemical	
	a	arterial blood
	air	air contacting skin
	alv	end-alveolar air
	b	blood
	bo	rest of the body
	cm	cellular matrix
	f	fat
	inh	inhaled air
	1	liver
	r	richly perfused tissues
	s	slowly perfused tissues
	sk	skin

	t	tissue "t"
	tb	tissue blood
	v	mixed venous blood
	vbo	venous blood leaving the rest of the body
	vf	venous blood leaving fat
	vl	venous blood leaving liver
	vr	venous blood leaving richly perfused tissues
	vs	venous blood leaving slowly perfused tissues
	vsk	venous blood leaving skin
	vt	venous blood leaving tissue "t"
	Subscripts representing tissue components	
	cf	cofactor in tissue "t"
	hb	hemoglobin in blood
	prot	microsomal protein
Cl	Clearance (liters hr−1)	
	Subscripts	
	e	efflux clearance
	f	functional clearance
	int	intrinsic clearance
	m	metabolic clearance
	u	uptake clearance
D0	Oral dose of chemical (mg)	
E	Hepatic extraction ratio	
F	Tissue content (fraction of tissue weight)	
	Subscripts	
	lb	lipid in blood
	lt	lipid in tissue "t"
	nb	neutral lipid in blood
	nt	neutral lipid in tissue "t"
	nleb	neutral lipid equivalent in blood
	nlet	neutral lipid equivalent in tissue "t"
	pb	phospholipid in blood
	pt	phospholipid in tissue "t"
	wb	water in blood
	wt	water in tissue "t"
	web	water equivalent in blood
	wet	water equivalent in tissue "t"
Ftiss	Volume fraction of the tissue (g tissue/g body weight)	
k	Transfer constant (liters hr−1)	
K	Binding affinity constants or metabolic rate constants	
	Subscripts representing affinity	
	m	Michaelis–Menten affinity constant (mg/liter)

Symbol or abbreviation	Description
	Subscripts representing reaction rates
	f first-order metabolism (hr^{-1})
	o oral absorption (hr^{-1})
	p skin permeability constant (cm hr^{-1})
	s second-order metabolism (liters mg^{-1} hr^{-1})
K0	zero-order infusion constant (mg hr^{-1})
n	Number of binding sites/protein molecule
P	Partition coefficient
	Subscripts
	b blood:air

ss	Steady-state
	Apparent transport maximum of the carrier system (mg hr^{-1})
	Volume (liters)
	Subscripts
	alv alveolar
	b blood
	cm cellular matrix in a tissue
	t tissue "t"
	tb tissue blood
Vmax	Maximal velocity of enzymatic reaction (mg hr^{-1})

Of the various clearance processes described above, the basic process that applies to all PBPK model compartments is chemical uptake, that is, inter- and intra-tissue transfers of chemicals. The uptake of a chemical by a tissue from the blood is described according to Fick's law of simple diffusion, which states that the flux of a chemical is proportional to its concentration gradient:

$$\text{Flux} = \frac{dC_t}{dt} = k\Delta C \quad (2)$$

For high molecular weight compounds, diffusion is often the rate-limiting process; therefore, their uptake through the tissue sub-compartments (Figure 5.6) must be considered. This requires that tissue blood and cellular matrix be described separately.

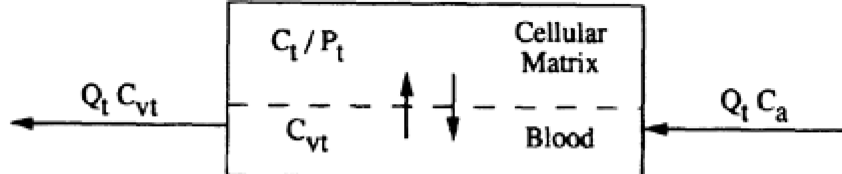

FIG. 5.6. Schematic of a tissue compartment. Qt is tissue blood flow rate, Ca is arterial blood concentration, Cvt is the concentration of the chemical in the venous blood leaving tissue, Ct is the tissue concentration, and Pt is the tissue-blood partition coefficient.

The rate of change in the amount of chemical in cellular matrix is equal to the product of the diffusion rate constant and the net flux from tissue blood:

$$V_{cm}\frac{dC_{cm}}{dt} = PA_t\left(C_{vt} - \frac{C_t}{P_t}\right) \tag{3}$$

The rate of change in the tissue blood sub-compartment equals the sum of the net retention from blood flow plus the net flux from cellular matrix:

$$V_{tb}\frac{dC_{tb}}{dt} = Q_t(C_a - C_{vt}) + PA_t\left(\frac{C_t}{P_t} - C_{vt}\right) \tag{4}$$

If the diffusion of a chemical from tissue blood to cellular matrix is slow with respect to total tissue blood flow, both equations are necessary. On the other hand, if tissue blood flow (i.e., perfusion) is slow with respect to diffusion, tissues are described as homogeneous, well-mixed compartments such that the rate of change in the amount of chemical in the tissue is described with a single equation for the whole tissue mass [cellular matrix plus tissue blood, i.e., Eq. (3) plus Eq. (4)] as follows:

$$V_t\frac{dC_t}{dt} = Q_t(C_a - C_{vt}) \tag{5}$$

In the perfusion-limited tissue descriptions, the transfer constant is the rate of blood flow to the compartment and the effluent venous blood concentration *(Cvt)* is in equilibrium with the tissue concentration *(Ct)* as specified by the tissue-blood partition coefficient *(Pt)* such that *Cvt=Ct/Pt*.

When a tissue included in a PBPK model contributes to the clearance of the chemical by metabolism and macromolecular binding, the MBDE for that tissue becomes:

$$V_t\frac{dC_t}{dt} = [Q_t(C_a - C_{vt})] - \frac{dA_{met}}{dt} - \frac{dA_{bm}}{dt} \tag{6}$$

Rate of change in the amount of the chemical in the tissue=(blood flow×arteriovenous concentration difference)—rate of loss due to metabolism—rate of loss due to macromolecular binding.

The rate of the amount of chemical consumed by macromolecular binding process has been calculated either as a second order reaction or using equations based on reversible equilibrium relationships. The rate of the amount metabolized can be described as a first order, second order, or a saturable process as follows:

$$\frac{dA_{met}}{dt} = K_f C_{vt} V_t \quad (7)$$

$$\frac{dA_{met}}{dt} = K_s C_{vt} V_t C_{cf} \quad (8)$$

$$\frac{dA_{met}}{dt} = \frac{V_{\max} C_{vt}}{K_m + C_{vt}} \quad (9)$$

Conjugation reactions are traditionally described as a second order process (Equation 5.8) with respect to the concentration of the cofactor and the chemical (70, 151). Alternatively, descriptions based on a ping-pong mechanism have also been used successfully (50).

The saturable [Eq. (9)] or first-order [Eq. (7)] metabolism descriptions presented above use the venous blood concentration, and appear to describe metabolism independent of the blood flow limitations. Once this equation becomes a part of Eq. (6), the blood flow limitation is accounted for. Alternatively, metabolism can be described using the following equation:

$$\frac{dA_{met}}{dt} = Q_l \times E \times C_a \quad (10)$$

Since $Ql \times E$=hepatic clearance (L/h), the above equation represents the classical way of calculating the amount of chemical metabolized from knowledge of hepatic clearance and arterial blood concentration. Since $Cv1 = Ca\,(1-E)$, and $Vmax/Km$ or $Clint = Q \times E/(1-E)$, Eqs. (9) and (10) are mathematically equivalent (219).

In several PBPK models, the rate of metabolism has been calculated using Eq. (9) which uses the venous blood concentrations of chemicals (i.e., $Cv1$). This is equivalent to the venous equilibration model for hepatic metabolism. Other types of physiological descriptions of liver metabolism include the parallel tube model and the distributed sinusoidal perfusion model (234, 235). The parallel tube model describes the flow of substrate through the sinusoids lined with enzymes, by considering them to be functionally homogeneous. On the contrary, however, the distributed sinusoidal model accounts for the functional heterogeneity among sinusoids by including statistical distributions of enzyme contents and sinusoidal blood flow (234). Although the distributed sinusoidal perfusion model is physiologically more realistic than the venous equilibration model, the latter simpler model may often be sufficient. Even though the predictions of tissue dose might vary in cases where the metabolizing organ alone is considered in isolation (237), the difference in predictions between these models might not be significant when considering the whole-body clearance of chemicals. A recent effort has produced a geometric multicompartmental description for liver, which can be used to simulate regional protein induction (2). The decision to use a multicompartmental liver depends on the objective and intended use of the model.

In perfusion-limited PBPK descriptions, the tissues that exhibit no significant capacity to bind or metabolize chemicals are described with the form of Eq. (5), and those tissues that exhibit significant binding and metabolic capacity are described as per Eq. (6). Thus, the basic form of equation representing chemical flux is the same for all tissues. In the case of metabolizing and eliminating tissues, however, additional terms are included to represent chemical loss due to specific biochemical processes. All tissue compartments receive the chemical via systemic arterial blood and lose the chemical via venous blood (Figures 5.3–5.5). The venous effluents of the various tissue compartments combine to yield a mixed venous concentration.

In PBPK models for volatile chemicals without a specific venous blood compartment, the mixed venous blood concentration has been calculated as follows (223):

$$C_v = \frac{\sum_t^n Q_t C_{vt}}{Q_c} \quad (11)$$

The above equation represents the steady-state solution of the MBDE for venous blood:

$$V_b(dC_b/dt) = \sum^{n} Q_t C_{vt} - C_v Q_c \quad (12)$$

The chemical in venous blood, on reaching the pulmon ary compartment, may be exhaled or retained and further introduced into systemic arterial blood along with new chemical that is inhaled during the passage via the lungs. In PBPK models for some volatile chemicals, arterial blood has not been represented as a separate compartment and described with a MBDE, but, instead, described with the steady-state solution of the MBDE for the combined lung tissue-alveolar air compartments (223) as follows:

$$C_a = \frac{Q_p C_{inh} + Q_c C_v}{Q_c + \left(\frac{Q_p}{P_b}\right)} \quad (13)$$

The above algebraic expression is derived from the following mass conservation equation for lung, which specifies that the loss of chemical from the air is balanced

by an identical gain of the chemical in the pulmonary blood:

$$Qp(Cinh-Calv)=Qc(Ca-Cv) \quad (14)$$

Since the lung equilibrates vapor between alveolar air and blood, $Calv=Ca/Pb$. This relationship assumes rapid equilibrium of the chemical across the alveolar walls, no significant metabolism by the lung tissue, and negligible storage capacity in the lungs. Pulmonary metabolism, in addition to uptake, can be included by describing both functions of the lung (151). The concentration of the chemical appearing in the systemic arterial blood is then affected by the pulmonary first-pass effects associated with metabolic processes (6, 151). The types of mathematical descriptions used for calculating the rate of uptake following oral, iv, and dermal administrations are presented elsewhere (see below).

It is not essential to have both (arterial and venous) blood compartments or the lung compartment to provide venous-to-arterial interconnections for the tissues. The linkage can be done as well without a lung or a separate blood compartment (223). In these cases, the blood volume is not specified explicitly in the model but distributed implicitly among the tissues (223). However, in such descriptions it is not possible to calculate the amount of chemical in the blood compartment. Therefore, it is important to formulate the questions to be answered with the model during the "problem identification" step so a desirable model structure can be chosen.

PBPK models are based on various assumptions. Some may be reasonable, others might be questionable. Their appropriateness and accuracy should be verified experimentally. The experimentally obtained mechanistic data can then be used to accept, replace, or modify the assumptions/empirical descriptions included in the model. Some of the more general assumptions that apply to many PBPK models are (232):

(a) the mixing of the chemical in the effluent blood from the tissues is instantaneous and complete;
(b) blood flow is unidirectional, constant, and non-pulsatile; and
(c) the flow of chemicals through the blood is smaller than the blood flow, with the former not adding appreciably to the total flow.

In basic PBPK models, certain processes are considered together and described in simple mathematical terms; however, simplified terms can later be replaced with specific mechanistic details as relevant information becomes available. The level of mechanistic detail in the model description conforms to the intended use of the model. PBPK models, then, are of varying complexities according to the particular model's intended purpose (2). A list of toxicologically important chemicals for which PBPK models have been developed in one or more species is provided in Table 5.2. The following paragraphs provide examples of prototypical representations employed in PBPK models for diverse groups of chemicals.

Examples of Model Representations

Organic Chemicals

Volatile organics, lipophilic. The tissue uptake of low molecular weight, non-polar, volatile organic chemicals is a perfusion-limited process, whereas the inhalational uptake may either be blood flow- or ventilation-limited (223). The basic mathematical representation that is applicable to many members of this category is provided in Figure 5.7. In this example, the model consists of four tissue compartments—liver, fat, richly perfused tissue group, and slowly perfused tissue group—similar to the conceptual representation shown in Figure 5.3. Here the chemical input to the model results from the inspiration of the chemical in the inhaled air at a flow rate equal to the alveolar ventilation rate. The chemical in alveolar air is assumed to equilibrate very rapidly with arterial blood so that the concentration of chemical in arterial blood and in alveolar air leaving the lungs maintains a constant ratio specified by the blood-air partition coefficient (PC). Arterial blood, flowing at a rate equal to the cardiac output, is apportioned among liver, fat, richly perfused tissue, and slowly perfused tissue. Venous blood leaving each tissue compartment mixes simultaneously to yield the chemical concentration in the mixed venous blood returning to the lungs at a flow rate equal to cardiac output. In this example, tissue uptake of the chemical is assumed to occur rapidly and metabolism is assumed to occur only in the liver by a single saturable process. It is entirely possible that extrahepatic metabolism is important and that there is a need to estimate the total amount of a chemical in the blood (151). In such cases, the metabolic capacity of each tissue included in the model is characterized, and blood is included as a separate compartment and described explicitly (151).

Volatile organics, hydrophilic. In the models presented above, pulmonary uptake is represented by assuming that all the chemicals disappearing from the inspired air appear in the arterial blood and that the chemicals in alveolar air and arterial blood are in instantaneous equilibrium. In these descriptions, the conducting airways (i.e., nasal passages, larynx, trachea, bronchi, and bronchioles) are considered inert tubes that carry the chemical to the pulmonary region, where diffusion occurs. There is mounting

evidence that this kind of a simple, continuous ventilation equilibration model is

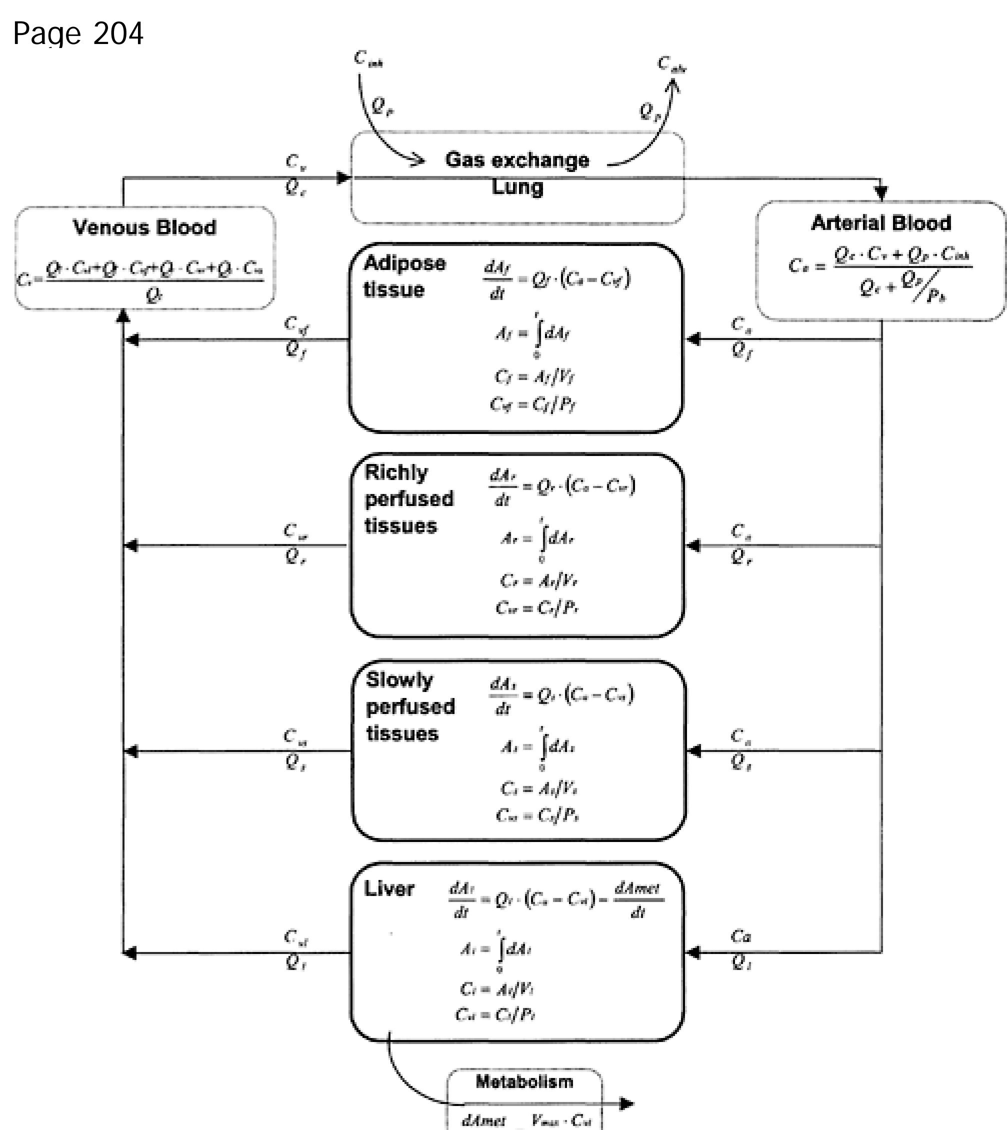

FIG. 5.7. A schematic of the PBPK model for styrene. In this model, the rat is represented as a four-compartment system interconnected by systemic circulation. The input for the system is the product of the inhaled concentration of styrene times the alveolar ventilation rate. The resulting arterial blood concentration is in turn provided as input to the tissue compartments, the effluent venous blood concentrations of which are provided as input for the calculation of mixed venous concentration. All abbreviations are defined in Table 5.1.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_204.html[2010/10/28 18:41:50]

not predictive of either total respiratory uptake or regional uptake of highly soluble polar solvents (126). With these chemicals there are complex relationships between uptake and the blood-air partition coefficient. Further, several studies have shown that the total respiratory uptake is less than 100 percent as predicted by the continuous ventilation equilibration model (126). It has been suggested that the reduced pulmonary uptake of polar solvents is due to their adsorption and/or dissolution in the surface of the respiratory epithelium during inhalation, and their desorption during exhalation (126). This adsorption-desorption mechanism is a consequence of both the aqueous solubility of the chemicals and the cyclic nature of respiratory exchange.

PBPK models for polar solvents, then, include a description of the adsorption of vapors during inhalation and desorption during exhalation in addition to accounting for the anatophysiological characteristics of the respiratory tract, blood flow rates, and partition coefficients of the chemical (105, 126). The PBPK model for polar solvents developed by Johanson (126) consists of nine serially connected central compartments, each one corresponding to an anatomical level of the respiratory tree. The first central compartment corresponds to the trachea and the last compartment to the alveolar region. Each of the central compartments corresponds to the airway and the outermost layer of mucus lining the airway wall. Radial diffusion of solvent from the outermost layer and deeper portions of the airway wall is accounted for by linking a peripheral compartment with each of the first eight compartments. The central compartment of the ninth and final region corresponds to the pulmonary or gas exchange region of the respiratory tract (respiratory bronchioles, alveolar ducts, and alveoli), the volume of which increases during inhalation and decreases during exhalation. The peripheral compartment of this ninth region represents the rest of the body, where immediate equilibrium between alveolar air and arterial blood is assumed. Either a single compartmental or a multi-compartmental physiological description can be used to account for chemical disposition in the body.

Nonvolatile organic chemicals, uncharged. PBPK models for nonvolatile organics describe chemical uptake as a diffusion-limited or a perfusion-limited process, and accommodate descriptions for chemical input via oral, dermal, intraperitoneal, and intravenous routes. These models typically consist of the following compartments: liver, fat, slowly perfused tissues, richly perfused tissues, and blood. Evidently, lung tissue or a description for pulmonary uptake is not included if its contribution to the overall kinetic behavior of the chemical is negligible (9). When there is evidence to the contrary, and, also, when there is evidence for pulmonary metabolism, lungs should be separated from the richly perfused tissues group and described as a separate compartment. In the case of diffusion-limited uptake description, each tissue compartment has a specified cellular matrix volume and tissue blood volume. The movement of a chemical from tissue blood into cellular matrix is described as being proportional to the permeation coefficient-surface area cross-product *(PAt)* for the tissue (t). Tissue uptake is diffusion-limited when $PAt<Qt$. Binding to tissue macromolecules and other clearance processes are described as appropriate (9, 135, 240).

Nonvolatile organic chemicals, charged species. The distribution of water-soluble, charged species, such as weak acids and weak bases, is determined primarily by the *pKa* of the compound and pH of the body fluids. The tissue uptake of these chemicals can be defined by the conventional flow-limited exchange between plasma/ blood and tissues, with partitioning being determined by the *pKa* of the chemical and the pH of the body fluids in accordance with the Henderson–Hasselbach equation (195). The elimination of these chemicals is mainly via urine, and therefore time-course information on this process may be necessary to adequately describe the kinetics of excretion.

Inorganic Chemicals

Gases and vapors. For inorganic gases that do not interact with walls of the conducting airways, simple dosimetry descriptions similar to those discussed in the preceding sections have been employed (5, 126). For reactive inorganic gases, however, simulation models should incorporate critical elements of local absorption in the lower respiration tract and reactions with the biological constituents (185, 196). Typically, these dosimetry models use quantitative information on the physiology of the lower respiratory tract, i.e., ventilation parameters and varying airway dimensions during breathing cycle. Lung dimensions are taken into account by making use of the airway models, in which airways of the lower respiratory tract are represented by a sequence of sets of right circular cylinders. All cylinders in series corresponding to a particular generation are of the same size. The upper respiratory tract (if used) consists of pre-tracheal generations or sequential segments. For each generation, the simulation model requires the specification of the number of airways or segments and their diameters and lengths. Additionally, for the pulmonary region, the alveolar volume and the surface area for each generation are needed. Similarly, the surface area of each upper respiratory segment is included.

The processes of transport and chemical reactions are described with a series of partial differential equations. In the liquid lining, tissue, and blood compartments, where only the processes of molecular diffusion and chemical reactions are considered, the form of the equation is the same. In the lumen of the airway and

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_205.html[2010/10/28 18:41:50]

in the alveolar air spaces, axial convection, axial dispersion, the loss of chemical to the liquid lining, and lung expansion and contraction are taken into account. With quantitative information on the boundary conditions, initial conditions, and the physical, chemical, and biological parameters, these equations are solved to simulate dose and dose patterns. In this case, computational requirements are greater than those associated with the simpler PBPK models discussed above. More recently, a hybrid computational fluid dynamics and PBPK model has been constructed to estimate the regional tissue dose of organic acids in rodent and human nasal cavity (88).

Metals. The functional description used in PBPK models for metals is basically similar to that for organics; however, the common assumptions of flow-limited tissue uptake and linear partitioning into tissues may not be applicable for some metals (191). Further, the systemic uptake of metals may be mediated by ion channels or carrier-mediated transport mechanisms, and metabolism may be limited to oxidation state transitions and alkylation/dealkylation reactions. In the PBPK models for metals, the uptake has been described as a diffusionlimited process in some tissues and as a flow-limited process in others, to obtain adequate fitting of the model to experimental data (123). Clearance associated with binding to subcellular proteins occurs to a greater extent in the case of metals. Another important phenomenon associated with certain metals is their storage in bone. The metals for which PBPK models have been developed include arsenic, nickel, lead, chromium, zinc, and mercury (Table 5.2).

MODEL PARAMETERIZATION

Model parameterization refers to obtaining independent measures of the mechanistic determinants, namely, physiological parameters, physicochemical parameters, and biochemical rate constants, which are included in one or more of the PBPK model equations.

Physiological Parameters

Physiological parameters included in most PBPK models include alveolar ventilation rate, cardiac output, tissue blood flow rates, and tissue volumes. Additional parameters (e.g., tissue DNA levels, hematocrit) may be required in certain cases. The physiological parameters can generally be measured directly in the animal species of interest (33, 67, 120, 236, 244). For example, breathing rates can be measured with the use of a spirometer, plethysmograph, pneumotachograph, hotwire anemometer, or nonbreathing valves (179). Cardiac output has been determined from dye dilution curves using oximeters (65). Representative data from compilations of reference physiological parameters for laboratory animals and humans (13, 26, 57) are presented in Tables 5.3–5.5.

Physicochemical Parameters

The physicochemical parameters required for PBPK models refer primarily to the partition coefficients (PCs), which represent the relative distribution of a chemical between two phases at equilibrium. Partitioning between

two media (e.g., blood and air) as described by Henry's law for gases is a balance of the solubility of a chemical in the two media. PCs are represented as the ratio of the concentration of a chemical in the two media (e.g., blood:air, tissue:blood) at equilibrium. These physicochemical parameters are necessary to describe the tissue distribution of most uncharged xenobiotics as well as the pulmonary uptake of volatile organic chemicals. Several in vitro, in vivo, and animal replacement methods are available for estimating the PCs of chemicals.

In Vitro Methods

Vial equilibration. This in vitro method invol ves comparison of the equilibrium concentration of a chemical in the headspace of test vials containing tissues with empty/reference vials (81, 97, 100, 127, 242). The experimental procedure for determining the tissue: air and blood: air PCs of volatile organic chemicals by vial equilibration is given below:

1. Prepare a batch of 16 glass vials (volume ~25 ml) stoppered with Teflon septa. Transfer a measured quantity of raw ground tissue (e.g., 200 mg) or blood (e.g., 200 *µ*l) into even-numbered vials. The odd-numbered empty vials are used as reference vials. All vials are placed in a shaker-incubator at 37°C.
2. Aerate the vials after a 5-min initial equilibration at 37°C, and cap them again.
3. Remove a predetermined volume of air (e.g., 0.5 or 1.0 ml) from each vial individually with a gas-tight syringe inserted through the septa, and replace it with an equal volume of air containing a known quantity of the chemical.
4. Draw a sample of headspace atmosphere (e.g., 1.0 ml) from one set of eight individual vials (four reference+four sample) at either of the sampling time points (e.g., 1 h and 2 hr).
5. The tissue:air (or blood:air) PCs is calculated as follows (97):

$$P_{t:a} = \frac{(C_{ref} V_{ref}) - [C_{sam}(V_{ref} - V_{sam})]}{C_{sam} V_{sam}} \quad (15)$$

where C_{ref}=chemical concentration in the headspace of reference vial, C_{sam}=chemical concentration in the headspace of sample vial, V_{ref}= volume of the reference vial, and V_{sam}=volume of sample.

If the $P_{t:a}$ values obtained at both time points are not significantly different from each other, they can be averaged and standard deviations calculated. If the $P_{t:a}$ values obtained at the later time point are significantly different from those obtained at the earlier time point, they are not considered to represent a true measure of solubility. An increase in $P_{t:a}$ values with incubation time indicates chemical reactions in the aqueous phase, and/or the non-attainment of equilibrium during the time points chosen for sampling. In such cases, additional experiments have been conducted to generate a time course of the distribution ratio to estimate $P_{t:a}$ by extrapolating to time 0 (151). Metabolic inhibitors may also be added in excess before introducing the chemical. The latter approach has been shown to eliminate chemical uptake by tissues due to specific and known reactions (e.g., glutathione conjugation) (89, 103). On the other hand, if the calculated $P_{t:a}$ value decreases with incubation time, then deterioration of the tissue sample during incubation is likely; in such cases, headspace sampling for the determination of PCs should be conducted at earlier time points.

The tissue and blood samples do not have to be used as raw preparations in these experiments. Especially for chemicals with low solubility, the tissue and blood samples can be prepared as a 1:2 or 1:3 homogenate in saline (0.9% NaCl). The corresponding reference vials will contain saline alone. The $P_{t:a}$ value in this case is obtained using the following formula (97):

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_207.html[2010/10/28 18:41:51]

$$P_{t:a} = [C_{ref}(V_{ref} - V_{liq})] \frac{-[C_{sam}(V_{ref} - V_{liq} - V_{sam})] + [(C_{ref} - C_{sam})(V_{liq}P_{liq})]}{C_{sam}V_{sam}} \quad (16)$$

where *Vliq*=volume of the diluent liquid and *Pliq*=diluent liquid-air PC.
PCs for nonvolatile chemicals have been determined in vitro using equilibrium dialysis or ultrafiltration techniques.

Equilibrium dialysis. In this technique, the cell cavities are separated with dialysis membrane of desired molecular weight specifications. The experimental procedure consists of dialyzing the tissue homogenate or whole blood prepared in a buffer (e.g., Tris HCl, 0.1 M, pH 7.4) against the same buffer in a metabolic shaking bath (118, 167, 254). These experiments are conducted for several different initial concentrations of the chemical (radiolabeled+cold). Preliminary studies using different dialysis durations should be conducted to determine the time needed to attain equilibrium. At the end of the incubation, radioactivity in both the tissue and buffer is determined separately by liquid scintillation counting. The sum of the buffer and tissue radioactivity should account for all the radioactivity initially added to the dialysis cells. The unbound fraction of radioactive chemical in the tissue is determined by dividing the chemical concentration in buffer by the concentration in the tissue homogenate (167, 168). The P*t* values obtained from these experiments will be accurate only if the ratio of the bound to free form of chemical is constant over a wide range of concentrations.

Ultrafiltration. The ultrafiltration assembly consists of an ultrafiltration device, and a semipermeable membrane. In this approach, the tissue homogenates are spiked with a known amount of a chemical (radiolabeled+cold) and allowed to equilibrate for a predetermined time. Following equilibration, they are transferred into the reservoir portion of the ultracentrifugation device, placed in an angle rotor, and spun in a superspeed centrifuge. The concentrations of the chemical in the tissue homogenate and the buffer are determined and solved for the concentration of the chemical in the tissue (167).

The time and speed of ultracentrifugation should be determined for particular cases so that a desired volume of the ultrafiltrate is collected. Untreated tissues should be used to generate a protein-free ultrafiltrate for measuring the nonspecific binding onto the surface of the ultrafiltration device.

In Vivo Methods

Methods for estimating *Pt* values based on the analysis of data on blood and tissue concentrations of parent chemical after a single-bolus dose, or at steady-state condition following constant intravenous infusion or administration by other routes, have been published (35, 91, 92, 155). *Pt* values have also been estimated from the slope of best-fit straight line with a unit slope drawn through the log-log plot of tissue concentration vs. blood concentration of the parent chemical for each tissue (59).

The steady-state approach will work only if the chemical is not removed by active binding/metabolic processes in one or more tissues. In this case where there is active tissue metabolism, the estimated *Pt* values tend to underestimate the true *Pt* values. Estimates of *Pt* for these tissues can be obtained if the amount of chemical consumed by the metabolic process is accounted for. Thus, for metabolizing tissues, the partition coefficients are determined after adjusting for clearance (35).

A potential problem associated with the determination of the PCs relates to the presence of residual blood in the tissues. The contamination of tissues with blood in the tissue vasculature might introduce errors in the estimated PCs. The importance of this problem has been investigated and the means of correcting these errors proposed (138).

Animal Replacement Approaches

Tissue: air partition coefficients. The partitioning of a chemical between two matrices can be predicted if its solubility and binding in each of the matrices can be estimated with reasonable accuracy. Using this basic premise, mechanistic animal replacement approaches for predicting tissue: air, blood: air, and tissue: blood PCs have been developed. Accordingly, the tissue: air PCs of low-molecular-weight VOCs, for which macromolecular binding is negligible, have been calculated as follows (74, 200):

$$Pt{:}a = (Pl{:}a \times Flt) + (Pw{:}a \times Fwt) \qquad (17)$$

In the above equation, $Pl{:}a \times Flt$ represents the partitioning of a chemical between the tissue lipids and air, and $Pw{:}a \times Fwt$ represents the partitioning between tissue aqueous phase and air. Po:a has been used as a predictor of *Pl*:a, and *Pw:a* as a surrogate of chemical partitioning between tissue water and air (74, 200). However, "tissue lipids" is too generic to represent the differential lipophilicity characteristics of neutral lipids (e.g., triglyceride) and polar lipids (e.g., phospholipid). Therefore, the partitioning of a chemical into neutral lipids and polar lipids may have to be considered separately. The physicochemical properties of phospholipids are dependent on the presence of a hydrophobic (e.g., glyceride) and hydrophilic (e.g., phosphomonoester) groups. Therefore, the use of *Po:a* or *Pw:a* alone cannot adequately predict tissue phospholipid:air PCs. The partitioning of a chemical between tissue polar lipids (i.e., phospholipids) and air can be calculated as a fractional additive function of their partitioning into neutral lipids ($0.3 \times Po{:}a$) and water ($0.7 \times Pw{:}a$). This approximation of chemical partitioning into tissue phospholipids is based on the assumption that the lipophilicity-hydrophilicity characteristics of tissue phospholipids is similar to that of commercial lecithin (220). Based on this working hypothesis, Poulin and Krishnan (216, 217) have proposed the following equation to predict

Pt:a of volatile organic chemicals, con-

sidering separately the partitioning of chemicals into neutral lipid and polar lipid portions:

$$P_{t:a} = (P_{o:a} \times F_{nt}) + (P_{o:a} \times 0.3F_{pt}) + (P_{w:a} \times 0.7F_{pt}) + P_{w:a} \times F_{wt} \quad (18)$$

The above equation can be rewritten as:

$$[Pt{:}a = Po{:}a(Fnt + 0.3Fpt)] + [Pw{:}a(Fwt + 0.7Fpt)] \quad (19)$$

In Eqs. (18) and (19), the partitioning of a chemical between tissue neutral lipids and air is assumed to correspond directly to *Po:a*, while the partitioning between tissue water and air is assumed to correspond to *Pw:a*. Accordingly, *Pt:a* can be calculated with knowledge of tissue composition data (*Fnt*, *Fpt*, *Fwt*), and physicochemical properties of chemicals (*Po:a* and *Pw:a*). Compilations of species-specific tissue composition data (72, 216, 217, 220), *Po:a* and *Pw:a* values of several VOCs at 37°C are available in the literature (97, 200). To facilitate the use of *Po:w* values instead of *Po:a* values which are not readily available in the literature, Equation 19 can be rewritten as follows:

$$Pt{:}a = [Po{:}wPw{:}a(Fnt + 0.3Fpt)] + [Pw{:}a(Fwt + 0.7Fpt)] \quad (20)$$

Eq. (20) has been used to predict rat and human *Pt:a* (liver, muscle, fat) of several alkanes, haloalkanes, and aromatic hydrocarbons (204, 216–219, 221). In general, the predicted *Pt:a* values were within a factor of two of the experimentally determined PCs. For chemicals such as alcohols, acetate esters, and ketones, the values of rat and human fat: air calculated using Eq. (20) differed substantially from the experimental data (214, 216, 217). These results have been explained by the choice of the surrogate of biotic lipid used in Eq. (20). n-Octanol, being an alcohol, would appear to solubilize other alcohols to a greater extent than biotic neutral lipids. Based on its hydrophilicity-lipophilicity characteristics and its fatty acid composition, vegetable oil has been suggested as an acceptable alternative to n-octanol as a surrogate of biotic neutral lipids, especially for hydrophilic organics (214). Then, to predict *Pt:a* of hydrophilic VOCs, especially for fatty tissues, *Po:w* in Eq. (16) should represent vegetable oil: water PCs. However, in the case of relatively lipophilic VOCs (log $Po{:}w > 1.25$), there is little difference between the n-octanol: water PCs and vegetable oil: water PCs. Therefore, either one of these PCs can be used as the biotic lipid surrogate for solving Eq. (20) to predict tissue: air PCs of these chemicals (217).

Blood: air partition coefficients. Based on Eq. (20), Poulin and Krishnan (215, 217) proposed the following equation for predicting *Pb* of VOCs that do not bind sig nificantly to blood proteins:

$$Pb = [Po{:}wPw{:}a(Fnlep)] + [Pw{:}a(Fweb)] \quad (21)$$

where *Fnlep*=neutral lipid equivalents, calculated as the sum of neutral lipids plus 0.3× phospholipid content, and Fweb=water equivalents, calculated as the sum of tissue water content plus 0.7× phospholipid content.

Accordingly, *Pb* of VOCs can be calculated with the knowledge of blood composition data, *Po:w* and *Pw:a*. The data on lipid and water levels in rat and human blood are available in the literature (215) and so are the numerical values of *Po:w* and *Pw:a* at 37°C for several VOCs (97, 127, 200) The predictions of rat *Pb* obtained using Eq. (21) are adequate for relatively hydrophilic organics (e.g., alcohols, ketones, acetate esters), but are not the case for relatively lipophilic organic chemicals (e.g., alkanes, haloalkanes, aromatic hydrocarbons). *Pb* of a chemical is a composite number that potentially represents two processes occurring in the blood, namely, solubility and binding. While chemical solubility is likely to be determined by the neutral lipid, phospholipid, and water contents in blood, the binding would appear to be associated with plasma proteins and/or hemoglobin. For alcohols, acetate esters, and ketones, rat and human *Pb* appear to be adequately predicted solubility-based algorithms [i.e., Eq. (21)] (215, 217). For more lipophilic VOCs (e.g., alkanes, haloalkanes, aromatic hydrocarbons), however, the rat *Pb* calculated using Eq. (21) were lower (60–80%) than the experimental data (215, 217). The fact that the rat *Pb* of lipophilic VOCs are under-predicted could be explained by the potential binding of these substances to blood proteins (215), a phenomenon not considered in Eq. (21). At the present time, there does not exist a validated animal replacement algorithm for predicting association constants for blood protein binding of organic chemicals.

Tissue:blood partition coefficients. Tissue:blood PCs of VOCs, for which macromolecular binding in tissue and blood is negligible, can be estimated from n-octanol:water PCs or vegetable:water PCs (*Po:w*) using the following general equation (64, 221):

$$P_t = \frac{(P_{o:w} \times F_{nlet}) + F_{wet}}{(P_{o:w} \times F_{nleb}) + F_{web}} \quad (22)$$

The numerator and denominator of Eq. (22) correspond to Eqs. (20) and (21) divided by *Pw:a*. In the

case of VOCs then, *Pt* values can be obtained by dividing *Pt:a* by *Pb*. The predictions of Eq. (22) will therefore be identical to the ratio of the predictions obtained using Eqs. (20) and (21) (214, 217, 220). In the above equation, the neutral lipid equivalent has in some cases been considered to be equivalent to total lipid content (74). The sum of *Fnlet*+*Fwet* is not equal to 1 in most cases due to the presence of other tissue components such as

Table 5.6

Neutral lipid and water equivalent of major tissues in human and rat blood (221)

	Water equivalent		Neutral lipid equivalent	
Tissues	*Rat*	*Human*	*Rat*	*Human*
Blood	0.8423	0.8217	0.0020	0.0040
Fat	0.1215	0.1514	0.8536	0.7986
Liver	0.7176	0.7400	0.0425	0.0473
Muscle	0.7471	0.7573	0.0117	0.0378

proteins. This aspect should be appropriately considered while using the tissue composition data for calculating PCs of chemicals.

When the tissue:air, blood:air, and tissue:blood PCs of unionized organic chemicals are not known, Eqs. (20), (21), and (22) can be used to provide first-cut estimates. Since the tissue and blood composition data can be estimated experimentally or obtained from literature (Table 5.6), only the numerical values of the physicochemical properties are needed for each new chemical. The *Po:w* and *Pw:a* of chemicals can be predicted from molecular structure information (217). An example of the prediction of tissue:blood PC from molecular structure information of 1,1,1-trichloroethane is presented in Figure 5.8. Semi-empirical methods relating

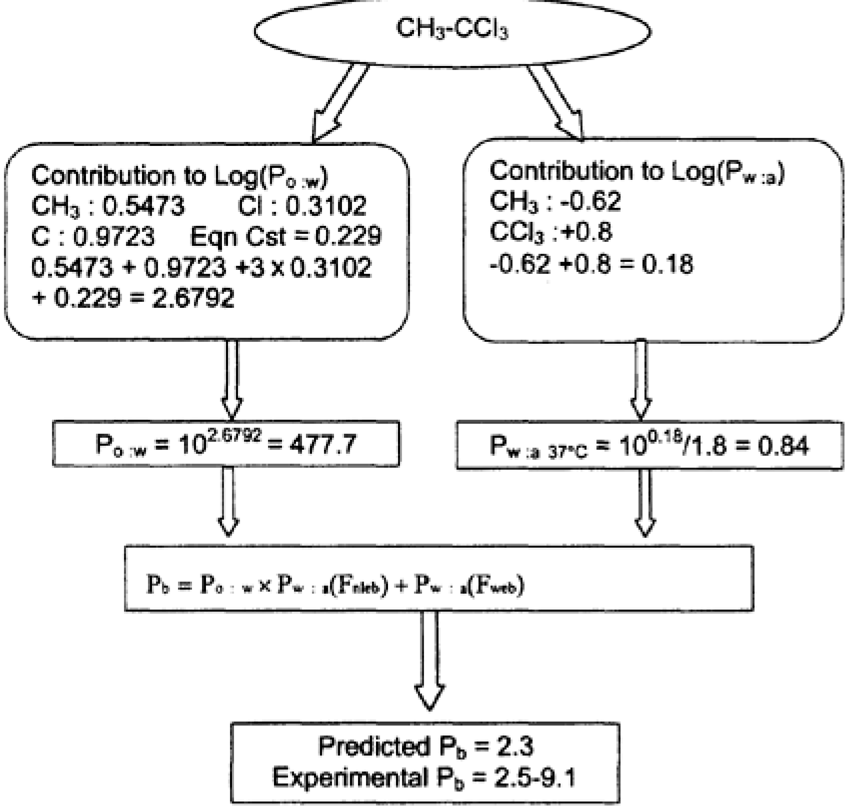

FIG. 5.8. Prediction of the human blood: air partition coefficient (Pb) of 1,1,1-trichloroethane from knowledge of its molecular structure, according to Reference 217.

molecular structure information to tissue:blood and blood:air PCs of chemicals may also be used as appropriate (64, 198).

Biochemical Parameters

Biochemical parameters such as the rates of absorption, biotransformation, macromolecular binding, and excretion can be determined by conducting time-course analysis in vivo or in vitro. One strategy for accurate estimation of specific biochemical parameters in vivo is to conduct experiments under conditions where pharmacokinetic behavior of a chemical is related to one or two dominant factors and thereby derive estimates of these parameters.

Thus, the rate constant for dermal absorption of VOCs has been determined by conducting body-only exposure of animals covered with a latex face mask. The total amount of the chemical absorbed through the skin during exposure is calculated by analyzing the blood-time course data collected during the exposure with a PBPK model that has all parameters except *Kp* defined. The value of *Kp* is estimated by

fitting PBPK model simulations to the blood-time course concentration data obtained experimentally (180, 181).

The skin permeability constant can also be determined in vitro using excised skin tissue. In these experiments, the test material is placed on excised skin in a vehicle and its appearance in the bathing medium determined (3). A plot of concentration in the bath vs. skin has a time lag, a period of increasing slope, and a final phase of constant slope (Figure 5.9). The plot of rate of uptake—the first derivative of this curve—gives the maximum uptake rate. The permeability uptake rate *Kp* (cm/hr) is calculated by

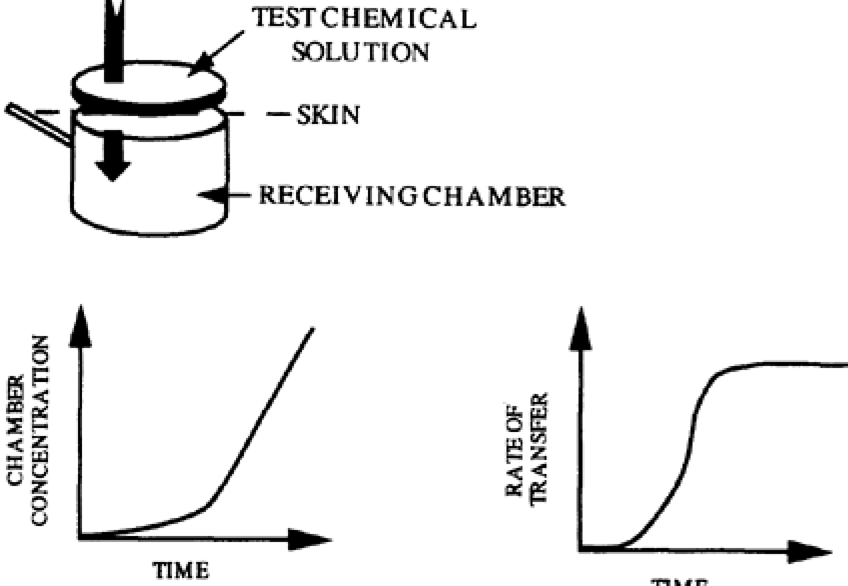

FIG. 5.9. Schematic representation of in vitro approaches to estimate skin permeability constants. Redrawn with permission from Reference 3.

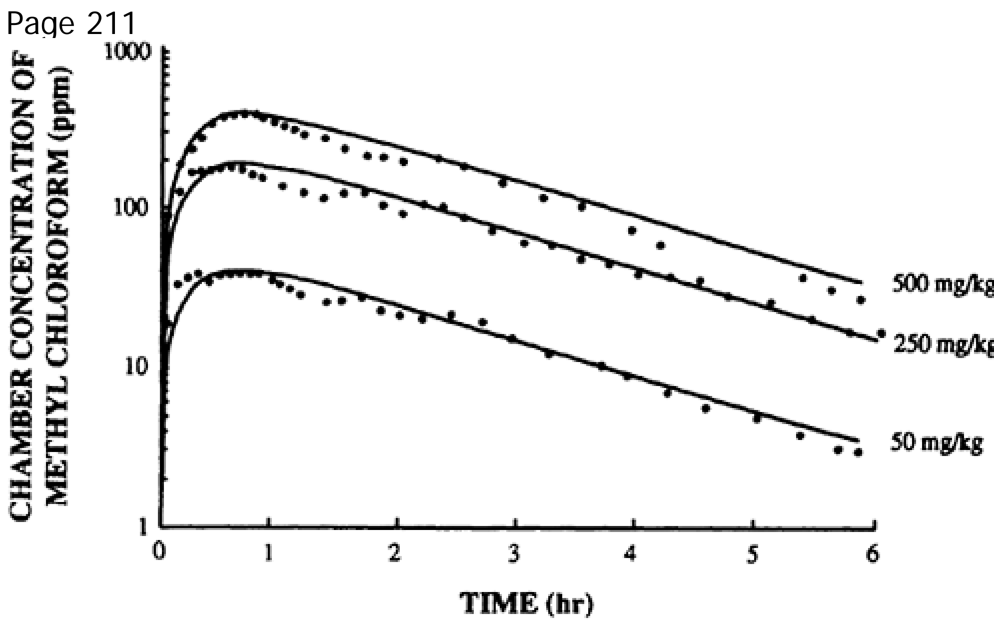

FIG. 5.10. Exhaled breath chamber time course for groups of four mice following oral dose of 50, 250, or 500 mg 1,1,1-trichloroethane/kg body weight. Redrawn with permission from Reference 93.

dividing the uptake rate (mg/cm2/hr) with applied concentration (mg/cm).

The rate constant for gastrointestinal absorption of volatile organics has been estimated by analyzing the time course of exhalation of the parent chemical after oral administration, with a PBPK model that had all parameters except *Ko* defined (Figure 5.10) (93). The estimation of the rate of gastrointestinal absorption for hydrophilic chemicals (*Pb*>90) has been performed by determining the blood concentration following oral dosing and analyzing the data with a PBPK model that defined all parameters except *Ko* (87).

The rate constants for metabolism can be determined in vivo or in vitro. Two innovative noninvasive methods have been devised for the estimation of the in vivo metabolic rate constants of VOCs. These are

(a) the closed chamber or gas uptake method, and
(b) the exhaled breath chamber method.

The closed chamber or gas uptake method uses a desiccator-type chamber with a recirculating atmosphere for exposing groups of animals to volatile chemicals (7, 78). This approach involves periodically monitoring the chamber concentration of a chemical during exposures. The rate of change in the chamber concentration of the chemical both in the absence and in the presence of animals is determined for various starting concentrations. The net difference in the rates determined in these two sets of experiments represents the loss of chemical due to uptake and metabolism by the animals. The rate of spontaneous loss of chemicals in the empty chamber, corresponding to degradation and/or adsorption to chamber surface, should not exceed ~2 percent per hour. Otherwise the decline in the chamber concentration may not be sensitive enough to enable the determination of metabolic rate constants. When animals are placed in the gas uptake chamber, the rate of decline in chamber concentration of the chemical increases, the magnitude being proportional to the rate of metabolism once the chemical has equilibrated within the organism.

The data analysis is conducted with a PBPK model that has all parameters defined except the metabolic rate constants (95). Initially, the PBPK model for closed chamber exposures is run for several starting concentrations with the metabolic rate constants set to 0 (i.e., Vmax=0, *Kf*=0). The model simulations obtained at this stage reflect chemical uptake by the organism in the absence of tissue metabolism. Then, by setting the *V*max, *Km*, and *Kf* to some numerical values, it can be seen that the model simulations correspond to experimentally observed decline in chamber chemical concentrations. By optimization to get the best fit to the set of gas uptake curves, the values of metabolic rate constants are estimated. A single set of *Km* and *V*max obtained in these in vivo experiments has been considered to represent the role of a single isoenzyme, or the average of the sum of the activities of multiple enzymes. This method has been used successfully to obtain metabolic rate constants of VOCs that are biotransformed by a single first-order process, a saturable process, or a combination of both (6, 98).

It is important to monitor the oxygen concentration, humidity level, and chamber pressure during gas uptake studies. Any change in the respiratory rate should be investigated so that modeling of gas uptake exposure provides reliable estimates of metabolic rates (51, 128). Control gas uptake runs, during which naive animals are placed in the chamber without any added chemical, are necessary to ensure the absence of interfering chromatographic peaks of exhaled endogeneous chemicals.

Since the gas uptake studies involve whole-body exposures, there is a possibility for adsorption to fur and also dermal uptake. If dermal absorption is

important, or if the PBPK model cannot satisfactorily simulate the chamber decline data with only pulmonary uptake description, then rate constants for dermal absorption process should be determined independently and included in the model. To determine whether or not adsorption to fur has contributed significantly to chemical uptake during whole-body exposures, the animals, after termination, should be placed in a clean chamber and the time course of the appearance of the chemical determined (94).

The gas uptake method is not particularly well suited for use with those organic chemicals that
(a) have low vapor pressure,
(b) exhibit high chamber loss rates, or
(c) are highly soluble in blood and tissue.

For example, in the case of a chemical with blood-air PC greater than 60, the equilibration phase may become prolonged, thus occupying most of the gas uptake curves. The behavior in these gas uptake curves is restricted largely to tissue uptake. In such cases, the metabolic rate constants have been assessed using an exhaled breath chamber (93, 94).

The exhaled breath method involves placing an animal, previously exposed to a chemical, in a flow-through type of chamber and collecting samples of the chamber effluent for chromatographic analysis. Several exhaled breath samples are taken at periodic intervals during the experiment. The time intervals are chosen based on the appearance of the decay phase or whenever transitions in the elimination behavior are expected or observed. These curves are then analyzed with a PBPK model in which all parameters except metabolic rate constants are defined. The metabolic rate constants are estimated by obtaining an optimal fit of the PBPK model simulations to the exhaled breath curves.

Metabolic rate constants also have been determined by measuring the production of a stable metabolite resulting from the conversion of the parent compound in vivo (99). For a particular metabolite to provide a quantitative measure of metabolism of the parent chemical, it is ideal if it is produced in the first step of metabolism and is resistant to further biotransformation. Only very few metabolites exhibit these attributes. An example of this kind is bromide ion resulting from the initial metabolism of dibromomethane. This metabolite is distributed almost exclusively in the extracellular fluid spaces and is excreted slowly in the urine. In this case, the metabolic rate constants were estimated by fitting the simulations of a PBPK model that accounted for the formation, distribution, and excretion of bromide to experimental data on plasma bromide levels (99).

The blood time-course data obtained after intravenous administration also have been used to determine the rate constants of metabolism (229). Accordingly, the blood or tissue time course of the parent chemical is obtained following its intravenous administration over a dose range. The experimental data are then analyzed with a PBPK model that has all parameters defined except metabolic rate constants. A single combination of metabolic rate constants (i.e., *V*max, *Km*, and/or *Kf*) that best describes the data is obtained by fitting the model simulations to the set of blood time-course curves (Figure 5.11). Similarly, pharmacokinetic data obtained following other modes of administration can be used to determine the metabolic rate constants, provided the rate constant of absorption for the particular exposure pathway has been obtained independently.

In the above methods, we know or hypothesize that the decline in the blood/chamber level of parent chemical is determined by the magnitude of the metabolic rate constants, and that metabolism occurs via a single first-order, second-order, or saturable process, or via a combination of any two processes in a particular tissue. In the case of chemicals that are metabolized by more than two competing metabolic pathways to varying extents in several tissues, the gas uptake, exhaled breath chamber, or intravenous pharmacokinetic studies alone cannot be used to determine the rate constants for each of the multiple pathways occurring in several tissues. The use of these methods in this case will yield one set of rate constants that represent the overall metabolic clearance of the chemical (i.e., the sum total of metabolism via all metabolic pathways). Alternatively, if the rate constants for

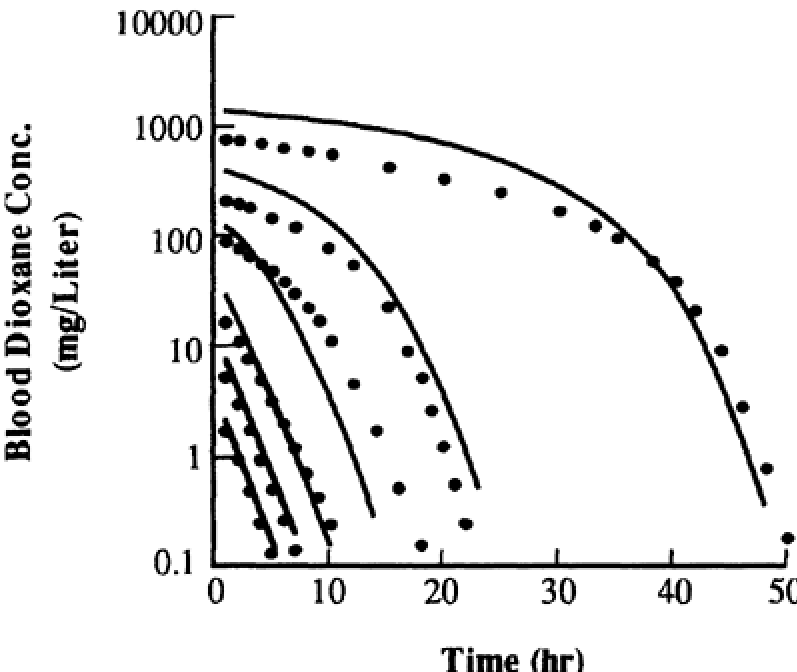

FIG. 5.11. Comparison of PBPK model simulations (solid lines) with the experimental data (symbols) of blood concentrations of 1,4-dioxane following intravenous dosing (3, 10, 30, 100, 300, and 1000 mg/kg). Model simulations were obtained using metabolic rate constants estimated by statistical optimization of the model fit to the experimental data. Redrawn with permission from Reference 229.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_212.html[2010/10/28 18:41:55]

all metabolic pathways except one have been determined independently, then an intravenous dosing or a gas uptake study can be conducted to obtain the rate constants for this pathway (151). The rate constants for individual metabolic pathways can potentially be obtained from in vitro studies.

Subcellular fractions, postmitochondrial preparations, isolated cells, tissue slices, and isolated perfused organs are all potentially useful as in vitro systems for the estimation of metabolic rate constants (58, 60, 62, 63, 103, 116, 121, 167, 170, 186-188, 228, 231, 241). The relevance of rate constants determined in vitro to the intact animal is not clear in all cases. However, several studies using microsomes, post-mitochondrial fractions preparations, or hepatocytes to determine metabolic rate constants for direct incorporation into PBPK models have successfully described the kinetics of volatile and nonvolatile organic chemicals (150). The *Km* obtained in in vitro studies has been used directly [or scaled to reflect the in vitro/in vivo ratios in a test species (231)], but the *V*max obtained in vitro has been scaled to the whole organism based on the mass recovery of the particular fraction. For example, the *V*max for the intact animal has been estimated from the *V*max obtained using rat liver microsomes as follows:

$$V\text{max (in vivo)} = V\text{max (in vitro)} \times 60 \times Cprot \times Vt \qquad (23)$$

where *V*max(in vivo) is expressed in mg/hr/kg, *V*max(in vitro) is expressed in mg/min/mg protein, 60 is the factor for converting the per-minute rate to per-hour rate, *Cprot* is the concentration of protein in the microsomal sample (mg protein/g tissue), and *Vt* refers to the volume of tissue (g).

Care must be taken to check the validity of the various in vitro systems to adequately predict the kinetics of chemicals in vivo (50). For example, the clearance of dichloromethane (DCM) by oxidative metabolism estimated in vitro using rat liver microsomes is lower than the actual clearance estimated by in vivo methods. The examination of the in vitro- and in vivo- derived rate constants for oxidative metabolism revealed that the *V*max agreed well, but there are differences of up to four orders of magnitude in the *Km* values between the two approaches. Use of these in vitro *Km* values in a PBPK model would underestimate severely the amount of DCM metabolized via the oxidative pathway at low exposure concentrations (5). Such a description would have the oxidative pathway competing less efficiently with the glutathione (GSH) conjugation pathway, thus over-predicting the metabolite production via the GSH pathway. Products from the GSH pathway have been correlated with tumor outcome and this parameter misspecification would lead to substantial errors in assessing the carcinogenic risk associated with low-level DCM exposures (5).

The identification of in vitro systems for determining metabolic rate constants that give values consistent with those operative in vivo is crucial for eventually predicting human dosimetry. Recent studies indicate that freshly isolated hepatocytes are a better system that provides rate constants comparables to the in vivo estimates (e.g., 133). Other studies have succeeded in conducting extrapolations between in vitro metabolic systems, based on an understanding of biochemical principles at the quantitative level (e.g., Lipscomb et al. (170)). Our ability to predict metabolic rates from one in vitro system to another is a significant step forward in predicting the rate constants for the in vivo system.

Mechanistic animal-replacement approaches for predicting the numerical values of *E, V*max, *Km,* or *Clint* of chemicals are not available yet. However, semi-empirical approaches relating the molecular structure information to PBPK model parameters such as PCs and metabolic rate constants have been developed (198, 199, 281). A major limitation of these approaches is that experimental data need to be collected before developing equations that consistently describe the relationship between molecular structure and PBPK model parameters. Truly predictive approaches can be developed only as our understanding of the biochemical processes improve. At the present, however, the hepatic extraction can be assumed to be complete or negligible in PBPK models in order to generate simulations. Accordingly, the numerical value of E in Eq. (10) should be set to 0 or 1 during the model simulations. The region encompassed by the simulated lines obtained with $E=0$ and $E=1$ will naturally contain the experimental data for that particular exposure scenario (e.g., Figure 5.12).

The rate constants of chemical reaction with hemoglobin and tissue proteins determined in vitro or in vivo, have been incorporated into the PBPK model to make predictions of these phenomena in vivo (89, 151). Attempts also have been made to include receptor binding and DNA binding properties of chemicals into a PBPK modeling framework based on in vitro-derived data (77, 260).

Some PBPK models, in which perfusion-limited tissue descriptions are used, may predict greater tissue uptake of chemicals than that which actually is observed. In such cases, tissue uptake is described as a diffusion-limited process and the mass transfer coefficient for each tissue is required. PAt is estimated by fitting model simulations to experimental data on tissue concentration of the parent chemical by varying the numerical value of the PAt term (9, 59) (Figure 5.13).

Once the mathematical representation of a PBPK model is prepared and its parameters estimated, the model can be used to simulate the kinetic behavior of a chemical in the test species.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_213.html[2010/10/28 18:41:55]

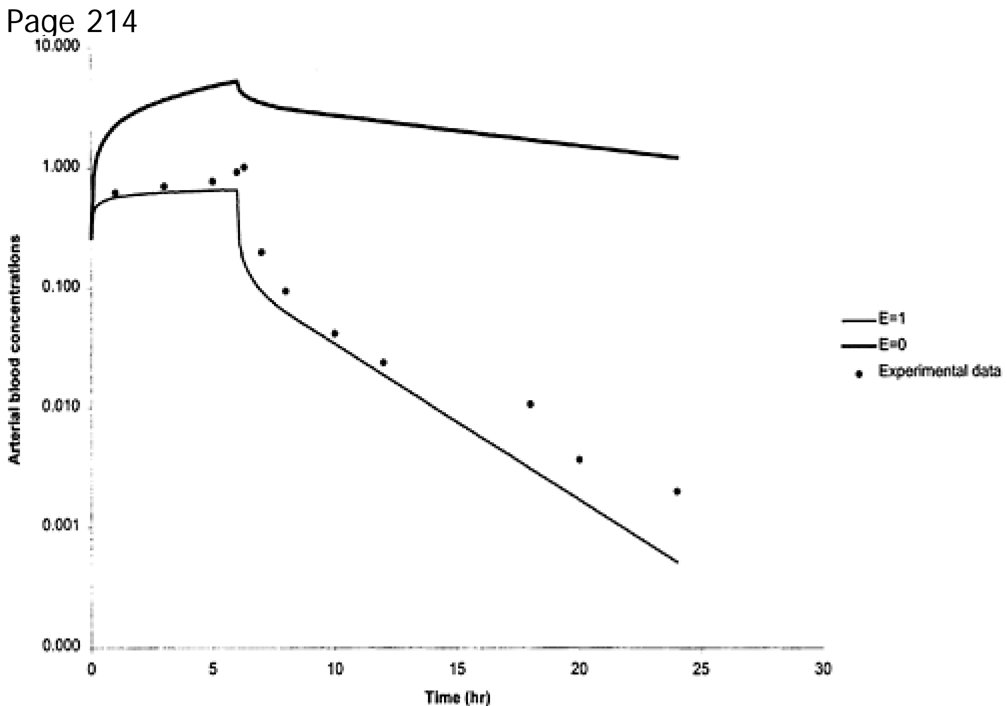

FIG. 5.12. Comparison of experimental data (closed circles) on arterial blood concentration with the envelope simulated by rat PBPK model for a 6-h exposure to 80 ppm styrene (solid lines). The upper line corresponds to the simulation obtained when the hepatic extraction was set to zero, and the lower line represents simulation obtained when the hepatic extraction ratio was set to 1. The experimental data were obtained from Reference 223.

MODEL SIMULATION

Simulation is the system behavior predicted by solving the differential equations representing the quantitative interrelations among the various model parameters. In the context of PBPK modeling, simulation refers to the prediction of the kinetic profiles of chemicals in blood and tissues by solving the set of MBDEs. Typically, simulation is chosen when:

(a) the real system does not exist,
(b) the real system exists but experimentation is expensive,
(c) a forecasting model is required to analyze events occurring over long periods of time in a compressed format, and
(d) the model does not have practical analytical solutions (e.g., stochastic models, nonlinear systems) (232).

Since PBPK models often contain differential equations and describe nonlinear processes, it is usually impractical to obtain analytical solutions and, therefore, a numerical simulation approach is adopted. For conducting computer simulations, the mathematical equations should be written in such a way as to facilitate their solution by a fixed, step-by-step procedure (i.e., algorithm).

Algorithms

Algorithms for simulation are chosen based primarily on the following criteria:

(a) thoroughness of the theoretical basis of the algorithm,
(b) self-starting capability,
(c) automatic control of step size and method order,

(d) ability to deal with both stiff and nonstiff problems and to detect stiffness automatically, and, finally, (e) proof that the algorithm works for test problems of the same kind as the one(s) under consideration (232).

Some of the commonly used algorithms include those of Euler and Gear, Runge-Kutta routines, and predictor-corrector methods. The general principle underlying these algorithms used for solving first-order ordinary differential equations can be represented in simple terms as follows:

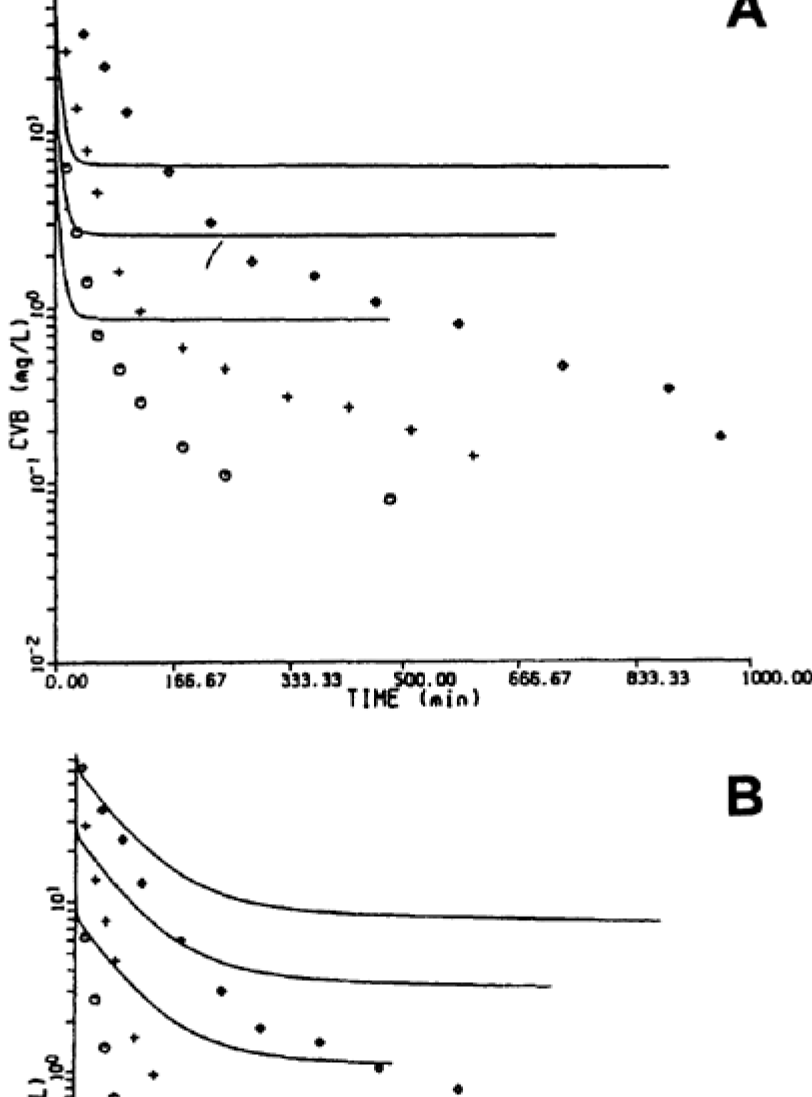
$$\text{New value} = \text{Old value} + (\text{slope} \times dt) \quad (24)$$

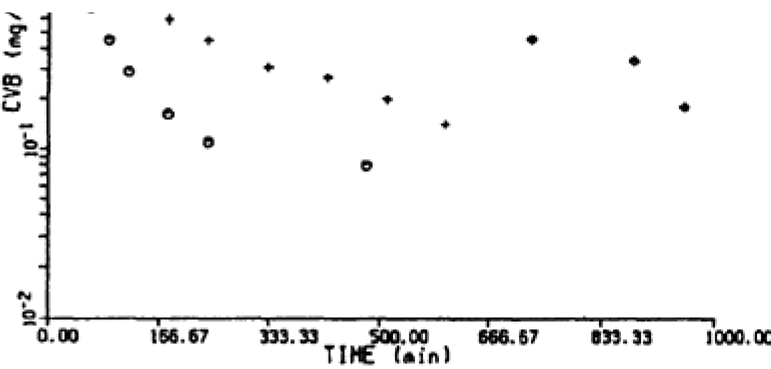
For a tissue compartment in PBPK model,

$$A_{t,1} = A_{t,0} + (dA_t/dt \times dt) \quad (25)$$

where dt is the integration interval or the predetermined length of time for which solution is obtained. Using the above algorithm, the numerical solution will approach the reality as long as the dt is prohibitively short. The specific form of the numerical solution represented in Eq. (25) is referred to as the Euler algorithm. In this method, the error arises from the negligence of the second- and other higher-order derivatives of the Taylor expansion series (110). In other words, the error associated with the Euler method is proportional to dt^2. Therefore, with the use of smaller dt values, the error associated with this first-order integration method can be minimized.

Some of the algorithms (e.g., Gear) and not others (e.g., Euler) can deal with stiff systems (101, 110). The stiffness in models is reflected by the ratio (generally of several orders of magnitude) of the largest to the smallest time constant in the model. The stiffness requires that variable integration intervals be used as simulation progresses due to the compartments with the smallest time constants attaining steady-state condition gradually. The fact that the integration interval is not changed with the progression of simulation time, in accordance with the





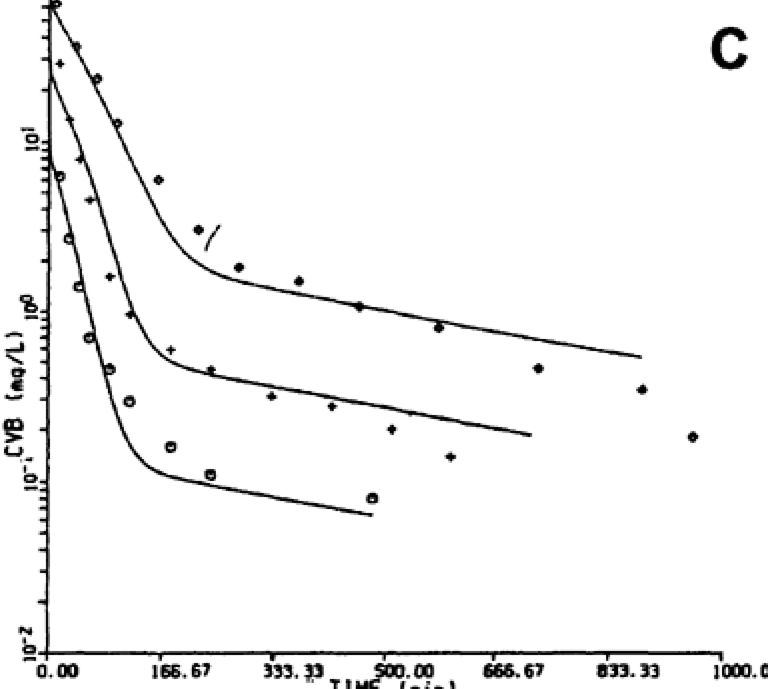


FIG. 5.13. Comparison of the experimental data (symbols) on the venous blood concentration of unchanged pyrene in rats with PBPK model simulations (solid lines). The simulations were obtained with a model that described uptake as a perfusion-limited process in all tissues (A), or as a diffusion-limited process in adipose tissues and slowly perfused tissues (B). With the additional description of metabolism in appropriate tissues, the PBPK model simulations correspond to the experimental data (C). The dose levels were 2, 6, 15 mg/kg (iv). Reproduced with permission from Reference 111.

existing stiffness state, represents only a disadvantage of the Euler algorithm taking a longer time to complete a given simulation. This is particularly because at steady-state conditions (at which $dAt/dt=0$) larger integration intervals can be used, thus saving time without losing the accuracy of the simulation. The adequacy of the Euler algorithm for numerical integration of differential equations used in PBPK models has been demonstrated (110, 131).

Software

The PBPK model equations, along with the integration algorithms, can be written and solved using programming languages, simulation software, or spreadsheets. In the first two cases, the style of computational representation of a model is determined by the grammatical and precedence rules of the programming language (FORTRAN, BASIC, etc.) or simulation language to be used. Simulation languages are computer programming packages that are general in nature but may have special features for modeling certain types of systems. Examples of simulation languages that possess features particularly useful for PBPK modeling are listed in Table 5.7. When selecting a particular simulation language for modeling, it is important to ensure that it

(a) provides a convenient means for initializing the status of the model (e.g., generating random numbers in case of stochastic models),

(b) permits the introduction of changes in both the status and temporal structure of the model as simulation time evolves (i.e., scheduling the occurrence of events),

Table 5.7

(c) provides simple methods by which model results and statistical summaries can be obtained,

(d) allows considerable flexibility in conducting sensitivity and other types of model analyses, and

(e) contains error detection facilities (232).

The choice of a particular simulation software is up to the individual as long as the software package provides the framework for creating and solving the type of model equations under consideration. Several commercially available simulation or programming software packages can be used for conducting PBPK model simulations (184). These programs/ packages are easily accessed and understood by individuals who are familiar with the techniques of programming or mechanics of simulation. The models constructed and solved using simulation packages appear like a "black box" to the analyst, who gets to see the end results but not the temporal evolution of solutions to the complex mathematical formulations constituting the basis of the end results. The "internal mechanics" of computer simulation in such cases can be visualized if the user can reconstruct the way in which the simulation software

(a) solves each equation in the model, and

(b) takes the output of one equation and provides it as input to other equations of the model.

This can be accomplished using spreadsheet programs such as Lotus 1–2-3, QuattroPro, and Microsoft Excel. The limitations of the spreadsheet approach relate to

(a) the number of cells to be selected in the spreadsheet, and

(b) the runtime required to solve complex PBPK models.

Therefore, this approach is recommended for individuals who do not have sufficient knowledge of numerical integration algorithms and simulation software. Once a beginner understands how the PBPK models work using the spreadsheets-based methodology, he or she can move on to using advanced techniques and specialized simulation languages offering flexibility, speed, and additional features (sensitivity analysis, optimization routines, etc).

Hardware

The equations and algorithms constituting PBPK models can be solved using programming languages, simulation software, or spreadsheet programs on many types of computers—mainframes, workstations, microcomputers, or minicomputers. In general, for running large models, dedicated workstations and

multiuser mainframe computers offer the lowest execution times, thus providing overall time savings. For a PBPK modeler working with small models and simple descriptions, the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_216.html[2010/10/28 18:41:57]

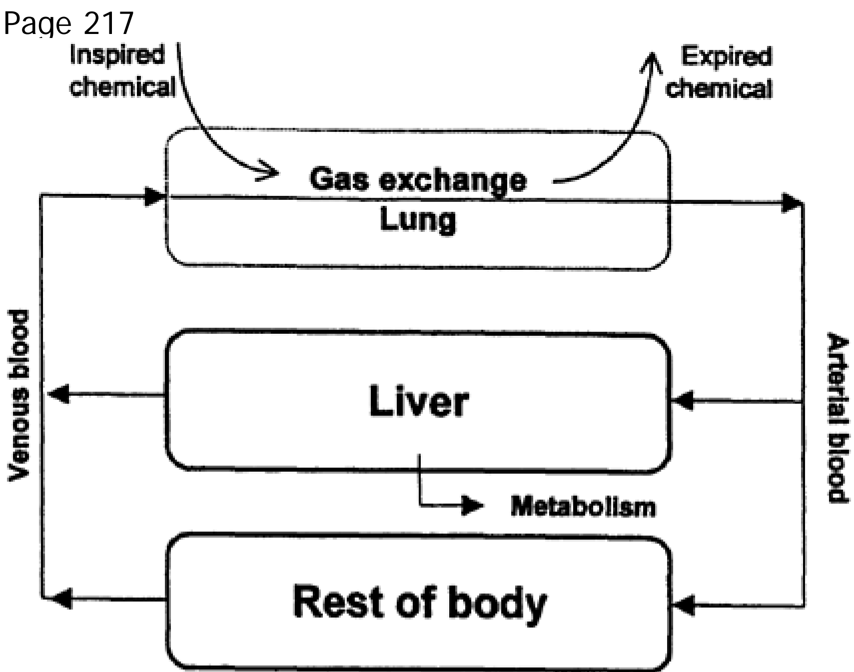

FIG. 5.14. Conceptual representation of a two-compartmental PBPK model for styrene in the rat.

Macintosh or IBM PC-based modeling packages are sufficient (114, 131, 145, 223). The processing speed, hard disk space, and run time memory of computers marketed currently are quite adequate for PBPK modeling. The methodological approach of PBPK modeling using spreadsheets is presented in the following section.

PBPK Modeling Using Spreadsheets

Consider a simple, physiologically based model with compartments interconnected by systemic circulation for simulating the pharmacokinetics of inhaled styrene in the rat (Figure 5.14). The parameters and equations of this hypothetical PBPK model should be entered in spreadsheets to obtain simulations of styrene pharmacokinetics in the rat. The numerical values for each of the PBPK model parameters should be entered into a specific cell in the spreadsheet and identified appropriately. For example, the numerical value contained in cell C5 is referred to as *Qp* (Table 5.8). Since the alveolar ventilation is referred to as *Qp* in this example, whenever *Qp* is typed in any other cell of the spreadsheet, the numerical value found in cell C5 will be imported automatically.

Table 5.9 lists the manner in which the model equations are written in the spreadsheets. In addition to the equations for computing blood concentrations, four equations per compartment are written. These correspond to the tracking of:

(a) the rate of change in the amount of chemical in tissue,
(b) the amount of chemical in tissue,
(c) the concentration of chemical in tissue, and
(d) the concentration of chemical in venous blood leaving tissue.

The calculation of the amount of chemical in tissue is based on the Euler algorithm. If intended, other integration algorithms can be used. In the various equations (Table 5.9), the model parameters are referred to using the appropriate abbreviations (e.g., *Qp*, *Qc*, *Vl*) and the variables are referred to with the use of relative reference expressions. The relative reference expression

Table 5.9

Equations used in the calculation of tissue, arterial and venous blood concentrations of styrene, and their expression in EXCEL spreadsheet.

Compartment	Equations*a*	Expression in EXCEL*b*
Arterial blood	$C_{a,n}=\frac{Q_c\times C_{v,n-1}+Q_p\times C_{inh,n}}{Q_c+Q_p/P_b}$	D36=((Qc*M35)+(Qp*C36))/(Qc+(Qp/Pb))
Liver	$dA_l/dt_n=Q_l\times(C_{a,n}-C_{vl,n-1})-\frac{V_{\max}\times C_{vl,n-1}}{K_m+C_{vl,n-1}}$	E36=(Ql*(D36-H35))–(Vmax*H35/(Km+H35))
	$A_{l,n}=dA_l/dt_{,n}\times t+A_{l,n-1}$	F36=E36*t+F35
	$C_{l,n}=\frac{A_{l,n}}{V_l}$	G36=F36/Vl
	$C_{vl,n}=\frac{C_{l,n}}{P_l}$	H36=G36/Pl
Rest of body	$dA_{bo}/dt_n=Q_{bo}\times(C_{a,n}-C_{vbo,n-1})$	I36=Qbo*(D36–L35)
	$A_{bo,n}=dA_{bo}/dt_n\times t+A_{bo,n-1}$	J36=I36*t+J35
	$C_{bo,n}=\frac{A_{bo,n}}{V_{bo}}$	K36=J36/Vbo
	$C_{vbo,n}=\frac{C_{bo,n}}{P_{bo}}$	L36=K36/Pbo
Venous blood	$Cv_n=\frac{Q_l\times C_{vl,n}+Q_{bo}\times C_{vbo,n}}{Q_c}$	M36=((Q1*H36)+(Qbo*L36))/Qc

*a*All abbreviations and symbols used in the equations, except n and n–1, are defined in Table 5.1. Subscripts n and n–1 refer to the current and previous simulation times. The difference between n and n–1 in the styrene example was 0.005 hr.

*b*The components of these equations refer either to absolute references (in the case of constant input parameters, as defined in Table 5.8) or to relative references (in the case of state variables).

involves referring to a cell according to its location relative to another cell where the calculation is being carried out. This option is particularly useful when the output of an equation contained in one cell is to be provided as input for an equation contained in another (e.g., adjacent) cell. Thus, the use of relative reference expressions in spreadsheets may be useful to facilitate loop-type calculations essential for advancing the state of a system during simulations.

Table 5.10 presents a part of the spreadsheet depicting how equations presented in Table 5.9 are actually entered into spreadsheets. Accordingly, in the spreadsheet, the descriptions of the two tissue compartments occupy eight columns (columns E–L, in Table 5.10 and Figure 5.15) and the calculation/representation of the simulation time, exposure concentration, arterial concentration, and venous blood concentration occupy one column each (columns B, C, D, and M, respectively). The mixed venous blood concentration resulting from that of the venous blood exiting the two tissue compartments described in a particular row is calculated in the same row (i.e., cell M35 in Table 5.10 and Figure 5.15). This *Cv* then is used along with *Cinh* (i.e., cell C36) to calculate *Ca* in the subsequent row (e.g., cell D36). In this structure then, according to the schematics shown in Figures 5.14 and 5.15, all model equations are interconnected by specifying the proven/hypothetical input-output connections among them.

Once

(a) the numerical values of model parameters are provided,
(b) the equations in the first and subsequent rows of the spreadsheet are entered,
(c) the time interval for integration is specified, and
(d) the required number of cells are chosen, the simulation begins.

One has only to repeat the calculations shown in row 36 of Figure 5.15 for each time interval of integration until the end of the desired duration of simulation. In the present example, the time interval of integration was fixed at 0.005 h. Each line in the Excel spreadsheet then rep-

35	=t	=Cinh	=[(Qc*0) + (Qp*C36)]/(Qc + (Qp/Pb))	=(Ql*(D36-0)) − (Vmax*0/(Km + 0))	=E36*t + 0	=F36/Vl	=G36/Pl	=Qbo*(D36-0)	=I36*t + 0	=J36/Vbo	=K36/Pbo	=[(Ql*H36) + (Qbo*L36)]/Qc
36	=t + B35	=Cinh	=[(Qc*M35) + (Qp*C36)]/(Qc + (Qp/Pb))	=(Ql*(D36-H35)) − (Vmax*H35/(Km + H35))	=E36*t + F35	=F36/Vl	+G36/Pl	=Qbo*(D36-L35)	=I36*t + J35	=J36/Vbo	=K36/Pbo	=[(Ql*H36) + (Qbo*L36)]/Qc

The row and column coordinates are designated by an Arabic numeral and an alphabetical letter, respectively. The equations found in rows 35 and 36 correspond to calculations at the first and second integration intervals. For continuing the simulation, the set of equations in row 36 should be copied onto desired number of subsequent rows. In this table, column B represents the state of the system which advances during each time interval (t). Column C contains the exposure concentration at any given time during the simulation, and columns D and M represent calculations of arterial and venous blood concentrations of the chemical. In between, four columns per compartment (e.g., liver: columns E–H, rest of the body: columns I–L) are devoted for calculation of

(1) the rate of change in the amount of chemical in tissue,
(2) amount of chemical in tissue,
(3) concentrations of chemical in tissue, and
(4) concentrations of chemical in venous blood leaving tissue. All abbreviations are defined in Table 5.8.

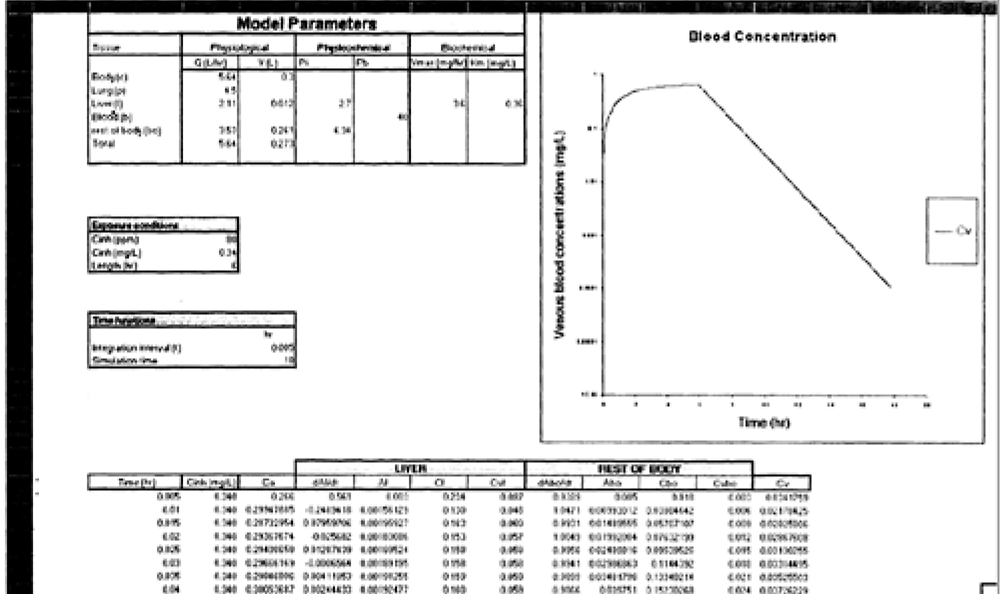

FIG. 5.15. Printout of a computer screen depicting an EXCEL spreadsheet with
(1) the plot of a two-compartment PBPK model simulation of venous blood concentrations of styrene during and following a 6-h exposure of rats to 80 ppm of this chemical,
(2) the numerical values of the PBPK model parameters, and
(3) a portion of the raw numbers corresponding to the rate of change in the amount of styrene in tissue, amount in tissue, concentration in tissue, and venous blood concentration leaving the tissues, generated during simulations between time 0.005 and 18 h.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_220.html[2010/10/28 18:41:59]

resents calculations characterizing the state of the system at every 0.005 h. In the present example, simulations were conducted for 24 h using 0.005 h as the integration interval (Figure 5.15). Therefore, in total, 4800(=24/0.005) lines were used up for conducting PBPK simulations. The solution to the set of PBPK model equations is generated every time the numerical values in cells corresponding to model parameters are changed, since these cells are specified in one or more equations appearing in the spreadsheet (Figure 5.15). Figure 5.16 presents simulations of the pharmacokinetics of styrene obtained using the parameters and equations for a four-compartment model developed by Ramsey and Andersen (223).

MODEL VALIDATION

Model validation refers to the evaluation of the adequacy of the conceptual and mathematical representations of the system under study in specific use conditions. Since PBPK models are only simplified representations of the actual systems, only those system variables that the investigator hypothesizes to be critical determinants are described in detail. The purpose of the validation process is then to determine whether all major determinants/processes that are essential for describing the system behavior have been adequately identified and characterized. When model predictions and experimental data agree, there is a higher level of confidence regarding the adequacy of the model and its use in decision-making (i.e., risk assessment). The approaches used for testing the adequacy of PBPK models can be classified into three categories:

(a) inspection approach,
(b) discrepancy measures, and
(c) statistical tests.

Inspection Approach

The testing of the degree of concordance between PBPK model simulations and experimental data to date has been conducted by eye balling or a visual inspection approach. This approach involves visual comparison of the plots of simulated data (usually continuous and represented by solid lines) with experimental values (usually discrete and represented by symbols) against a common independent variable (usually time). The rationale behind this approach is that the greater the commonality between the simulated and experimental data, the greater will be our confidence in the model. Instead of simply visualizing the degree of concordance between experimental data and simulation results, the residuals (i.e., difference between experimental and simulated data) can be examined. The residual analysis can be applied either to the whole model as it is or, in some other cases (as in diagnostic checkup during model building), to some estimated parameters of a tentatively ascertained theoretical model, so as to pinpoint inadequacies (122). The residuals should be random if the model is adequate. Time plots of residuals as well as the plots of residuals with respect to various controllable variables can detect possible model inadequacies, which can shed light on how to improve the model (122).

The inspection approach to model validation continues to be used pending the validation of statistical tests and discrepancy measure tests appropriate for application to PBPK models.

Statistical Tests

Statistical comparison of the model output with experimental observations is not as easy as it might appear. None of the classical tests (*t*, Mann-Whitney, two-sample *X*2, two-sample Kolmogrov, etc.) to determine whether the underlying distributions of the two data sets are similar is applicable, since the output processes of almost all real-world systems and simulations are non-stationary and autocorrelated. Furthermore, there is a question of whether the use of statistical hypothesis tests is even appropriate. Since the model is only an approximation of the actual system, a null hypothesis that the system and model are the same is clearly false. The more appropriate question is to ask whether or not the differences between the system and the model are significant enough to affect conclusions derived from the model. In this regard, Haddad et al. (109) screened various statistical procedures (correlation, regression, confidence interval approach, lack fit *F* test, univariate analysis of variance, and multivariate analysis of variance) for their potential usefulness in testing the degree of agreement of PBPK model simulations and experimental data obtained in intact animals. According to these authors, the multivariate analysis of variance represents the most appropriate test, with the variance for the simulation data permitting. Alternatively, lack of fit *F* test represents a useful way of evaluating the adequacy of simulation models. Particularly, this simple procedure permits the consideration of multiple data sets (e.g., data for several endpoints collected at various time intervals) in conducting such an evaluation of model validity.

The *F* statistic in model fitting may be defined as lack of fit

$$\frac{\text{Mean square}}{\text{Pure error mean square}}$$

This ratio is compared to the critical value of *F* at the required degree of confidence and the corresponding

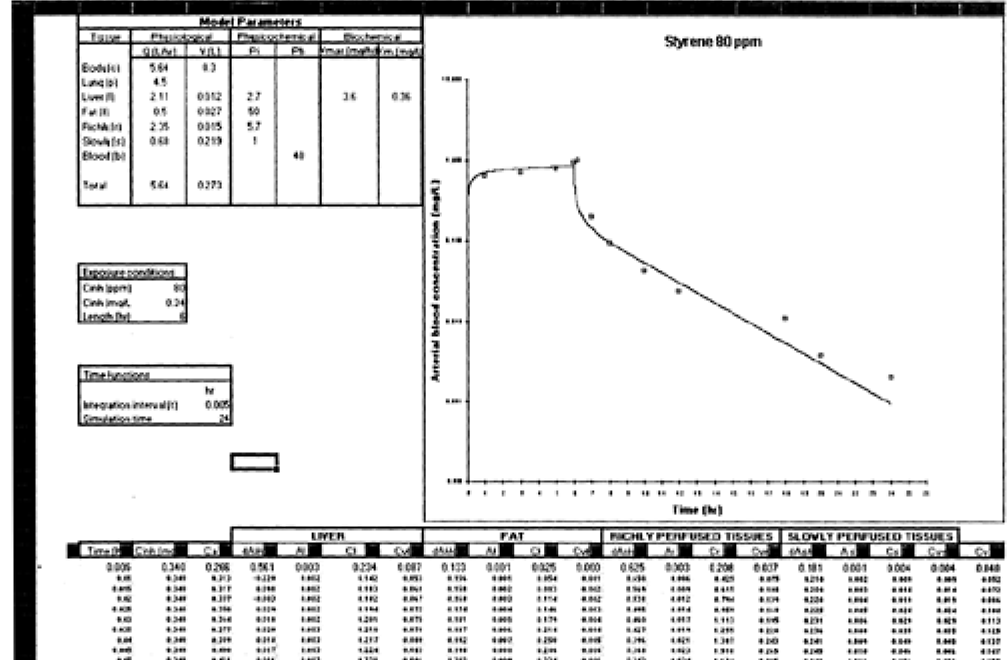

FIG. 5.16. Printout of a computer screen depicting an EXCEL spreadsheet with
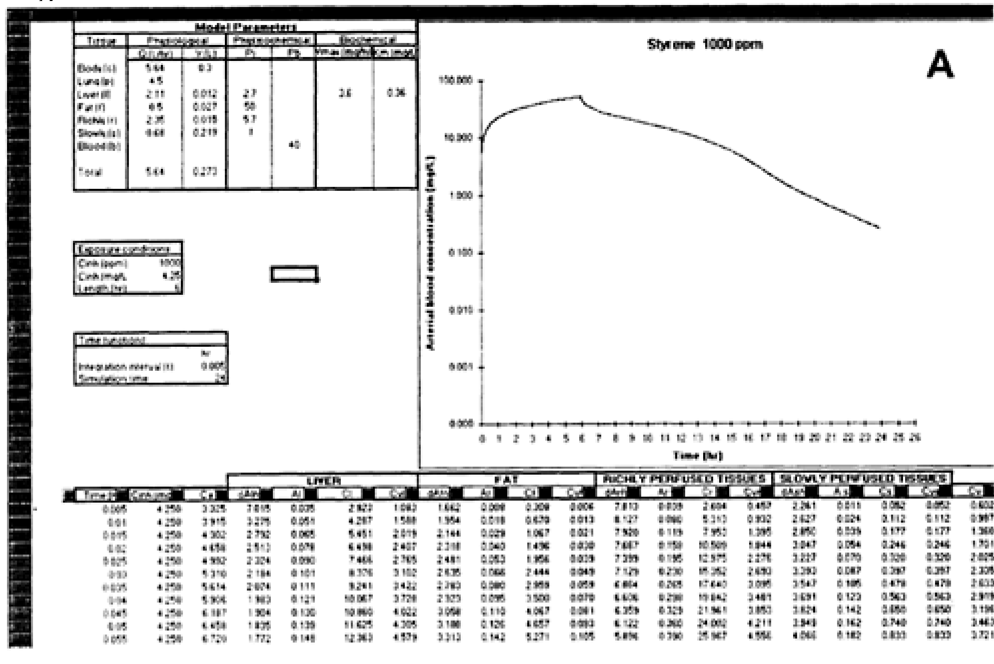
(1) the plot of experimental data (symbols) and a four-compartment PBPK model simulations (solid line) of arterial blood concentrations of styrene during and following a 6-h exposure of rats to 80 ppm of this chemical,
(2) the numerical values of the PBPK model parameters, and
(3) a portion of the raw numbers corresponding to the rate of change in the amount of styrene in tissue, amount in tissue, concentration in tissue, and venous blood concentration leaving the tissues, generated during simulations between time 0.005 and 24 h.
Experimental data were obtained with permission from Reference 223.



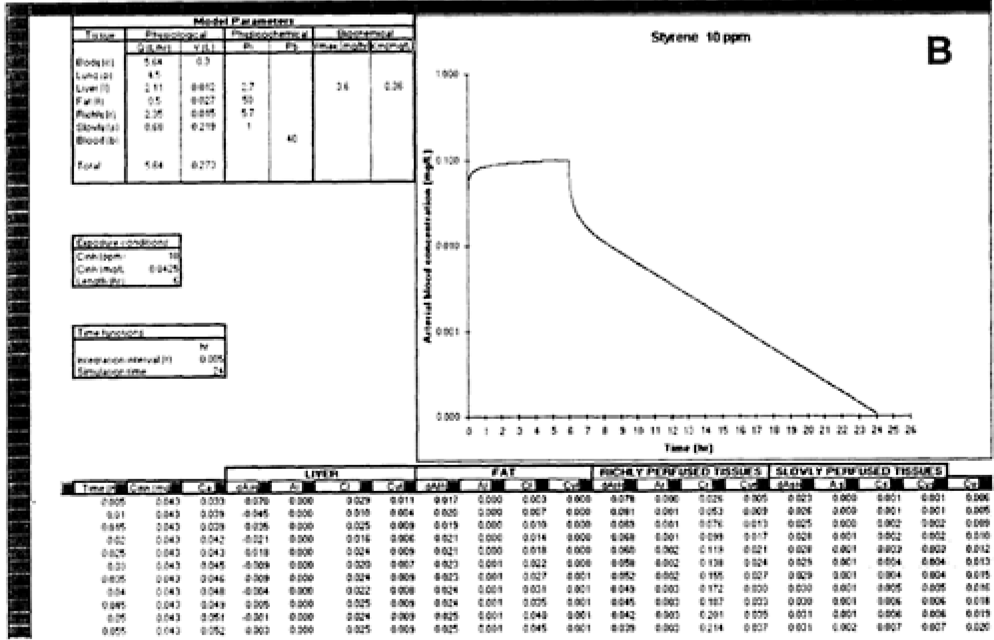


FIG. 5.17. Printout of computer screens depicting EXCEL spreadsheets with the PBPK modeling results obtained in rats exposed to
(A) 1000 ppm and
(B) 10 ppm of styrene.
Each of the two panels contain
(1) a plot of PBPK model simulation of arterial blood concentrations of styrene during and following a 6-h exposure,
(2) the numerical values of the PBPK model parameters, and
(3) a section of the raw numbers corresponding to the rate of change in the amount of styrene in tissue, amount in tissue, concentration in tissue, and venous blood concentration leaving the tissues, generated during simulations between time 0.005 and 24 h.
Note that only the exposure concentration (cell C19), and no other input parameter, differs between the two simulation exercises presented here.

degrees of freedom. If the above ratio is greater than F_{crit}, then the model is considered inadequate (122).

Discrepancy Measures

The application of appropriate statistical tests provides a means of evaluating whether or not model simulations are significantly different from experimental values. Regardless of the outcome of such statistical analyses, it is often necessary and useful to be able to represent, in a quantitative manner, the extent to which the model simulations differ from experimental data. In this context, Krishnan et al. (148) have developed a simple index, referred to as the PBPK index, to represent the degree of closeness or discrepancy between model predictions and experimental data used during the model validation phase.

This approach involved the calculation of the root mean square of the error (representing the difference between the individual simulated and experimental values for each sampling point in a time course curve), and division by the root mean square of the experimental values. The resulting numerical values of discrepancy measures for several data sets (each corresponding to an endpoint) obtained in a single experimental study are then combined on the basis of a weighting proportional to the number of data points contained in the data set. Such consolidated discrepancy indices obtained from several experiments (e.g., exposure scenarios, doses, routes, and species) are averaged to get an overall discrepancy index. The application of this kind of a "quantitative" method, which has not been done routinely yet, may help remove the ambiguity in communicating the degree of concordance or discrepancy between PBPK model simulations and experimental data. The routine calculation of this kind of index for PBPK models at the end of the model development phase should result in tagging each model with an index value, and such an open declaration of the face value of PBPK models might be appreciated by the end users.

MODEL REFINEMENT

Since errors or difficulties relating to computational representations can be solved easily, model failure during the validation stage would primarily reflect incorrect presentation of the system (i.e., conceptual representation), or failure to include specific mechanistic determinants or biochemical processes (i.e., mathematical representation). Further experimentation in such cases has resulted in significant improvement in the biological understanding of the system under study (39, 111).

The use of a discrepancy measure test or statistical test to show that a priori predictions of a particular end point are in agreement with the experimental data does not provide sufficient proof of the validity of the assumptions and model-building approaches used. These approaches are only useful in providing a quantitative measure of differences, and do not provide any information on either the model robustness or the reliability of the model structure. In this context, it is important to verify the influence of variability, uncertainty, and sensitivity associated with model parameters.

PBPK models contain a number of parameters; the uncertainty associated with the values of these parameters influences the predictions of tissue dose. Whereas uncertainty represents our imprecise knowledge about the actual value of a parameter, variability reflects the range of values for a parameter expected among individuals in a given population. On the other hand, sensitivity analysis refers to the evaluation of the effect of changes in the value of a particular parameter on tissue dose estimates provided by a PBPK model. Sensitivity is expressed as the magnitude of change in the endpoint of interest (e.g., tissue dose) as a function of change in the value of a particular model parameter. Sensitivity analysis involves determination of the response of the system to defined changes in the parameter values to identify the most critical model parameters. This approach does not provide an indication of the likelihood of a particular output or range of outputs. Monte Carlo methods are designed to provide an estimate of this probability, the idea being to make repeated computations using inputs selected at random that have the same statistical properties expected of each input parameter. After performing a large number of such computations, a statistical distribution of the output can be generated. If the output is sensitive to certain aspects of the model, then those aspects must be modeled carefully. Sensitivity and uncertainty analyses with PBPK models have been conducted with respect to specific endpoints, related either to pharmacokinetic behavior or to cancer risk estimates (21, 22, 41, 75, 114, 115, 119, 146, 213, 262, 263). The greatest potential for uncertainty/ sensitivity analysis is perhaps in improving experimental design and resource allocation in risk assessment-oriented research.

The validated PBPK models can be applied to predict the behavior of chemicals administered by various exposure routes, at differing doses, and in several animal species. This is particularly important because human health risk assessment is based on responses seen in animal toxicity studies in which the test

chemical is administered at high doses by routes often different from anticipated human exposures. With advances in mathematical modeling and molecular biology fronts, the tissue dose of chemicals in an individual can be simulated by accounting for the individual-specific information, including data on polymorphism of enzymes (73).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_224.html[2010/10/28 18:42:02]

MODEL APPLICATIONS

The principal application of PBPK models is to predict the target tissue dose of the toxic parent chemical or its reactive metabolite. Using the tissue dose of the toxic moiety of a chemical in risk assessment calculations provides a better basis of relating to the observed toxic effects than the external or exposure concentrations of the parent chemical (8, 16). Because PBPK models facilitate the prediction of target tissue dose for various exposure scenarios, routes, doses, and species, they can help reduce the uncertainty associated with the conventional extrapolation approaches.

High-Dose to Low-Dose Extrapolation

High-dose-low-dose extrapolation of tissue dose is accomplished with PBPK models by accounting for the nonlinear kinetic behavior of chemicals (39). The description of metabolism in these cases frequently involves the use of a Michaelis-Menten equation. Nonlinearity arising from mechanisms other than saturable metabolism, such as enzyme induction, enzyme inactivation, and depletion of glutathione reserves, also has been described with PBPK models (39, 70, 151). An example of high-dose-low-dose extrapolation is presented in Figure 5.17. Panel A of this figure shows the blood kinetic profile of styrene in rats exposed for 6 h to 1000 ppm styrene, whereas Panel B depicts the concentration vs. time course profile following a 6-h inhalation exposure to 10 ppm styrene. For conducting high-dose to low-dose simulation, in this particular example, the numerical value of the exposure concentration (indicated in cell C19) alone was changed. With the change in the numerical value of this input parameter, all calculations in the spreadsheet are carried out automatically, thus providing the simulations corresponding to the exposure concentration specified.

Route-to-Route Extrapolation

The extrapolation of the kinetic behavior of a chemical from one exposure route to another can be performed by adding appropriate equations to represent each exposure pathway. For simulating the intravenous administration of a chemical, a single input *(K0)* representing the dose administered to the animal can be included in the equation for mixed venous concentration:

$$Cv=(Qf\times Cvf+Ql\times Cvl+Qr\times Cvr+Qs\times Cvs+K0)/Qc \qquad (26)$$

More accurate description of intravenous administration includes the specification of time of infusion to calculate the rate of entry of the chemical. The parameters (iv dose, infusion time, and iv rate) essential for calculating the dose received intravenously should be included and linked to the rest of the equations constituting the PBPK model. Once the equations describing the route-specific entry of chemicals into systemic circulation are included in the model, it is possible to conduct extrapolations of kinetics. This approach is illustrated in Figure 5.18 for inhalation → iv extrapolation of the kinetics of styrene in rats. For simulating the inhalation pharmacokinetics, the iv dose is set to zero, while for simulating styrene kinetics following iv administration Cinh is set to 0 (Figure 5.18).

Similarly, for simulating oral absorption of a chemical, appropriate equations should be additionally included to describe process(es) occurring in the stomach compartment. At time zero, there is no chemical in the stomach. Appearance of the chemical in the stomach, and thereafter in the liver, will depend on the rate constant of absorption. For the chemical, whose oral absorption is first order, certain parameters (i.e., oral dose [mg/kg], rate of absorption [h−1)], and equations are added to basic inhalation model depicted in Figure 5.7:

$$\frac{dA_o}{dt} = K_o A_{stom} \qquad (27)$$

$$A_{stom} = D_o - \int_0^t \frac{dA_o}{dt} \qquad (28)$$

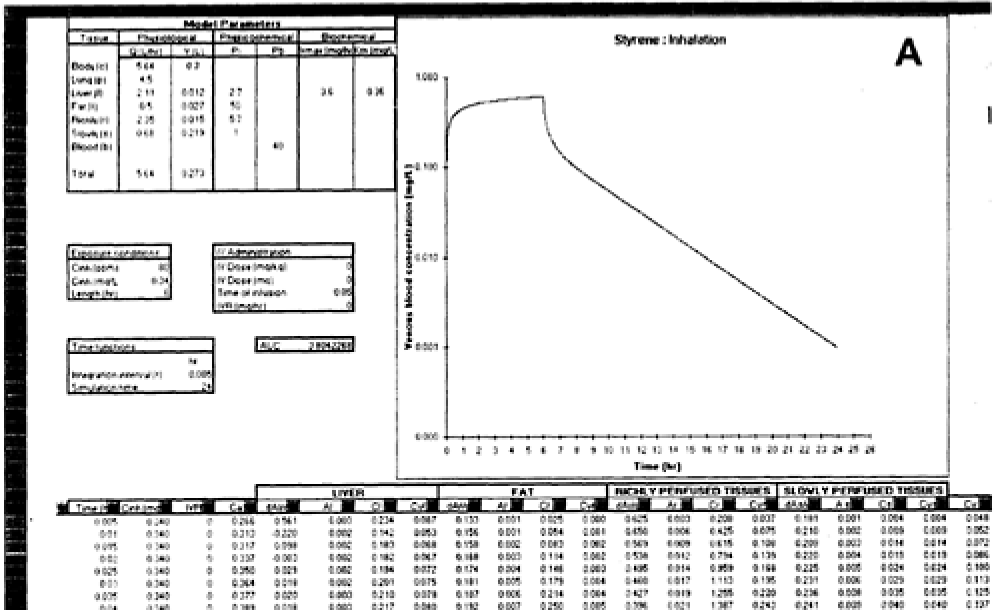
$$\frac{dA_l}{dt} = Q_l(C_a - C_{vl}) - \frac{dA_{met}}{dt} + K_o A_{stom} \qquad (29)$$

The above approach requires that parameters to define oral dose in mg/kg, and *Do* in mg and rate of oral absorption *(Ko)* be included along with mass balance equations for the stomach compartment and modifications to the liver reflecting the input from the stomach. More complicated descriptions may be required in certain cases depending on the vehicle of administration, extent of intestinal retention, and other factors (129, 251).

For simulating dermal absorption of chemicals, it is essential to introduce a skin compartment in the model and write the mass balance differential equation (MBDE) for that compartment. The chemical uptake by the skin may be described in the same way as the other tissues. To this MBDE, however, an

additional term to account for the absorption of chemical present in the environment should be added as follows (181):

$$\frac{dA_{sk}}{dt} = Q_{sk}(C_a - C_{vsk}) + K_p \times S[C_{air} - (C_{sk}/P_{s:a})] \quad (30)$$



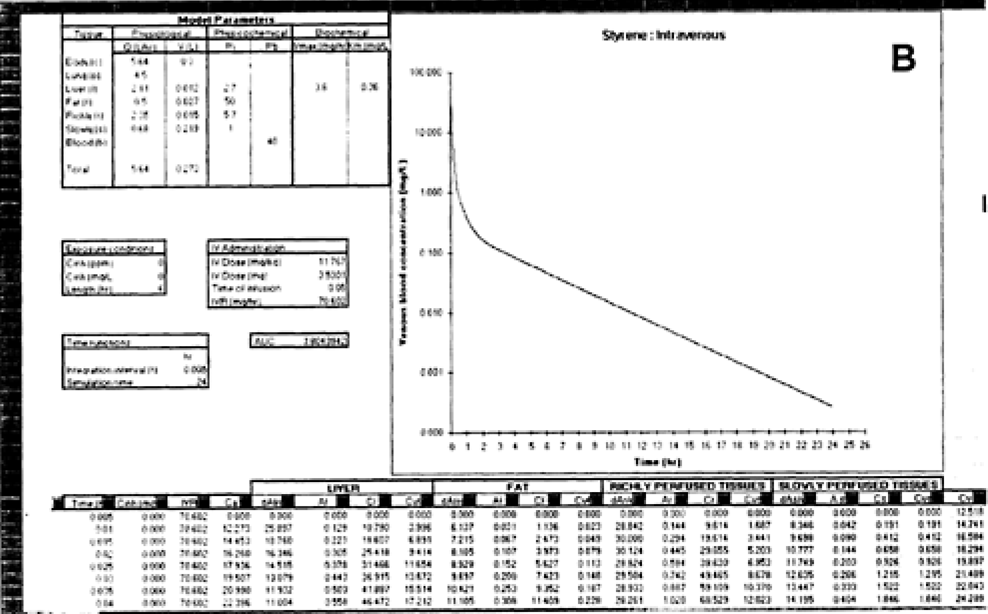


FIG. 5.18. Printout of computer screens depicting EXCEL spreadsheets with the PBPK modeling results obtained in rats exposed to styrene
(A) by inhalation (80 ppm, 6 h) or
(B) by intravenous administration (11.767 mg/kg). Each of the two panels contains
(1) a plot of PBPK model simulation of venous blood concentrations of styrene during and following exposure,
(2) the numerical values of the PBPK model parameters, and
(3) a section of the raw numbers corresponding to the rate of change in the amount of styrene in tissue, amount in tissue, concentration in tissue, and venous blood concentration leaving the tissues, generated during simulations between time 0.005 and 24 h.
Note that only the parameters related to the exposure route (Cinh, iv dose) differ between the two simulation exercises presented here.

(A) rats and
(B) humans exposed to 200 ppm of styrene.
Each of the two panels contains
(1) a plot of PBPK model simulation of arterial blood concentrations of styrene during and following a 6-h exposure,
(2) the numerical values of the PBPK model parameters, and
(3) a section of the raw numbers corresponding to the rate of change in the amount of styrene in tissue, amount in tissue, concentration in tissue, and venous blood concentration leaving the tissues, generated during simulations between time 0.005 and 24 h.
Note that the numerical values of all species-specific parameters are different between the two simulation exercises presented here.

Table 5.11

Algebraic expressions for calculated blood and tissue concentrations under steady-state conditions

Parameter	Algebraic expression
Concentration in arterial blood[a,b]	$C_{a,ss} = \frac{C_{inh}}{1/P_b + Q_{lc}E}$
Concentration in venous blood[b]	$C_{v,ss} = C_{a,ss}(1 - Q_{1c}E)$
Concentration in non-metabolizing tissues	$C_{t,ss} = C_{a,ss}P_t$
Concentration in metabolizing tissues (e.g., liver)b	$C_{l,ss} = C_{a,ss}(1 - E) \times P_l$

[a] If $Q_p \neq Q_c$, $C_{a,ss} = \frac{Q_p C_i}{Q_p/P_b + Q_l E}$

[b] $E = \frac{V_{max}/K_m}{(V_{max}/K_m) + Q_l}$

Exposure Scenario Extrapolation

PBPK models also have been used to predict the kinetic behavior and tissue dosimetry of chemicals during unusual exposure scenarios (39). The ability to predict tissue dose of toxic moieties of chemicals during short-duration exposures to higher concentrations or during variable-exposure concentrations is a real challenge. Such extrapolations can be conducted with PBPK models by introducing a mathematical function that is consistent with the temporal change in the exposure concentration. In the spreadsheet depicted in Figure 5.19, all one has to do is change the numerical value corresponding to exposure concentration (Column C) at specific time points as required. This capacity of the PBPK models has been used to determine the adjusted threshold limit values (TLVs) during extended hours of work (25, 156). Further, quantitative changes in pharmacokinetics of chemicals due to environmental, pathological, and physiological alterations can be predicted by perturbation of the appropriate model parameter(s), for example physical activity/workload (156, 243), pregnancy and lactation (82, 91, 149, 246), or co-exposure to chemicals (147). During continued exposures, a steady-state is attained. Steady-state is a condition during which the rate of change in concentration of parent chemicals in tissues is equal to zero. The steady-state concentrations predicted using PBPK models can also be obtained using simple algebraic equations (Table 5.11) (203).

Interspecies Extrapolation

For conducting interspecies extrapolation of pharmacokinetic behavior of a chemical, quantitative estimates of species differences in the model parameter values (i.e., partition coefficients [PCs], physiological parameters, and metabolic rate constants) should be obtained.

The tissue-air PCs of chemicals appear to be relatively constant across species, while blood-air PCs show some species-dependent variability (92, 97). Therefore, the tissue-blood PCs, for species (e.g., humans) to which the pharmacokinetic data are to be scaled, have been calculated by dividing the rodent tissue-air PCs by the appropriate (e.g., human) blood-air partition values (223). The tissue: air and blood: air PCs for volatile organic chemicals (VOCs) may also be predicted using appropriate data on the content of lipids and water in human tissues and blood (Table 5.6; Figure 5.8) (217, 220).

Even though the physiological parameters vary coherently across species, the kinetic constants for metabolizing enzymes do not necessarily follow any type of readily predictable pattern, making the interspecies extrapolation of xenobiotic metabolism difficult. It is therefore preferable to obtain the metabolic rate constants for xenobiotics in the species of interest. In vivo approaches for determining metabolic rate constants are not always feasible for application in humans. The alternative is to obtain such data under in vitro conditions while the default position is to scale the metabolic rate constants obtained in vivo in rodents or in vitro using rodent and human tissue fractions. In the case of chemicals exhibiting high affinity (low *Km*) for metabolizing enzymes, V max has been scaled to approximately the 3/4th power of body weight, keeping the *Km* species-invariant. This approach may be useful as a crude approximation but should be used only when other direct measurements of metabolic parameters are not available or feasible. An example of rat-human extrapolation of the kinetics of styrene using a PBPK model is presented in Figure 5.19. In this example, the model was validated using human data for styrene. Whenever the human data

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_228.html[2010/10/28 18:42:04]

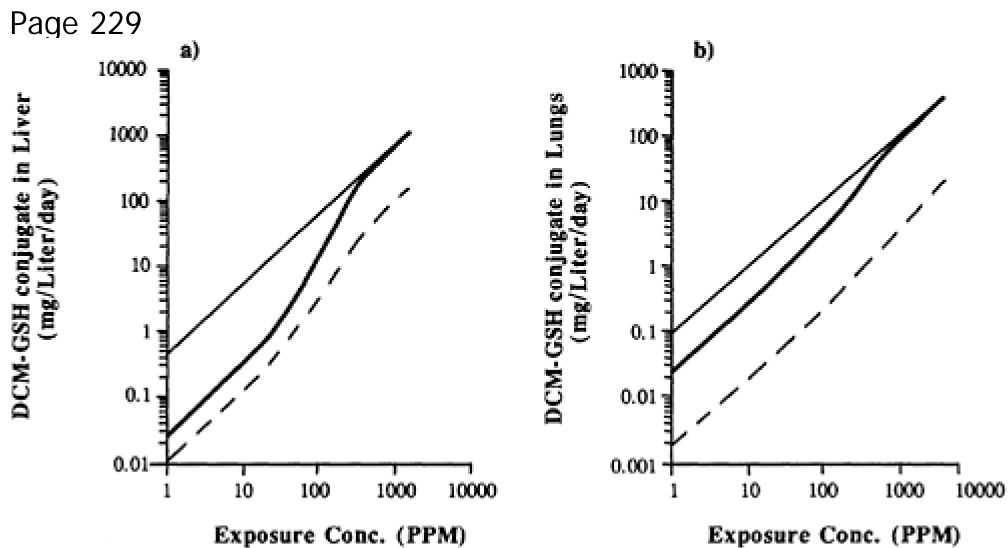

FIG. 5.20. Quantitative relationship between (a) liver or (b) lung dose of DCM-GSH conjugate and external exposure concentration of DCM determined with a PBPK model for B6C3F1 mice (heavy solid line) and humans (dashed line). The lighter solid line depicts linear back-extrapolation to 1 ppm. Redrawn with permission from Reference 10.

for a particular chemical are not available for validation purposes, a corollary approach permitting the use of human data on similar chemicals may be attempted (280).

Example of PBPK Model Application

The usefulness of PBPK models in reducing the uncertainties associated with high-dose-low-dose, route-route, and interspecies extrapolations has been demonstrated during the risk assessment process for a number of chemicals. This aspect was initially demonstrated with dichloromethane (DCM) (5). DCM caused liver and lung tumors in mice exposed to 2000 or 4000 ppm, 6 hr/day, for their lifetimes (189). DCM is metabolized by two processes:

(a) oxidation leading to the production of highly reactive formyl chloride, as well as carbon monoxide and small amounts of carbon dioxide, and

(b) GSH conjugation, yielding chloromethylglutathione (a reactive intermediate) and carbon dioxide (152).

Either of the reactive metabolites resulting from the oxidation or GSH conjugation could be involved in the mutagenic changes leading to cancer. In the PBPK model for DCM, these metabolic pathways were described according to their different kinetic characteristics. DCM metabolism in lung and liver was described with a saturable term for oxidation and with a linear term for reaction with GSH (5).

The PBPK model for DCM developed for the mouse by integrating quantitative information on physiological characteristics, partition coefficients, and metabolic rate constants, described adequately the disposition of DCM. The mouse DCM model then was used to calculate the tissue dose of metabolites and parent chemical arising from exposure scenarios comparable to those of the NTP bioassay studies (Table 5.12). The relationship of tissue dose of metabolic and parent chemical to the observed tumor incidence then was examined. Since the parent chemical is unreactive, it is unlikely to be directly involved in the tumorigenicity. Hence, the relationship between the tissue exposure to its metabolites and tumor incidence was examined (Table 5.12). Although the dose surrogate based on oxidative pathway did not vary between DCM exposure concentrations of 2000 and 4000 ppm, the flux through the GSH pathway did correspond well with the degree of DCM-induced cancer at these exposure concentrations. These observations are consistent with a role for the metabolite(s) arising from the GSH conjugation pathway in DCM-induced lung and liver cancer. The GSH conjugation of DCM, mediated by glutathione *S*-transferase enzymes, yields

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_229.html[2010/10/28 18:42:05]

Table 5.12

Tumor incidence and calculated tissue dose of dichloromethane (DCM) metabolites following inhalation exposures of 0, 2000, or 4000 ppm DCM in female mice

DCM exposure concentration	Tumor incidence (%)	Tissue dose (amount in mg/liter tissue/day)	
		GSH pathway	Oxidative pathway
	A. Liver		
0	6	—	—
2000	33	851	3575
4000	83	1800	3701
	B. Lung		
0	6	—	—
2000	63	123	1531
4000	85	256	1583

formaldehyde as a metabolite. Casanova et al. (32) reported DNA–formaldehyde-protein crosslinks resulting from DCM exposure, further strengthening the case for GSH conjugation as the pathway leading to potentially carcinogenic metabolites. Therefore, high-doselow-dose extrapolation and interspecies extrapolation of DCM-induced cancer risk were conducted with the tissue dose of the GSH pathway metabolite predicted by the PBPK model.

High-Dose-Low-Dose Extrapolation

The model prediction of the target tissue dose of the DCM-GSH conjugate resulting from 6-h inhalation exposures to 1–4000 ppm of DCM is presented in Figure 5.20. The estimation of target tissue dose of DCM–GSH conjugate by linear back-extrapolation gives rise to a 21-fold higher estimate than that obtained by the PBPK modeling approach. This discrepancy arises from the nonlinear behavior of DCM metabolism at high exposure concentrations (Figure 5.21). At exposure concentrations exceeding 300 ppm, the cytochrome P450-mediated oxidation pathway is saturated, giving rise to a corresponding disproportionate increase in the flux through the GSH conjugation pathway.

Interspecies Extrapolation

The interspecies extrapolation of DCM disposition behavior was possible because the critical biological determinants were first identified in the test species, the mouse. Thus, the physiological parameters in the mouse PBPK model were scaled allometrically, the metabolic parameters were determined experimentally, and

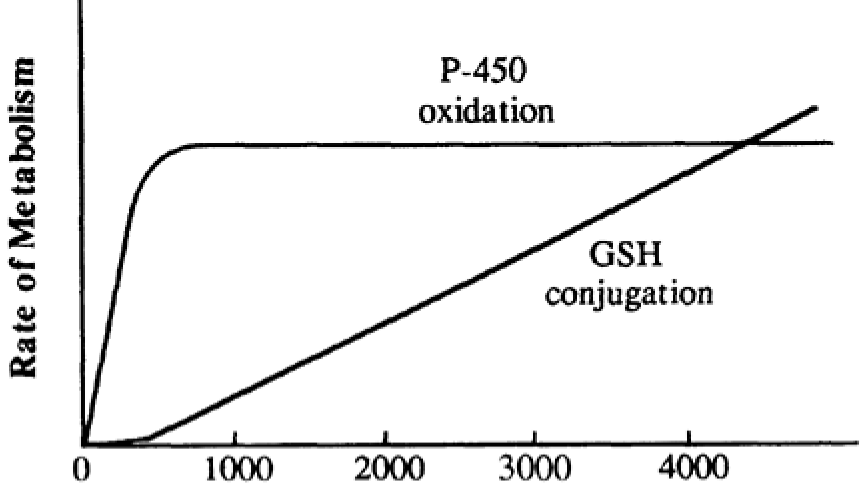

FIG. 5.21. Representation of the rate of metabolism of dichloromethane (DCM) at various inhaled concentrations. DCM is metabolized by P450-mediated oxidation and by conjugation with GSH. These two metabolic pathways have different characteristics. At low inhaled concentrations, oxidation is the preferred manner of metabolism, but at higher concentrations GSH conjugation becomes more favored. From Reference 10, with permission.

the tissue–blood PCs were assumed to be species-invariant. The PBPK model adequately simulated the blood levels of DCM observed in humans after a 6-h inhalation exposure to 100 or 350 ppm DCM. The target tissue-dose for humans was estimated to be some 2.7 times lower than that for the mouse. Considered together, the human tissue dose of DCM-GSH conjugate for a 6-h exposure to 1 ppm DCM is expected to be some 57 times lower than that expected by linear extrapolation of its behavior at high exposure concentrations, such as the ones used in the mouse cancer bioassay.

The cancer risk assessment for DCM, then, was conducted using the linearized multistage (LMS) model to relate tissue dose of DCM-GSH metabolite (rather than DCM exposure concentration) to the tumor incidence rates observed at high exposure concentrations in the mouse. In assessing the tumorigenic risks associated with human exposure to this chemical, it was assumed that humans are as sensitive as the most sensitive test species. Therefore, equal target tissue doses are expected to produce similar tumor incidence regardless of the species. This PBPK model-based DCM risk assessment predicted human low-dose risk about 100- to 200-fold less than that predicted by the U.S. Environmental Protection Agency (EPA) using standard default assumptions (249). With further refinement of the model with the estimation of the metabolic rate constants for humans in vitro (231), the PBPK model-based approach using tissue dose of the DCM-GSH conjugate predicted a cancer risk of 3.7×10^{-8} for a lifetime inhalation exposure of 1 $\mu g/m^3$.

Table 5.13

Examples of chemicals for which risk assessment has been performed using PBPK models

Chemical	References
Benzene	47
Chloroform	227
1,4-Dioxane	161, 229
Methylene chloride	213
Tetrachloroethylene	30, 34, 267
Trichloroethylene	19, 38, 49, 84
Vinyl chloride	38, 226

This risk estimate was still lower, by more than two orders of magnitude, than that calculated by the EPA using the standard default assumptions and exposure concentrations of DCM (270).

Following the DCM example, there have been several reports of the use of PBPK models for enhancing the scientific and mechanistic basis of cancer and non-cancer risk assessments of environmental agents (37, 197), (Table 5.13) The use of PBPK models in quantitative risk assessment does not always result in the estimation of risk lower than that derived from the conventional approach adopted by regulatory agencies. For example, if the test chemical is a direct-acting agent, the PBPK approach actually could predict greater risk to humans than conventional methods because enzyme-mediated metabolic clearance (detoxification) is expected to be lower in larger species. Similarly, if the toxicity of a chemical is mediated by reactive intermediates resulting from a saturable metabolic process, then the high-dose-low-dose extrapolation conducted with the PBPK modeling approach would predict a risk greater than that predicted by the linear extrapolation procedure.

CONCLUDING REMARKS

Modeling, in general terms, involves mathematical description of the interrelationships among critical parameters that determine the behavior of the system under study. Mathematical models can be constructed to fit experimental data by adjusting one or more model parameters, or by deriving an equation that describes the data. The latter approach reflects the methodological basis of conventional pharmacokinetic models. This approach might well be sufficient to describe the kinetics of prescription drugs and other pharmaceutical products, since these substances are often tested in humans in the dose range of prescription. Such empirical models are not sufficient in the case of environmental contaminants for which human health risk assessments need to be performed based on data obtained in animal studies conducted by administering high doses of chemicals by routes often different from anticipated human exposures. In this respect, mechanistically based PBPK models are useful for conducting the required extrapolations. So, the kind of modeling approach—physiological or nonphysiological—that is required/sufficient to describe the kinetics of a chemical depends on the intended use. If extrapolation to untested scenarios and design of useful mechanistic toxicology studies is the goal, then the choice will be PBPK modeling. However, the ability to conduct extrapolations with PBPK models will be compromised if the methods employed for developing and validating the models are inappropriate.

For example, PBPK models should not be constructed by assembling sets of equations, in which the parameters are not interpretable in terms of physicochemical, biochemical, or physiological properties. That sort of an approach will compromise the very basis of PBPK modeling, that is, the mechanistic basis. In other words, the mathematical equations employed in PBPK modeling should show clearly the interrelationships among the critical biological determinants. One should be able to dissect each equation into subsections, each of which describes a particular phenomenon (e.g., tissue uptake, metabolism). Further, the dissociation of each term should provide parameters that are biologically meaningful (e.g., breathing rate, tissue volume). If the mathematical descriptions employed in the model do not satisfy this basic criterion (i.e., use biologically relevant parameters), then it should not be considered a "true" physiologically based model, and the appropriateness of the use of such models in conducting extrapolations is questionable. The guiding principles of modeling in toxicology and the characteristics of a good modeling paper are summarized elsewhere (4).

A related problem is circularity in PBPK modeling. This aspect refers to the practice of using sets of experimental data to construct the model and then using the model to simulate the same data. Even though such an approach provides a framework to integrate various data sets, it does not instill confidence in using the model to predict the kinetic behavior of chemicals at untested exposure scenarios. Genuine PBPK modeling efforts should ensure that

(a) the assumptions on which the model is based are appropriate,

(b) the coding of model equations is errorless,
(c) the model parameter values are accurate, and
(d) the model is adequately tested/validated.

The model is as good as the input parameters. Therefore, accurate parameterization is fundamentally important for constructing useful PBPK models.

Methodological aspects of some of the important and widely used techniques for model parameterization were provided in the earlier sections of this chapter. A number of prototypical descriptions have also been provided to serve as examples for developing PBPK models for other chemicals of interest. These prototypical structures and descriptions may not be directly applicable to a chemical of interest to the researcher. The model structure and the phenomena to be represented in a particular model depend on the chemical whose kinetics are being modeled. Each chemical may possess some unique properties, thus presenting some very different problems and requiring the modification of existing model structures and functional representations. This might lead to the development of totally new descriptions. Thus, PBPK modeling is as much an art as a science. The creativity of the researcher is as much implied in the formulation of these models as the experimental techniques to obtain parameter estimates, such that novel model structures and descriptions will evolve continually in this field.

Parameter identifiability and model overspecification are problems inherent in these PBPK models or in any other multiparameter model. Direct measurement of model parameters by experimental methods, independent of analysis of tissue time-course curves, is the preferred approach. Nonetheless, limited numbers of parameters often will still have to be estimated by analysis of time-course data by curve-fitting techniques, under well-defined experimental conditions where the curves are particularly sensitive to the parameter(s) of interest.

The motivation for the use of PBPK models in toxicology research is to uncover the biological determinants of tissue dosimetry. These models are part of a systematic approach to studying how chemicals gain entry into, are distributed within, and are eliminated from the body. A major advantage of PBPK models is their use in designing critical mechanistic toxicological studies. With respect to the design of studies, PBPK and other biologically based models provide an opportunity to evaluate the various plausible hypotheses by computer simulation. We can ask questions of an "if-then" nature. For example, if the model structure is correct and the rate of a reaction or another process is varied, what is the expected impact on tissue dosimetry? The PBPK model can be used to generate quantitative predictions of the expected experimental outcome based on the most attractive hypothesis of the experimentalists, and this then can be verified experimentally. In this case, the model serves as a tool in designing experimental studies to enable efficient resource utilization and maintenance of the focus on human health risk assessment endpoints.

For example, examining the PBPK model-based risk assessment approach for DCM presented in this chapter, the following questions arise: Is GSH conjugation really the key determinant in DCM tumorigenesis? Are all the important biological determinants of uptake, metabolism, and disposition of DCM included in the model description? These are essentially biological, research-oriented questions with answers that rely on the state of knowledge of mechanisms of toxicokinetics and carcinogenicity of this chemical. Further, in the DCM example presented in this chapter, the low-dose extrapolation of the tissue response was conducted with the LMS modeling approach. The improvement over the conventional methodology is that here the independent variable specified in the LMS model—dose—is not administered dose or inhaled concentration; it is the tissue dose of the toxic moiety estimated with the PBPK model. The uncertainties associated with the low-dose extrapolation using the LMS model can be addressed with the use of biologically based response models (43).

Unlike the mandated mathematical models used in conventional risk assessment, the biologically based dosimetry and response models are versatile and, often, but not always, difficult to validate. In contrast to the "mandated" models, which are useful only for generating a risk number, the biologically based models allow integration of various observations, identification of critical data gaps, and estimation of risk numbers, along with attendant appreciation of areas of significant biological uncertainty.

QUESTIONS

1. Calculate the fat: blood partition coefficient for a chemical with a *Po:w* of 152.
2. Develop a conceptual representation for PBPK modeling of human exposure to airborne n-octane (*Po:w*=151356, *Pw:a*=0.00762).
3. Calculate the alveolar ventilation rate *(Qp)* for a human weighing 64 kg, knowing that the body weight-normalized *Qp* for mammals is 15 L/hr/kg.
4. The *V*max and *Km* of pyrene determined in vitro using rat liver post-mitochondrial fractions were 5.935×10^{-4} μmol/min per mg protein and 27.73 *μ*mol/L, respectively. Convert these potentially useful in vitro values for incorporation into in vivo model (protein concentration=88 mg protein/g liver, and liver weight=10 g).
5. Using the rat PBPK model for styrene presented in Figure 5.16 of this chapter, determine the external exposure concentration of styrene corresponding to an area under the curve for liver concentration of

150 mg/L/h (for the parent chemical). Set the exposure duration and the length of simulation to 24 hr.

GENERAL OVERVIEW OF DRUG DEVELOPMENT

The World Health Organization (WHO) Scientific Group has defined a drug as "…any substance or product that is used or intended to be used to modify or explore physiological systems or pathological states for the benefit of the recipient" (152). The drug discovery process covers a wide range of therapeutic areas and treatment regimens, and is a risky, multifaceted, expensive undertaking. The goal is to develop a new product with therapeutic benefits (efficacy) and few side effects (toxicity) (3). The drug development process for a new chemical entity (NCE) starts at the chemist's bench with its isolation; moves through efficacy pharmacology testing using various in vivo and in vitro models; then proceeds through an abbreviated toxicology profile, including pharmacological profiling (the determination of pharmacological effects other than the desired therapeutic effect), based on the proposed clinical plan for first human dose (FHD).

The principal aim of nonclinical safety testing is to understand the toxicity of the candidate drug well enough to make a judgment that it is safe to initiate clinical trials (89). Provided the efficacy pharmacology and initial toxicology profiles are acceptable, clinical safety, pharmacokinetic, and pharmacodynamic studies are initiated. As the human clinical trials progress, the drug candidate moves through nonclinical subchronic studies, chronic, and developmental toxicology studies, and oncogenic evaluations. Zbinden (209) has provided a summary of the biological parameters that should be evaluated for new drug candidates (Table 6.1).

The technical risks in new drug development programs are enormous. The risk of failure related to one or more of these aspects has been reviewed by Chien (26), where it is reported that <0.02 percent of NCEs result in marketed drug products, and even fewer, 0.002%, return a profit to support continued drug research (Figure 6.1). Very little of what enters the drug development pipeline ever enters the marketplace (58). It has been estimated that the cost of developing a NCE ranges from $0.5 billion to $1.2 billion.

By its nature, a drug must modify a biological process, that is, alter or adjust a physiological system in some way (43). Toxicology is a critical part of both earlyand late-phase drug development. The role of toxicology in that process has been extensively reviewed (79, 55, 59). The initial purpose of toxicology testing programs is to identify the circumstances—for example, dose, treatment duration, route—under which a NCE produces potentially harmful effects (44). A general approach to developing a toxicity profile for a pharmaceutical agent is given in Figure 6.2, and will be discussed more extensively below. During the discovery process, toxicologists employ rapid, quantitative screening methods, focusing on a limited spectrum of toxicity, to help identify potential drug candidates with the best safety profile. These early

screening procedures, however, are only a prelude to the required comprehensive safety assessments expected from the toxicologist. Regulatory requirements, termed Good Laboratory Practices (GLPs), dictate many aspects of the toxicology study protocol, and must be followed closely for all definitive (those that support human studies) toxicology studies (64). The early toxicology studies, conducted in the discovery phase, are not required to be in full compliance with the GLPs.

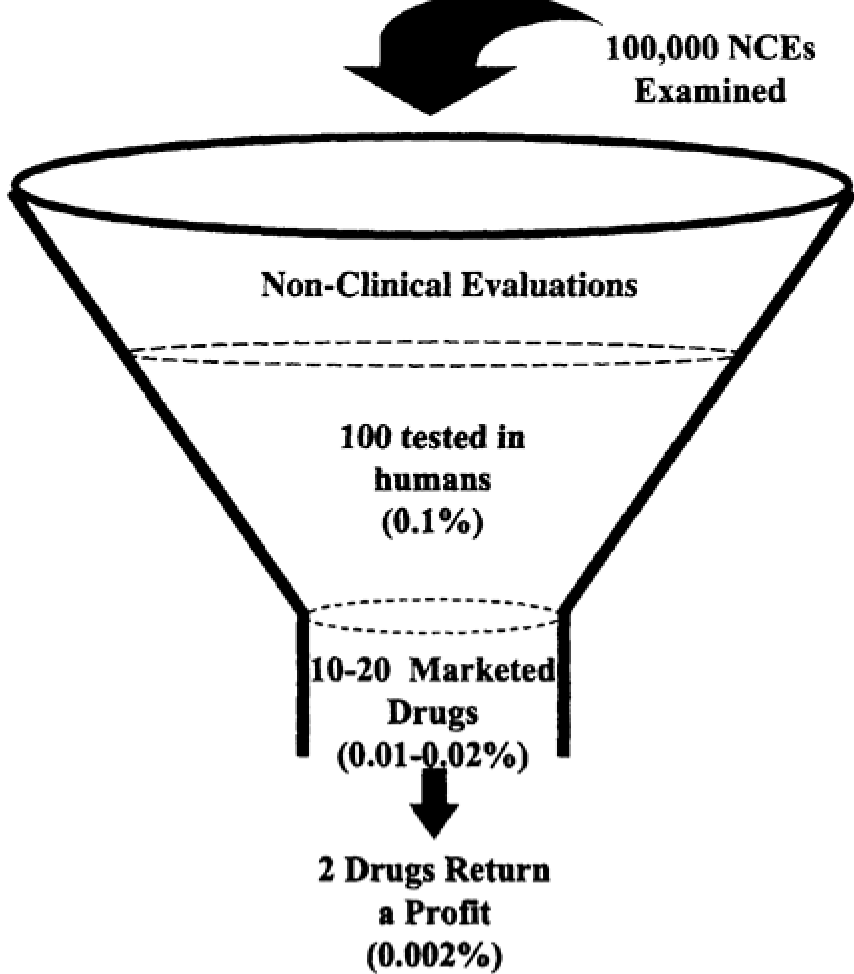

FIG. 6.1. Attrition rate of new drug candidates. Drawn from information presented in Reference 28.

Prior to initiating clinical trials, physicians need an estimate of the extent of toxicity produced by the drug candidate in relevant animal models. Obviously, prior to FHD, the determination of the relevance of animal models, that is, metabolism relative to humans, is limited to in vitro evaluations using human and animal tissue preparations. On the basis of the clinicians' needs, the toxicology profile of a NCE is characterized by a number of questions (124):

• What dose/exposure produces toxic effects in animals?

- What dose/exposure does not produce toxic effects in animals?
- Were the animals relevant models for predicting human toxicity?
- What were the signs and duration of toxic responses?
- Did effects differ following single or multiple dosing?
- Were the toxic responses reversible?
- What were the target organs or systems?
- Was the toxicity expected for this chemical class?
- Are toxic metabolites produced?
- Was accommodation to the toxic effects observed?

The answers to these questions form the basis of the toxicology profile supporting initial and continued clinical trials.

The major objectives of toxicological evaluation change according to the stage of the development process (208). The early stages of development focus on toxicological screening (Table 6.2). Definitive toxicology studies are very time-consuming and costly. Thus, relatively inexpensive, short-term screening procedures are used to eliminate the most toxic compounds (205). Inherent to these initial approaches to evaluate potential drug toxicity are a number of imperfections—the affected systems may not be routinely examined; the assay procedures are inadequate or improperly timed relative to the onset of the toxic response; target organ exposure is insufficient; there is an inability to identify and measure adverse effect (lack of functional evaluations); there is an inability to predict metabolic, anatomical, and physiological differences between species; and, the test animals may not express human-specific responses (212). There is no simple answer to the often asked question: "What toxicity profile would cause a company to stop development of a new drug candidate?" (100). However, the demonstrated toxicity of other compounds in the class, if available, and the gravity of the disease state under study often provide guidance as to what might be an acceptable safety profile for a NCE. Varied opinions on the occurrence of drug toxicity in the human population have been reported (31, 115).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_244.html[2010/10/28 18:42:14]

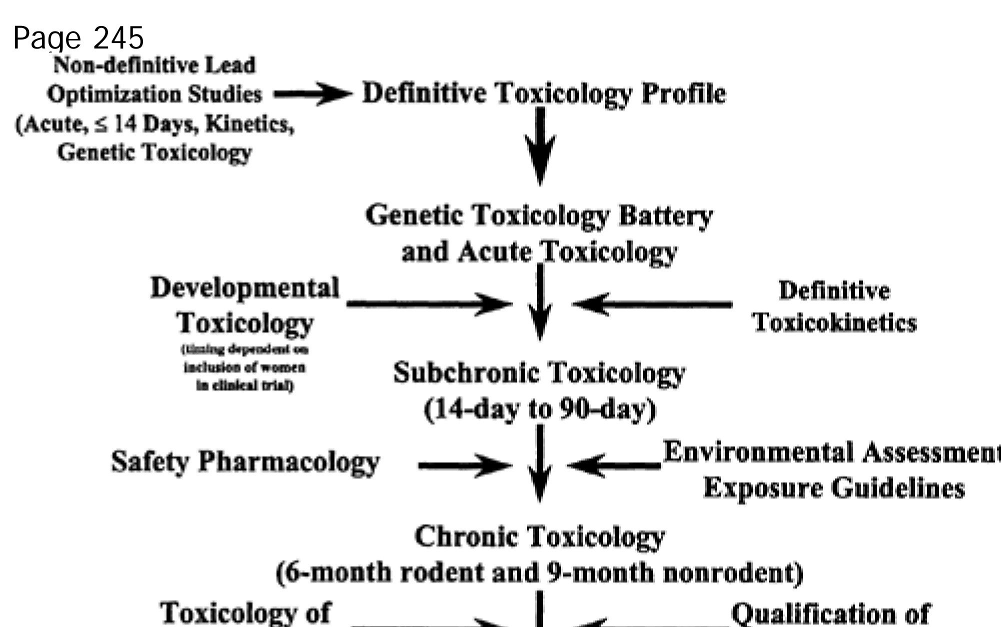

FIG. 6.2. General approach to developing a toxicity profile for pharmaceutical agents.

Although the magnitude of adverse responses seems small—1 per 10,000 patients demonstrates untoward adverse reactions (115)—focus must be placed on identification of all potentially adverse effects (31).

In addition to the drug substance, the delivery system may also require nonclinical evaluation because it may alter pharmacodynamic (action of the drug on the body) and pharmacokinetic (action of the body on the drug) relationships. The regulatory requirements for known and novel drug delivery systems have been reviewed by Weissinger (192).

Commercially advantageous forms of genetic manipulation date back to antiquity, that is, inbreeding, cross fertilization, and so on. The introduction of modern recombinant DNA (rDNA) technology has had a major impact on life science research, and has allowed for the large-scale production of protein pharmacological agents that would have been very difficult to produce by normal chemical synthetic means.

A New Biological Entity (NBE) is defined as a complex, high molecular weight material, which cannot be fully characterized by standard chemical analysis, and which

may require immunological, biochemical, or bioassay techniques to measure the quantity present and to assess activity (46). The development, utility, and relative safety of human insulin (83), human growth hormone (133), and interferon (139) have fueled the current interest in the production of biologically active peptides. As the interests of pharmacologists in biotechnology research expand, the difficulties of producing a comprehensive set of safety guidelines increase.

As NBEs were introduced, starting with insulin, regulatory concepts were not in place to address the problems presented by this new technology (210). The regulatory issues relating to recombinant products are formidable, and the possibility that each biotechnology product might require customized safety testing has been given serious consideration (40, 163, 171). Clearly, the immunological response to foreign proteins may compromise the utility of using traditional animal models in the safety assessment of these agents. Other major regulatory issues include the assurance that recombinant production methods do not result in addition of contaminants, and the demonstration to regulators that biosynthetic products are identical to natural substances (81). In the biosynthetic human insulin approval process, meetings between regulatory agencies and industry scientists to review the manufacturing process, molecular biology, and purification of the hormone, as well as clinical trial programs, were critical in facilitating eventual approvals. Industry and regulatory agency representatives agreed that the chemistry of a NBE should prove its identity (188). The identity and purity of the rDNA insulin, therefore, received much attention (26). Anticipation of problems, and communication of concerns, was the key to the rapid New Drug Application (NDA) approval for biosynthetic human insulin (5.5 months). The U.S. Food and Drug Administration (FDA) has strongly recommended that it be involved early in the nonclinical and clinical development plan to facilitate the approval process for both NCEs and NBEs (87). The U.S. biotechnology policy states "...the same physical and biological laws govern the response of organisms modified by modern molecular and cellular methods and those produced by classical methods. ... No conceptual distinction exists between genetic modification of plants and microorganisms by classical methods or by molecular techniques that modify DNA and transfer genes" (183). Thus, it would not be expected that NBEs, per se, pose an unusual risk to human health and the environment (183). The toxicologist should be aware, however, that compounds made via rDNA techniques are not necessarily identical to the natural material, as might be assumed (198). Dayan (45) suggested that the toxicology profile for a NBE should be defined in terms of chemical identity of the material, extent of prior knowledge, and intended use. The U.S. Pharmaceutical Research and Manufacturers Association (PhRMA) has recommended that nonclinical toxicological evaluations of NBEs should be decided on a case-by-case basis (171), and regulatory and industry representatives attending the first International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) also supported this position (111). The established toxicology information will guide the clinical trial and address possible hazards in the workplace, where humans are exposed to the compound, and its precursors and contaminants that are also contained in the bulk material to be tested, during the chemical or biological synthetic process.

The role of the toxicologist is usually less routine and requires more innovation in study design when dealing with NBEs than when dealing with NCEs (46). However, as is the case with NCEs, the principal goals of the toxicological evaluation of recombinant products are: to detect major toxicity; to identify lesser toxicity; to determine the dose relationship of toxic effects and their duration in order to guide the clinical dose schedule; and, to investigate the mechanisms of action related to the toxic response. There are three main areas of concern relative to the toxicity of NBEs: toxicity per se, exaggerated pharmacodynamic effects (anticipated toxicity based on the pharmacological mechanism of action), and allergic reactions (210) (Figure 6.3). Intrinsic toxicity has been defined as undesirable effects having no obvious relationship to the molecule's pharmacodynamic properties. Pharmacodynamic toxicity is defined as an exaggerated pharmacological response, e.g., hypoglycemic shock from insulin. Immunotoxicity has been related to hypersensitivity, cell transformation, and production of neutralizing antibodies. The loss of a recombinant therapeutic agent's biological activity through production of neutralizing antibodies or the development of immune complex disease in experimental animals are factors that must be given individual attention (171). It has been suggested that animal models of immunotoxicity are of limited usefulness because no animal model may be fully suitable for predicting the toxicity of highly species-specific proteins. Friedmann (78) has indicated, however, that the lack of hypersensitivity reactions in response to small peptides in animal experiments may be viewed as an indication of their acceptability in humans. Graham (88) emphasized the use of a case-by-case approach to toxicological evaluations of NBEs based on their similarity to natural human proteins, immune response in animal models, and production of neutralizing antibodies in nonclinical and clinical studies.

The unique regulatory approval of recombinant insulin most likely resulted in unrealistic expectations in the biotechnology industry regarding the rapidity of review

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_246.html[2010/10/28 18:42:15]

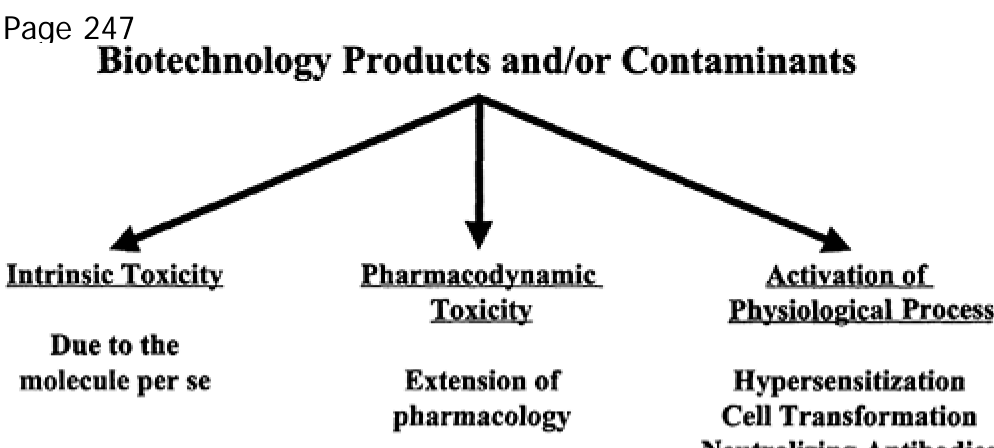

FIG. 6.3. Main areas of concern with response to biotechnology products. Redrawn, with permission, from Reference 210, pp. 143–159.

of NBE applications (121). Two factors facilitate the regulatory approval of NBEs. As is true in the development requirements for all NCEs, the first factor is therapeutic importance, and the FDA has established a "fast-track" rapid approval procedure for NBEs that target unsatisfied indications. The second factor is the relationship of the NBE to an established drug. It appears likely that new therapeutic agents derived from biotechnology will have to satisfy all the usual demands of regulatory agencies (121). The possibility that subtle changes in chemical structure may exist, and may thus influence pharmacokinetics, pharmacodynamics, and/or immunogenicity, is used to support this regulatory position (80).

Questions of safety are not only properly asked about the NBE per se, but about contaminants or residues resulting from the manufacturing and/or purification processes, or antigenic variation or reversion to the wild type of a living organism (46). Worker exposure in the production process may be of concern due to relatively high-level, long-term exposure to various end products of the biotechnology process—live and dead microorganisms and mammalian cells and their derivatives (198). This leads to the area where traditional scientific approaches and techniques do not provide a satisfactory toxicological profile, for example, transfer of an immortalization factor from a mammalian cell; allergic reactions (198).

RELEVANCE OF ANIMAL MODELS IN TOXICOLOGICAL ASSESSMENT

The suitability of experimental animal data for assessing risk to humans is an important contemporary issue in toxicology. Animals and humans have much in common anatomically, physiologically, and biochemi cally (202). There are two main guiding principles of experimental toxicology: that effects produced in animals, when properly qualified, are applicable to humans; and, that exposure of experimental animals to high doses of a test compound is necessary and valid in determining human hazard (117). Although it is generally agreed that animal assays are not as predictive of human effects as would be desired, they are more predictive than generally thought (93, 156). It has been reported that animal assays are predictive of human toxicity in all but 10 percent of comparisons (130). It must be recognized, however, that major differences in response to chemical agents can exist both within and between species (101). The most serious differences between laboratory animal studies and human clinical trials are related to anatomical and physiological "species differences," such as metabolism and genetics (hypersensitivity responses), and experimental design, including quantity, route, and duration of drug administration (122). Humans can be as much as 50 times more sensitive on a mg/kg basis than experimental animals (122).

Regulatory agencies and research-based pharmaceutical companies consider laboratory animal toxicology studies a critical part of the assessment of new drug candidates (74, 128). Confidence in the validity of experimental toxicology is based on the large inventory of chemically induced lesions that occur both in animals and humans (215). It may be incorrect to assume that what is demonstrated in animal toxicology studies will occur in human clinical trials, but until it is shown that the toxicity expressed is not relevant to humans, that assumption must be made (8). Also, until our knowledge base expands, animal data must be extrapolated to the human situation using a conservative approach, that is use of relatively high doses, assumption that humans are more sensitive than the most sensitive species, and so on (16).

The ultimate goals of the toxicology assessments are to characterize toxicity in animal models to identify potential problems in short- and long-term clinical studies, identify the circumstances under which toxicity occurs, evaluate the extent to which the data warrant extrapolation to humans, recommend safe levels of exposure, and contribute to the decision whether to test the new drug candidate in humans (8, 44, 129, 185, 179). It has been recognized that qualitative extrapolation of drug toxicity from animals to humans is more reliable than estimation of the magnitude of dose producing a similar effect in animals and humans; the pharmacodynamics of an agent are more predictable than its pharmacokinetics (144). Complicating the ability to extrapolate data from animals to humans are the excessive doses sometimes used, and often required, in animal studies. As a result, adverse effects are described that may be the result of frank intoxication of the animal and that are irrelevant in humans. Zbinden (203) has reported that the ability of animal toxicity studies to predict potential human toxicity is related to the mechanism of drug action. Within limitations, animals and humans respond in ways similar enough, from a pharmacodynamic perspective, for animal toxicity evaluations to serve as useful predictors of human toxicity (41, 96, 125, 129, 172). However, toxicological evaluations in animals can predict toxic responses in humans only if the response is not unique to humans (74). Those compounds that are toxic to humans but relatively nontoxic to animals—for example thalidomide—are of greatest concern. The extrapolation of animal data to humans is likely to become even more complicated as molecular biology techniques continue to allow the more sophisticated characterization of specific human therapeutic targets (human enzymes, receptors) and the ultimate development of drugs specific for these targets. Table 6.3 lists common undesirable drug effects seen in human studies; 76 percent of the findings are predictable from animal studies. Predictability is enhanced for those adverse effects that can be directly related to the compounds pharmacological mechanism of action. Adverse responses commonly referred to as dose- and time-related are relatively well predicted from animal studies. It is more difficult to extrapolate effects that are not doseor time-related (207).

There is a small element of toxicity that cannot be predicted until large-scale clinical studies are conducted (96). This may be the result of a very low incidence of occurrence, or idiosyncratic responses in a small subset of the patient population. However, considering the increased use of pharmaceutical agents and the relative infrequency of major incidence of human toxicity, the initial laboratory studies are clearly serving a valuable function (8). A large majority of human drug exposures are free of toxicity, and in good accordance with the results of animal toxicity studies (207). The use of adequate test systems is critical to the predictive ability of animal toxicity evaluations. Cahn (20) reported that the cardiac effects of calcium antagonists—ectopic beats, ventricular tachycardia, and ventricular fibrillation —were seen in humans, but were not described in long-term animal studies. However, these effects were demonstrable in animals using appropriate functional evaluations not always included in routine toxicological testing. Oftentimes, toxicologically important end points, such as cardiac, pulmonary, or renal function, are not

Table 6.3

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_248.html[2010/10/28 18:42:16]

taken into consideration in the design of "routine" toxicology studies. The above example emphasizes the importance of using an adequate test system to evaluate the toxicity of new drug candidates. The toxicologist is challenged to consider potential adverse effects related to the pharmacodynamics of the test compound in the design of appropriate safety studies (172).

As with standard pharmaceuticals, no animal model is fully appropriate to evaluate the toxicity of highly species-specific proteins in humans (88). Animal testing for biotechnology products is limited to the species showing the same pharmacological response as humans, without showing signs of immunity (45, 80). This is only feasible when proteins are highly conserved across species. The production of neutralizing antibodies will limit the study duration and, thus, support for clinical trials. Administration of a highly specific human protein to laboratory animals for a sufficient duration to produce immune complex disease will do nothing to reveal effects anticipated in clinical trials. Antigenicity of the test material can be a major complicating factor because the potential allergic etiology of all lesions developing in animals treated with human proteins must be considered (214). Alternatively, nonclinical toxicology studies of biotechnology products may be less predictive of allergic responses that may occur in humans following chronic therapy (198). The appropriate laboratory species for biotechnology product testing should demonstrate similar pharmacodynamics and adverse responses relative to humans. If an animal model demonstrating similar pharmacological response to humans cannot be selected, species selection based on toxicity likely to be representative of effects expected in humans may be acceptable (191). The FDA does not currently require the study of recombinant proteins in primate models, but these animals demonstrate many similarities to humans at the molecular level, and often turn out to be the most appropriate species for toxicity testing (88).

TOXICOKINETICS

Species differences in expression of toxicity (Figure 6.4) due to differences in pharmacokinetics (metabolic processes and physicochemical characteristics of the compound that affect its absorption, disposition, metabolism, and elimination related to the expression of pharmacological endpoints) or toxicokinetics (related to toxicological endpoints), are important factors in toxicology studies (47, 152). Toxicokinetic analyses have become common components of nonclinical toxicology profiles of NCEs and NBEs. Toxicokinetic analyses provide information on dose proportionality, potential dose accumulation, and sex and species differences in drug candidate distribution and elimination (42). A major purpose

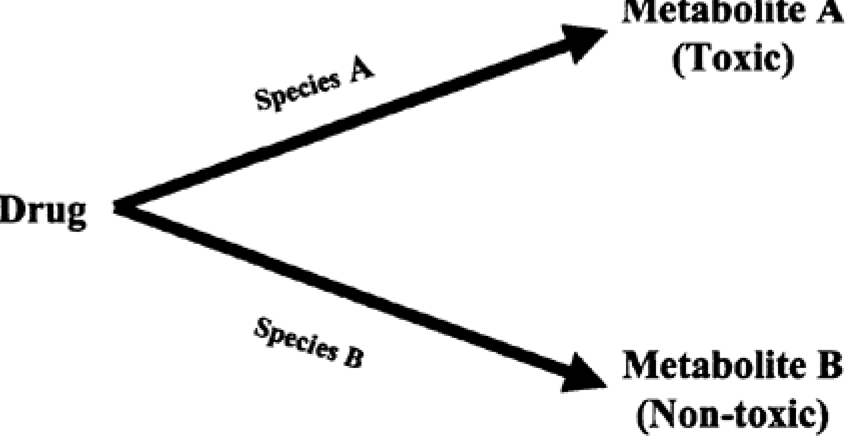

FIG. 6.4. Hypothetical drug metabolism pathways in two species, demonstrating the importance of metabolic data when interpreting toxic responses.

of kinetic studies is to evaluate the level of parent drug or metabolite in various body fluids, tissues, and/or excreta and to use these data to determine suitability of animal data for human hazard assessment (30, 43, 150, 164). Another purpose is to determine the levels of the compound, and its potentially active metabolites, that result in toxicity.

To fully interpret the results and applicability of toxicology studies, the metabolic profile and kinetics of the drug candidate in animal models and in humans must be compared (143). Wherever possible, species that handle the chemical in a manner similar to humans should be used in toxicology studies (190). Rapid detoxification in animals can cause the toxicologist to miss signs of potential human toxicity (207). Alternatively, signs of toxicity in experimental animals may be the result of a metabolic conversion that is only slightly present in humans. For example, the increased liver weights seen with ketotifen (Zaditen, an antianaphylactic agent) in dogs were due to an N-oxide metabolite which is produced in insignificant amounts in humans (172). Toxic responses in humans can be predicted from animal studies

more accurately if the absorption, distribution, metabolism, and excretion of the test chemical are compared (10).

The determination of metabolic and pharmacokinetic profiles in animals is of great value in the design of extended clinical trials, once these parameters have also been characterized in initial limited human testing. Specifically, interspecies variation in response that may preclude extrapolation of animal toxicity data to humans could be explained by toxicokinetics (57). Qualitative metabolic profiles are remarkably similar among the four or five laboratory animals commonly used in toxicology studies and humans (23). Quantitative differences in drug metabolism parameters among species, however, are apparently the rule. It may be unreasonable to expect that, from the few animal species used in toxicological

evaluations, one will be found that handles a test chemical exactly as humans do (207). In a review of the comparative metabolism of 32 compounds, Caldwell (22) has reported that the rhesus monkey is a good model for humans approximately 73 percent of the time; the rat, approximately 29 percent of the time; and the dog, approximately 32 percent of the time. The rhesus monkey was a poor model for humans in only 4 percent of cases. In actual practice, however, the rat is the more frequently used species in long-term toxicology evaluations (23).

Toxicokinetic evaluations have a great deal of relevance in explaining species differences in toxicology profiles (56). The kinetic parameters that are pertinent to an understanding of toxic responses across species are absorption (extent, rate, and relationship to route of administration); distribution (blood and tissue levels of parent compound and metabolites, accumulation in various body compartments); metabolism (species differences, activation); and elimination (route, rate), better known as ADME (164). These processes are interdependent and occur simultaneously (132). Association of drug toxicity with parent compound or metabolite, or the association of enzyme induction with the late accumulation of a novel metabolite, can be characterized by kinetic evaluations (114).

Toxicokinetic data provide another important contribution to toxicology evaluations, that is, assessment of nonlinear kinetics, which frequently occur at the high dose levels used in toxicity testing (151). In this situation, the relationship of dose to internal concentration is not representative of the relationship at the lower, unsaturated, linear dose levels that occur in humans. It is very important that toxicity be evaluated in conjunction with kinetics over a dose range wide enough to define whether a transition from linear to nonlinear kinetics occurs (151). This kinetic information can be used to establish a more realistic upper dose level for a toxicity study, rather than the maximum tolerated dose (MTD), which may far exceed the metabolic capabilities of the animal, and thus result in irrelevant toxicity. If the kinetic evaluations are not conducted simultaneously with the toxicology study, they should be conducted at doses encompassing those actually used in the toxicity evaluation, as well as those which produce the desired pharmacological effect (185). This assessment of systemic exposure to parent drug and metabolites allows a more realistic expression of the difference between the doses that result in efficacy and toxicity (margin of safety) than comparing the doses administered on a mg/kg basis.

The use of in vitro techniques allows the toxicologist to establish some level of comfort for comparative metabolic similarities between humans and the common species employed in toxicity testing. In vitro techniques have several advantages: rapid assessment of permeability and metabolism; study of molecular mechanisms of toxicity; drug targeting; early studies comparing human and animal systems; and, minimization of animal usage (5). The in vitro models do not provide the entire metabolic picture, but they are useful in illuminating parts of a very complex process. Dedrick and Bischoff (52) have stated that it should be possible to use in vitro comparative metabolic information to provide a basis for predicting drug behavior in any mammalian species, providing anatomy and physiology are known.

Several in vitro methods are available that are applied to human and animal liver samples: liver subcellular fractions (14), that is, postmitochondrial supernatant or microsomes; specific forms of cytochromes P450, that is, species-specific metabolism and effects of enzyme induction/inhibition (62, 95); hepatocytes (162); and, liver slices (15, 165). Subcellular fractions are easy to prepare and cryopreserve, but may be altered in the preservation process (148). Hepatocytes allow for the study of integrated hepatocellular metabolism, express many of the functional activities of the intact liver, and may provide a good compromise between cell extracts and isolated organs (52, 62). Liver slices have the additional advantage of maintaining the structural heterogeneity of the liver, and are not exposed to the potential hepatocyte membrane damaging effects of collagenase used during their preparation. Currently, the most commonly used in vitro preparations are subcellular fractions, hepatocytes, and liver slices (75), and the early assessment of metabolic pathways in cultured human and animal hepatocytes and liver slices is widely practiced (215).

The correlation of the in vitro techniques with in vivo metabolic profiles has been demonstrated with hepatocyte suspensions from rat, rabbit, dog, squirrel monkey, and human livers (90). In general, the metabolic profile from the hepatocytes corresponded to the profile of urinary metabolites previously established for each species (90). As a further positive comparison, the metabolism of caffeine by human liver microsomes, slices, or hepatocyte cultures compared very well with its in vivo metabolism (12). An understanding of the mechanism of species-specific acetaminophen toxicity in rat, rabbit, dog, and cynomolgus monkey was provided by studies in primary hepatocyte cultures (166). The applicability of this in vitro approach has been further demonstrated for diazepam and ketotifen (27, 123). Wrighton and Stevens (200) have compared and contrasted specific human P450s, involved in the metabolism of a very large number of endogenous and exogenous lipophilic compounds, with P450s of several

experimental animal species. The evaluation of the metabolism of drug candidates by individual P450 isozymes from animals and humans may provide valuable information relative to both species differences and potential idiosyncratic responses in the human population. These in vitro test systems generally provide a more rapid, less expensive means of evaluating

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_250.html[2010/10/28 18:42:17]

toxicity and mechanisms of toxicity, across species during early drug development (165, 178).
The use of these in vitro systems may also improve the selection of appropriate species for subsequent in vivo testing. Importantly, how the drug is metabolized relative to other drugs that may be administered simultaneously, may provide critical guidance in the design of subsequent clinical studies to address potential drug-drug interaction issues. Many animal and human subcellular, cellular, and tissue preparations that can aid the toxicologist in selecting species for toxicity testing or extrapolating animal data to humans are now commercially available.
Toxicity studies are designed to produce a higher level of exposure in the experimental animals than anticipated in the human clinical trial. Generally, small animals (rats and mice) have more rapid basal metabolic rates, shorter life spans, and more rapid drug metabolic activity than humans (23). Thus, small animals usually require a higher dose of the drug, administered more frequently, to mimic the human clinical exposure (136). Campbell and Ings (23) have provided an example showing that, all else being equal, rats would have to be dosed at 5 mg/kg/day to achieve similar systemic exposure as humans receiving 1 mg/kg/day. It should be realized, therefore, that a dose multiple comparison based on a mg/kg relationship is often an inappropriate measure of safety. It is now generally accepted that exposure (plasma level) provides a better estimate of safety margin than administered dose. Issues related to tissue accumulation, measures of exposure, and safety margins are discussed below.
The assessment of systemic exposure in toxicity studies has been addressed by the ICH and the objectives of toxicokinetic evaluation and specific recommendations are contained in ICH Topic S3A (107).

TOXICOLOGY GUIDELINES

Drug Development Time Lines

Development time has become an important focus for the pharmaceutical industry. The available data indicate a four fold increase in drug development time between the 1960s and the 1980s. From the early 1980s to 1996, however, mean drug development times have been relatively constant at about 10–12 years, with a very wide variability (177). The pharmaceutical industry has committed to increasing drug discovery/development efficiency leading to a halving of the mean drug development time.
NBEs generally have had a shorter development time than NCEs. The NBEs have a mean development time of approximately 6–9 years. The NBEs registered to date have generally been well-characterized natural molecules and the shorter development time is probably related to a better understanding of their actions in humans. The introduction of analogs of natural proteins, some designed to be used at supra-physiological levels, will probably lead to an increase in development time for NBEs.

Regulatory Guidelines for Toxicity Testing

In this section, the toxicology support packages for the registration of NCEs and NBEs are reviewed from slightly different perspectives. More detailed information on the specific studies conducted, their results, and interpretation are included for the classical agents (omeprazole and zidovudine [AZT]) since the majority of compounds currently in development would fall into this category and thus require similar testing strategies. Omeprazole was selected for discussion because it has a comprehensive toxicology package and represents an example of where additional mechanistic studies were critical in the approval process. Zidovudine is discussed due to its proposed use to treat life-threatening disease where no adequate therapy was available. The rapid approval of AZT, in spite of significant toxicology findings and an abbreviated toxicology support package, demonstrates the inherent flexibility in the approval system even with regard to NCEs.
The discussion of specific human NBEs (gonadotropin-releasing hormone analogs, interferon, human insulin) is presented from a more philosophical perspective. Since these agents are naturally occurring, and since the major limiting toxicity in animal studies (immunogenicity) is not applicable to clinical trials, the design of the toxicology package posed special issues that were considered on a case-by-case basis. Furthermore, the toxicological profile was anticipated based on extensive clinical experience with less specific agents (animal-derived insulins) and/or a broad understanding of the hormones' physiological functions. Thus, the following discussion of the NBEs poses questions, concerns, and general guidelines to be considered in the development of these agents.

Acute, Subchronic, and Chronic Testing

Toxicity testing can be considered to be composed of several major types (44). Acute (single-dose), subchronic (multiple-dose, less than 6 months duration), and chronic (multiple-dose, greater than or equal to 6 months duration), studies are intended to elucidate the target organs for toxicity and demonstrate dose-response relationships. They are useful for determining the mechanism of toxic action

and often provide important information for dose selection in other study types. A variety of endpoints are routinely evaluated in subchronic

and chronic studies, including body weight, feed consumption, hematology, clinical chemistry, urinalysis, and gross and histological pathology of numerous tissues. A list of common parameters assessed in subchronic/chronic studies is presented in Table 6.4. However, the toxicologist is continually challenged to modify study design to address the anticipated actions of the compound under investigation. This may result in the addition of certain parameters or tissues to be evaluated, or a more comprehensive analysis of tissues (i.e., electron microscopic evaluation, immunohistochemistry). Furthermore, previous studies, or knowledge of the toxicity of other agents in the therapeutic class or those that have a similar structure, may recommend alternative assessments, such as the determination of the propensity of the agent to induce hepatic microsomal enzymes, cause phospholipid accumulation, or result in peroxisome proliferation.

An assessment of bioavailability and pharmacokinetics is often an important endpoint of subchronic and chronic studies. As discussed previously, these data are critical to extrapolate toxicity findings to humans. Often, the kinetic profile of the compound is determined early and late in the study so that the potential for drug accumulation can be revealed. Alternatively, drug levels may be lower toward study termination, or the metabolite profile may differ, due to the induction of drug metabolizing enzymes. Tissues may also be collected for drug analysis, so that levels in affected tissues can be related to the extent of the histopathological findings. Finally, important dose-response relationships can be established, relative to both parent compound and metabolites, that may be critical in the interpretation of toxicity data.

Acute (single dose followed by a 2-week observation period) and subchronic (usually 2-week or 1-month studies) testing is required prior to FHD. One-month studies in one rodent (usually rat or mouse) and one nonrodent (usually dog or primate) species usually will support 1 to 2 weeks of dosing in humans. Where possible, the animal studies should be carried out using the same route of administration anticipated for use in patients. As an aside, it should be acknowledged that clinical studies may initially be conducted by the intravenous route, regardless of the desired ultimate route of administration, particularly for those molecules that are anticipated to show efficacy rapidly, in order to demonstrate the proof of concept of a new pharmacological mechanism. Drug developers might thus avoid the time and expense associated with formulation development and maximization of the desired properties of the chemical if it has been demonstrated that the molecule/ mechanism is ineffective. These clinical trials require the support of intravenous toxicology assessments. In these circumstances, it is extremely important to evaluate the risk associated with the potential for demonstrating toxicity in the intravenous study that may be irrelevant to the ultimate route of administration.

Phases II and III, efficacy testing in patients, are supported by longer-term studies. Depending on the proposed duration of human exposure, toxicity studies to support Phases II/III may be of 3, 6, and/or 9/12 months duration. Two or more subchronic/chronic studies may be conducted simultaneously (i.e., 3-month and 6-month studies may be initiated at the same time) so that patients can be placed on the trial earlier (upon completion of the 3-month study), and maintained on the trial longer (supported by the 6-month study) if the human efficacy and safety data support continued therapy. A potential problem with this approach is that dose selection for the more extended study may be found to be inadequate (doses either too low or too high) based on the findings of the shorter test.

There has been much discussion surrounding the utility of 1-year studies. The FDA has been a strong proponent of the 1-year study approach, while Japan and the European Union (EU) have suggested that 1-year studies reveal little new information beyond that gained from 6-month studies. These data have been reviewed by Lumley et al. (127), who suggest that for 154 compounds in which short-(≤6 months) and long- (>6 months) term animal data are available, tests lasting longer than 6 months (excluding carcinogenicity studies) have not provided new substantive safety information. They also point out that although new findings became evident after 6 months of treatment in 9 out of 75 cases, the data did not influence the decision whether to continue the development of the compound.

Based on the present ICH position, it is generally accepted that 6-month rodent and 9-month nonrodent multiple-dose studies are acceptable for a tripartite development plan (108). Even so, it is strongly recommended that the sponsor have a written commitment from the appropriate reviewing division of the FDA on the acceptability of the 9-month versus the 1-year nonrodent chronic toxicity study.

Additional Toxicology Studies to Support Clinical Trials

Other tests conducted prior to initial clinical trials include mutagenicity studies and pharmacological assessments. A variety of mutagenicity studies currently are employed that assess various types of DNA damage in vitro and in vivo in an attempt to predict the oncogenic potential of the compound under investigation. In pharmacological screening, the ability of the compound to produce toxicities or "side

effects" based on its pharmacological mechanism of action is assessed. For example, an agent that is shown to bind to β-receptors in vitro might be anticipated to influence cardiac function in subsequent toxicity and clinical testing. Both of these study types are often employed as a very early screen in the

evaluation of potential drug candidates to select one of a group of structurally related compounds that would be least likely to result in carcinogenicity, and most likely to demonstrate the specific desired pharmacological activity. The types and utility of these studies are further described below.

Finally, special studies might be conducted prior to initial clinical testing to address specific issues, for example, irritation testing of an agent proposed for topical use in the patient population.

Reproductive and Developmental Toxicity Studies

Since the thalidomide incident, there has appropriately been a great deal of concern relative to predictive testing for developmental toxicity, as well as, fertility effects in both males and females. Although regulations have differed substantially among countries, worldwide harmonized guidelines for reproductive toxicity testing have now been established (109, 110). The ultimate goal of reproductive and developmental toxicity studies is to assess reproductive risk to adults as well as to the developing individual at all stages from conception to sexual maturity. Traditionally, animal studies have been conducted in three "segments"—in adults, treatment pre-mating through mating in the male, and pre-mating through either implantation or lactation in the female (Segment I); in pregnant animals, treatment during organogenesis (Segment II or teratology studies); and in pregnant/lactating animals, treatment from the completion of organogenesis through lactation (Segment III—perinatal and postnatal study). Although guidelines addressing treatment regimens have been rather similar throughout the world, the required endpoints measured, in both the adult and developing organism, have varied widely, and this is an area where much duplicative testing has occurred to support worldwide registration.

The harmonized ICH guidelines (109, 110) stress the need for flexibility in testing for reproductive and developmental toxicity, and challenge the toxicologist to "custom design" a combination of studies that will reveal potential effects on all the parameters considered in the classical Segments I, II, and III studies. For treated adults, these include development and maturation of gametes, mating behavior, fertilization, implantation, parturition, and lactation. In the developing organism, where the maternal animal may be exposed to the drug candidate from prior to mating through lactation, assessments of early embryonic development, major organ formation, fetal development and growth, postnatal development and growth, including behavioral assessments, and attainment of full reproductive function are required. These evaluations might be carried out as one comprehensive study with interim assessments, or they might be segmented into several treatment components. Thus, the new guidelines have not diminished the extent of evaluation, but allow flexibility in study design based on what is already known of the compound under investigation. The harmonized guideline suggests a three-study design that is likely to provide all the developmental toxicity data necessary to support product registration, assuming no untoward toxicity (Figure 6.7). Should toxicity be demonstrated, further mechanistic studies would be conducted to clarify effects and determine whether the responsible mechanism(s) would be applicable to humans. Clearly, the results from previous subchronic/chronic studies (i.e., was there evidence for an effect on spermatogenesis upon histopathological examination of the testes) are critical in the design of an appropriate reproduction package.

Women of child bearing potential are generally first recruited into Phase II trials, and several countries require that efficacy be demonstrated in male patients prior to recruitment of women of child bearing potential into trials, regardless of the outcomes of the nonclinical reproductive studies. However, the FDA has encouraged the inclusion of women of child bearing potential in early clinical trials, especially in the case of drugs intended to treat life-threatening conditions or in the study of disease states that more commonly afflict women. Typically, prior to the inclusion of such women into clinical trials, studies are conducted to evaluate effects on organogenesis (Segment II) in two species (usually the rabbit and the rodent species that has been selected for the subchronic and chronic studies). Female fertility assessments are also usually undertaken prior to longer-term treatment or addition of significant numbers of patients. Early studies in men are supported by histological evaluation of the testes at the conclusion of the subchronic and chronic studies, and specific animal studies to examine drug effects on male fertility are not required until Phase III. Unless there are concerns regarding a specific chemical class or mechanism of action, the more sophisticated analyses of perinatal and postnatal development and behavior (Segment III studies) are often conducted in conjunction with the Phase III clinical trials. Frequently, as is the case with other toxicity evaluations, special studies may be conducted to determine the mechanism(s) of observed reproductive effects in an effort to assess whether these findings are meaningful to humans, and whether use of the compound should be restricted depending on the reproductive status of the patient (i.e., the drug should not be administered to pregnant women).

Finally, the inclusion of female patients in clinical trials may be allowed following a more limited assessment of reproductive/developmental parameters if the compound under development is shown to

be efficacious, and/or thought to provide distinct advantages over available therapies, in the treatment of life-threatening disease.

Carcinogenicity Studies
Among the final toxicity studies to be conducted to support the registration of chronic-use therapeutics are the carcinogenicity bioassays. These lifetime studies are usually conducted in two rodent species (normally rat and mouse). Selection of the top dose for the carcinogenicity bioassays has been an intensely debated topic of discussion in the international harmonization process. The international consensus has based the selection of the top dose for carcinogenicity bioassay on any one of the following (104):
1. Maximum tolerated dose (MTD) (see discussion below).
2. Area under the plasma concentration: time curve (AUC): ratio of 25-fold (rodent:human):applies when there is no genotoxicity.
3. Saturation of absorption.
4. Dose-limiting pharmacodynamics: that is, hypotension, hypoglycemia, decreased blood clotting time.
5. The use of a limit dose (1500 mg/kg): applies when the maximum recommended human dose is **<500 mg/day, and the AUC (rodent:human) is ≥10.**
The middle and low doses should also be selected to provide additional information to use in the risk assessment. The consideration of dose linearity, saturation of metabolic pathways, margin of safety, pharmacodynamics, specific animal physiology, threshold effects, and progression of toxic effects should be included in the selection of the middle and low doses for carcinogenicity evaluations.
The use of an MTD as the top dose in a carcinogenicity study is a subject of some controversy. The MTD has been classically defined as the dose that causes no more than a 10 percent decrease in body weight, and does not produce mortality, clinical signs of toxicity, or pathological lesions that would be predicted to shorten the natural life span of an experimental animal for any reason other than the induction of neoplasms (167). The MTD is suggested to produce a level of toxicity indicative of sufficient chemical challenge to define chronic toxic manifestations (99). Many regulatory bodies default to the use of the MTD as the maximum dose in the rodent bioassays. A major concern with the MTD approach is that metabolic saturation, as discussed above, may occur at high doses, leading to abnormal metabolism (138), or in the case of inhaled therapeutics, abnormal clearance (137). Chemicals administered at the MTD in animal bioassays tend to induce mitogenesis as a result of cell death due to frank intoxication, with the target tissues differing among species and sexes (86). This stimulation of cell proliferation, a natural recovery process in response to severe toxicological insult that does not normally occur at reasonable multiples of human exposure levels, can account for the carcinogenic response of nongenotoxic compounds (32). Thus, the fact that a chemical is a carcinogen at MTD levels in rodents may provide little meaningful information relative to low-dose risk assessment in humans (2). MTDs for chronic toxicity studies are usually estimated based on the results of subchronic toxicity studies. However, since compound distribution and disposition may be affected by dose and/or duration of treatment, this may be a very crude estimate (138, 140).
The choice of an MTD is a critical aspect of chronic toxicity evaluations (173). Cell proliferation indices in subchronic toxicology studies may provide a useful estimation of an appropriate MTD by determining the highest dose that does not result in the phenomenon (19). The use of kinetic parameters (Cmax, AUC related to dose), would better predict the dose at which saturation (nonlinearity) might occur, and therefore provide a better estimate of the MTD in a particular species. Also, changes in urinary metabolite profile, in relation to dose, may be a good way of indicating metabolic overload, and aid in more accurately selecting upper dose levels in toxicology studies (199).
The utility of using two rodent species has also been an active area for discussion. The ICH has indicated that the rat would be preferable to the mouse for the conduct of carcinogenicity studies (103). The rat seems to have been given a preference because background mechanistic data are usually available for rats (not mice), studies of metabolic disposition are more often carried out in rats than in mice, and mouse carcinogenicity studies are dominated by liver tumors of questionable relevance to humans. A review of the European Regulatory Database has concluded that studies in the mouse add little to the ability to detect carcinogenic risk from pharmaceuticals (184, 34); but it found, however that carcinogenicity studies in two rodent species are necessary to identify transspecies tumorigens. NCEs active across species are considered to pose a relatively greater risk to humans than NCEs positive in only one specie. The conduct of a study using an alternative in vivo carcinogenicity model along with a standard bioassay in one specie was considered to be an acceptable alternative for assessing carcinogenic potential (34).
The use of alternative models for carcinogenicity assessment meet the desire of the FDA to have an assessment in two species, and provides the advantages of using fewer animals, being of shorter

duration, and being capable of improving the accuracy of the rodent bioassay (33). A number of transgenic animal models are currently being evaluated as alternatives to the two-year bioassay (84, 33, 4). It is early, yet, however, to evaluate the contribution of alternative models of carcinogenic potential to the risk assessment process, and it would be advisable

to discuss the selection of alternative models with the appropriate regulatory agency prior to study initiation.
Within the FDA, it is highly recommended that protocols, dose justification documents, and supporting data be submitted to the Carcinogenicity Assessment Committee (CAC) for evaluation prior to the initiation of carcinogenicity studies. The CAC provides consultation on study designs, assures consistency and quality in the analysis and interpretation of animal carcinogenicity studies, and monitors scientific developments to ensure that scientific standards of design and interpretation are upheld.
Since 1982, there has been a rise in the number of NBEs presented for registration. Even so, this represents a relatively small number of molecules. Due in part to this lack of practical experience, the safety programs for the NBEs have been designed on a case-by-case basis. The ICH has provided two guidelines that address carcinogenicity studies with products of biotechnology (103, 111). There is general acknowledgment that carcinogenicity studies are not appropriate for biotechnology products given essentially as replacement therapy, at physiological levels, especially when clinical experience exists (e.g., insulin, calcitonin, pituitary derived growth hormone) (111, 103, 94). Product-specific assessment of carcinogenic potential may be needed depending on clinical dosing regimen, patient population, and/or biological activity of the product. For products that have the potential to induce cell proliferation (e.g., growth factors), an in vitro evaluation of receptor expression, in cells relevant to the patient population, may be conducted. If these data indicate a need for further evaluation of carcinogenic potential, two-year studies in a single rodent species should be considered.
Long-term carcinogenicity evaluations with endogenous peptides and proteins, or their analogs, are generally indicated when (103):
1. there are significant differences in biological effects to the natural substances.
2. modifications lead to significant changes in structure compared to the natural substance.
3. therapeutic exposure levels exceed those that normally occur in the systemic circulation or in tissues.
A specific example of studies recommended for the analog of a naturally occurring decapeptide, gonadotropin-releasing hormone (GnRH), is presented below (149).
Regulatory guidelines exist as to when and why carcinogenicity studies should be conducted with naturally occurring substances and their analogs. There are opinions from industry, academia, and regulatory agencies on the propriety of conducting these studies (94). For each NBE under development, the existing opinions and guidance must be considered, a reasonable plan to establish safety must be developed, and a discussion held with the appropriate regulatory agency to test the plan. Safety evaluation of NBEs is still very much a case-by-case consideration. The pharmaceutical industry must be careful not to over-interpret the position that carcinogenicity studies are not usually appropriate for biotechnology products.

New Chemical Entities

The extent and types of safety testing of synthetic organic pharmaceutical agents in animal models depend on a variety of factors, including the potential duration of treatment of patients (e.g., short-term—antibiotics; chronic—antihypertensives), route of administration, pharmacological mechanism of action, proposed patient population, and clinical experience with other agents in that therapeutic class. Furthermore, the design of animal toxicity studies that occur later in development must carefully consider the results of previous tests in animals and humans relative to bioavailability, unanticipated toxic responses, and relevance of species selected.
Generally, toxicity testing in animals can be considered in three phases—testing to support FHD (single- and multiple-dose, Phase I), testing to support longer-term and broader efficacy studies (weeks to months, Phase II), and testing to support final registration and, if appropriate, chronic treatment (Phase III) (Figure 6.5). Although the great majority of testing is performed prior to registration, special studies may be requested by regulatory agencies during the review and approval processes. Following widespread clinical use of a new agent, further testing may be appropriate to examine potential mechanisms of action for unanticipated side effects that become evident in the increasing patient population or sub-populations. These may occur due to genetic differences, environmental factors, age, patient history, existence of other diseases/pathologies, and drug interactions. Other tests may be considered if new formulations of the drug are developed, if the drug is suggested for new indications, or if it will be used in patient populations that were not anticipated during initial development (e.g., pediatrics).
The primary purposes of initial clinical testing (support for FHD) are to determine the toxicity and pharmacokinetics (and oral bioavailability, if appropriate) of the drug candidate in humans following one or several doses. Usually, the drug is administered to humans at doses below the anticipated efficacious

dose, and doses are escalated until a satisfactory multiple over the anticipated efficacious dose is achieved or toxicity becomes evident. Unless the drug candidate has known, serious toxicity, as is the case with many oncolytics, it is usually first tested

in a limited male, non-patient population. As indicated above, the FDA supports the early inclusion of women in clinical trials for new therapies, especially those to be used in the treatment of life-threatening diseases (65, 66). Because of this interest, studies of developmental toxicity, which usually occur later, may be moved to a much earlier point in the drug development process (142).

When designing animal studies to support FHD, a major consideration in dose selection must be the anticipated "margin of safety" between animals and humans. Ideally, doses in animal studies should provide exposure to the compound well in excess of what is anticipated at the highest doses to be tested in humans. As discussed previously, a comparison of these doses on a mg/kg basis is no longer considered to provide adequate information in this respect due to potential species differences in absorption and rates and routes of metabolism. Thus, a good estimate of the pharmacokinetic behavior of the agent in animals is an important goal of nonclinical testing. There is no firm guideline regarding what should be considered an adequate margin of safety. However, a "smaller" margin between the potentially efficacious dose and a toxic dose is tolerated for those compounds under development for life-threatening diseases, particularly if they are expected to offer a distinct therapeutic advantage over other agents currently marketed in the class.

Based on the activities of the ICH, the designs and goals of clinical trials are similar throughout the world. Figure 6.6 shows the recommendations for the duration of animal tests relative to proposed human exposure to NCEs. It is possible to discuss the nonclinical and clinical programs with regulatory bodies, and, depending on the characteristics and proposed use of the chemical, modify these recommendations.

The duration of animal tests necessary to support a specific duration of clinical trials for NBEs is much more flexible (111). Short-term clinical trials for life-threatening conditions may be supported by 2-week nonclinical toxicology studies. Subchronic clinical trials

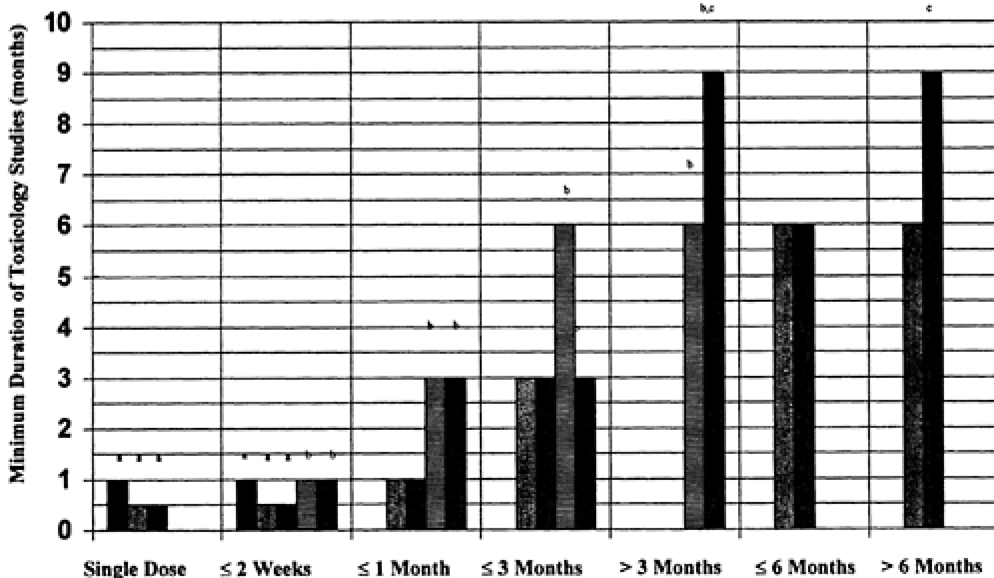

FIG. 6.6. International guidelines for the duration of animal toxicology studies necessary to support clinical trials of various duration. Assessment of reversibility may be necessary in three-month or six-month toxicology studies. Carcinogenicity studies are not needed in advance of clinical trials, unless there is a cause for concern. They may be conducted post-approval for some indications. From Reference 102.

a. In the United States and the European Union (EU), two-week rodent and nonrodent studies are the minimum duration. In: Japan, four-week rodent and two-week nonrodent are needed. In the United States, single-dose toxicity with extended examinations can support single-dose CT.

b. Studies in support of Phase III trials in EU, and marketing in all regions.

c. Nine-month nonrodent study is an international consensus, EU and Japan favor six-month, United States favors 12-month. Check with regulators before initiating study.

can be supported with toxicology studies of 1–3 months. Clinical trials to support long-term, chronic therapy, can be supported with 6-month toxicology studies.

Regulators throughout the world have recognized that resources could be used more efficiently, and efficacious and safe drugs could be made available more rapidly, if guidelines for nonclinical clinical testing and registration were comparable across countries. The ICH has developed a comprehensive set of safety guidelines to harmonize the regulatory requirements of the EU, United States, and Japan. The ICH Expert Working Groups (EWG) have considered appropriate guidelines for all of the various types of toxicity tests, including acute and subchronic testing, chronic and carcinogenicity testing, reproduction and developmental toxicity studies, and mutagenicity testing. The required duration of animal studies to support human exposure has also been addressed. There has been a good deal of collaboration between regulatory agencies and pharmaceutical companies in the development of the safety guidelines. Dorato and Buckley (59) have provided a more complete discussion of the role of the ICH process in drug development. The ICH guidelines addressing the various nonclinical studies required to support clinical trials and registrations in the three major regions (EU, United States, Japan) are shown in Table 6.5. Selected Internet websites providing information on design of toxicology studies to support clinical trials are shown in Table 6.6.

Specific Agents

Omeprazole (Prilosec)

Omeprazole (Figure 6.8) is a substituted benzimidazole that is a potent inhibitor of H^+/K^+ ATPase ("proton pump") at the secretory surface of the gastric parietal cell, thereby inhibiting gastric acid secretion (155, 189). Omeprazole is indicated for the short-term (4- to

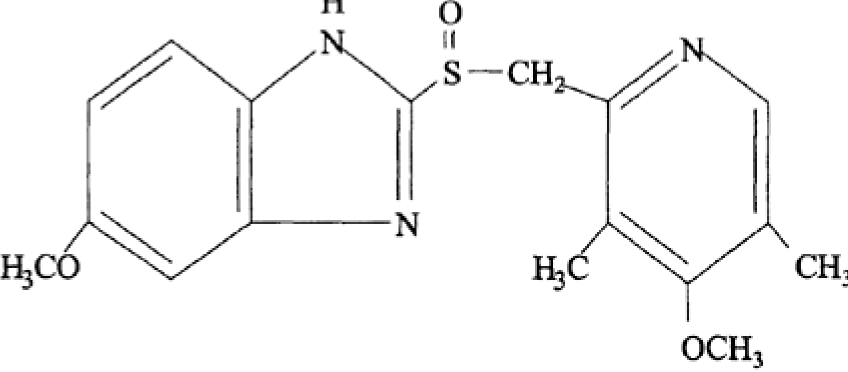

FIG. 6.8. Structure of omeprazole.

12-week) treatment of active duodenal and gastric ulcer, gastroesophageal reflux disease (GERD), severe erosive esophagitis, and the maintenance of healing of erosive esophagitis; and the long-term treatment of pathological hypersecretory conditions such as the Zollinger-Ellison syndrome. It is also

approved for use, with clarithromycin, for treatment of *H. pylori* infections. The recommended dosage for the short-term indications is 20–40 mg daily (approximately 0.4–0.8 mg/kg in a 50 kg individual). For the long-term indications, the recommended initial dose is 60 mg daily; however, doses up to 120 mg three times daily have been administered (146). Table 6.7 lists the toxicology studies that were submitted to the FDA (68) to support the U.S. registration of omeprazole. The content of the toxicology package suggests that the intravenous route may have also been a considered route for therapy.
The results of acute, subchronic, and chronic studies suggested that the toxicology profile of omeprazole was generally unremarkable (24, 61, 68, 97). The acute

ICH guidelines for the conduct of nonclinical studies

Single- and Repeat-Dose Toxicity Studies
Topic S4 Single-Dose and Repeat-Dose Toxicity Tests (STEP 5)
- LD50 determination should be abandoned
- Reduction in duration of longest-term repeat-dose toxicity study in rodents from 12 to 6 months

Topic S4A Repeat-Dose Toxicity Tests in Nonrodents (STEP 3)
- Reduction of duration of repeat-dose toxicity studies in nonrodents from 12 months to 9 months

Carcinogenicity Studies
Topic S1A Need for Carcinogenicity Studies of Pharmaceuticals (STEP 5)
- Defines circumstances requiring carcinogenicity studies, taking into account known risks, indications, and duration of exposure

Topic S1B Testing for Carcinogenicity in Pharmaceuticals (STEP 5)
- Need for studies in two species
- Alternatives to two-year rodent bioassay

Topic S1C & S1CR Dose Selection for Carcinogenicity Studies in Pharmaceuticals (STEP 5)
- Criteria for selection of high dose

Genotoxicity Studies
Topic S2A Genotoxicity: Specific Aspects of Regulatory Tests (STEP 5)
- Specific guidance for in vitro and in vivo tests pluss glossary of terms

Topic S2B Genotoxicity: Standard Battery Tests (STEP 5)
- Identification of a standard set of assays
- Extent of confirmatory experimentation

Reproductive Toxicology
Topic S5A Detection of Toxicity to Reproduction from Medicinal Products (STEP 5)
- Specific guidance for testing reproductive toxicity

Topic S5B Reproductive Toxicology: Male Fertility Studies (STEP 5)
- Recommendation for pre-mating treatment during and observations

Toxicokinetics and Pharmacokinetics
Topic S3A Toxicokinetics: Guidance on the Assessment of Systemic Exposure in Toxicity studies (STEP 5)
- Integration of kinetic information into toxicity testing

Topic S3B Pharmacokinetics: Guidance for Repeat-Dose Tissue Distribution Studies (STEP 5)
- Need for tissue distribution studies, when appropriate data cannot be derived from other sources

Biotechnology Products
Topic S6 Safety Studies for Biotechnology Products (STEP 5)
- Nonclinical safety studies, use of animal models of disease and other alternative methods, need for genotoxicity and carcinogenicity studies, impact of antibody formation

Multidisciplinary Safety/Efficacy Studies
Topic M3 Timing of Nonclinical Studies in Relation to Clinical Trials (STEP 5)
- Principles for development of nonclinical testing strategies
- Addresses full range of studies to support clinical trials for NCEs

toxicity of the compound in rats and mice was low as demonstrated by oral LD50s (the dose that kills 50% of the animals tested) generally in excess of 4 g/kg. Multiple-dose studies in rats were conducted at doses up to 414 mg/kg/day for 3 months, and up to 138 mg/kg/day for 6 months. There were no consistent effects on body weight or food consumption reported in those studies. Treatment-related findings that occurred at high doses in these studies included decreases in several erythrocytic parameters, and decreases in plasma glucose and triiodothyronine. The latter finding was ascribed to a reduction in the peripheral conversion of thyroxine to triiodothyronine. Increased liver and kidney weights were observed in both studies, as well as in the 24-month rat oncogenicity study. Elevated kidney weights were correlated with an apparent exacerbation of the progress of chronic nephropathy that normally occurs in aging Sprague–Dawley rats.

Dogs were treated with omeprazole for 3 months at doses up to 138 mg/kg/day or 12 months at doses up to 28 mg/kg/day. Clinical chemistry findings were generally unremarkable, although as observed in the rat, some decreases in hematology parameters and plasma triiodothyronine were noted.

The most significant nonclinical finding in both rats and dogs was a reversible gastric mucosal cell hyperplasia with increases in mucosal thickness and folding. In the 6-month study in rats, omeprazole induced a dose-related eosinophilia of the zymogen granules of the pepsinogen-secreting chief cells, with slight atrophy of these cells occurring at the high dose. Slight chief cell atrophy was also observed in dogs given the high dose of omeprazole for 3 or 12 months. To characterize these gastric changes more rigorously, a rather extensive reversibility study was conducted in rats in which animals were treated with either 0 or 138 mg omeprazole/kg/day for 14 days, and 1, 3, or 6 months. Other groups of animals were treated with that dose of omeprazole for 3 or 6 months, followed by recovery periods of 14 days, and 1, 3, or 6 months. This study demonstrated the time dependency and complete reversibility of the gastric lesions in rats. A 3-month recovery period following 3 months of treatment in dogs showed that the slight chief cell atrophy observed at 3 months was reversible, and a 4-month recovery period following 12 months of treatment in dogs demonstrated the reversibility of mucosal hyperplasia and chief cell atrophy, although increased mucosal folding was still evident.

No teratological findings were observed in the rat at omeprazole doses up to 138 mg/kg/day administered on days 6–15 of pregnancy. The two highest doses tested in rabbits (approximately 70 and 140 mg/kg), administered during days 6–18 of pregnancy, resulted in maternal toxicity as evidenced by anorexia and reduced water intake. Signs were sufficiently severe that treatment of animals at the high dose was discontinued on day 14. Fetal mortality was increased in conjunction with maternal toxicity, but fetal development was unaffected by maternal omeprazole treatment. The major finding of the fertility and perinatal and postnatal studies was a decrease in weight gain of pups of maternal animals given the high dose of 138 mg/kg/day during late pregnancy and lactation. This correlated with a decrease in maternal body weight and food consumption during late lactation. Whether the decrease in pup weight gain was the result of the decrease in maternal feed consumption, or whether it may have been a direct effect on offspring via the breast milk transfer of the compound is not known, and whether nursing or drug therapy ought to be discontinued in the nursing woman, for this and other pharmacological agents, should be considered.

In the mouse oncogenicity study, animals were treated with up to 138 mg omeprazole/kg/day for 18 months. A decrease in survival was noted at the high dose, but no neoplasia was observed in any organ. Different results, however, were obtained in the rat oncogenicity study, in which animals were treated with 13.8, 43, or 138 mg omeprazole/kg/day for 24 months. Enterochromaffin-like (ECL) cell hyperplasia, progressing to ECL cell carcinoids, occurred in dose-related fashion in these animals, with males being affected at doses of 43 and 138 mg/kg/day, and females being affected at all dose

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_261.html[2010/10/28 18:42:23]

levels. These positive findings resulted in the temporary suspension of the clinical trial program. The carcinoids were characterized as "end-of-life" tumors, since the first was discovered at 82 weeks of treatment in an animal that had died prematurely. Carcinoid tumors were not identified as the cause of death in any animals, and no metastases were found. A 2-year study was repeated in females in an attempt to define a dose at which ECL cell carcinoids did not occur. However, carcinoid formation again occurred in a dose-related fashion, including at the lowest dose tested (1.7 mg/kg/day).

A major question that must be addressed following positive results in a carcinogenicity bioassay is whether tumorigenesis was the direct result of chemical insult, or whether it can be related to the pharmacological mechanism of action of the compound. Furthermore, whether the model is appropriate for extrapolation of these findings to humans requires evaluation. For example, at this late stage in the development of a compound, sufficient pharmacokinetic data should be available in both the animal species tested and humans to determine whether a finding might be restricted to a species that metabolizes the compound quite differently from humans. If this is the case, further mechanistic studies can be designed to support or refute the applicability of the findings.

A number of in vivo and in vitro mutagenicity studies were conducted with omeprazole (Table 6.7). An initial mouse micronucleus test with omeprazole administered to animals at a high dose of 5000 mg/kg produced equivocal results, with slight increases in the mean numbers of micronucleated cells compared to controls (approximately 2-fold, compared to 30-fold following a 0.4 mg/kg dose of the positive control, mitomycin C). It was noted that the dose of 5000 mg/kg was not well tolerated. A second mouse micronucleus test was conducted, using a maximum dose of approximately 800 mg/kg, which did not show evidence of mutagenic potential. All other mutagenicity tests conducted produced negative results, suggesting that the tumorigenesis observed in the 2-year rat studies was not the result of a genotoxic action of omeprazole or its metabolites.

Mechanistic studies in dogs and rats, combined with correlative data from clinical trials, ultimately provided the information to support the safe use and registration of omeprazole. At the doses selected for the toxicity studies, the sustained decrease in luminal pH of the stomach resulting from the inhibition of gastric acid secretion by omeprazole caused a substantial increase in the release of gastrin into the blood. In fed rats, gastrin levels in plasma normally range from 150–200 pg/ml. Omeprazole administered at doses of 13.8–138 mg/kg/ day increased plasma gastrin concentrations to 1000–3000 pg/ml. Gastrin has a trophic effect on the gastric mucosa and results in the hyperplasia of several

cell types, including ECL cells, and consequent mucosal thickening. These data suggest that omeprazole does not inherently cause ECL cell hyperplasia and resulting carcinoid formation. Indeed, in antrectomized dogs, where the major source of gastrin is surgically removed, high doses of omeprazole for 1 year resulted in neither hypergastrinemia nor mucosal hyperplasia (61). Similarly, antrectomy in rats prevents the hypergastrinemia and ECL cell hyperplasia associated with omeprazole treatment (120).

The course of development of omeprazole demonstrates the importance of conducting mechanistic studies to elucidate the significance of findings in animal safety studies, and whether the effects can be meaningfully extrapolated to humans. A close collaboration between the toxicologist and clinician during advancing human trials is critical to resolve questions related to human safety. The extensive clinical experience with omeprazole has confirmed its safe and effective use

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_262.html[2010/10/28 18:42:24]

for treatment of the described indications (146, 11). In a group of patients who required continuous treatment with 40 mg of omeprazole for up to 4 years, there was no evidence for dysplastic or neoplastic changes (39). Over 12,000 endoscopic biopsies further support the clinical safety of omeprazole relative to its potential for causing hyperplastic changes.

Zidovudine (Retrovir/AZT)

Zidovudine (azidothymidine, AZT, Figure 6.9) inhibits viral RNA-dependent DNA polymerase (reverse transcriptase) and, thus, viral replication. Furthermore, as a thymidine analog, zidovudine becomes incorporated into growing strands of DNA by viral reverse transcriptase, and inhibits the further addition of nucleotides. It is intended for use in the management of adult patients with HIV infection when antiretroviral therapy is warranted (147). It is also indicated for the prevention of maternal–fetal HIV transmission during gestation and labor, and in the neonate after birth. The recommended dose for adults is 600 mg/day in divided doses in combination with other antiretroviral agents and 500 mg/day (100 mg every 4 hours while awake) or 600 mg/day in divided doses for monotherapy. Zidovudine is also available for intravenous infusion in

patients with advanced disease and for use in women during labor and delivery. In spite of the intended long-term use of the compound, it was approved with a minimal toxicology package due to the serious nature of the disease and lack of alternative efficacious therapies.

The studies listed in the upper portion of Table 6.8 were either submitted as part of the original NDA in December 1986, or as amendments to the application shortly thereafter (69). At the time of the initial pharmacology–toxicology review, a variety of chronic toxicity studies were still underway or planned. The FDA commentary indicated that

"nonclinical toxicity data submitted in support of the application include results of studies in rats, dogs and cynomolgus monkeys. FDA guidelines would have prescribed more extensive nonclinical testing than that reported thus far. However, the urgency for developing an anti-AIDS drug has been so great that clinical testing has preceded the usual/customary nonclinical testing. For example, while data from a 6-month *clinical* study are available, results for the supporting 6-month *nonclinical* toxicity studies have not yet been submitted" (emphasis added).

An approvable letter issued by the FDA in March 1987, less than four months following submission of the NDA, stipulated the timing for the conduct of these outstanding studies. Comprehensive reviews of the acute, subchronic, chronic, genetic, carcinogenic, reproductive, and developmental toxicity studies have been published (6, 7, 91).

Zidovudine demonstrated relatively low acute toxicity with intravenous MLDs (median lethal doses) of greater than 750 mg/kg in rats and mice. The most consistent findings in the subchronic/chronic studies with rats, dogs, and monkeys were effects on hematological parameters. In rats given two divided doses of zidovudine at approximately 50, 150, or 500 mg/kg/day orally for 3 or 6 months, there were reversible decreases in red blood cell counts and hemoglobin concentration primarily in the mid- and high-dose groups. The severity of these effects appeared to progress slightly between 3 and 6 months of treatment. No remarkable histopathology was noted in these studies. A subsequent 1-year study, submitted well following the initial approval of zidovudine, revealed a similar toxicity profile to that observed in the 3- and 6month studies. The severity of anemia did not progress between 6 and 12 months of exposure, and effects were again reversible following discontinuation of treatment.

Dogs were more sensitive to zidovudine treatment. In a 2-week study in which animals were administered 125-500 mg/kg/day orally in divided doses, decreases in erythroid values, and leukopenia and thrombocytopenia were observed at all dose levels. Cytostatic effects were observed in the small intestine at the high dose, and were also evidenced by slight to moderate non-dose-related lymphoid depletion, and mild to marked dose-related bone marrow hypocellularity at all dose levels. No cytostatic effects were observed at similar or higher doses in either rats or monkeys. Studies revealed that zidovudine was metabolized almost identically in monkeys and humans, and as a result, the continued nonclinical development of the drug was conducted in the monkey, rather than the dog. However, the species differences in metabolism were not of sufficient magnitude to account for the much greater sensitivity of the dog to zidovudine, and the design of subsequent nonclinical and clinical studies continued to respect the significant findings in this species.

Monkeys responded to a 2-week treatment at divided doses of 125–500 mg/kg/day with a slight reduction in hemoglobin concentrations in one animal at the low dose, and in both monkeys given the high dose. In a 3-month monkey study, at divided doses of 35–300 mg/kg/day, dose-related decreases in erythron parameters were noted as early as day 15 of treatment and progressed to live-phase termination. Platelet counts were also increased. Values returned to normal during the 6-week recovery phase of the study. Subsequent (post-approval) 6- and 12-month studies were conducted in the monkey. In addition to the findings in the 3-month study, bone marrow cytology revealed changes consistent with the hematology findings, and marginal decreases in white blood cell counts were observed at the 300 mg/kg/day dose. All findings were again reversible.

Teratology studies were also carried out in rats and rabbits prior to approval of zidovudine. Divided doses up to 500 mg/kg/day resulted in no evidence for teratogenicity in either species, but non-treatment-related low fertility rates and mortalities in the rabbit study prompted the FDA to request that a second study be initiated prior to drug approval. Effects were limited to an increase in fetal resorptions and an associated decrease in fetal body weights at the maternally toxic high dose. The potential use of zidovudine in pregnant women to inhibit transplacental HIV transmission prompted additional in vitro and in vivo reproductive and developmental toxicity studies following the initial approval of the compound. These subsequent studies demonstrated that zidovudine is embryotoxic in rats at doses that are not overtly maternally toxic. Postnatal survival, growth, and development of offspring from zidovudine-treated rats were unaffected following several treatment regimens. In general, exposure levels associated with the effects observed in the reproductive and developmental toxicity studies were significantly higher than those observed clinically.

No evidence for mutagenicity by zidovudine was observed in the Ames Salmonella study either with or without mammalian metabolic activation. The compound was weakly mutagenic in the mouse lymphoma assay without metabolic transformation at concentrations of 4000 and 5000 μg/ml; it was also weakly mutagenic with metabolic activation at concentrations greater than or equal to 1000 μg/ml. A positive response was obtained in the mammalian cell transformation assay at concentrations of 0.5 μg/ml or greater. In an in vitro cytogenetic assay in human lymphocytes, zidovudine caused structural chromosomal abnormalities at concentrations equal to or greater than 3 μg/ml. However, in an in vivo rat assay, no chromosomal abnormalities were noted following the intravenous administration of doses up to 300 mg/kg (plasma levels over 400 μg/ml). Subsequent in vivo micronucleus studies in mice and rats revealed dose-related increases in micronucleated erythrocytes, reflecting chromosome breakage or mitotic spindle damage.

Carcinogenicity studies in mice were initiated using single daily doses of 30, 60, or 120 mg/kg. These doses were reduced to 20, 30, or 40 mg/kg at 3 months of treatment due to treatment-related anemia. Rats were dosed with 80, 220, or 600 mg/kg/day, with the high dose being reduced to 450, then 300 mg/kg. As expected, hematological changes were observed, but there were no deaths or morbidities that were considered

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_264.html[2010/10/28 18:42:25]

treatment-related in either study. In the mouse study, one benign vaginal neoplasm occurred at 30 mg/kg, and five malignant and two benign neoplasms occurred at 40 mg/kg. Two vaginal neoplasms occurred at the high dose of the rat study. In both cases, the tumors were late-occurring and non-metastasizing. An eloquent argument has been put forth suggesting that these vaginal tumors result from high local exposure to zidovudine due to the retrograde flow of urine containing high levels of the excreted compound into the vagina. An additional lifetime mouse study to support this hypothesis was conducted in which animals were administered zidovudine intravaginally. Thirteen vaginal squamous cell carcinomas occurred in animals receiving the highest concentration in that study, supporting the contention that systemic exposure to the drug was unlikely to be responsible for the neoplasia observed in the oral studies.

A variety of adverse reactions have been documented in patients receiving zidovudine. Due to the wide range of symptoms associated with the opportunistic infections seen in AIDS patients, it is difficult to assess which adverse reactions are clearly the result of zidovudine therapy. However, the animal safety studies were highly predictive of the major hematological toxicities of zidovudine described in humans—granulocytopenia and severe anemia.

Similar to what was described previously under the development of omeprazole, additional mechanistic studies were conducted with zidovudine to explain toxicity findings, even though the drug was intended for the treatment of a fatal disease.

Although the toxicology support package for zidovudine ultimately responded to existing guidelines for registration of a chronic-use pharmaceutical in the United States, its development history demonstrates that the approval system allows considerable flexibility in cases where the market for a life-threatening disease is clearly not satisfied (i.e., antivirals, antifungals, oncolytics). This type of development strategy can only occur with close collaboration between the submitter and the regulatory agency, and after careful consideration of the risk-benefit assessments.

New Biological Entities

The development of highly purified species-specific protein pharmaceutical agents, made possible through advances in rDNA technology, presents a significant challenge to toxicologists. The major question presented is, “What nonclinical toxicology evaluations should be conducted to insure safety in human clinical trials?” The major issue is the testing of these specific proteins in nonhomologous animal species, where the possibility of immunogenicity, not applicable to the clinical trial, exists (174). As there are no universally accepted methods/procedures for the nonclinical evaluation of new biological entities (NBEs), decisions of appropriate nonclinical study design are made on a case-by-case basis. The general consensus is that nonclinical toxicity evaluations with species-specific proteins reveal little more than enhanced pharmacodynamic activity rather than predicting the potential for adverse effects. Furthermore, the toxicity observed in animal studies may be the result of an immunological response to the foreign protein. Toxicology studies with NBEs should demonstrate that the product has no adverse effects other than those specifically related to pharmacodynamics, and that safety for the expected clinical dose range, rather than exaggerated toxicity (i.e., MTD), should be demonstrated (9, 145, 174). Regulatory agencies have placed great emphasis on chemical characterization of the NBE as a means of establishing that it is identical to the naturally occurring protein (manufacturing contaminant issues aside). Establishing this identity has allowed for appropriate modification of toxicology requirements and abbreviation of the toxicology support package. However, NBEs are being developed that contain amino acid sequences that have been purposefully manipulated to differ from the naturally occurring protein in order, for example, to result in a prolonged duration of action over the naturally occurring agent. These molecules may require a more comprehensive toxicology package, such as established for NCEs (see above).

Safety testing of NBEs can be presented in three categories (Table 6.9). The reasonably clear-cut time sequence of nonclinical and clinical studies established with NCEs often is not feasible with NBEs. The interactions between toxicologists and clinicians are important in addressing suspected adverse reactions in the clinical trials (9). Nonclinical toxicology evaluations of NBEs should be designed according to the risks anticipated from the type of product, the contaminant profile, and the intended clinical use (9). There will continue to be major questions and differences of opinion relative to

Table 6.9

Safety testing of biotechnology products*a*

[a]From Reference 9.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_265.html[2010/10/28 18:42:26]

the evolution of nonclinical toxicology testing strategies of NBEs. The major questions will arise concerning appropriate species (174, 216), the need to conduct genetic toxicology studies (9, 174), and the conduct of reproductive toxicology assessments (174).

As examples of NBEs, we have chosen to discuss toxicology support for the registration of gonadotropin-releasing hormone (GnRH) analogs, interferon, and human insulin. The development of interferon has provided a great deal of guidance for nonclinical toxicity testing of NBEs. The pharmacological effects of insulin are well known from extensive clinical experience. This experience has aided the relatively rapid approval of rDNA insulin products, and has allowed the chemical characterization of test material to play a major role in supporting a more limited toxicology profile. Human insulin, therefore, provides an example of a NBE that was approved rapidly, in approximately five months (121).

Gonadotropin-Releasing Hormone (GnRH) Analogs

GnRH analogs are either agonists or antagonists of the receptor for the naturally occurring hypothalamic decapeptide GnRH. The chemical modifications either increase the biological activity and duration of action or affect the solubility, potency, and kinetics of the molecule. GnRH analogs were first introduced for the treatment of cancer (e.g., prostatic carcinoma) and their toxicological assessment was less complete than usually recommended for new drugs. Since their first introduction, the use of GnRH analogs has expanded into treatment of non-life-threatening conditions, and they now are expected to have to undergo the same rigorous toxicology evaluation as other new drugs (149). In the case of GnRH analogs, the FDA has allowed the multi-dose toxicity studies to be conducted at a multiple of human exposure (30- to 50-fold) rather than at doses that define the toxic limits of the compound. Due to the chronic nature of therapy, and chemical dissimilarity with native GnRH, the FDA has recommended that both rat and mouse carcinogenicity studies be conducted. As is the case with the multiple-dose toxicity studies, the FDA has allowed the MTD not to be used, but required, instead, that some multiple of the human clinical exposure be used to set the top dose in the carcinogenicity studies (e.g., 15- to 50-fold). The full toxicity profile recommended for GnRH analogs includes: single-dose acute toxicity (rodent and nonrodent), repeat-dose toxicity studies through 6 months in rodents and 9 months in nonrodents, genetic toxicology, developmental toxicology, and carcinogenicity (149).

Interferon

Interferons (IFNs) are classified as IFN-α (leukocyte), -*β*(fibroblast), or *γ* (immune) (Figure 6.10). IFN-α con sists of a family of at least 14 highly homologous species. The amino acid sequence homology of the IFN-α subtypes has been reported to be 52 to 75 percent (168, 169, 181). The biological activities of IFNs include antiviral, anticellular, and immunomodulatory activities (181). The properties of interferons and their potential uses have been reviewed by Bocci (13).

The adverse clinical experiences reported with the use of IFNs include: fever, chill/rigor, headache, tremor, nausea, vomiting, myalgia, anxiety, fatigue, malaise, anorexia, confusion, local inflammation, cardiovascular toxicity, hepatotoxicity, and abnormal EEGs (71, 160, 161, 169, 187). The most commonly reported adverse effects are fever, fatigue, and leukopenia (169). The effects that cause the most distress in clinical subjects are those related to central nervous system (CNS) depression (187). The toxicity seen with very pure and single clone IFN preparations is almost identical to that reported for the less pure, more heterogeneous preparations of IFNs. The responses reported, particularly the influenza-like syndrome, therefore, are likely intrinsically related to IFNs, and not to a contaminant or impurity (169, 187).

The species specificity of highly purified human IFNs implies that classical animal (nonhomologous) efficacy and toxicity models are not applicable in evaluation of these materials. Nonclinical safety testing of IFNs has not identified an appropriate animal model (72, 98, 153, 157, 170, 213), supporting the recommendation that the routine safety tests applied to NCEs should not be applied haphazardly (174) to NBEs. Yet, given the traditional significance and predictive nature of nonclinical toxicology evaluations, and acknowledging the lack of generally accepted and validated nonclinical animal models for the testing of these entities, drug regulatory agencies have published safety testing guidelines that place NBEs on a level with conventional drugs relative to the comprehensive requirements for animal safety studies (77, 112). A representative example of these guidelines/requirements is given in Table 6.10.

Interferon-α2a (Roferon-A,) is a commercially available NBE identical to one of the 15 subtypes of human leukocyte IFN (182). At the time clinical trials were initiated with this drug, considerable clinical data were available from studies with other leukocyte IFNs to indicate the types of adverse reactions, described above, that might be expected (169, 187). The species specificity of recombinant IFN-α2a has led to production of neutralizing antibodies in rodent and nonrodent species (182). This has impaired

the ability of toxicology studies to detect the expected adverse clinical signs in common toxicology species.

Acute, single-dose toxicology studies (Table 6.11) were conducted in a variety of species in an attempt to disclose any unexpected acute toxicity related to the clinical dos-

age form (excipients, active ingredients). No mortalities were noted in the species tested. The LD50 of IFN-α2a was determined to be >22.8×106 units/kg iv. These studies were conducted at multiples of a single clinical dose (3×106 units/kg), ranging from 10- to 167-fold. Multiple-dose toxicology studies were conducted over a range of 5 to 26 weeks at 3- to 78-fold the weekly clinical dose (9×106 units/kg) (Table 6.12). A low frequency of treatment-related adverse findings was reported: slight weight loss in rats; a slight, reversible, increase in platelets and total leukocytes in mice; a slight decrease in hemoglobin and hematocrit in squirrel monkeys; dose-dependent anorexia and weight loss in *M. mulatta;* and transient anorexia in *M. fasicularis*. In studies longer than 2 weeks, neutralizing antibodies developed in rabbits, guinea pigs, and *M. fasicularis* (182). These results were expected, and may have affected the signs of toxicity. Reproductive studies carried out in *M. mulatta* indicated that a dose-dependent increase in abortion was related to the administration of IFN-α2a.

Insulin

The nonclinical toxicity of biosynthetic human insulin (BHI) (Figure 6.11) was evaluated in an unconventional way. The use of graded increments of dose representing multiples of the projected clinical exposure was not feasible due to the pharmacological effect of hypoglycemia caused by the insulin molecule. Since the pharmacological effects of insulin were well known, a primary goal of the toxicology evaluations was to determine whether BHI contained potentially toxic contaminants/impurities (i.e., *E. coli* proteins, endotoxins, etc.) that are introduced as a result of the synthetic process. Toxicology studies on BHI were conducted simultaneously with purified porcine pancreatic insulin (PPI) as a positive control, at doses previously established to produce hypoglycemia but not mortality. The doses selected for toxicology studies were varied according to species sensitivity, route of administration, and duration of treatment. In acute, single-dose toxicity studies (Table 6.13), the minimal lethal dose of BHI to rats and mice was >10 units/kg sc. Dogs given single doses of two units BHI/kg sc, showed the expected hypoglycemia but no toxicity. No toxic effects were seen in either rats or dogs given BHI sc or iv for one month (Table 6.14). Chronic toxicity, reproductive toxicity, and carcinogenicity studies were not conducted due to the extensive clinical experience with insulin, and the extensive chemical analysis of the NBE, establishing its identical nature with natural human insulin. BHI was negative in a genetic toxicology screen composed of bacterial mutation, DNA repair, and sister chromatid exchange evaluations. BHI was also not pyrogenic. Overall, BHI did not induce any effects different from those induced by PPI, and all effects seen were extensions of known insulin pharmacology. Investigations demonstrating the virtual absence of endogenous *E. coli* proteins, and the absence of antigenic response in rats

Special Issues

Immunotoxicology

Immunotoxicology can be defined as the discipline concerned with the study of adverse effects on the immune system as a result of exposure to xenobiotics (51). It is not the purpose of this section to review in detail the specific evaluations conducted to define immunotoxicity (48, 51, 179, 201), but, rather, to discuss the use of these evaluations in a hazard assessment tier approach. Adverse responses of the immune system are known to occur secondary to malnutrition, radiation exposure, neonatal thymectomy, and exposure to certain drugs and chemicals (54, 186). Historically, few chemicals have been shown to be immunosuppressive in toxicology evaluations, probably because the lymphoid organs and the immune system, in general, have been poorly examined. It would be desirable, therefore, to establish an effective tier approach to detect immunotoxicity in standard subchronic and chronic toxicology studies, and also to evaluate the functional nature of the changes observed as a result of drug exposure. It is presumed that a functional change detected in the immune system is predictive of adverse health effects (201). It must be remembered that a critical function must be depressed beyond a defined,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_269.html[2010/10/28 18:42:28]

minimal point (reserve capacity) to indicate a health risk (131). The tier approach is encouraged because it more carefully directs the use of resources, and a single immune function assay may not comprehensively characterize the myriad of potential toxic effects on the immune system (51).
Specific immune function tests for increasing the capability of toxicology studies to reveal effects on lymphoid tissue, and to evaluate more fully the risk of chemical exposure by determining the functional significance of the responses observed, have been reviewed (48). It is known that acute and chronic effects of drug exposure on the immune system can result in three principal undesirable effects: immunosuppression or enhancement, autoimmunity, and allergic reactions (131). Immunosuppression has also been related to an increased incidence of neoplasia, though the relationship between immunosuppression and carcinogenesis is not a direct one (54). An early consensus meeting held by the National Institute for Environmental Health Sciences (1979) resulted in the development of a list of relevant immunological parameters for evaluating chemically induced immunotoxicity. This immunology screening panel has been reviewed (48), and includes: pathotoxicology, hematology, host resistance, radiometric delayed hypersensitivity, lymphoproliferation, humoral immunity, and evaluation of bone marrow progenitor cells.
Some of the first guidelines for immunotoxicology testing were those developed by the EU in the late 1970s. The focus of these guidelines was to evaluate the potential risk of chemical exposure by evaluating the functional significance of any histopathological or hematological effects seen on lymphoid organs in routine toxicity studies (141). The intention was to pursue the significance of these effects with specific function tests as necessary. It is known that immunotoxicity following drug exposure may take the form of changes in lymphoid tissue organ weights or histology, or changes in bone marrow or peripheral leukocytes (51). Norbury (141), however, pointed out that the evaluation of drug effects on the immune system is related to immune responsiveness, and is not simply a single point examination of lymphoid tissue using histopathology and hematology. Histopathological changes are generally not believed to be sensitive indicators of drug-induced immunotoxicity, are seen only at fairly high dose levels, and do not necessarily equate with functional immune alterations (51, 141, 201). The route and time of exposure relative to the maturational development of the immune system are important considerations in designing an immunotoxicity protocol (25, 49).
The application of nonspecific immunotherapy for bacterial and viral diseases has led to an increased level of importance in the determination of immunotoxic effects. The standard acute, subchronic, and chronic/oncogenic studies that form the basis of toxicological evaluations should be complemented with specific evaluations useful in determining functional effects on the immune system, especially if the agent in question is a known immune modulator. Immune system function results from a balance of the activities of various cellular components and their soluble factors (154), and an alteration in any factor could result in an imbalance of the entire system (63). The effects of immunomodulating agents, therefore, could result in either enhancement (i.e., hypersensitivity, autoimmunity) or suppression (i.e., decreased host resistance) (Figure 6.12).
Several tier approaches to immunotoxicity testing have been proposed (50, 131). For one example, the National Toxicology Program (NTP) has proposed an immunotoxicology testing strategy including a limited number of functional and host resistance assays (50). The first tier (Tier 1) of the two-tier approach consists of a screen which represents a limited effort that includes the assessment of cell-mediated immunity, humoral immunity, and immunopathology. Tier 1 provides little information on the specificity of an observed immune defect, or its relevance to the host; however, it can detect an immune alteration resulting from drug exposure (131). Tier 2 represents an in-depth evaluation, initiated only if functional changes are seen in Tier 1 at otherwise nontoxic doses (131). The in-depth immune function and host resistance evaluations provide information on the mechanism(s) of the immunotoxicity and aid risk assessment. Luster et al. (131) have reported that no compound evaluated to date has been found to produce an effect in Tier 2 without demonstrating some effect in Tier 1. The NTP procedure for detection of immune alterations following chemical or drug exposure in rodents is shown in Table 6.15. The concept of performing func-

[a]From Reference 131.

tional tests is critical to defining potential mechanisms of the toxic response and their applicability to humans. An international collaborative effort has focused on the evaluation of limited pathology or enhanced pathology evaluations to better understand potential immunotoxicity (176). The enhanced pathology approach—for example, weight determination, examination of additional lymphoid organs, and grading of changes in the principal compartments of lymphoid tissue—was determined to provide an advantage in revealing effects on the immune system.

The direction for pharmaceutical development is to include tests of potential immune system involvement in the traditional toxicological evaluations for subchronic and chronic toxicity. Due to the sensitivity of the immune system to toxicants that could adversely affect the critical balance of the various immune factors, and the adverse health effects that could ensue, it is extremely important to define any potential interaction of a new drug and immune system function (201).

As can be anticipated from the previous discussion, immunogenicity is a major scientific issue relative to the development of biotechnology products. Concern has been raised over the comparison of the recombinant protein and the naturally occurring protein, since animal models are thought to be inadequate to assess the chemically subtle, but potentially immunologically significant, differences in the human response to these molecules. It has been assumed that a recombinant protein, designed for human use, would produce a number of adverse effects, including the production of neutralizing antibodies, in experimental animals. It has now become clear, through chronic exposures in nonclinical studies, that some small molecular weight human proteins are not immunogenic in animals, or are only weakly so. They have also been observed not to produce neutralizing antibodies. In the case where antibodies to human proteins have been detected in nonclinical studies, they do not necessarily cause expected immunopathology or neutralization activity. The rhesus monkey has been shown to predict the relative immunogenicity of several recombinant proteins in humans (216), and may serve as a good model. A further question is, Should all recombinant DNA products be routinely screened in animals prior to their introduction into humans? The major reason for conducting immunotoxicity evaluations in experimental animals is to detect those compounds which could induce anaphylaxis or anaphylactoid reactions in humans (193). New molecules, previously minimally tested in animals, such as enkephalins, would have a greater potential risk than well-known molecules, such as insulin. An approach to testing recombinant proteins, as well as NCEs, for immunogenicity/antigenicity has been suggested based on the extent of the clinical database and the existing regulatory requirements (Figure 6.13). Although studies in animals seem well justified for poorly characterized chemicals, it remains an open question whether or not regulatory agencies will accept an existing extensive clinical database as justification for not performing immunogenicity evaluations. Again, the chemical characterization of the recombinant product relative to

Page 272

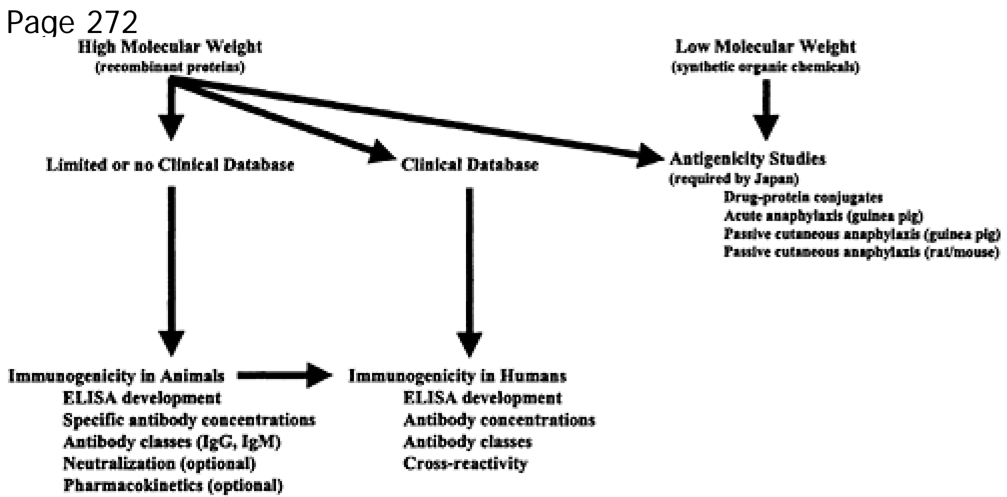

FIG. 6.13. Proposed approach for addressing immunogenicity and antigenicity issues with established and novel biotechnology products and NCEs. From Reference 193.

the natural material will have some bearing on this debate.

Genetic Toxicology

Genotoxicity has been defined as the ability of either a chemical or physical agent to damage DNA, resulting in a mutation (29). An important element of toxicology is the early identification of potentially hazardous substances. Since the actions of toxins are ultimately exerted at the cellular level, isolated cell systems represent an important model for identifying toxic effects. In vitro assays allow a greater control over xenobiotic metabolism (i.e., addition of enzymes or inhibitors), and facilitate mechanistic studies that could not be performed in vivo (113). In vitro tests generally provide a reasonable approximation of the potential for an agent to have an effect on genetic material; in vivo procedures provide a better test for the potential for genetic alterations to occur in the intact organism (119). The short-term in vitro tests for genotoxicity, potentially predictive of in vivo carcinogenicity, are among the most important techniques available for the rapid determination of potential severe undesirable effects of compounds selected for development. They are also useful in the prioritization of compounds to be studied in the more extended and expensive in vivo toxicology studies.

A number of assays are available to evaluate the potential for genotoxicity. The majority opinion is in favor of a battery approach to identify potential genotoxic activity since different assays assess different types of genetic damage (116, 158). The ICH has published a guideline on how to conduct genotoxicity tests, and a guideline on the recommended standard genotoxicity testing battery for evaluations of pharmaceuticals (105, 106). The ICH test battery includes:

1. gene mutation in bacteria: detect relevant genetic changes and the majority of genotoxic rodent carcinogens.
2. in vitro mammalian cell chromosomal aberration, or in vitro mouse lymphoma tk assay: detect either gross chromosomal damage or detection of gene mutation and clastogenic effects.
3. In vivo chromosomal damage in rodent hematopoietic cells: allows evaluation of additional relevant factors, for example, absorption, distribution, metabolism, and excretion.

This battery may be expanded when appropriate, such as when compounds with structural alerts are negative in the three standard tests (106).

Excellent reviews of methods to study genotoxic potential, and issues concerning nongenotoxic, yet carcinogenic, chemicals are available (17, 18, 194, 195). In vivo exposure assays have the advantage of an intact metabolic system to effectively assay those compounds which must be activated (metabolized to a reactive entity) to achieve an effect. The in vitro assays may be conducted with or without the addition of a postmitochondrial supernatant from livers of rats treated with polychlorinated biphenyls to maximally induce drug metabolizing enzyme activities, and, thus, enhance the detection of indirect-acting agents.

In vitro genotoxicity assays are often used in the early drug discovery process aimed at selecting drug candidates for further development. The definitive in vitro genotoxicity evaluations of mutation and chromosomal damage are generally submitted prior to FHD. The complete battery of recommended tests should be submitted prior to Phase II clinical development.

The conduct of genotoxicity screens on NBEs has been an area of much discussion. The ICH has recognized that the standard genotoxicity testing battery may not be applicable to NBEs (111). Despite this, many pharmaceutical companies conduct genotoxicity evaluations on NBEs primarily to evaluate process impurities, to meet perceived regulatory expectations, or to meet specific regulatory agency requests (94).

Safety Pharmacology

Safety pharmacology involves establishing the pharmacological profile of new drug candidates by evaluating the pharmacodynamics related to the therapeutic indication and by evaluating the pharmacodynamics on other organ systems not related to the therapeutic indication (37). These studies are usually conducted at doses well below those used to establish the toxicology profile. It is not necessary, or even desirable, to produce frank toxicity to establish a valid pharmacological profile. Pharmacological profiling was initially focused on guiding the synthetic chemist in the discovery of new pharmacologically active chemicals, rather than on the detection of adverse drug effects in humans (204). In reviewing the common adverse drug findings in humans, Zbinden (204) pointed out that some responses are easily detected in both humans and experimental animals, including sedation, anorexia, body weight changes, tremor, and tachycardia; and some responses are only detectable in humans, such as tinnitus, vertigo, nausea, and headache. In any event, when one considers the nature of the functional disturbances encountered in both nonclinical and clinical testing, it becomes evident that pharmacological profiling is critical to the safety evaluation of potential therapeutic agents (196, 197). Every chemical that enters the body has the potential for creating effects that may or may not be related to its pharmacological activity. Antihistamines, for example, produce sedation, related to their pharmacological effects, and anticholinergic responses, which are not (196). Pharmacological profiling can help identify the potential incidence of effects unrelated to the known pharmacological activity.

The Japanese Ministry of Health and Welfare (MHW) has published Guidelines for General Pharmacology Studies (60). These studies are designed to characterize effects and potency, and to determine mechanism. The guidelines include studies to determine effects on: general activity and behavior; the CNS; auto nomic nervous system and smooth muscle; respiratory and cardiovascular systems; gastrointestinal tract; and, renal excretion.

A proposal has been made to the ICH for establishment of an EWG to harmonize the safety pharmacology requirements for submission in the EU, United States, and Japan. The EU and Japan have completed similar draft guidelines for safety pharmacology (37). The proposed approach is based on a flexible strategy, including a basic evaluation and a complementary evaluation of safety pharmacology parameters. It has been suggested that the basic evaluation include:

1. Central nervous system: behavioral changes, motor activity, reflex responses, and cardiovascular potential.
2. Cardiovascular system: heart rate, ECG, contraction force, resistance, flow rate, and blood pressure.
3. Respiratory system: frequency, tidal volume, resistance, blood gases.

The following have been proposed for the complementary evaluation:

4. Renal system: volume, pH, fluid/electrolyte balance, protein, and glomerular filtration rate.
5. Immune system.
6. Gastrointestinal system: gastric secretion (pH), ulcerogenic potential, and gastrointestinal transit time.

In addition, the EU Committee for Proprietary Medicinal Products (CPMP) has introduced a guideline to address the potential for QT-interval prolongation by non-cardiovascular medicinal products (36).

Measure of Exposure

The relationship of administered dose to toxicological response is not always a simple correlation. Traditionally, the administered dose (mg/kg) has been the most commonly used expression to compare toxicological responses between species. The value of the administered dose term as the most appropriate comparator with toxicological response, however, has been questioned in scientific and regulatory circles. It is becoming increasingly well recognized that both beneficial and toxic effects of therapeutic agents are dependent on the quantity of material reaching the target site (134, 211, 179). Knowledge of the magnitude of drug exposure is necessary in substantiating efficacy and drug safety evaluations. Furthermore, exposure data have provided important information relative to the interpretation of unanticipated toxicity (143). Toxicologists, therefore, must make an effort to monitor

concentrations of parent compound and/or major active metabolites in the blood and, when possible, the tissues. Measurement of plasma concentrations in toxicology studies provides much

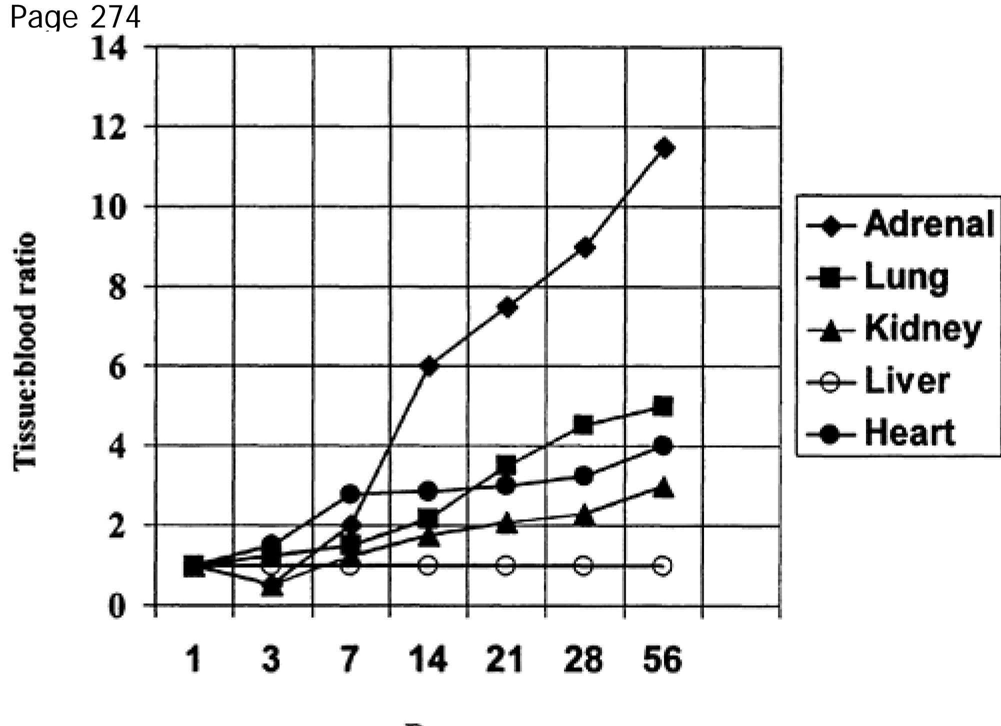

FIG. 6.14. Tissue to blood ratio, over time, in various tissues following single daily doses of chlorphentermine. Redrawn with permission from Reference 126.

needed proof of absorption and exposure. It also, provides a more appropriate dose comparator than administered dose when responses between species are being evaluated. For example, because of differences in metabolism, bioavailability, and so on, rats may have much lower exposure (plasma level) for a given administered (mg/kg) dose than humans receiving the same administered dose. Therefore, the use of multiples of the administered human dose on a mg/kg basis in the experimental animal species may result in an actual exposure that is unpredictable, and differs substantially (either greater or less), from that achieved in patients. The potential of expressing toxicity that is poorly correlated with exposure to a clinical dose, therefore, increases. Setting clinical dose multiples for toxicology studies on the basis of exposure is much more appropriate. Measures of exposure are also useful in establishing nonlinearity in kinetics, which, as described above, is important in explaining toxic responses seen in particular species (134). It seems more rational to establish an upper dose in toxicology studies based on linearity of kinetics rather than at the MTD, since it is often the case that the MTD falls in the range of nonlinear kinetics, saturating normal metabolic processes. Thus, an animal treated at the MTD may be exposed to much higher levels of parent drug, or toxic metabolite(s), than would be observed at meaningful multiples of the clinical dose.

The relationship of administered dose to delivered dose remains a central issue in the interpretation of toxicology data. The measurement of plasma concentrations of parent compound and metabolites represents a partial resolution of this problem. There are limitations, however, in using plasma concentration as a relevant measure of exposure for those compounds that are tissue-sequestered (135). Although many therapeutic agents achieve tissue levels proportional to plasma concentration, some continue to accumulate in tissue with continued dosing (77). In studies of phentermine and chlorphentermine, it was found that the blood to tissue ratios of phentermine remained constant over the entire period of treatment, while those for chlorphentermine significantly increased with time in most of the tissues studied (Figure 6.14) (126). In addition to becoming tightly bound to tissue, chlorphentermine also induced new binding sites during treatment. The difference in behavior between the two closely related chemicals was related to the increased amphiphilic nature of chlorphentermine (126).

Extrapolation of toxicological test results across species is based on the assumption that mammalian species will respond to toxicants in a similar fashion. The convention in toxicology has been to express dose on the basis of mg/kg body weight. Whether body weight is the most appropriate scaling factor for toxicity data has been the subject of much discussion. It had been previously observed that the toxicity of a variety of anticancer drugs was best predicted across species if the dose was expressed on the

basis of body surface area rather than body weight (76). Others, however, have

Table 6.16

Dose by weight and surface area (1 mg/kg)*a*

Species	Body Weight (g)	Surface Area (cm2)	Total Dose (mg/animal)	Administered Dose (mg/cm2)	Multiple of Human Dose
Mouse	20	45	.02	.00044	0.10
Rat	200	325	.20	.00061	0.16
Monkey	4000	2980	4.00	.00134	0.34
Dog	12000	5770	12.00	.00207	0.53
Human	70000	18000	70.00	.00389	1.00

*a*From References 23, 118.

reported that although heat loss appears to be related to body surface area, basal metabolic rate, an important aspect of toxicity evaluation, is more closely related to body weight (82). The use of surface area for the purpose of dose extrapolation is a more conservative approach than the use of body weight (21, 21, 82, 118) (Table 6.16). Assuming that the average adult mouse (0.02 kg) and the normal adult human (70 kg), are given the same administered dose on a body weight basis, the adult human will receive 3500 times the total dose received by the mouse. The same dose, given on a body surface area basis to mice and men, would represent only a 400-fold difference. Although there is support for using surface area as the most appropriate dose extrapolation factor, there is an increasing body of data that suggest the use of body weight to be the most accurate factor (1). Target organ specificity may be a deciding factor in the selection of the most appropriate allometric relationship (that is, antihypertensives vs. oncolytics), The appropriate scaling factor can probably only be determined on a case-by-case basis using data from a variety of species.

Clinical Trials in Pediatric Populations

The FDA has found that most products indicated for treatment of diseases that occur in both adults and children have little clinical trial support for pediatric use. As a result, a new regulation requiring pediatric studies for certain NCEs and NBEs has been proposed (67). The EU Committee for Proprietary Medicinal Products (CPMP) has also concluded that specific age-dependent differences in pharmacokinetics, pharmacodynamics, growth process and development, and specific pathology require that therapeutic agents be tested in the target age group (35). The ICH has recommended that pediatric clinical trials be supported by repeated dose toxicity studies of an appropriate duration, all developmental toxicity studies, and the full battery of genotoxicity tests. These studies should be concluded before the pediatric clinical trials begin (102). Due to the potentially long duration of treatment, carcinogenicity studies must be considered prior to the initiation of long-tenn pediatric clinical trials. The performance of nonclinical studies in juvenile animals may also be necessary if previous toxicology evaluations and human safety data are not sufficient or raise a cause for concern.

Nonclinical Evaluation of Anticancer Drugs

The development of drugs for life-threatening diseases, such as cancer and AIDS, requires a modification of the approach established for the safe development of NCEs or NBEs (see above). The treatment of cancer usually includes the use of potent agents designed to halt cell replication. The therapeutic index for these agents is often small. Due to the life-threatening nature of the disease, a greater risk of drug toxicity and a shorter nonclinical testing strategy is generally accepted for therapeutic agents in this class, since serious drug effects are often less threatening than the targeted disease. However, due to the greater intrinsic toxicity of the agents in this class, the early clinical trials are often conducted in patients rather than normal volunteers, as with other therapeutic agents.

The history of anticancer drug development has been extensively reviewed (92, 53, 180). The basic approach for development of anticancer drugs includes:

1. Establishment of a safe clinical trial entry dose.
2. Determination of potential dose limiting target organ toxicity.
3. Evaluation of reversibility of effects.
4. Determination of MTD in animals.
5. Determination of dose schedule toxicity.

The use of nonclinical studies has been successful in accurate predictions of the MTD in humans and a safe starting dose for clinical trials (92).

The CPMP has provided a specific note for guidance on the nonclinical evaluation of anticancer agents (38). Safety pharmacology is generally required prior to Phase I studies, as are the determination of Cmax (maximum plasma concentration of the drug) and AUC at the animal MTD. Other kinetic parameters are expected to be determined prior to Phase II/III testing. Determination of

the single-dose MTD in rodents and the approximate MTD in nonrodents, using a relevant route of exposure, is also expected prior to Phase I. Repeated-dose toxicity studies in two rodent species are expected prior to Phase I clinical studies. Longer-term repeat-dose studies, in a rodent and nonrodent species, equal in duration to the clinical trial but <6 months, are expected prior to Phase II/III. Genotoxicity testing is not necessary prior to Phase I/II, but the genotoxicity battery is expected to be conducted prior to Phase II/III. Since cytotoxic anticancer agents are known to have an adverse effect on reproduction, developmental toxicity studies are not required but are encouraged.

The development of anticancer drugs and other therapies for life-threatening diseases has unique characteristics based on the life-threatening nature of the disease and the inherent toxicity of the therapeutic agents.

Alternative Methods for Carcinogenicity Determination

The testing for carcinogenic potential has relied primarily on the rodent bioassay. Recently, through the ICH process, the rat has been identified as either the most acceptable or most relevant model for the two-year bioassay. In addition to the rat bioassay, an alternative short-term method of carcinogenicity evaluation is recommended (ICH S1b). These approaches may include studies in transgenic mice—for example, p53+/− heterozygous gene deficient mouse or Tg/AC mouse—or use of a neonatal rodent tumorigenicity model.

To evaluate and verify the available alternative models, the International Life Sciences Institute (ILSI) has initiated a collaborative effort among industry, academic, and government laboratories to study chosen chemicals in the alternative models and evaluate the results in light of the known bioassay data. Currently, there is insufficient information to guide us in the choice of suitable alternative models for carcinogenicity evaluation.

Once validated, the proposed transgenic animal models may be used as follows (33):

1. To confirm results in equivocal 2-year rodent bioassays.
2. To set priorities for 2-year carcinogenicity bio assays.
3. As an alternative to the mouse 2-year bioassay, in conjunction with the rat 2-year bioassay.
4. To assess carcinogenic potential of new genotoxic contaminants/degredants in a drug product after 2-year bioassays are completed.

In addition, the use of transgenic animals may support weight-of-evidence decisions, is relatively short-term, and is generally less expensive than the 2-year rodent bioassay.

Several transgenic mouse models are available to complement the rat 2-year bioassay. The Tg/AC mouse and the p53+/− heterozygous-gene-deficient mouse are taken as examples. It must be remembered that these models are not fully validated.

The Tg/AC mouse model (175) presents an animal model of initiated skin as a target for tumorigenesis. The Tg/AC line may be able to differentiate carcinogens from noncarcinogens, but may not be able to differentiate genotoxic carcinogens from those that cause only tumor promotion activity. This model may only be useful in combination with other transgenic animal models (159).

The p53+/− heterozygous-gene-deficient mouse model is based on rendering mice heterozygous for the p53 tumor suppressor gene (84). These animals are at elevated risk for tumor development. The model has been proposed to best approximate humans at risk for heritable forms of cancer. This model may be able to detect genotoxic carcinogens in a 6-month period.

The neonatal mouse assay has been available longer than the transgenic animal models. The detailed protocol for this 1-year study has been reviewed previously (73). Neonates are treated with the test compound on days 8 and 15 of age, and then observed to 1 year of age. At that time the animals are evaluated for tumor production. This assay is sensitive to direct-acting carcinogens, primarily those that work through formation of covalently bound DNA adducts.

The assessment of carcinogenicity in the drug development process is at a crossroad. The rodent bioassay has been used for over 25 years, and has provided useful data, although it is not a perfect system and is one that has received much criticism. The investigation of alternatives to the standard bioassay in two rodent species has been encouraged by ICH. Conducting a 2-year study in the rat, and an alternative study in the mouse, may provide an acceptable transition. There is, however, much work to be done before the alternative models are validated and fully useful in carcinogenicity risk assessments. The alternative assays are relative newcomers, full of promise but short on experience. There should not be undue enthusiasm about their ability to dramatically improve our carcinogenicity risk assessment process.

Development of Stereoisomeric Drugs

The development of individual enantiomers and racemates requires specific considerations and

interactions with regulatory agencies, especially the FDA. In 1992, the FDA, developed a specific policy statement to deal with development of enantiomers and racemates (70). It is recognized that the properties of enantiomers may be similar and desirable. For example, both enantiomers of dobutamine have positive inotropic properties. It may also occur that the isomers may have desirable but different properties, for example, the d-isomer of propoxyphene is an analgesic, the s-isomer is an

antitussive. It is also recognized that toxicity may be linked to one member of a stereoisomeric pair, for example, granulocytopenia is ascribed to the d-isomer of the antiparkinsonian drug levodopa.
The FDA position is that the establishment of a relatively benign nonclinical toxicological profile for the racemate should support the clinical development of the enantiomer without a separate toxicological evaluation. Since the FDA policy statement (1992) leaves some room for interpretation of "benign toxicology profile," it is highly advisable to engage in a conversation with the agency before proceeding with development.
The FDA makes specific recommendations for pharmacokinetic and toxicology profiles. The potential for interconversion of the isomers must be monitored in nonclinical studies and compared to the clinical profile. It is sufficient to carry out toxicity studies with the racemate unless toxicity unrelated to the pharmacology of the drug occurs at relatively low multiples of the clinical exposure. In that case, the drug developer should investigate the individual enantiomers to examine whether the pharmacological and toxicological effects can be segregated.
The development of a single stereoisomer after the racemate had been evaluated in nonclinical studies requires abbreviated toxicology studies:
1. 3-month toxicology studies of the single enantiomer in rodent and nonrodent species.
2. Segment II (teratology) developmental toxicology study of the single enantiomer in the most sensitive species.
3. A positive control group consisting of the racemate. If there are no differences between the toxicological profile of the single enantiomer and the racemate, no further toxicology studies would be needed.

CONCLUSION

The next decade promises to be another exciting one for the industrial toxicologist. The physician and patient continue to demand more efficacious and safer medications more quickly. Basic research efforts in biochemistry, physiology, and pharmacology have allowed the more precise characterization of receptors, and the normal and perturbed sequelae of receptor binding, which continues to stimulate the development of more specific, potent modulators of cellular functions. The etiologies of human diseases are becoming better understood, thanks to the technological ability to elucidate their characteristics at the molecular level. This has resulted in the potential to therapeutically modify the disease process at its origin—the human genome. These molecular approaches have already resulted in the development of agents that are highly species-specific, and the use of these techniques to elucidate normal and pathological cellular function will only continue to escalate. It is unlikely that the classical tools of toxicology will be adequate to ensure the human safety of the highly specific potential therapeutics forthcoming from these sophisticated technologies. The development of NBEs has already challenged the established norms of safety assessment.
Consider the example of an agent that has shown selectivity for modifying the activity of a human-specific enzyme critical to a pathological process. Although traditional animal studies are likely to be predictive of toxicity that is unrelated to the pharmacology of the compound, they will not be useful for the prediction of adverse findings relative to the action of the drug at the enzyme which will occur only in humans. Thus, not only may data generated from classical animal studies be inadequate to predict toxic responses in humans, but the information may be irrelevant or misleading. A major concern is whether modification of this enzyme activity in the only responsive species, humans, might result in unanticipated, severe toxicity. How can this best be predicted prior to the initiation of clinical trials?
The future direction of discovery research suggests that industrial and regulatory toxicologists will need to collaborate more closely in the design of the toxicology studies to support registration, and ultimately, these may have to be considered on a case-by-case basis. Indeed, the current guidelines resulting from global harmonization efforts repeatedly emphasize the need for defending the scientific rationale supporting the design of proposed toxicological assessments. Although these guidelines are viewed as much more flexible than the country-specific regulations of the past, they also place a greater burden on toxicologists relative to defending the relevance of their studies. The era of "checking the tox box" has, thankfully, come to a close.
Another challenge on the horizon concerns the need to improve the efficiency of the drug development process without compromising its quality. Currently, the drug development and approval processes are taking longer, and costing more than ever before. More stringent regulatory requirements have resulted in the conduct of more studies (in both animals and humans), taking more time and costing more money. These costs are passed on to the patient, who ultimately must also compensate for the resultant decreased market life, due to patent length restrictions, of the registered product. Furthermore, the use

of large numbers of experimental animals remains a concern from both the ethical and financial points of view. One approach to solving these dilemmas is to ensure that the toxicological studies conducted meet the needs of the regulatory agency, the physician, and, ultimately, the patient. As suggested earlier, this can be most

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_277.html[2010/10/28 18:42:33]

efficiently accomplished by early and routine interactions between the industry and these customers, especially in cases where the agent under development represents a unique therapeutic approach.

Finally, the major role of the toxicologist as a mechanistic scientist will continue to be enhanced. For the reasons discussed above, the interpretation of toxicology data will become increasingly more sophisticated, requiring a broad knowledge base in a variety of other scientific disciplines. Elucidation of the mechanisms responsible for observed toxicities would improve the ability to achieve the traditional, ultimate purpose of the discipline of toxicology—the appropriate extrapolation of these data to humans. Achievement of this goal will surely become more challenging, but also more exciting, in the future.

ACKNOWLEDGMENTS

The authors gratefully acknowledge and appreciate the efforts of Ms. Arlene Adkins in the preparation of this document.

QUESTIONS

1. What are the major objectives of toxicity testing relative to the development of pharmaceuticals?
2. In what major ways would a toxicology submission package differ for a drug intended to be prescribed chronically (e.g., for essential hypertension) as opposed to one that will be used acutely (e.g., an antibiotic)?
3. In what situations would the conduct of oncogenicity studies most likely be encouraged? For NCEs? For NBEs?
4. Why is the use of the maximum tolerated dose (MTD) as the high dose in oncogenicity studies controversial?
5. What are the different phases of clinical testing and what is the purpose of each phase?
6. Why is exposure in animal models considered a better parameter than administered dose when extrapolating toxicity data to humans?
7. Under what conditions might a compound with significant animal toxicity be considered for regulatory approval?
8. What are some of the special considerations necessary in designing the toxicology package for NBEs?

Over the years that have passed since the writing of the third edition of this chapter, the rate of change in toxicology, statistics, and in the interface between these two disciplines has continued to accelerate. The author is hopeful that this complete revision adequately reflects these changes.

PHILOSOPHY AND GENERAL PRINCIPLES

This chapter has been written for both practicing and student toxicologists as both a basic text and a practical guide to the common statistical problems encountered in toxicology and the methodologies that are available to solve them. The chapter has been enriched by the inclusion of discussions of why a particular procedure or interpretation is recommended, by the clear enumeration of the assumptions that are necessary for a procedure to be valid, and by worked-through examples and problems drawn from the actual practice of toxicology.

Since 1960, the field of toxicology has become increasingly complex and controversial in both its theory and practice. Much of this change is due to the evolution of the field. As in all other sciences, toxicology started as a descriptive science. Living organisms, be they human or otherwise, were dosed with or exposed to chemical or physical agents, and the adverse effects which followed were observed, but as a sufficient body of descriptive data was accumulated, it became possible to infer and study underlying mechanisms of action to determine in a broader sense why adverse effects occurred. Toxicology has thus entered a later state of development, the mechanistic stage, where active contributions to the field encompass both descriptive and mechanistic studies.

Studies continue to be designed and executed to generate increased amounts of data. The resulting problems of data analysis have then become more complex and toxicology has drawn more deeply from the well of available statistical techniques. Statistics have also been very active and growing during the last 35 years, to some extent, at least, because of the parallel growth of toxicology. These simultaneous changes have led to an increasing complexity of data and, unfortunately, to the introduction of numerous confounding factors that severely limit the utility of the resulting data in all too many cases.

A major difficulty is that there is a very real need to understand the biological realities and implications of a problem, as well as to understand the peculiarities of toxicological data before procedures are selected and employed for analysis. These characteristics include the following:

(1) The need to work with a relatively small sample set of data collected from the members of a population (laboratory animals, cultured cells, bacterial cultures) that are not actually the population of interest (i.e., humans or a target animal population).

(2) Dealing frequently with data resulting from a sample that was censored on a basis other than by the investigator's design. By censoring, of course, we mean that not all data points were col lected as might be desired. This censoring could be the result of either a biological factor (the test animal being dead or too debilitated to manipulate) or a logistic factor (equipment being inoperative or a tissue being missed in necropsy).

(3) The conditions under which our experiments are conducted are extremely varied. In pharmacology (the closest cousin to at least classical toxicology), the possible conditions of interaction of a chemical or physical agent with a person are limited to a small range of doses via a single route over a short course of treatment to a defined patient population. In toxicology, however, all of these variables (dose, route, time span, subject population) are determined by the investigator.

(4) The time frames available to solve our problems are limited by practical and economic factors. This frequently means that there is not time to repeat a critical study if the first attempt fails, so a true iterative approach is not possible.

The training of most toxicologists in statistics remains limited to a single introductory course that concentrates on some theoretical basics. As a result, the armamentarium of statistical techniques of most toxicologists is limited and the tools that usually are used (t-tests, chi-square, analysis of variance, linear regression) are neither fully developed nor well understood. It is hoped that this chapter will help change this situation.

As a point of departure, it is essential that any analysis of study results be interpreted by a professional who firmly understands three concepts: the difference between biological significance and statistical significance, the nature and value of different types of data, and causality.

For the first concept, we should consider the four possible combinations of these two different types of significance for which we find the relationship shown below.

		STATISTICAL SIGNIFICANCE	
		NO	YES
BIOLOGICAL	NO	CASE I	CASE II
SIGNIFICANCE	YES	CASE III	CASE IV

Cases I and IV give us no problems, as the answers are the same statistically and biologically, but cases II and III present problems. In case II (the false-positive) we have a circumstance where there is a statistical significance in the measured difference between treated and control groups, but there is no

true biological significance to the finding. This is not an uncommon happening (e.g., in the case of clinical chemistry parameters). This is called type I error by statisticians, and the probability

Table 7.1

Approximate total sample sizes for comparisons using the t-test and equal group sizes

	β=0.1		β=0.2	
Δ/σ	α=0.05	α=0.10	α=0.05	α=0.10
0.25	672	548	502	396
0.50	168	138	126	98
0.75	75	62	56	44
1.00	42	34	32	24
1.25	28	22	20	16
1.50	18	16	14	12

Δ is the difference in the treatment group means and σ is the standard deviation.

of this occurring is called the a (alpha) level. In case III (the false-negative) we have no statistical significance, but the differences between groups are biologically/ toxicologically significant. This is called type II error by statisticians, and the probability of such an error happening by random chance is called the β (beta) level. An example of a type II error is when a few of a very rare tumor type are seen in treated animals. For both type I and II errors, numerical analysis, no matter how well done, is no substitute for professional judgment. One must have a feeling for the different types of data and for the value or relative merit of each. Note that the two error types interact, and in determining sample size we need to specify both α and β levels. Table 7.1 demonstrates this interaction in the case of the t-test. There are many reasons that biological and statistical significance are not identical and often are multiple, but certainly a central reason is causality. Through our consideration of statistics, we should keep in mind that just because a treatment and a change in an observed organism are seemingly or actually associated with each other does not "prove" that the former caused the latter. Though this fact is now widely appreciated for correlation (e.g., the fact that the number of storks' nests found each year in England is correlated with the number of human births that year does not mean that storks bring babies), it is just as true in the general case of significance. Timely establishment and proof that treatment causes an effect requires an understanding of the underlying mechanism and proof of its validity. At the same time, it is important that we realize that not finding a good correlation or suitable significance associated with a treatment and an effect likewise does not prove that the two are not associated (that a treatment does not cause an effect). At best, it gives us a certain level of confidence that under the conditions of the current test, these items are not associated.

These points, along with other common pitfalls and shortcomings associated with the method, will be discussed in greater detail in the Assumptions section for each method. To help in better understanding the sections to come, terms frequently used in discussion throughout this chapter should first be considered. These are presented in Table 7.2.

Each measurement we make—each individual piece of experimental information we gather—is called a datum; however, we gather and analyze multiple pieces at one time, with the resulting collection being called data. Data are collected on the basis of their association with a treatment (intended or otherwise) as an effect (a property) that is measured in the experimental subjects of a study, such as body weights. These identifiers (i.e., treatment and effect) are termed *variables*. Treatment variables (those that the researcher or nature control and that can be directly controlled) are termed *independent,* whereas effect variables (such as weight, life span, and number of neoplasms) are termed dependent variables (their outcome is believed to dependent on the "treatment" being studied).

All of the possible measures of a given set of variables in all of the possible subjects that exist are termed the population for those variables. Such a population of variables cannot be truly measured (e.g., one would have to obtain, treat, and measure the weights of all the Fischer-344 rats that were, are, or ever will be). Instead, we deal with a representative group—a sample. If our sample of data is appropriately collected and of sufficient size, it serves to provide good estimates of the characteristics of the parent population from which it was drawn.

Two terms refer to the quality and reproducibility of our measurements of variables. The first, accuracy, is an expression of the closeness of a measured or computed value to its actual or "true" value in nature. The second, precision, reflects the closeness or reproducibility of a series of repeated measurements of the same quantity.

If we arrange all of our measurements of a particular variable in order as a point on an axis marked as to the values of that variable, and if our sample were large enough, the pattern of distribution of the data in the sample would begin to become apparent. This pattern is a representation of the frequency distribution of a given population of data (i.e., of the incidence of different measurements, their central

tendency, and dispersion).

The most common frequency distribution—and one we will talk about throughout this chapter—is the normal (or Gaussian) distribution. The normal distribution is such that two thirds of all values are within one standard deviation of the mean (or average value for the entire population), and 95% are within 1.96 standard

Page 288

Table 7.2 Some frequently used terms and their general meanings (171)

Term	Meaning
95% confidence interval	A range of values above, below, or above and below the sample mean, median, mode, etc., has a 95% chance of containing the true value of the population (mean, median, mode). Also called the fiducial limit equivalent to the Pc 0.05.
Bias	Systemic error as opposed to a sampling error. For example, selection bias may occur when each member of the population does not have an equal chance of being selected for the sample.
Degrees of freedom	The number of independent deviations, usually abbreviated *df*.
Independent variables	Also known as predictors or explanatory variables.
P-value	Another name for significance level; usually 0.05 or 0.01
Power	The effect of the experimental conditions on the dependent variable relative to sampling fluctuation. When the effect is maximized, the experiment is more powerful. Power can also be defined as the probability that there will not be a type II error (1-Beta). Conventionally, power should be at least .07.
Random	Each individual member of the population has the same chance of being selected for the sample.
Robust	Having inferences or conclusions little effected by departure from assumptions.
Sensitivity	The number of subjects experiencing each experimental condition divided by the variance of scores in the sample.
Significance level	The probability that a difference has been erroneously declared to be significant, typically 0.05 and 0.01 corresponding to 5% and 1% chance of error, respectively.
Type I error (false-positives)	Concluding that there is an effect when there really is not an effect. Its probability is the alpha level.
Type II error (false-negatives)	Concluding there is not an effect when there really is an effect. Its probability is the beta level.

deviations of the mean. The mathematical equation describing the normal distribution is

$$y = \frac{1}{\sigma\sqrt{2\pi}} e^{-(x-\mu)^2/2\sigma^2}$$

where μ is the mean and σ is the standard deviation. Other common frequency distributions include the Poisson and chi square.

In all areas of biological research, optimal design and appropriate interpretation of experiments require that the researcher understand both the biological and technological underpinnings of the system being studied and of the data being generated. From the point of view of the statistician, it is vitally important that the experimenter both knows and is able to communicate the nature of the data and understands its limitations. One classification of data types is presented in Table 7.3.

The nature of the data collected is determined by three considerations. These are the biological source of the data (the system being studied), the instrumentation and techniques being used to make measurements, and the design of the experiment. The researcher has some degree of control over each of these, with least control over the biological system (he/she normally has a choice of only one of several models to study) and most control over the design of the experiment or study. Such choices, in fact, dictate the type of data generated by a study.

Statistical methods are based on specific assumptions. Parametric statistics—those that are most familiar to the majority of scientists—have more stringent underlying assumptions than do nonparametric statistics. Among the underlying assumptions for many parametric

Table 7.3 Types of variables (data) and examples of each type

Classified by		Type	Example
Scale	Continuous	Scalar	Body weight
		Ranked	Severity of a lesion
	Discontinuous	Scalar	Weeks until the first observation of a tumor in a carcinogenicity study
		Ranked	Clinical observations in animals
		Attribute	Eye colors in fruit flies
		Quantal	Dead/alive or present/absent
Frequency distribution		Normal	Body weights
		Bimodal	Some clinical chemistry parameters
		Others	Measures of time to incapacitation

statistical methods (such as the analysis of variance) is that the data are continuous. The nature of the data associated with a variable (as described previously) imparts a "value" to that data, the value being the power of the statistical tests that can be employed.

Continuous variables are those that can at least theoretically assume any of an infinite number of values between any two fixed points (such as measurements of body weight between 2.0 and 3.0 kg). Limitations on our ability to measure a specific parameter constrain the extent to which the real-world situation approaches the theoretical, but many of the variables studied in toxicology are, in fact, continuous. Examples of these are lengths, weights, concentrations, temperatures, periods of time, and percentages. For these continuous variables, we may describe the character of a sample with measures of central tendency and dispersion that we are most familiar with—the mean, denoted by the symbol μ and also called the arithmetic average, and the standard deviation SD, which is denoted by the symbol σ and is calculated as being equal to

$$\sqrt{\frac{\sum X^2 - \frac{(\sum X)^2}{N}}{N-1}},$$

where X is the individual datum and N is the total number of data in the group.

Contrasted with these continuous data, however, we have discontinuous (or discrete) data that can only assume certain fixed numerical values with no possible intermediate values (such as counts of 5 and 6 dead animals respectively). In these cases our choice of statistical tools or tests is, as we will find later, more limited.

Probability

Probability is simply the frequency with which, in a sufficiently large sample, a particular event will occur or a particular value will be found. Hypothesis testing, for example, generally is structured so that the likelihood of a treatment group being the same as a control (the so called "null hypothesis") can be assessed as being less than a selected low level (very frequently 5%), which implies that we are 1.0-α (i.e., 1.0–0.05, or 95%) sure that the groups are *not* equivalent.

Functions of Statistics

Statistical methods may serve to do any combination of three possible tasks. The one we are most familiar with is hypothesis testing (i.e., determining if two [or more] groups of data differ from each other at a predetermined level of confidence). A second function is the construction and use of models that may be used to predict future outcomes of chemical-biological interactions. This is most commonly seen in linear regression or in the derivation of some form of correlation coefficient. Model fitting allows us to relate one variable (typically a treatment or "independent" variable) to another. The third function, reduction of dimensionality, continues to be less commonly used than the first two. This final category includes methods for reducing the number of variables in a system while only minimally reducing the amount of information, therefore making a problem easier to visualize and to understand. Examples of such techniques are factor analysis and cluster analysis. A subset of this last function, discussed later under descriptive statistics, is the reduction of raw data to single expressions of central tendency and variability (such as the mean and standard deviation). There also is a special subset of statistical techniques that is part of both the second and third functions of statistics. This is data transformation, which includes such things as the conversion of numbers to log or probit values.

This chapter is primarily designed to address the first of the three functions of statistical methods that we pre

sented (hypothesis testing). The second function, modeling (especially in the form of risk assessment), is becoming increasingly important as the science continues to evolve from the descriptive phase to a mechanistic phase. Likewise, because the interrelation of multiple factors is becoming a real concern, a discussion of reduction of dimensionality has been included.

Descriptive Statistics

Descriptive statistics are used to summarize the general nature of a data set. As such, the parameters describing any single group of data have two components. One of these describes the location of the data, whereas the other gives a measure of the dispersion of the data in and about this location. Often overlooked is the fact that the choice of which parameters are used to give these pieces of information implies a particular type of distribution for the data.

Most commonly, location is described by giveing the (arithmetic) mean and dispersion by giving the standard deviation (SD) or the standard error of the mean (SEM). The calculation of the first two of these has already been described. If we again denote the total number of data in a group as N, then the SEM would be calculated as

$$\mathrm{SEM} = \frac{\mathrm{SD}}{\sqrt{N}}.$$

The SD and the SEM are related to each other but yet are quite different. To compare these two, let us first demonstrate their calculation from the same set of 15 observations:

Data Points (Xi): 1, 2, 3, 4, 4, 5, 5, 5, 6, 6, 6, 7, 7, 8, 9
Sum(Σ)=78.

Squares (X_i^2): 1, 4, 9, 16, 16, 25, 25, 25, 36, 36, 36, 49, 49, 64, 81
Sum=472

The standard deviation can then be calculated as

$$\mathrm{SD} = \frac{\sqrt{472 - \frac{(78)^2}{15}}}{15 - 1} = \frac{\sqrt{472 - \frac{(6084)}{15}}}{14}$$

$$= \frac{\sqrt{472 - 405.6}}{14} = \sqrt{4.7428571} = 2.1778$$

with a mean $(\bar{x})$ of $\frac{78}{15} = 5.2$ for the data group. The SEM for the same set of data, however, is

$$\mathrm{SEM} = \frac{2.1778}{\sqrt{15}} = \frac{2.1778}{3.8730} = 0.562303.$$

The SEM is quite a bit smaller than the SD, making it very attractive to use in reporting data. This size difference is because the SEM actually is an estimate of the error (or variability) involved in measuring the means of samples and not an estimate of the error (or variability) involved in measuring the data from which means are calculated. This is implied by the *Central Limited Theorem,* which tells us three major things:

• The distribution of sample means will be approximately normal regardless of the distribution of values in the original population from which the samples were drawn.
• The mean value of the collection.
• The standard deviation of the collection of all possible means of samples of a given size, called the SEM, depends on both the standard deviation of the original population and the size of the sample.

The SEM should be used only when the uncertainty of the estimate of the mean is of concern, which is almost never the case in toxicology. Rather, we are concerned with an estimate of the variability of the population, for which the standard deviation is appropriate.

The use of the mean with either the SD or SEM implies, however, that we have reason to believe that the sample of data being summarized are from a population that is at least approximately normally distributed. If this is not the case, then we should rather use a set of statistical descriptions that do not require a normal distribution. These are the median, for location, and semiquartile distance, for a measure of dispersion. These somewhat less familiar parameters are characterized as follows.

Median

When all of the numbers in a group are arranged in a ranked order (i.e., from smallest to largest), the

median is the middle value. If there is an odd number of values in a group, then the middle value is obvious (in the case of 13 values, for example, the seventh largest is the median). When the number of values in the samples is even, the median is calculated as the midpoint between the (N/2)th and the ([N/2]+1)th number. For example, in the series of numbers 7, 12, 13, 19, the median value would be the midpoint between 12 and 13, which is 12.5.

Semiquartile Distance

When all the data in a group are ranked, a quartile of the data contains one ordered quarter of the values. Typically, we are most interested in the borders of the middle two quartiles Q1 and Q3, which together represent the semiquartile distance and which contain the median as their center. Given that there are N values in an ordered group of data, the upper limit of the jth quartile (Qj)

may be computed as being equal to the [(jN÷l)/4th] value. Once we have used this formula to calculate the upper limits of Q1 and Q3, we can then compute the semiquartile distance (which is also called the quartile deviation, and as such is abbreviated as the QD) with the formula QD=(Q3–Q1)/2.

For example, for the 15 value data set 1, 2, 3, 4, 4, 5, 5, 5, 6, 6, 6, 7, 7, 8, 9, we can calculate the upper limits of Q1 and Q3 as

$$Q_1 = \frac{1(15+1)}{4} = \frac{16}{4} = 4,$$

$$Q_3 = \frac{3(15=1)}{4} = \frac{48}{4} = 12.$$

The 4th and 12th values in this data set are 4 and 7, respectively. The semiquartile distance can then be calculated as

$$\mathrm{QD} = \frac{7-4}{2} = 1.5.$$

One final sample parameter that sees some use in toxicology (primarily in inhalation studies) is the geometric mean, denoted by the term $\bar{X}_g$. This is calculated as

$$\overline{X}_g = (X_1.X_2 \ldots X_N)^{1/N}$$

and has the attractive feature that it does not give excessive weight to extreme values (or "outliers"), such as the mass of a single very large particle in a dust sample. In effect, it "folds" extreme values in toward the center of the distribution, decreasing the sensitivity of the parameter to the undue influence of the outlier. This is particularly important in the case of aerosol samples, where a few very large particles would cause the arithmetic mean of particle diameters to present a misleading picture of the nature of the "average" particle.

There are times when it is desired to describe the relative variability of one or more sets of data. The most common way of doing this is to compute the coefficient of variation (CV), which is calculated simply as the ratio of the SD to the mean, or

$$CV = \frac{SD}{\overline{X}}$$

A CV of 0.2 or 20% thus means that the standard deviation is 20% of the mean. In toxicology the CV is frequently between 20% and 50% and may at times exceed 100%.

Outliers and Rounding of Numbers

These two considerations in the handling of numerical data can be, on occasion, of major concern to the toxicologist because of their pivotal nature in cases of borderline significance. Outliers should also be of concern for other reasons, however. On the principle that one should always have a plan to deal with all reasonably likely contingencies in advance of their happening, early decisions should be made to select a policy for handling both outliers and the rounding of numbers.

Outliers

Outliers are extreme (high or low) values that are widely divergent from the main body of a group of data and from what is our common experience. They may arise from an instrument (such as a balance) being faulty, the apparently natural urge of some animals to frustrate research, or they may be indicative of a "real" value. Outlying values can be detected by visual inspection of a data, use of a scattergram (described later), or (if the data set is small enough, which is usually the case in toxicology) by a large increase in the parameter estimating the dispersion of data, such as the SD.

When we can solidly tie one of the above error-producing processes (such as a balance being faulty) to an outlier, we can safely delete it from consideration, but if we cannot solidly tie such a cause to an outlier (even if we have strong suspicions), we have a much more complicated problem, for then such a value may be one of several other things. It could be the result of a particular parameter that is the grounds for the entire study (i.e., the very "effect" that we are looking for) or it could be because of the collection of legitimate effects which constitute sample error. As will be discussed later (under exploratory data analysis), and is now more widely appreciated, outliers can be an indication of a biologically significant effect that is not yet statistically significant. Variance inflation can be the result of such outliers and can be used to detect them. Outliers, in fact, by increasing the variability within a small sample set, decrease the sensitivity of our statistical tests and actually preclude our having a statistically significant result (12).

Alternatively, the outlier may be the result of, for example, an unobserved technician error and may change the decisions made from a set of data. In this case we want to reject the data point—to exclude it from consideration with the rest of the data, but how can one identify these legitimate statistical rejection cases?

There are a wide variety of techniques for data rejection. Their proper use depends on one's having an understanding of the nature of the distribution of the data. For normally distributed data with a single extreme value, a simple method such as Chauvenet's criterion (107) may legitimately be employed. This states that if the probability of a value deviating from the mean is greater than 1/2 N, one should consider that there are adequate grounds for its rejections. This approach is demonstrated below.

USE OF CHAUVENET'S CRITERION

Having collected 20 values as a data set, we find they include the following values: 1, 6, 7, 8, 8, 9, 9, 9, 10, 10, 10, 10, 10, 11, 11, 11, 12, 12, 13 and 14. Was the lowest value (1) erroneous and should it be rejected as a outlier? Some simple calculations are performed, as

Mean (X)=9.55,

Standard deviation (SD)=2.80,

$$\text{Chauvenet's Criterion Value} = \tfrac{1}{2}\text{N} = \frac{20}{2} = 10.$$

So we would reject the value of "1" if its probability of occurrence were less than 10%. Going to a table of Z scores, we see that 10% of the values in a normal distribution are beyond ±1.645 SDs of the mean. Multiplying this by the SD for the sample, we get (1.645)(2.80)=4.606. This means we would reject values beyond this range from the mean—that is, less than (9.55–4.606)=4.944 or greater than (9.55+4.606)=14.156. We therefore reject the value of "1."

One should note that as the sample size gets bigger, the rejection zone for Chauvenet's Criterion will also increase, as N of 20 is about as large as this method is useful for.

A second relatively straightforward approach, for use when the data are normally distributed but contain several extreme values is to winsorize the data. Though there are a number of variations to this approach, the simplest (called the *G-1 method*) calls for replacing the highest and lowest values in a set of data. In a group of data consisting of the values 54, 22, 18, 15, 14, 13, 11, and 4, we would replace 54 with a second 22, and 4 with a replicate 11. This would give us a group consisting of 22, 22, 18, 15, 14, 13, 11, and 11, which we would then treat as our original data. Winsorizing should not be performed, however, if the extreme values constitute more than a small minority of the entire data set.

Another approach is to use Dixon's Test (42) to determine if extreme values should be rejected. In Dixon's test, the set of observations is first ordered according to their magnitude (as we did earlier for the data set used to demonstrate Chauvenet's Criterion, though there this step was simply to make the case clearer). The ratio of the difference of an extreme value from one of its nearest neighbor values in the range of values in the sample is then calculated using a formula that varies with sample size. This ratio is then compared to a table value, and if found to be equal or greater, is considered to be an outlier at the $p \leq 0.05$ level. The formula for the ratio varies with sample size and according to whether it is the smallest or largest value that is suspect.

If we have more information as to the nature of the data or the type of analysis to be performed, there are even better techniques to handle outliers. Extensive discussions of these may be found elsewhere (10, 12, 76, 137).

Rounding Off

When the number of digits in a number is to be reduced (due to limitations of space or to reflect the extent of significance of a number), we must carry out the process of rounding off a number. Failure to have a rule for performing this operation can lead to both confusion and embarrassment for a facility (during such times as study audits). One common rule follows.

A digit to be rounded is not changed if it is followed by a digit less than 5; the digits following it are simply dropped off ("truncated"). If the number is followed by a digit greater than 5 or by a 5 followed by other nonzero digits, it is increased to the next highest number. When the digit to be rounded is followed by 5 alone or by 5 followed by zeros, it is unchanged if it is even but increased by one if it is odd. Examples of this rule, in effect, are (in a case where we must reduce to 3 digits)

137.4 becomes 137

137.6 becomes 138

138.52 becomes 139

137.5 becomes 138

and 138.5 becomes 138

The rationale behind this procedure is that over a period of time the results should even out—as many digits that increased are also decreased.

Sampling

Sampling—the selection of which individual data points will be collected, whether in the form of selecting which animals to collect blood from or to remove a portion of a diet mix from for analysis—is an essential step upon which all other efforts toward a good experiment or study are based. There are three assumptions about sampling that are common to most of the statistical analysis techniques that are used in toxicology. These are that the sample is collected without bias, that each member of a sample is collected independently of the others, and that members of a sample are collected with

replacements. Precluding bias, both intentional and unintentional, means that at the time of selection of a sample to measure, each portion of the population from which that selection is to be made has an equal chance of being selected. Ways of precluding bias are discussed in detail in the section on experimental design.

Independence means that the selection of any portion of the sample is not affected by and does not affect the selection or measurement of any other portion.

Finally, sampling with replacement means that, in theory, after each portion is selected and measured, it is returned to the total sample pool and thus has the opportunity to be selected again. This is a corollary of the assumption of independence. Violation of this

assumption (which is almost always the case in toxicology and all of the life sciences) does not have serious consequences if the total pool from which samples are taken is sufficiently large (say 20 or greater) so that the chance of reselecting that portion is small anyway.

There are four major types of sampling methods—random, stratified, systematic, and cluster. Random is by far the most commonly employed method in toxicology. It stresses the fulfillment of the assumption of avoiding bias. When the entire pool of possibilities is mixed or randomized (procedures for randomization are presented in a later section), then the members of the group are selected in the order that they are drawn from the pool.

Stratified sampling is performed by first dividing the entire pool into subsets or strata and then random sampling from each strata. This method is employed when the total pool contains subsets that are distinctly different but the data within each subset are similar. An example is a large batch of a powdered pesticide in which it is desired to determine the nature of the particle size distribution. Larger pieces or particles are on the top, whereas progressively smaller particles have settled lower in the container; at the very bottom, the material has been packed and compressed into aggregates. To determine a timely representative answer, proportionally sized subsets from each layer or strata should be selected, mixed, and randomly sampled. This method is used more commonly in diet studies.

In systematic sampling, a sample is taken at set intervals (such as every fifth container of reagent or taking a sample of water from a fixed sample point in a flowing stream every hour). This is most commonly employed in quality assurance or (in the clinical chemistry lab) in quality control.

In cluster sampling, the pool is already divided into numerous separate groups (such as bottles of tablets), and we select small sets of groups (such as several bottles of tablets) and then select a few members from each set. This results in a cluster of measures. Again, this is a method most commonly used in quality control or in environmental studies when the effort and expense of physically collecting even a small number of data points is significant.

In classical toxicology studies, sampling arises in a practical sense in a limited number of situations. The most common of these are as follows:

(1) Selecting a subset of animals or test systems from a study to make some measurement (which either destroys or stresses the measured system or is expensive) at an interval during a study. This may include such cases as doing interim necropsies in a chronic study or collecting and analyzing blood samples from some animals during a subchronic study.

(2) Analyzing inhalation chamber atmospheres to characterize aerosol distributions with a new generation system.

(3) Analyzing diet in which test material has been incorporated.

(4) Performing quality control on an analytical chemistry operation by having duplicate analyses performed on some materials.

(5) Selecting data to audit for quality assurance purposes.

EXPERIMENTAL DESIGN

Toxicological experiments generally have two purposes. The first is to determine whether or not an agent results in an effect on a biological system. The second, never far behind, is to find how much of an effect is present. It has become increasingly desirable that the results and conclusions of studies aimed at assessing the effects of environmental agents be as clear and unequivocal as possible. It is essential that every experiment and study yield as much information as possible and that the results of each study have the greatest possible chance of answering the questions it was conducted to address. The statistical aspects of such efforts, so far as they are aimed at structuring experiments to maximize the possibilities of success, are called *experimental design*.

We have now become accustomed to developing exhaustively detailed protocols for an experiment or study prior to its conduct. A priori selection of statistical methodology (as opposed to the post hoc approach) is as significant a portion of the process of protocol development and experimental design as any other and can measurably enhance the value of the experiment or study. Prior selection of statistical methodologies is essential for proper design of other portions of a protocol such as the number of animals per group or the sampling intervals for body weight. Implied in such a selection is the notion that the toxicologist has both an in-depth knowledge of the area of investigation and an understanding of the general principles of experimental design, as the analysis of any set of data is dictated to a large extent by the manner in which the data are obtained.

The four basic statistical principles of experimental design are replication, randomization, concurrent ("local") control, and balance. In abbreviated form, these may be summarized as follows.

Replication: Any treatment must be applied to more than one experimental unit (animal, plate of cells,

litter of offspring, etc.). This provides more accuracy in the measurement of a response than can be obtained from a single observation, as underlying experimental errors tend to cancel each other out. It also supplies an estimate

< previous page page_293 next page >

of the experimental error derived from the variability among each of the measurements taken (or "replicates"). In practice, this means that an experiment should have enough experimental units in each treatment group (i.e., large enough "N") so that reasonably sensitive statistical analysis of data can be performed. The estimation of sample size is addressed in detail later in this chapter.

Randomization: This is practiced to ensure that every treatment has its fair share of extreme high and extreme low values. It also serves to allow the toxicologist to proceed as if the assumption of "independence" is valid (i.e., there is not avoidable [known] systematic bias in how one obtains data).

Concurrent Control: Comparisons between treatments should be made to the maximum extent possible between experimental units from the same closely defined population. Therefore, animals used as a "control" group should come from the same source, lot, age, etc. as test group animals. Except for the treatment being evaluated, test and control animals should be maintained and handled in exactly the same manner.

Balance: If the effect of several different factors is being evaluated simultaneously, the experiment should be laid out in such a way that the contributions of the different factors can be separately distinguished and estimated. There are several ways of accomplishing this using one of several different forms of design, as will be discussed later.

Types of Experimental Design

There are four basic experimental design types used in toxicology: the randomized block, latin square, factorial design, and nested design. Other designs that are used are really combinations of these and are rarely employed in toxicology. Before examining these four basic types, however, we must first examine the basic concept of blocking.

Blocking is, simply put, the arrangement or sorting of the members of a population (such as all of an available group of test animals) into groups based on certain characteristics that may (but are not sure to) alter an experimental outcome. Such characteristics, which may cause a treatment to give a differential effect, include genetic background, age, sex, overall activity levels, and so on. The process of blocking then acts (or attempts to act) so that each experimental group (or block) is assigned its fair share of the members of each of these subgroups.

We should now recall that randomization is aimed at spreading out the effect of undetectable or unsuspected characteristics in a population of animals or some portion of this population. The merging of the two concepts or randomization and blocking leads to the first basic experimental design, the randomized block. This type of design requires that each treatment group have at least one member of each recognized group (such as age), with the exact members of each block being assigned in an unbiased (or random) fashion.

The second type of experimental design assumes that we can characterize treatments (whether intended or otherwise) as belonging clearly to separate sets. In the simplest case, these categories are arranged into two sets that may be thought of as rows (for, say, source litter of test animal, with the first litter as row 1, the next as row 2, etc.), and the secondary set of categories may be thought of as columns (for, say, our ages of test animals, with 6–8 weeks as column 1, 8–10 weeks as column 2, and so on). Experimental units are then assigned so that each major treatment (control, low dose, intermediate dose, etc.) appears once and only once in each row and each column. If we denote our test groups as A (control), B (low), C (intermediate), and D (high), such an assignment would appear as below:

		Age			
Source Litter		6–8 Weeks	8–10 Weeks	10–12 Weeks	12–14 Weeks
1	:	A	B	C	D
2	:	B	C	D	A
3	:	C	D	A	B
4	:	D	A	B	C

The third type of experimental design is the factorial design in which there are two or more clearly understood treatments, such as exposure level to test chemical, animal age, or temperature. The classical approach to this situation (and to that described under the latin square) is to hold all but one of the treatments constant and at any one time to vary just that one factor. Instead, in the factorial design, all levels of a given factor are combined with all levels of every other factor in the experiment. When a change in one factor produces a different change in the response variable at one level of a factor than at other levels of this factor, there is an interaction between these two factors that can then be analyzed as an interaction effect.

The last of the major varieties of experimental design are the nested designs, where the levels of one factor are nested within (or are subsamples of) another factor. That is, each subfactor is evaluated only

within the limits of its single larger factor.

Censoring

A second concept and its understanding are essential to the design of experiments in toxicology, that of censoring.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_294.html[2010/10/28 18:42:43]

Censoring is the exclusion of measurements from certain experimental units, or indeed of the experimental units themselves, from consideration in data analysis or inclusion in the experiment at all. Censoring may occur either prior to initiation of an experiment (where, in modern toxicology, this is almost always a planned procedure), during the course of an experiment (when they are almost universally unplanned, resulting from events such as the death of animals being tested), or after the conclusion of an experiment (when data usually are excluded because of being identified as some form of outlier).

In practice, a priori censoring in toxicology studies occurs in the assignment of experimental units (such as animals) to test groups. The most familiar example is in the practice of assignment of test animals to acute, subchronic, and chronic studies, where the results of otherwise random assignments are evaluated for body weights of the assigned members. If the mean weights are found not to be comparable by some preestablished criterion (such as a 90% probability of difference by analysis of variance), then members are reassigned (censored) to achieve comparability in terms of starting body weights. Such a procedure of animal assignment to groups is known as a *censored randomization*.

Sample Size

The first precise or calculable aspect of experimental design encountered is determining sufficient test and control group sizes to allow one to have an adequate level of confidence in the results of a study (i.e., in the ability of the study design with the statistical tests used to detect a true difference—or effect —when it is present). The statistical test contributes a level of power to such a detection. Remember that the power of a statistical test is the probability that a test results in rejection of a hypothesis, say $H0$ (the null hypothesis) when some other hypothesis, say H, is valid. This is termed the power of the test "with respect to the (alternative) hypothesis H."

If there is a set of possible alternative hypotheses, the power, regarded as a function of H, is termed the *power function* of the test. When the alternatives are indexed by a single parameter θ, simple graphical presentation is possible. If the parameter is a vector θ, one can visualize a *power surface*.

If the power function is denoted by $\beta(\theta)$ and $H0$ specifies $\theta=\theta0$, then the value of β (II)—the probability of rejecting $H0$ when it is in fact valid—is the significance level. A test's power is greatest when the probability of a type II error is the least. Specified powers can be calculated for tests in any specific or general situation.

Some general rules to keep in mind are

• The more stringent the significance level, the greater the necessary sample size. More subjects are needed for a 1% level test than for a 5% level test.

• Two-tailed tests require larger sample sizes than one-tailed tests. Assessing two directions at the same time requires a greater investment.

• The smaller the critical effect being measured, the larger the necessary sample size. Subtle effects require greater efforts.

• Any difference can be significant if the sample size is large enough.

• The larger the power required, the larger the necessary sample size. Greater protection from failure requires greater effort. The smaller the sample size, the smaller the power (i.e., the greater the chance of failure).

• The requirements and means of calculating necessary sample size depends on the desired (or practical) comparative sizes of test and control groups.

The necessary sample size (N) can be calculated, for example, for equalised test and control groups using the formula

$$N = \frac{(t_1 + t_2)^2}{d^2} S,$$

where t1 is the one-tailed t value with N-l degrees of freedom corresponding to the desired level of confidence, t2 is the one-tailed t value with N-l degrees of freedom corresponding to the probability that the sample size will be adequate to achieve the desired precision, d is the population standard deviation and S is the sample standard deviation, derived typically from historical data and calculated as

$$S = \sqrt{\frac{1}{N-1}\sum(V_1 - V_2)^2}.$$

Determination of the necessary sample size is demonstrated in Example 1.

Example 1

In a subchronic dermal study in rabbits, the principal point of concern is the extent to which the

compound causes oxidative damage to erythrocytes. To quantitate this, the laboratory will be measuring the numbers of reticulocytes in the blood. What then would be an adequate sample size to allow the question at hand to be addressed with reasonable certitude?
To do this, we use the one-tailed t value for an infinite number of degrees of freedom at the 95% confidence level (i.e., $p \leq 0.05$). Going to a set of t tables, we find this

number to be 1.645. From prior experience, we know that the usual values for reticulocytes in rabbit blood are from 0.5 to 1.9×106/ml. The acceptable range of variation, 0, is therefore equal to the span of this range, or 1.4. Likewise, examining the control data from previous rabbit studies, we find our sample standard deviation to be 0.825. When we insert all of these numbers into the equation (presented above) for sample size, we can calculate the required sample size (N) to be

$$= \frac{(1.645 + 1.645)^2}{(1.4)^2}$$

$$= \frac{10.824}{1.96}(0.825)$$

$$= 4.556.$$

In other words, in this case where there is little natural variability, measuring the reticulocyte counts of groups of only five animals each should be sufficient. There are many formulas for calculating sample sizes. Readers are referred to Gad (62) for a more detailed presentation.

Toxicology Experimental Design

There are a number of aspects of experimental design that are specific to the practice of toxicology. Before we look at a suggestion for step-by-step development of experimental designs, these aspects should first be considered as follows:

1. Frequently, the data gathered from specific measurements of animal characteristics are such that there is wide variability in the data. Often, such wide variability is not present in a control or low-dose group, but in an intermediate dosage group, variance inflation may occur (i.e., there may be a large SD associated with the measurements from this intermediate group). In the face of such a set of data, the conclusion that there is no biological effect based on a finding of no statistically significant effect might well be erroneous.
2. In designing experiments, a toxicologist should keep in mind the potential effect of involuntary censoring on sample size. In other words, though the study described in Example 1 might start with five rabbits per group, this provides no margin should any die before the study is ended and blood samples are collected and analyzed. Including just enough experimental units per group frequently leaves too few at the end of a study to allow meaningful statistical analysis, and allowances should be made accordingly in establishing group sizes.
3. It is certainly possible to pool the data from several identical toxicological studies. For example, after first having performed an acute inhalation study where only three treatment group animals survived to the point at which a critical measure (such as analysis of blood samples) was performed, we would not have enough data to perform a meaningful statistical analysis. We could then repeat the protocol with new control and treatment group animals from the same source. At the end, after assuring ourselves that the two sets of data are comparable, we could combine (or pool) the data from survivors of the second study with those from the first. The costs of this approach, however, would then be both a greater degree of effort expended (than if we had performed a single study with larger groups) and increased variability in the pooled samples (decreasing the power of our statistical methods).
4. Another frequently overlooked design option in toxicology is the use of an unbalanced design (i.e., of different group sizes for differential levels of treatment). There is no requirement that each group in a study (control, low dose, intermediate dose, high dose) have an equal number of experimental units assigned to it. Indeed, there frequently are good reasons to assign more experimental units to one group than to others, and, as we shall see later in this chapter, all of the major statistical methodologies have provisions to adjust for such inequalities, within certain limits. The two most common uses of the unbalanced design have larger groups assigned to either the highest dose to compensate for losses due to possible deaths during the study, or to the lowest dose to give more sensitivity in detecting effects at levels close to an effect threshold (or more confidence to the assertion that no effect exists).
5. We frequently are confronted with the situation where an undesired variable is influencing our experimental results in a nonrandom fashion. Such a variable is called a confounding variable. Its presence, as discussed earlier, makes the clear attribution and analysis of effects at best difficult and at worst impossible. Sometimes such confounding variables are the result of conscious design or management decisions, such as the use of different instruments, personnel, facilities, or procedures for different test groups within the same study. Occasionally, however, such confounding variables are the

result of unintentional factors or actions, called a *lurking variable*. Examples of such variables almost always are the result of standard operating procedures being violated—water not being connected to a rack of animals over a

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_296.html[2010/10/28 18:42:44]

weekend, a set of racks not being cleaned as frequently as others, or a contaminated batch of feed being used.

6. Finally, some thought must be given to the clear definition of what is meant by experimental unit and concurrent control. The experimental unit in toxicology encompasses a wide variety of possibilities. It may be cells, plates of microorganisms, individual animals, litters of animals, etc. The importance of clearly defining the experiment unit is that the number of such units per group is the "N," which is used in statistical calculations or analyses and critically affects such calculations.

The experimental unit is the unit that receives treatments and yields a response that is measured and becomes a datum. What this means in practice is that, for example, in reproduction or teratology studies, where we treat the parental generation females and then determine results by counting or evaluating offspring, the experimental unit is still the parent. Therefore, the number of litters, not the number of offspring, is the N (162).

A true concurrent control is one that is identical in every manner with the treatment groups except for the treatment being evaluated. This means that all manipulations, including gavaging with equivalent volumes of vehicle or exposing to equivalent rates of air exchanges in an inhalation chamber, should be duplicated in control groups just as they occur in treatment groups.

The goal of the four principles of experimental design is statistical efficiency and the economizing of resources. The single most important initial step in achieving such an outcome is to clearly define the objective of the study—get a clear statement of what questions are being asked. For the reader who would like to further explore experimental design, there are a number of more detailed texts available that include more extensive treatments of the statistical aspects of experimental design (28, 39, 54, 85, 99, 108).

GENERALIZED METHODOLOGY SELECTION

One approach for the selection of appropriate techniques to employ in a particular situation is to use a decision-tree method. Figure 7.1 is a decision tree that leads to the choice of one of three other trees to assist in technique selection, with each of the subsequent trees addressing one of the three functions of statistics that was defined earlier in this chapter. Figure 7.2 is for the selection of hypothesis-testing procedures, Figure 7.3 for modeling procedures, and Figure 7.4 for reduction of dimensionality procedures. For the vast majority of situations, these trees will guide the user into the choice of the proper technique. The tests and terms in these trees will be explained subsequently.

Computational Devices

The range, scope, and availability of aids for the calculation of mathematical techniques in general and for statistical techniques in particular have increased at an almost geometric rate since the mid-1970s. There is no longer any reason to use paper and pencil to perform such calculations; the capabilities of electronic systems are sufficiently developed at each level (as discussed later), and the cost, compared to labor savings, are minimal.

There are now three tiers of computational support available for statistical analysis (though it may be argued that the middle two tiers are becoming indistinguishable), and this chapter will attempt an overview of the major systems available within these tiers and the general

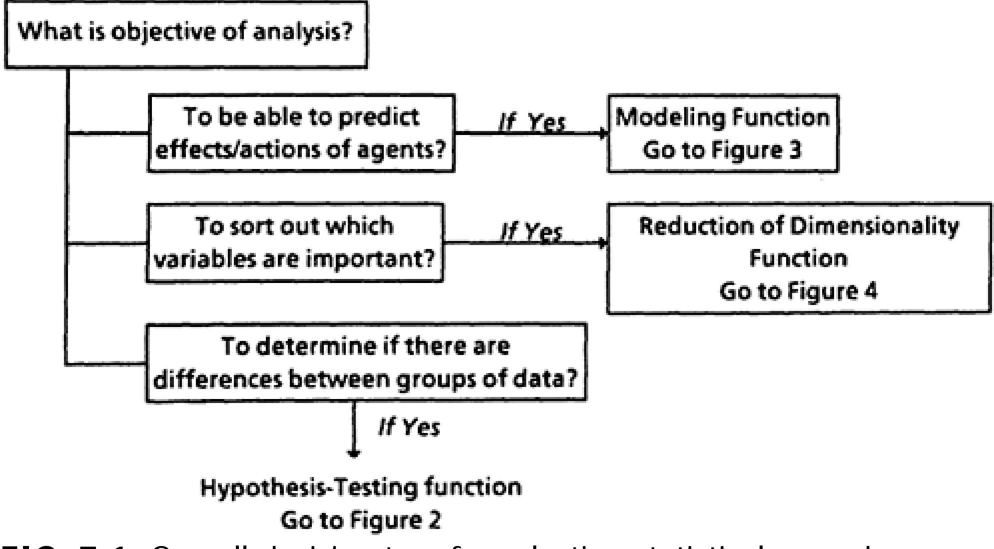

FIG. 7.1. Overall decision tree for selecting statistical procedures.

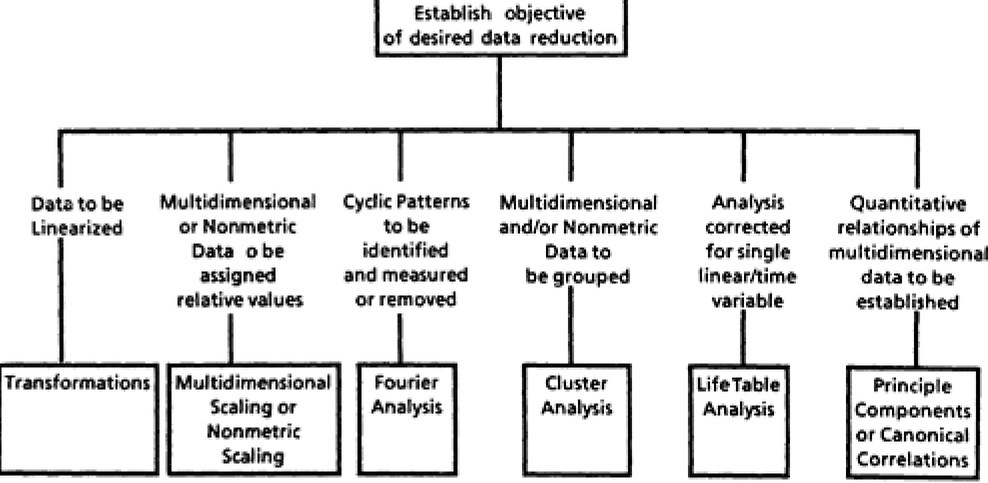

FIG. 7.4. Decision tree for selection of reduction of dimensionality procedures.

characteristics and limitations of each. The three tiers range from programmable calculators (which represent Tier I and include such devices as the Texas Instruments TI-83 and the Hewlett-Packard HP-41) to complete statistical packages available on mainframe computers (the Tier III systems, which include such packages as Statistical Analysis System [SAS], Statistical Package for Social Sciences [SPSS], and Minitab). As a general rule, as one goes from the systems in Tier 1 to those in Tier II, the cost, power, and capabilities of the systems increase, whereas ease of use ("user friendliness") and flexibility decrease.

There are conventions associated with each system or instrument in these tiers, and these conventions should be known because they can affect both results and the ways in which results are reported. The first two conventions, which apply to all three tiers, have to do with the length of numbers. The first is that there is a specific number of digits that a machine (or software system) will accept as input, handle in calculations, and report as a result (either on a screen or as a printout). The most common such limit is 13 digits (i.e., a number such as 12325.67890123). If, in the course of performing calculations, a longer string of digits is produced (e.g., by dividing our example number of four, which should produce the actual number 3086.4197253075), a 14-digit number, a 13-digit system would then handle the last (‘extra") digit in one of two ways: it would either truncate it (i.e., just drop off the last digit) or it would round it by some rule (rounding was discussed earlier). Truncation, particularly on the result of a long series of calculations (as is often the case in statistics) is more likely to produce erroneous results. Rounding is much less likely to produce errors, but knowledge of the rounding method used can be helpful.

The second convention that applies to all systems is that there is also a limit to how long a series of digits any system will report out. There are different ways in which systems report out, and there are different ways in which systems report longer digit series. The first, less common, is truncation; the second is rounding combined with presentation of the results as an exponential. Exponentials are a series of digits followed by an expression of the appropriate powers of 10. Examples of such exponential expressions are

(a) 1.234567×1016

(b) 1.234567×10−16

(c) 1.234567 E 16

(d) 1.234567 E−16

(a) and (c) are the same number expressed two different ways, as are (b) and (d).

Tier I Systems (Programmable and Preprogrammed Statistical Calculators)

The two major Tier I systems (described more fully below) can readily perform all of the univariate (i.e., two variable) procedures described in this book. Data sets may also be stored, and by the clever coding of programs and data sets of extreme length may be processed, but longer programs or longer data sets run extremely slowly. Accordingly, use of these instruments is limited, in practice, to univariate procedures and small data sets.

The two Tier I systems are the Texas Instruments TI-83 and the Hewlett-Packard HP-41. These differ mainly in that the HP programs and data entry systems are in reverse Polish notation (RPN) form, whereas the TI has a straightforward entry form. There are printers available for both units to provide hard copy. Both have unique but simple programming languages.

Tier II Systems (Microcomputers and Software)

At levels above Tier I there are additional conventions as to the way systems operate and handle data. Additionally, there are a larger number of options for both machines and software systems because only a few common programming languages are involved.

The first common convention that must be understood and considered is that the systems actually perform a statistical operation in one of two modes: batch or interactive. In batch mode, the entire desired sequence of analysis is specified, and then the entire set of data is processed in accordance with this specified sequence. The drawback to this approach is that if a result early in the sequence indicates that an alternative latter set of procedures should be performed, there is no opportunity to change to these alternative (as opposed to the originally specified) procedures. In this interactive mode, procedures are specified (and results calculated) one step at a time, usually by the use of a series of menus.

The second convention concerns the structure of commonly used software systems. They are almost always divided into three separate parts or modules:

• A database manager, which allows the person using the system to store data in (and recall it from) a desired format, to perform a transformation(s) or arithmetic manipulation(s), and to transfer the data elsewhere.

• The actual analysis of the data module. Such modules also allow one to tailor reports to one’s specifications.

• A graphics module, which presents (on a display screen) and prints out in any of a wide range of graphics and charts. The range may be limited to line, bar, and pie charts or may extend to contour, cluster, and more exotic plots.

There are now two major microcomputer operating systems that support extensive statistical packages:

the Macintosh and IBM/clone (usually some form of Windows operating system). Each of these have virtually unlimited operating and storage memories, and printers and plotters are available. "Zip" drives, which significantly expand working memory, are also available for both.

Before reviewing software packages, several considerations should be presented. First, systems perform in one of two modes, either as libraries of programs, each of which can be selected to perform an individual procedure, or as an integrated system, where a single loading of the file allows access to each and every procedure. In the first mode, each step in an analysis (such as Bartlett's test, analysis of variance, and Duncan's mul

tiple range test) requires loading a separate file and then executing the procedure. Second, software may load from CD-ROMs or Zip drive media. Third, the available range of transformations should be carefully considered. At least a small number (log, reciprocal, probit, addition, subtraction, multiplication, division, and absolute value) is essential. If unusual data sets are to be handled or exploratory data analysis (discussed later) performed regularly, a more extensive set is required. Fourth, all of the packages listed in Table 7.4 have at least a basic set of capabilities. They can each perform, besides database management and basic transformation and graphic functions, the following simple tests:

- Analysis of Variance (ANOVA)
- 2×2 Chi Square
- Linear Regressions
- Student's t-Test

Table 7.4 presents an overview of 12 widely available commercially statistical packages for microcomputers that the author is familiar with; there are at least 120 additional packages available. Woodward et al. (168) presents an overview of many of these. For each package, the following information is presented:

TITLE—the name of the package. OPERATING SYSTEMS—which systems the package will operate on
EDA—does the system perform exploratory data analysis?
GRAPHICS—how extensive are the graphic functions that the package performs?
SPREADSHEET IMPORT/EXPORT—can the system accept data-give output to popular spreadsheets such as EXCEL and LOTUS?
MENU (M) OR COMMAND (C) DRIVEN—how does the user primarily interface with the system?

Tier III Systems (Main Frame Programs)

The Tier III system programs are all large commercial software packages that run on large computer systems on a time-sharing basis. By definition, this means that these programs operate in a batch mode and use a unique (for each package) code language. Four of these libraries are briefly described below.

PACKAGE	REFERENCE	DESCRIPTION
SPSS	113	With manipulation, SPSS will perform all the procedures described in this book and the full range of graphics.
BMD	41	Has generally wider capabilities than SPSS (which are constantly being added to) and easily manipulated.
SAS	127	Widely available. Easier to format and very strong on data summarization. Has its own higherlevel programming language.
MINITAB	125	Easiest to use and least expensive of these six, but does not have the full range of capabilities.

The difficulty with the recently achieved, wide availability of automated analysis systems is that it has become increasingly easy to perform the wrong tests on the wrong data and from there to proceed to the wrong conclusions. This serves to make at least a basic understanding of the procedures and discipline of statistics a vital necessity for the research toxicologist.

Methods for Data Examination and Preparation

The data from toxicology studies should always be examined before any formal analysis. Such examinations should be directed to determining if the data are suitable for analysis, and if so, what form the analysis should take (see Figure 7.2). If the data as collected are not suitable for analysis or if they are only suitable for low-powered analytical techniques, one may wish to use one of many forms of data transformation to change the data characteristics so that they are more amenable to analysis.

The above two objectives, data examination and preparation, are the primary focus of this chapter. For data examination, two major techniques are presented—the scattergram and Bartlett's test. Likewise, for data preparation (with the issues of rounding and outliers having been addressed in a previous chapter), two techniques are presented—randomization (including a test for randomness in a sample of data) and transformation. Exploratory data analysis (EDA) is presented and briefly reviewed later. This is a broad collection of techniques and approaches to "probe" data (i.e., to both examine and to perform some initial, flexible analysis of the data).

Scattergram

Two of the major points to be made throughout this chapter are (a) the use of the appropriate statistical tests and (b) the effects of small sample sizes (as is often the case in toxicology) on our selection of statistical techniques. Frequently, simple examination of the nature and distribution of data collected from a study can also suggest patterns and results that were unanticipated

Page 302

Table 7.4 Popular microcomputer statistical packages

Title	Operating Systems	EDA Performed	Graphics	Spreadsheet Import/Export	Menu(M) or Command(C) Driven
BMD8	Windows	No	Largely	Limited	C

SYSTAT	Windows	No	Complete	Full	C

and for which the use of additional or alternative statistical methodology is warranted. It was these three points that caused the author to consider a section on scattergrams and their use essential for toxicologists.

Bartlett's test may be used to determine if the values in groups of data are homogeneous. If they are, this (along with the knowledge that they are from a continuous distribution) demonstrates that parametric methods are applicable, but, if the values in the (continuous data) groups fail Bartlett's tests (i.e., are heterogeneous), we cannot be secure in our belief that parametric methods are appropriate until we gain some confidence that the values are normally distributed. With large groups of data, we can compute parameters of the population (kurtosis and skewness, in particular), and from these parameters determine if the population is normal (with a certain level of confidence). If our concern is especially marked, we can use a chi-square goodness-of-fit test for normality, but when each group of data consists of 25 or fewer values, these measures or tests (kurtosis, skewness, chi-square goodness-of-fit) are not accurate indicators of normality. Instead, in these cases we should prepare a scattergram of the data and then evaluate the scattergram to estimate if the data are normally distributed. This procedure consists of developing a histogram of the data and then examining the histogram to get a visual appreciation of the location and distribution of the data.

The abscissa (or horizontal scale) should be in the same scale as the values and should be divided so that the entire range of observed values is covered by the scale of the abscissa. Across such a scale we then simply enter symbols of each of our values. Example 2 shows such a plot.

Example 2

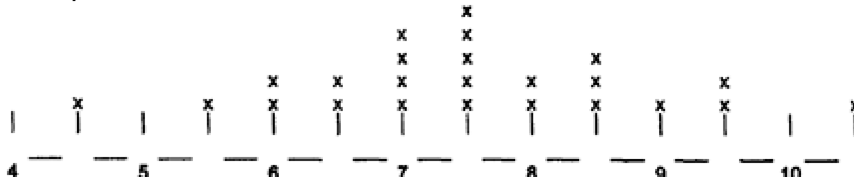
Suppose we have the two data sets below:

Group 1:4.5, 5.4, 5.9, 6.0, 6.4, 6.5, 6.9, 7.0, 7.1, 7.0, 7.4, 7.5, 7.5, 7.5, 7.6., 8.0, 8.1, 8.4, 8.5, 8.6, 9.0, 9.4, 9.5, and 10.4.

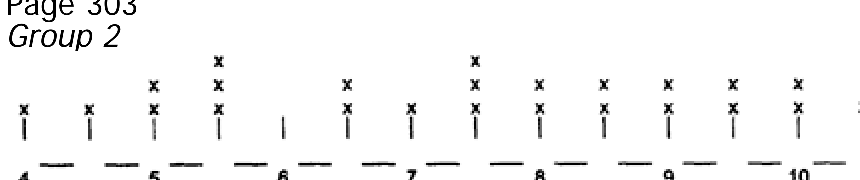
Group 2:4.0,4.5, 5.0, 5.1, 5.4, 5.5, 5.6, 6.5, 6.5, 7.0, 7.4, 7.5, 7.5, 8.0, 8.1, 8.5, 8.5, 9.0, 9.1, 9.5, 9.5, 10.1, 10.0, and 10.4.

Both of these groups contain 24 values and cover the same range. From them we can prepare the following scattergrams.

Group 1



Group 2



Group 1 can be seen to approximate a normal distribution (bell-shaped curve); we can proceed to perform the appropriate parametric tests with such data, but group 2 clearly does not appear to be normally distributed. In this case, the appropriate nonparametric technique must be used.

Example 2 is a traditional and rather limited form of scatterplot, but such plots can reveal significant information about the amount and types of association between the two variables, the existence and nature of outliers, the clustering of data, and a number of other two-dimensional factors (7, 23). Current technology allows us to add significantly more graphical information to scatterplots by means of graphic symbols (letters, faces, or different shapes, such as squares, colors, etc.) for the plotted data points. One relatively simple example of this approach is shown in Figure 7.5, where the simple case of dose (in a dermal study), dermal irritation, and white blood cell count are presented. This graph quite clearly suggests that as dose (variable x) is increased, dermal irritation (variable y) also increases, and as irritation becomes more severe, white blood cell count (variable z), an indicator of immune system involvement suggesting infection or persistent inflammation, also increases. There is no direct association of variables x and z, however.

Cleveland and McGill (25) presented an excellent, detailed overview of the expanded capabilities of the scatterplot, and the interested reader should refer to that article. Cleveland expanded this to a book (26). Tufte (145) has also expanded on this.

Bartlett's Test for Homogeneity of Variance

Bartlett's test (138) is used to compare the variances (values reflecting the degree of variability in data sets) among three or more groups of data, where the data in the groups are continuous sets (such as body weights, organ weights, red blood cells counts, or diet consumption measurements). It is expected that such data will be suitable for parametric methods (normality of data is assumed), and Bartlett's is frequently used as a test for the assumption of equivalent variances.

Bartlett's is based on the calculation of the corrected $\chi 2$ (chi-square) value by the formula

$$\chi^2_{corr} = 2.3026 \frac{\sum df\left(\log_{10}\left[\frac{\sum[df(S^2)]}{\sum df}\right]\right) - \sum[df(\log_{10} S^2)]}{1 + \frac{1}{3(K-1)}\left[\sum \frac{1}{df} - \frac{1}{\sum df}\right]},$$

$$\text{where } S^2 = \text{variance} = \frac{n\sum x^2 - \frac{(\sum x)^2}{n}}{n-1},$$

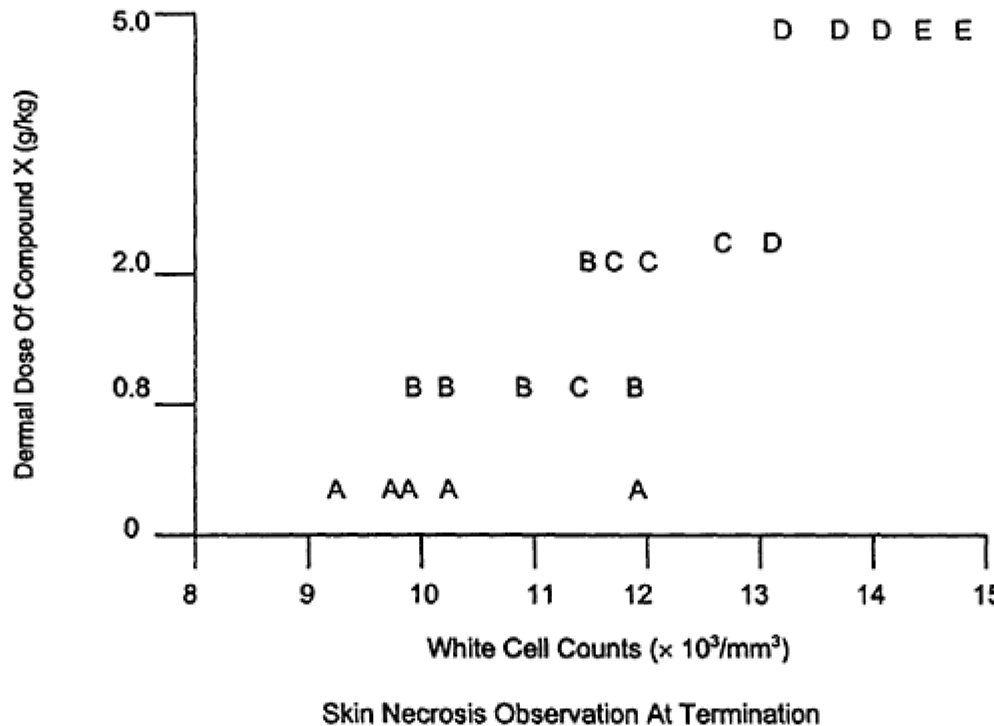


FIG. 7.5. Exploratory data analysis.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_303.html[2010/10/28 18:42:48]

X=individual datum within each group;
n=number of data within each group;
K=number of groups being compared;
d*f*=degrees of freedom for each group=(N−1).
The corrected $\chi 2$ value yielded by the above calculations is compared to the values listed in the chi square table according to the numbers of degrees of freedom (such as found in ref. 137, pp. 470–471). If the calculated value is smaller than the table value at the selected p level (traditionally 0.05), the groups are accepted to be homogeneous and the use of ANOVA is assumed proper. If the calculated $\chi 2$ is greater than the table value, the groups are heterogeneous and other tests (as indicated in Figure 7.2, the decision tree) are necessary. This is demonstrated in Example 3.

Example 3

If the monocytes in a sample of rat blood taken in the course of an inhalation study were counted, the results might appear as follows:

400 ppm		200 ppm		0 ppm	
(X1)	(X1)2	(X2)	(X2)2	(X3)	(X3)2
9	81	5	25	7	49
5	25	5	25	6	36
5	25	4	16	5	25
4	16	6	36	7	49
		7	49		
$\Sigma X_1 = 23$	$\Sigma X_1^2 = 147$	$\Sigma X_2 = 27$	$\Sigma X_2^2 = 151$	$\Sigma X_3 = 25$	$\Sigma X_3^2 = 159$

$${}^{2}_{1} = \frac{\frac{4(147) - (23)^2}{4}}{4-1} = 4.9167,$$

$${}^{2}_{2} = \frac{\frac{5(157) - (27)^2}{5}}{5-1} = 1.3000,$$

$${}^{2}_{3} = \frac{\frac{4(159) - (25)^2}{4}}{4-1} = 0.9167.$$

In continuing the calculations, it is helpful to set up a table as follows:

Concentration	n	d*f*=(N−l)	S2	(d*f*)(S2)	log S2
400 ppm	4	3	4.9167	14.7501	0.6917
200 ppm	5	4	1.3000	5.2000	0.1139
0 ppm	4	3	0.9167	2.7501	−0.0378
Sums (Σ)	13	10		22.7002	

Concentration	(d*f*)(log S2)	$\frac{1}{df}$
400 ppm	2.0751	0.3333
200 ppm	0.4556	0.2500
0 ppm	−0.1134	0.3333
Sums (Σ)	2.4173	0.9166

Now we substitute into our original formula for corrected $\chi 2$

$$\chi^2 = 2.3026\frac{10\left[\log_{10}\left(\frac{22.7002}{10}\right)\right] - 2.4173}{\frac{1}{3(3-1)}\left(0.9166 - \frac{1}{10}\right)}$$

$$= 2.3026\frac{10(0.3560) - 2.4173}{1 + 0.1667(0.8166)}$$

$$= 2.32.$$

The table value for two degrees of freedom at the 0.05 level is 5.99. As our calculated value is less than this, the corrected $\chi 2$ is not significant and the variances are accepted as homogeneous. We may thus use parametric methods (such as ANOVA) for further comparisons.

ASSUMPTIONS AND LIMITATIONS

1. Bartlett's test does not test for normality, but rather homogeneity of variance (also called equality of variances or homoscedasticity).
2. Homoscedasticity is an important assumption for Student's t-test, analysis of variance, and analysis of covariance.
3. The F-test (covered in the next chapter) is actually a test for the two-sample (i.e., control and one test group) case of homoscedasticity. Bartlett's is designed for three or more samples.
4. Bartlett's is very sensitive to departures from normality. As a result, a finding of a significant chi-square value in Bartlett's may indicate non-normality rather than heteroscedasticity. Such a finding can be brought about by outliers, and the sensitivity to such erroneous findings is extreme with small sample sizes.

Statistical Goodness-of-Fit Tests

A goodness-of-fit test is a statistical procedure for comparing individual measurements to a specified type of statistical distribution. For example, a normal distribution is completely specified by its arithmetic mean and variance (the square of the SD). The null hypothesis, that the data represent a sample from a single normal distribution, can be tested by a statistical goodness-of-fit test. Various goodness-of-fit tests have been devised to determine if the data deviate significantly from a specified distribution. If a significant departure occurs, it indicates only that the specified distribution can be rejected with some assurance. This does not necessarily mean that the true distribution contains two or more subpopulations. The true distribution may be a single distribution

based on a different mathematical relationship (e.g., log-normal). In the latter case, logarithms of the measurement would not be expected to exhibit by a goodness-of-fit test a statistically significant departure from a log-normal distribution.

Everitt and Hand (51) recommended using a sample of 200 or more to conduct a valid analysis of mixtures of populations. Even the maximum likelihood method, the best available method, should be used with extreme caution, or not at all, when separation between the means of the subpopulations is less than 3 SD and sample sizes are less than 300. None of the available methods conclusively establish bimodality, which may occur when separation between the two means (modes) exceeds 2 SD. Conversely, inflections in probits or separations in histograms *less than* 2 SD apart may arise from genetic differences in test subjects.

Mendal et al. (106) compared eight tests of normality to detect a mixture consisting of two normally distributed components with different means but equal variances. Fisher's skewness statistic was preferable when one component comprised less than 15% of the total distribution. When the two components comprised more nearly equal proportions (35%-65%) of the total distribution, the Engelman and Hartigan test (50) was preferable. For other mixing proportions, the maximum likelihood ratio test was best. Thus, the maximum likelihood ratio test appears to perform very well, with only small loss from optimality, even when it is not the best procedure.

The method of *maximum likelihood* provides estimators that usually are quite satisfactory. They have the desirable properties of being consistent, asymptotically normal, and asymptotically efficient for large samples under quite general conditions. Often they are biased, but the bias is frequently removable by a simple adjustment (Examples 4 and 5). Other methods of obtaining estimators are also available, but the maximum likelihood method is the most frequently used.

Maximum likelihood estimators also have another desirable property: *invariance*. Let us denote the maximum likelihood estimator of the parameter θ by $\hat{\sigma}$ Then, if *f(θ)* is a single-valued function of *θ,* the maximum likelihood estimator of *f*(*θ*) is $f(\hat{\sigma})$. Thus, for example, $\hat{\sigma} = (\hat{\sigma}^2)^{1/2}$.

The principle of maximum likelihood tells us that we should use as our estimate that value which maximizes the likelihood of the observed event. The following examples demonstrate the technique.

Example 4

Derive the maximum likelihood estimator *p* of the binomial probability *p* for a coin-tossing experiment in which a coin is tossed *n* times and *r* heads are obtained.

We know that the likelihood of the observed event is

$$L = \binom{n}{r} p^r (1-p)^{n-r}.$$

According to the principle of maximum likelihood, we choose the value of *p* which maximizes *L*. This value also maximizes

$$\ln L = \ln\binom{n}{r} + r \ln p + (n-r)\ln(1-p).$$

At the maximum, the derivative with respect to *p* must be zero; that is,

$$\frac{\partial}{\partial \rho} \ln L = r/p - (n-r)/\ln(1-p) = 0$$

and

$$\hat{p} = r/n.$$

Example 5

A sample of *n* observations x1,..., xn is drawn from a normal population. Derive the maximum likelihood estimators $\hat{\mu}$ and $\hat{\sigma}_2$ for the mean and variance of the population. The likelihood of the observed event is

$$L = \left[\frac{1}{\sigma(2\pi)\frac{1}{2}} \exp\left\{ -\frac{1}{2} \left(\frac{x_1 - \mu}{\sigma} \right)^2 \right\} \right]$$
$$\times \Lambda \left[\frac{1}{\sigma(2\pi)\frac{1}{2}} \exp\left\{ -\frac{1}{2} \left(\frac{x_n - \mu}{\sigma} \right)^2 \right\} \right].$$

According to the principle of maximum likelihood, we choose those values of μ and $\sigma2$ which maximize L. The same values maximize In L. So we equate the partial derivatives of In L with respect to $\hat{\mu}$ and $\hat{\sigma}^2$ to zero and find that

$$\hat{\mu} = \bar{x}-$$

and

$$\hat{\sigma}^2 = \frac{1}{n} \sum_{i=1}^{n} (x_i - \bar{x})^2.$$

The latter estimator is slightly biased, but the bias can be removed by multiplying by $n/(n-1)$ and using the estimator

$$\hat{\sigma}^2 \frac{1}{n-1} \sum_{i=1}^{n} (x_i - \bar{x})^2.$$

These maximum likelihood methods can be used to obtain *point estimates* of a parameter, but we must remember that a point estimator is a random variable distributed in some way around the true value of the parameter. The true parameter value may be higher or lower than our estimate. It is often useful, therefore, to obtain an interval within which we are reasonably confident the true value will lie, and the generally accepted method is to construct what are known as *confidence limits*.

The following procedure will yield upper and lower 95% confidence limits with the property that when we say that these limits include the true value of the parameter, 95% of all such statements will be true and 5% will be incorrect:

1. Choose a (test) statistic involving the unknown parameter and no other unknown parameter.
2. Place the appropriate sample values in the statistic.
3. Obtain an equation for the unknown parameter by equating the test statistic to the upper 2.5% point of the relevant distribution.
4. The solution of the equation gives one limit.
5. Repeat the process with the lower 2.5% point to obtain the other limit.

One can also construct 95% confidence intervals using unequal tails (e.g., using the upper 2% point and the lower 3% point). We usually want our confidence interval to be as short as possible, however, and with a symmetric distribution such as the normal or *t*, this is achieved using equal tails. The same procedure very nearly minimizes the confidence interval with other nonsymmetric distributions (e.g., chi-square) and has the advantage of avoiding rather tedious computation.

When the appropriate statistic involves the square of the unknown parameter, both limits are obtained by equating the statistic to the upper 5% point of the relevant distribution. The use of two tails in this situation would result in a pair of nonintersecting intervals. When two or more parameters are involved, it is possible to construct a region within which we are reasonably confident the true parameter values will lie. Such regions are referred to as confidence regions. The implied interval for p1 does not form a 95% confidence interval, however, nor is it true than an 85.7375% confidence region for p1, p2, and p3 can be obtained by considering the intersection of the three separate 95% confidence intervals because the statistics used to obtain the individual confidence intervals are not independent. This problem is obvious with a multiparameter distribution, such as the multinomial, but it even occurs with the normal distribution because the statistic that we use to obtain a confidence interval for the mean and the statistic that we use to obtain a confidence interval for the variance are not independent. The problem is not likely to be of great concern unless a large number of parameters is involved, as illustrated in Example 6.

Example 6

A sample of nine is drawn from a normal population with unknown mean and variance. The sample mean is 4.2 and the sample variance is 1.69. Obtain a 95% confidence interval for the mean μ. The confidence limits are obtained from the equations

$$\sqrt{9}(4.2-\mu)/(1.69)^{1/2} = 2.306;$$

$$\sqrt{9}(4.2-\mu)/(1.69)^{1/2} = -2.306.$$

From these we determine that the 95% confidence interval is from 3.2 to 5.2.

Randomization

Randomization is the act of assigning a number of items (plates of bacteria or test animals, for example) to groups in such a manner that there is an equal chance for any one item to end up in any one group. This is a control against any possible bias in assignment of subjects to test groups. A variation on this is censored randomization, which ensures that the groups are equivalent in some aspect after the assignment process is complete. The most common example of a censored randomization is one in which it is ensured that the body weights of test animals in each group are not significantly different from those in the other groups. This is done by analyzing group weights both for homogeneity of variance and by analysis of variance after animal assignment, then re-randomizing if there is a significant difference at some nominal level, such as $p \leq 0.10$. The process is repeated until there is no significant difference.

There are several methods for actually performing the randomization process. The three most commonly used are card assignment, use of a random number table, and use of a computerized algorithm.

For the card-based method, individual identification numbers for items (plates or animals, for example) are placed on separate index cards. These cards are then shuffled, placed one at a time in succession into piles corresponding to the required test groups. The results are a random group assignment.

The random number table method requires only that one have unique numbers assigned to test subjects and access to a random number table. One simply sets up a table with a column for each group to which subjects are to be assigned. We start from the head of any one column of numbers in the random table (each time the table is used, a new starting point should be used). If our test subjects number less than 100, we use only the last two digits in each random number in the table. If they

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_306.html[2010/10/28 18:42:51]

number more than 99 but less than 1000, we use only the last three digits. To generate group assignments, we read down a column one number at a time. As we come across digits that correspond to a subject number, we assign that subject to a group (enter its identifying number in a column), proceeding to assign subjects to groups from left to right filling one row at a time. After a number is assigned to an animal, any duplication of its unique number is ignored. We use as many successive columns of random numbers as we may need to complete the process.

The third (and now most common) method is to use a random number generator that is built into a calculator or computer program. Procedures for generating these are generally documented in user manuals.

One is also occasionally required to evaluate whether a series of numbers (such as an assignment of animals to test groups) is random. This requires the use of a randomization test, of which there are a large variety. The chi-square test, described later, can be used to evaluate the goodness-of-fit to a random assignment. If the result is not critical, a simple sign test will work. For the sign test, we first determine the middle value in the numbers being checked for randomness. We then go through a list of the numbers assigned to each group, scoring each as a "+" (greater than our middle number) or "–" (less than our middle number). The number of pluses and minuses in each group should be approximately equal. This is demonstrated in Example 7.

Example 7

In auditing a study performed at a contract lab, we wish to ensure that their assignment of animals to test groups was random. Thirty-three animals numbered 1 to 33 were assigned to groups of 11 animals each. Using the middle value in this series (17) as our check point, we assign signs as below.

Control		Test Group A		Test Group B	
Animal Number	Sign	Animal Number	Sign	Animal Number	Sign
17	0	18	+	11	−
14	−	1	−	2	−
7	−	12	−	22	+
26	+	9	−	28	+
21	+	5	−	19	+
15	−	20	+	3	−
16	−	33	+	29	+
6	−	27	+	10	−
25	+	8	−	23	+
32	+	24	+	30	+
4	−	31	+	13	−
Sum of signs	−2		+1		+1

Note that 17 is scored as zero, ensuring (as a check on results) that the sum of the sums of the three columns would be zero. The results in this case clearly demonstrate that there is no systematic bias in animal number assignments.

Transformations

If our initial inspection of a data set reveals it to have an unusual or undesired set of characteristics (or to lack a desired set of characteristics), we have a choice of three courses of action. We may proceed to select a method or test appropriate to this new set of conditions, or abandon the entire exercise, or transform the variable(s) under consideration in such a manner that the resulting transformed variates (X′ and Y′, for example, as opposed to the original variates X and Y) meet the assumptions or have the characteristics that are desired.

The key to all this is that scale of measurement of most (if not all) variables is arbitrary. Although we are most familiar with a linear scale of measurement, there is nothing that makes this the "correct" scale on its own, as opposed to a logarithmic scale (familiar logarithmic measurements are that of pH values, or earthquake intensity (Richter scale)). Transforming a set of data (converting X to X′) is really as simple as changing a scale of measurement.

There are at least four good reasons to transform data:

(1) To normalize the data, making them suitable for analysis by our most common parametric techniques, such as analysis of variance (ANOVA). A simple test of whether a selected transformation will yield a distribution of data which satisfies the underlying assumptions for ANOVA is to plot the cumulative distribution of samples on probability paper (i.e., a commercially available paper that has the probability function scale as one axis). One can then alter the scale of the second axis (i.e., the axis other than the one that is on a probability scale) from linear to any other (logarithmic, reciprocal, square

root, etc.) and see if a previously curved line indicating a skewed distribution becomes linear to indicate normality. The slope of the transformed line gives us an estimate of the SD, and if the slopes of the lines of several samples or groups of data are similar, we accordingly know that the variance of the different groups are homogeneous.

(2) To linearize the relationship between a paired set of data, such as dose and response. This is the most common use in toxicology for transformations and is demonstrated in the section under probit/logit plots.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_307.html[2010/10/28 18:42:51]

Page 308

Table 7.5 Common Data Transformations

Transformation	How Calculated[a]	Example of Use
Arithmetic	$x' = \frac{x}{y}$ or $x' = x + c$	Organ weight/body weight
Reciprocals	$x' = \frac{1}{x}$	Linearizing data, particularly rate phenomena
Arcsine (also called Angular)	$x' = \text{arcsine} \sqrt{x}$	Normalizing dominant lethal and mutation rate data
Logarithmic	x′=log ×	pH values
Probability (Probit)	x′=probability X	Percentage responding
Square roots	$x' = \sqrt{x}$	Surface area of animal from body weights
Box cox	x′=(xv−1)v: for v≠0 x′=In x: for v=0	A family of transforms for use when one has no prior knowledge of the appropriate transformation to use
Rank transformations	Depends on nature of samples	As a bridge between parametric and nonparametric statistics (174)

a x and y are original variables, x′ and y′ transformed values. "C" stands for a constant.

Note: Plotting a double reciprocal (that is, $\frac{1}{x}$ versus $\frac{1}{y}$ will linearize almost any data set. So will plotting the log transforms of a set of variables.

(3) To adjust data for the influence of another variable. This is an alternative in some situations to the more complicated process of analysis of covariance. A ready example of this usage is the calculation of organ weight to body weight ratios in in vivo toxicity studies, with the resulting ratios serving as the raw data for an analysis of variance performed to identify possible target organs. This use is discussed in detail later in this chapter.

(4) Finally, to make the relationships between variables clearer by removing or adjusting for interactions with third, fourth, etc. Uncontrolled variables that influence the pair of variables of interest. This case is discussed in detail under time series analysis.

Common transformations are presented in Table 7.5.

Exploratory Data Analysis

Over the past 20 years, an entirely new approach has been developed to get the most information out of the increasingly larger and more complex data sets that scientists are faced with. This approach involves the use of a very diverse set of fairly simple techniques that comprise exploratory data analysis (EDA). As expounded by Tukey (148), there are four major ingredients to EDA:

Displays: These visually reveal the behavior of the data and suggest a framework for analysis. The scatterplot (presented earlier) is an example of this approach.

Residuals: These are what remain of a set of data after a fitted model (such as a linear regression) or some similar level of analysis has been removed.

Re-expressions: These involved questions of what scale would serve to best simplify and improve the analysis of the data. Simple transformations, such as those presented earlier in this chapter, are used to simplify data behavior (e.g., linearizing or normalizing) and clarify analysis.

Resistance: This is a matter of decreasing the sensitivity of analysis and summary of data to misbehavior so that the occurrence of a few outliers, for example, will not complicate or invalidate the methods used to analyze the data. For example, in summarizing the location of a set of data, the median (but not the arithmetic means) is highly resistant.

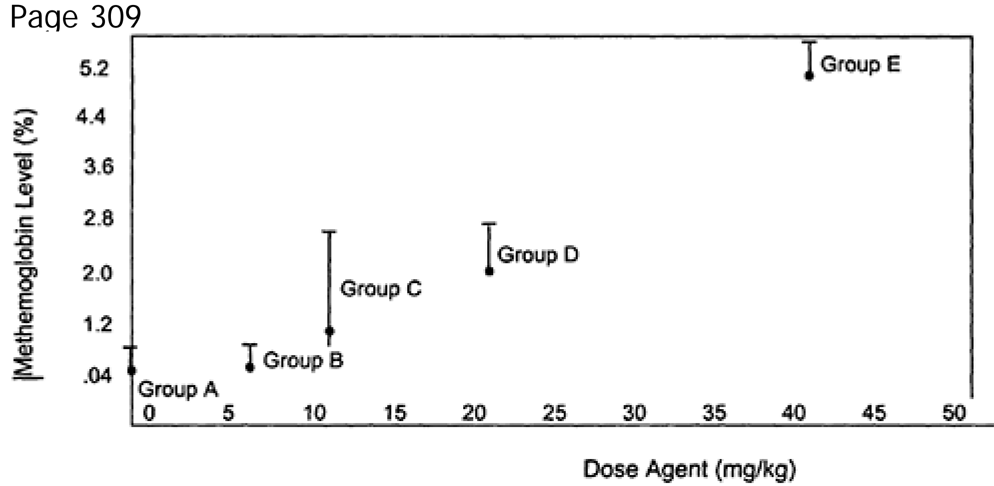

FIG. 7.6. Variance inflation.

These four ingredients are used in a process falling into two broad phases: an exploratory phase and a confirmatory phase. The exploratory phase isolates patterns in and features of the data and reveals them, allowing an inspection of the data before any firm choice of actual hypothesis testing or modeling methods has been made.

Confirmatory analysis allows evaluation of the reproducibility of the patterns or effects. Its role is close to that of classical hypothesis testing, but also often includes steps such as (a) incorporating information from an analysis of another closely related set of data, and (b) validating a result by assembling and analyzing additional data. These techniques are, in general, beyond the scope of this text; however, Velleman and Hoaglin (149) and Hoaglin et al. (86) present a clear overview of the more important methods, along with codes for their execution on a microcomputer (they have also now been incorporated into Minitab). A short examination of a single case of the use of these methods, however, is in order.

In the field of toxicology it has long been recognized that no population—animal or human—is completely uniform in its response to any particular toxicant. Rather, a population is composed of a (presumably normal) distribution of individuals, some resistant to intoxication (hyporesponders), the bulk that respond close to a central value (such as an LD50), and some that are very sensitive to intoxication (hyperresponders). Taking advantage of this population distribution can, in fact, result in additional statistical techniques. The sensitivity of techniques such as ANOVA is reduced markedly by the occurrence of outliers (extreme high or low values, including hyper- and hyporesponders), which, in fact, serve to markedly inflate the variance (standard deviation) associated with a sample. Such variance inflation is particularly common in small groups that are exposed or dosed at just over or under a threshold level, causing a small number of individuals in the sample (who are more sensitive than the other members) to respond markedly. Such a situation is displayed in Figure 7.6, which plots the mean and standard deviations of methaemoglobin levels in a series of groups of animals exposed to successively higher levels of a hemolytic agent.

Though the mean level of methaemoglobin in group C is more than double that of the control group (A), no hypothesis test will show this difference to be significant because it has such a large SD associated with it. Yet this "inflated" variance exists because a single individual has such a marked response. The occurrence of the inflation is certainly an indicator that the data need to be examined closely. Indeed, all tabular data in toxicology should be visually inspected for both trend and variance inflation.

A concept related (but not identical) to resistance and exploratory data analysis is that of robustness. Robustness generally implies insensitivity to departures from assumptions surrounding an underlying model, such as normality.

In summarizing the location of data, the median, though highly resistant, is not extremely robust, but the mean is both nonresistant and nonrobust.

HYPOTHESIS TESTING OF CATEGORICAL AND RANKED DATA

Categorical (or contingency table) presentations of data can contain any single type of data, but generally the contents are collected and arranged so that they can be classified as belonging to treatment and control groups, with the members of each of these groups then classified as belonging to one of two or more response

categories (such as tumor/no tumor or normal/ hyperplastic/neoplastic). For these cases, two forms of analysis are presented—Fisher's Exact Test (for the 2×2 contingency table) and the R×C chi-square test (for large tables). It should be noted, however, that there are versions of both of these tests that permit the analysis of any size of contingency table.

The analysis of rank data—what is generally called nonparametric statistical analysis—is an exact parallel of the more traditional (and familiar) parametric methods. There are methods for the single comparison case (just as Student's t-test is used) and for the multiple comparison case (just as ANOVA is used) with appropriate post hoc tests for exact identification of the significance with a set of groups. Four tests are presented for evaluating statistical significance in rank data—the Wilcoxon rank-sum test, distribution-free multiple comparisons, Mann-Witney U Test, and the Kruskal-Wallis nonparametric analysis of variance. For each of these tests, tables of distribution values for the evaluations of results can be found in any of a number of reference volumes (62).

It should be clearly understood that for data that do not fulfill the necessary assumptions for parametric analysis, these nonparametric methods are either as powerful, or, in fact, more powerful than the equivalent parametric test.

Fisher's Exact Test

Fisher's exact test should be used to compare two sets of discontinuous, quantal (all or none) data. Small sets of such data can be checked by contingency data tables, such as those of Finney et al. (56). Larger sets, however, require computation, including frequency data, such as incidences of mortality or certain histopathological findings, etc. Thus, the data can be expressed as ratios. These data do not fit on a continuous scale of measurement but usually involve numbers of responses classified as either negative or positive (i.e., a contingency table situation) (138).

The analysis is started by setting up a 2×2 contingency table to summarize the numbers of "positive" and "negative" responses as well as the totals of these responses as follows:

	"Positive"	"Negative"	Total
Group I	A	B	A+B
Group II	C	D	C+D
Totals	A+C	B+D	A+B+C+ D=Ntotal

Using the above set of symbols, the formula for P appears as follows:

$$P = \frac{(A+B)!(C+D)!(A+C)!(B+D)!^{*}}{N!A!B!C!D!}$$

The exact test produces a probability (P) that is the sum of the above calculation repeated for each possible arrangement of the numbers in the above cells (i.e., A, B, C, and D) showing an association equal to or stronger than that between the two variables.

The P resulting from these computations will be the exact one- or two-tailed probability, depending on which of these two approaches is being employed. This value tells us if the groups differ significantly (with a probability less than, say, 0.05) and the degree of significance. This is demonstrated in Example 8.

Example 8

The pathology reports from 35 control and 20 treated rats show that 2 control and 5 treated animals have tumors of the spleen. Setting this up as a contingency table, we see:

	Tumor-bearing	No tumors	Total
Control	2	33	35
Treated	5	15	20
Total	7	48	55

The probability for the worst case on this calculates as

$$prob_1 = \frac{(35)! \bullet (20)! \bullet (7)! \bullet (48)!}{(55)! \bullet (2)! \bullet (5)! \bullet (33)! \bullet (15)!} = 0.046.$$

Similarly, the probabilities for the secondary may be computed as prob2=0.007 and the tertiary as prob3=0.000, respectively. The exact one-tailed p-value is p=0.046+0.007+0.000=0.053. Because this is greater than 0.05, we would not reject the hypothesis of equal proportions at a significance level of 0.05 (this is close to 0.05, however, and may give the researcher encouragement to conduct a larger study).

ASSUMPTIONS AND LIMITATIONS

1. Tables are available that provide individual exact probabilities for small sample size contingency tables

(see ref. 171, pp. 518–542).
2. Fisher's exact must be used in preference to the chi-square test when there are small cell sizes.
3. The probability resulting from a two-tailed test is exactly double that of a one-tailed test from the same data.
4. Ghent (69) has developed and proposed a good (though, if performed by hand, laborious) method extending the calculation of exact probabilities to 2×3, 3×3,and R×C contingency tables.
5. Fisher's probabilities are not necessary symmetric. Although some analysts will double the one-tailed p-value to obtain the two-tailed result, this method usually is overly conservative.
* A! is A factorial. For 4!, as an example, this would be (4) (3) (2) (1)=24.

2×2 Chi Square

Though Fisher's Exact Test is preferable for analysis of most 2×2 contingency tables in toxicology, the chi-square test is still widely used and is preferable in a few unusual situations (particularly if cell sizes are large yet only limited computational support is available). The formula is simply:

$$\chi^2 = \frac{(0_1 - E_1)^2}{E_1} + \frac{(0_2 - E_2)^2}{E_2}$$

$$= \sum \frac{(0_i - E_i)^2}{E_i},$$

where 0 are observed numbers (or counts) and E are expected numbers. The common practice in toxicology is for the observed figures to be test or treatment group counts. The expected figure is calculated as

$$E = \frac{\text{(column total)(row total)}}{\text{grand total}}$$

for each box or cell in a contingency table. Example 9 illustrates this.

Example 9

In an subacute toxicity study, there were 25 animals in the control group and 25 animals in the treatment group. Seven days after dosing, control and 13 treatment animals were observed to be exhibiting fine muscle tremors; all other animals had no tremors. Do significantly more treatment animals have tremors?

	Tremors		No tremors		Σ
	Observed	(Expected)	Observed	(Expected)	
Control	5	(8.5)	20	(16.5)	25
Treated	12	(8.5)	13	(16.5)	25
Σ	17		33		50

$$\chi^2 = \frac{(5-8.5)^2}{8.5} + \frac{(12-8.5)^2}{8.5} + \frac{(20-16.5)^2}{16.5} + \frac{(13-16.5)^2}{16.5}$$

$$= \frac{12.25}{8.5} + \frac{12.25}{8.5} + \frac{12.25}{16.5} + \frac{12.25}{16.5}$$

$$= 1.441 + 1.441 + 0.762 + 0.742$$

$$= 4.366.$$

Our degrees of freedom are (R−1)(C−1)=(2−1) (2−1)=1. Looking at a chi-square table for one degree of freedom we see that this is greater than the test statistic at 0.05 (3.84) but less than that of 0.01 (6.64) so that 0.05>p>0.01.

ASSUMPTIONS AND LIMITATIONS

Assumptions:

(1) Data are univariate and categorical.
(2) Data are from a multinomial population.
(3) Data are collected by random, independent sampling.
(4) Groups being compared are of approximately same size, particularly for small group sizes.

When to use:

(1) When the data are of a categorical (or frequency) nature.
(2) When the data fit the assumptions above.
(3) To test goodness-to-fit to a known form of distribution.
(4) When cell sizes are large.

When not to use:

(1) When the data are continuous rather than categorical.
(2) When sample sizes are small and very unequal.
(3) When sample sizes are too small (e.g., when total N is less than 50 or if any expected value is less

than 5).
(4) For any 2×2 comparison (user Fisher's Exact test instead).

R×C Chi Square

The R×C chi-square test can be used to analyze dis-continuous (frequency) data as in the Fisher's exact or 2×2 chi-square tests; however, in the R×C test (R=row, C=column) we wish to compare three or more sets of data. An example would be comparison of the incidence of tumors among mice on three or more oral dosage levels. We can consider the data as "positive" (tumors) or "negative" (no tumors). The expected frequency for any box is equal to (row total)(column total)/(Ntotal).
As in the Fisher's exact test, the initial step is setting up a table (this time an R×C contingency table). This table would appear as follows:

	Positive	Negative	Total
Group I	$A1$	$B1$	$A1+B1=N1$
Group II	$A2$	$B2$	$A2+B2=N2$
	↓	↓	
Group R	AR	BR	$AR+BR=NR$
Totals	NA	NB	Ntotal

Using these symbols, the formula for chi-square ($\chi 2$) is

$$\chi^2 = \frac{N_{tot}^2}{N_A N_B N_K}\left(\frac{A_1^2}{N_1} + \frac{A_2^2}{N_2} + \ldots \frac{A_K^2}{N_K} - \frac{N_A^2}{N_{tot}}\right).$$

The resulting $\chi 2$ value is compared to table values (138, pp. 470–471) according to the number of degrees of freedom, which is equal to (R−1)(C−1). If $\chi 2$ is smaller than the table value at the 0.05 probability level, the groups are not significantly different. If the calculated $\chi 2$ is larger, there is some difference among the groups, and 2×R chi square or Fisher's exact tests will have to be compared to determine which group(s) differ from which other group(s). Example 10 demonstrates this.

Example 10

The R×C square can be used to analyze tumor incidence data gathered during a mouse-feeding study as follows:

Dosage (mg/kg)	No. of mice with tumors	No. of mice without tumors	Total no. of mice
2.00	19	16	35
1.00	13	24	37
0.50	17	20	37
0.25	22	12	34
0.00	20	23	43
Totals	91	95	186

$$\chi^2 = \frac{(186)^2}{91(95)}\left[\frac{19^2}{35}+\frac{13^2}{37}+\frac{17^2}{37}+\frac{22^2}{34}+\frac{20^2}{43}-\frac{91^2}{186}\right]$$

$$= (4.00)(1.71)$$

$$= 6.84$$

The smallest expected frequency would be (91)(34)/ 186+16.6, well above 5.0. The number of degrees of freedom is (5−1)(2−1)=4. The chi-square table value for four degrees of freedom is 9.49 at the 0.05 probability level. Therefore, there is no significant association between tumor incidence and dose or concentration.

ASSUMPTIONS AND LIMITATIONS

(1) Based on data being organized in a table (such as below) so that there are *cells* (below, A, B, C, and D are cells):

		Columns (C)		
		Control	Treated	Total
Rows (R)	No Effect	A	B	A+B
	Effect	C	D	C+D
Total		A+C	B+D	A+B+C+D

(2) None of the “expected” frequency values should be less than 5.0.

(3) Chi-square test is always one tailed.

(4) Without the use of some form of correction, the test becomes less accurate as the differences between group sizes increases.

(5) The results from each additional column (group) is approximately additive. Due to this characteristic, chi-square can be readily used for evaluating any R×C combination.

(6) The results of the chi-square calculation must be a positive number.

(7) Test is weak with either small sample sizes or when the expected frequency in any cell is less than 5 (this latter limitation can be overcome by “pooling”—combining cells.).

(8) Test results are independent of order of cells, unlike Kolmogorov-Smir nov.

(9) Can be used to test the probability of validity of any distribution.

$$\frac{(N)(N+1)}{2},$$

where N is the total number of data in both groups. The result should be equal to the sum of the sum of ranks for both groups.

The sum of rank values are compared to table values (14, pp. 409–413) to determine the degree of significant differences, if any. These tables include two limits (an upper and a lower) that are dependent on the probability level. If the amount of data is the same in both groups (N1=N2), then the lesser sum of ranks (smaller N) is compared to the table limits to find the degree of significance. Normally the comparison of the two groups ends here and the degree of significant difference can be reported. This is demonstrated in Example 11.

Example 11

If we recorded the approximate times of death (in hours) of rats dosed with 5.0 g/kg (Group B) or 2.5 g/kg (Group A) or a given material, we might obtain the following results:

Hours to Death (Group A)	Hours to Death (Group B)

4	3	7	4
6	6	3	3
7	1	6	1
7	7	7	2
2	7	2	5
5	4	5	4
7	6		
7	3		

With n1=16, n2=12 and n=28, the ranked value of the responses are as shown in parenthesis below:

(Group A)				(Group B)			
4	(11.5)	3	(7.5)	7	(24.5)	4	(11.5)
6	(18.5)	6	(18.5)	3	7.5	3	(7.5)
7	(24.5)	1	(1.5)	6	(18.5)	1	(1.5)
7	(24.5)	7	(24.5)	7	(24.5)	2	(4)
2	(4)	7	(24.5)	2	(4)	5	(15)
5	(15)	4	(11.4)	5	(15)	4	(11.5)
7	(24.5)	6	(18.5)				
7	(24.5)	3	(7.5)				

Sums R1=(261), R2=(145).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_312.html[2010/10/28 18:42:55]

As a chech, $R_1 + R_2 = 406, \ \frac{(28)(29)}{2} = 406 = R_1 + R_2.$ The test's statistic, based on a significance level of μ=0.05 in a normal approximation, becomes

Null hypothesis: H0: $\theta1=\theta2$.

Alt. hypothesis: HA: $\theta1 \neq \theta2$.

$$\text{Test statistic: } Z = \frac{|R_1 - \mu_{R_1}| - 0.5}{\sigma_{R_1}}.$$

$$\frac{(261 - 232) - 0.5}{\sqrt{448.38}} = 1.346.$$

Decision rule: reject H0 if |Z|>1.96.

Conclusion: Because 1.346 is not >1.96, we do not reject H0, concluding that there is insufficient evidence of a difference between the two doses in terms of time of death.

Distribution-Free Multiple Comparison

The distribution-free multiple comparison test should be used to compare three or more groups of nonparametric data. These groups are then analyzed two at a time for any significant differences (87, pp. 124–129). The test can be used for data similar to those compared by the rank-sum test. We often employ this test for reproduction and mutagenicity studies (such as comparing survival rates of offspring of rats fed various amounts of test materials in the diet).

As shown in Example 12, two values must be calculated for each pair of groups: the difference in mean ranks and the probability level value against which the difference will be compared. To determine the difference in mean ranks we must first arrange the data within each of the groups in order of increasing values. Then we must assign rank values, beginning with the smallest overall figure. Note that this ranking is similar to that in the Wilcoxon test except that it applies to more than two groups.

The ranks are then added for each of the groups. As a check, the sum of these should equal

$$\frac{N_{tot}(N_{tot}+1)}{2},$$

where Ntot is the total number of figures from all groups. Next we can find the mean rank (R) for each group by dividing the sum of ranks by the numbers in the data (N) in the group. These mean ranks are then taken in those pairs that we want to compare (usually each test group versus the control) and the differences are found (|R1−R2|). This value is expressed as an absolute figure (i.e., it is always a positive number).

The second value for each pair of groups (the probability value) is calculated from the expression

$$z[a/K(K-1)]\sqrt{\frac{N_{total}(N_{total}+1)}{12}}\sqrt{\frac{1}{N_1}\frac{1}{N_2}},$$

where a is the level of significance for the comparison (usually 0.05, 0.01, 0.001, etc.), K is the total number of groups, and Z is a figure obtained from a normal probability table and determining the corresponding "Z-score".

The result of the probability value calculation for each pair of groups is compared to the corresponding mean difference |R1−R2|. If |R1−R2| is smaller, there is no significant difference between the groups; if it is larger, the groups are different and |R1−R2| must be compared to the calculated probability values for a=0.01 and a=0.001 to find the degree of significance.

Example 12

Consider the following set of data (ranked in increasing order), which could represent the proportion of rats surviving given periods of time during diet inclusion of a test chemical at four dosage levels (survival index):

I		II		III		IV	
5.0 mg/kg		2.5 mg/kg		1.25 mg/kg		0.0 mg/kg	
% Value	Rank	% Value	Rank	% Value	Rank	% Value	Rank
40	2.0	40	2.0	50	5.5	60	9.0
40	2.0	50	5.5	50	5.5	60	9.0
50	5.5	80	12.0	60	9.0	80	12.0

100	17.5	80	12.0	100	17.5	90	14.0
		100	17.5	100	17.5	100	17.5
						100	17.5
Sum of ranks	27.0		49.0		55.0		79.0

$N_I = 4, \quad N_{II} = 5, \quad N_{III} = 5, \quad N_{IV} = 6.$

$N_{tot} = 20$

$$\text{Check sums of} = 210, \frac{20(21)}{2} = 210.$$

$$\text{Mean ranks (R):} \quad R_1 = \frac{27.0}{4} = 6.75, \quad R_2 = \frac{49.0}{5} = 9.80,$$

$$R_3 = \frac{55.0}{5} = 11.00, \quad R_4 = \frac{79.0}{6} = 13.17.$$

Comparison Groups	|R1−R2|	Probability test values
5.0 versus 0.0	6.42	$(0.05/4(3)) = Z_{0.00417} = 2.637$ $\sqrt{\frac{(20)(21)}{12}}\sqrt{\frac{1}{4}+\frac{1}{6}} = 10.07$
2.5 versus 0.0	3.37	$(0.05/4(3)) = Z_{0.00417} = 2.637$ $\sqrt{\frac{(20)(21)}{12}}\sqrt{\frac{1}{5}+\frac{1}{6}} = 9.45$
1.25 versus 0.0	2.17	$(0.05/4(3)) = Z_{0.00417} = 2.637$ $\sqrt{\frac{(20)(21)}{12}}\sqrt{\frac{1}{5}+\frac{1}{6}} = 9.45$

Because each of the |R1−R2| values is smaller than the corresponding probability calculation, the pairs of groups compared are not different at the 0.05 level of significance.

ASSUMPTIONS AND LIMITATIONS

1. As with the Wilcoxon Rank-Sum, too many tied ranks inflate the false-positive.
2. Generally, this test should be used as a post hoc comparison after Kruskal-Wallis.

Mann-Whitney U Test

This is a nonparametric test in which the data in each group are first ordered from lowest to highest values, and then the entire set (both control and treated values) is ranked, with the average rank being assigned to tied values (i.e., if two values tie for 12th rank—and therefore would be ranked 12th and 13th—both would be assigned the average rank of 12.5). The ranks are then summed for each group and U is determined according to

$$U_t = n_c n_t + \frac{n_t(n_t+1)}{2} - R_t,$$

$$U_c = n_c n_t + \frac{n_c(n_c+1)}{2} - R_c,$$

where nc, nt=sample size for control and treated groups and Rc, Rt=sum of ranks for the control and treated groups. For the level of significance for a comparison of the two groups, the larger value of Uc or Ut is used. This is compared to critical values as found in tables in Reference 137.

As demonstrated in Example 13, the Mann-Whitney U test is employed for the count data, but which test should be employed for the percentage variables should be decided on the same grounds as described later in a discussion of statistical requirements for reproduction studies.

Example 13

In a 2-week study, the levels of serum cholesterol in treatment and control animals are successfully measured and assigned ranks as follows:

	Treatment		Control	
	Value	Rank	Value	Rank
	10	1	19	4
	18	3	28	13
	26	10.5	29	14.5
	31	16	26	10.5
	15	2	35	19
	24	8	23	7
	22	6	29	14.5
	33	17	34	18
	21	5	38	20
	25	9	27	12
SUM OF RANKS		77.5		132.5

The critical value for one tailed $p \leq 0.05$ is $U \geq 73$. We then calculate

$$U_t = (10)(10) + \frac{10(10+1)}{2} - 77.5$$

$$= 100 + \frac{110}{2} - 77.5 = 77.5$$

$$U_c = (10)(10) + \frac{10(10+1)}{2} - 132.5 = 22.5.$$

As 77.5 is greater than 73, these groups are significantly different at the 0.05 level.

ASSUMPTIONS AND LIMITATIONS

1. It does not matter whether the observations are ranked from smallest to largest, or vice versa.
2. This test should not be used for paired observations.
3. The test statistics from a Mann-Whitney are linearly related to those of Wilcoxon. The two tests will always yield the same result. The Mann-Whitney is presented here for historical completeness, as it has been much favored in reproductive and developmental toxicology studies; however, it should be noted that the authors do not include it in the decision tree for method selection (Figure 7.2).

Kruskal-Wallis Nonparametric ANOVA

The Kruskal-Wallis nonparametric one-way analysis of variance should be the initial analysis performed when we have three or more groups of data that are by nature nonparametric (either not a normally distributed population, or of a discontinuous nature, or all the groups being analyzed are not from the same population) but not a categorical (or quantal) nature. Commonly these will be either rank-type evaluation data (such as behavioral toxicity observation scores) or reproduction study data. The analysis is initiated (119, pp. 170–173) by ranking all the observations from the combined groups to be analyzed. Ties are given the average rank of the tied values.

The sum of ranks of each group (r1, r2,...rk) is computed by adding all the rank values for each group. The test value H is then computed as

$$H = \frac{12}{n(n+1)} \sum r_1^2/n_1 + r_2^2/n_2 + \cdots + r_k^2/n_k) - 3(n+1),$$

where n1, n2,...nk are the number of observations in each group. The test statistic is then compared with a table of H values. If the calculated value of H is greater than the table value for the appropriate number of observations in each group, there is significant difference between the groups, but further testing (using the distribution-free multiple comparisons method) is necessary to determine where the difference lies (as demonstrated in Example 14).

Example 14

As part of a neurobehavioral toxicology study, righting reflex values (whole numbers ranging from 0 to 10) were determined for each of five rats in each of three groups. The values observed, and their ranks, are as follows:

	Control group		5 mg/kg group		10 mg/kg group	
	Reflex Score	Rank	Reflex Score	Rank	Reflex Score	Rank
	0	2	1	5	4	11
	0	2	2	7.5	4	11
	0	2	2	7.5	5	13
	1	5	3	9	8	14.5
	1	5	4	11	8	14.5
Sums of of ranks (r)		16		40		64

From these the H value is calculated as

From these the H value is calculated as

$$H = \frac{12}{15(15+1)} \left[\frac{16^2}{5} + \frac{40^2}{5} + \frac{64^2}{5} \right] - 3(15+1)$$

$$= \frac{12}{240} \left[\frac{(256 + 1600 + 4096)}{5} \right] - 48$$

$$= \frac{1}{20}(1190.4) - 48$$

$$= 59.52 - 48$$

$$= 11.52$$

Consulting a table of values for H, we find that for the case where we have three groups of five observations each, the test values are 4.56 (for p=0.10), 5.78 (for p=0.05), and 7.98 (for p=0.01). As our calculated H is greater than the p=0.01 test value, we have determined that there is a significant difference between the groups at the level of p<0.01 and would now have to continue to a multiple comparisons test to determine where the difference is.

ASSUMPTIONS AND LIMITATIONS

1. The test statistic H is used for both small and large samples.
2. When we find a significant difference, we do not know which groups are different. It is not correct to then perform a Mann-Whitney U test on all possible combinations. Rather, a multiple comparison method must be used, such as the distribution-free multiple comparisons.
3. Data must be independent for the test to be valid.
4. Too many tied ranks will decrease the power of this test and also lead to increased false-positive levels.
5. When k=2, the Kruskal-Wallis chi-square value has 1 d.f. This test is identical to the normal approximation used for the Wilcoxon Rank-Sum Test. As noted in previous sections, a chi-square with 1 d.f. can be represented by the square of a standardized normal random variable. In the case of k=2, the h-statistic is the square of the Wilcoxon Rank-Sum Z-test (without the continuity correction).

6. The effect of adjusting for tied ranks is to slightly increase the value of the test statistic, h. Therefore, omission of this adjustment results in a more conservative test.

Log-Rank Test

The log-rank test is a statistical methodology for comparing the distribution of time until the occurrence of the event in independent groups. In toxicology, the most common event of interest is death or occurrence of a tumor, but it could just as well be liver failure, neurotoxicity, or any other event that occurs only once in an individual. The elapsed time from initial treatment or observation until the *event* is the *event time,* often referred to as "survival time," even when the event is not "death."

The log-rank test provides a method for comparing "risk-adjusted" event rates, useful when test subjects in a study are subject to varying degrees of opportunity to experience the event. Such situations arise frequently in toxicology studies due to the finite duration of the study, early termination of the animal, or interruption of treatment before the event occurs.

Examples where use of the log-rank test might be appropriate include comparing survival times in carcinogenity bioassay animals that are given a new treatment with those in the control group or comparing times to liver failure for several dose levels of a new nonsteroidal anti-inflammatory drug (NSAID) where the animals are treated for 10 weeks or until cured, whichever comes first.

If every animal were followed until the event occurrence, the event times could be compared between two groups using the Wilcoxon Rank-Sum Test, however, some animals may die or complete the study before the event occurs. In such cases, the actual time of the event is unknown since the event does not occur while under study observation. The event times for these animals are based on the last known time of study observation and are called "censored" observations because

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_315.html[2010/10/28 18:42:57]

they represent the lower-bound of the true, unknown event times. The Wilcoxon Rank-Sum Test can be highly biased in the presence of the censored data.

The null hypothesis tested by the Log-Rank Test is that of equal event time distributions among groups. Equality of the distributions of event times implies similar event rates among groups not only for the clinical trial as a whole, but also for any arbitrary time point during the trial. Rejection of the null hypothesis indicates that the event rates differ among groups at one or more time points during the study.

The idea behind the log-rank test for comparison of two life tables is simple. If there were no difference between the groups, the total deaths occurring at any time should split between the two groups at that time. So if the numbers at risk in the first and second groups in (say) the sixth month were 70 and 30, respectively, and 10 deaths occurred in that month, we would expect

$$10 \times \frac{70}{70+30} = 7$$

of these deaths to have occurred in the first group, and

$$10 \times \frac{30}{70+30} = 3$$

of the deaths to have occurred in the second group.

A similar calculation can be made at each time of death (in either group). By adding together for the first group the results of all such calculations, we obtain a single number, called the extent of exposure (E1), which represents the "expected" number of deaths in that group if the two groups had the distribution of survival time. An extent of exposure (E2) can be obtained for the second group in the same way. Let O1 and O2 denote the actual total numbers of deaths in the two groups. A useful arithmetic check is that the total number of deaths O1+O2 must equal the sum E1+E2 of the extents of exposure.

The discrepancy between the O's and E's can be measured by the quantity

$$\chi^2 = \frac{(|O_1 - E_1| - 1/2)^2}{E_1} + \frac{(|O_2 - E_2| - 1/2)^2}{E_2}.$$

For rather obscure reasons, X2 is known as the *Log-Rank statistic*. An approximate significance test of the null hypothesis of identical distributions of survival time in the two groups is obtained by referring X2 to a chi-square distribution on 1 degree of freedom. This is demonstrated in Example 15.

Example 15

In a study of the effectiveness of a new monoclonal antibody to treat a specific cancer, the times to re occurrence of the cancer in treated animals in weeks were as follows:

Control Group			Treatment Group		
1	5	11	6	10	22
1	5	12	6	11	23
2	8	12	6	13	25
2	8	15	6	16	32
3	8	17	7	17	32
4	8	22	9	19	34
4	11	23	10	20	35

The table opposite presents the calculations for the log-rank test applied to these times. A chi-square value of 13.6 is significant at the $p<0.001$ level.

Illustration:

$$t = 23, 2 \times \frac{6}{7} = 1.7143, 2 \times \frac{1}{7} = 0.2857.$$

Test of significance:

$$x^2 = \frac{\left(|O_1 - E_1| - \frac{1}{2}\right)^2}{E_1} + \frac{\left(|O_2 - E_2| - \frac{1}{2}\right)^2}{E_2}$$

$$= \frac{\left(|9 - 19.2| - \frac{1}{2}\right)^2}{19.2} + \frac{\left(|21 - 10.8| - \frac{1}{2}\right)^2}{10.8} = 13.6.$$

Estimate of relative risk'.

$$\theta = \frac{(O_1/E_1)}{(O_2/E_2)}$$

$$\hat{\theta} = \frac{9/19.2}{21/10.8} = 0.24.$$

The log-rank test as presented by Peto et al. (118) uses the product-limit life-table calculations rather than the actuarial estimators shown above. The distinction is unlikely to be of practical importance unless the grouping intervals are very coarse.

Peto and Pike (118) suggest that the approximation in treating the null distribution of $\chi2$ as a chi-square is conservative, so it will tend to understate the degree of statistical significance. In the formula for $\chi2$ we have used the continuity correction of subtracting 1/2 from $|O1-E1|$ and $|O2-E2|$ before squaring. This is recommended by Peto et al. (118) when, as in nonrandomized studies, the permutational argument does not apply. Peto et al. (118) gives further details of the log-rank test and its extension to comparisons of more than two treatment groups and to tests that control for categorical confounding factors.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_316.html[2010/10/28 18:42:58]

Log-Rank Calculation for Tumor Data

Time,	At Risk			Relapses			Extent of Exposure		
t	*T*	*C*	Total	*T*	*C*	Total	*T*	*C*	Total
1	21	21	42	0	2	2	1.0000	1.0000	2
2	21	19	40	0	2	2	1.0500	0.9500	2
3	21	17	38	0	1	1	0.5526	0.4474	1
4	21	16	37	0	2	2	1.1351	0.8649	2

23	6	1	7	1	1	2	1.7143	0.2857	2
	Total			9	21	30	19.2080	10.7920	30
					(O1)	*(O2)*	*(E1)*	*(E2)*	

ASSUMPTIONS AND LIMITATIONS

(1) The endpoint of concern is or is defined so that it is "right censored"—once it happens, it does not reoccur. Examples are death or a minimum or maximum value of an enzyme or physiologic function (such as respiration rate).

(2) The method makes no assumptions on distribution.

(3) Many variations of the Log-Rank Test for comparing survival distributions exist. The most common variant has the form

$$\chi^2 = \frac{(O_1 - E_1)^2}{E_1} + \frac{(O_2 - E_2)^2}{E_2},$$

where Oi and Ei are computed for each group, as in the formulas given previously. This statistic also has an approximate chi-square distribution with 1 degree of freedom under H0.

A continuity correction can also be used to reduce the numerators by one half before squaring. Use of such a correction leads to even further conservatism and may be omitted when sample sizes are moderate or large.

(4) The Wilcoxon Rank-Sum Test could be used to analyze the event times in the absence of censoring. A "Generalized Wilcoxon" Test, sometimes called the Gehan Test, based on an approximate chi-square distribution, has been developed for use in the presence of censored observations. Both the Log-Rank and the Generalized Wilcoxon Tests are nonparametric tests and require no assumptions regarding the distribution of event times. When the event rate is greater early in the trial than toward the end, the Generalized Wilcoxon Test is the more appropriate test because it gives greater weight to the earlier differences.

(5) Survival and failure times often follow the exponential distribution. If such a model can be assumed, a more powerful alternative to the Log-Rank Test is the Likelihood Ratio Test. This parametric test assumes that event probabilities are constant over time. That is, the chance that a patient becomes event-positive at time t given that he is event-negative up to time t does not depend on t. A plot of the negative log of the event times' distribution showing a linear trend through the origin is consistent with exponential event times.

(6) Life tables can be constructed to provide estimates of the event time distributions. Estimates commonly used are known as the Kaplan-Meier estimates.

HYPOTHESIS TESTING: UNIVARIATE PARAMETRIC TESTS

Univariate case* data from normally distributed populations generally have a higher information value associated with them, but the traditional hypothesis testing techniques generally are neither resistant nor robust. All the data analyzed by these methods are also, effectively, continuous (i.e., at least for practical purposes, the data may be represented by any number and each such data number has a

measurable relationship to other data numbers).

Student's t-Test (Unpaired t-Test)

Pairs of groups of continuous, randomly distributed data are compared via this test. We can use this test

*That is, where each datum is defined by one treatment and one effect variable.

to compare three or more groups of data, but they must be intercompared by examination of two groups taken at a time and are preferentially compared by analysis of variance (ANOVA). Usually this means comparison of a test group versus a control group, although two test groups may be compared as well. To determine which of the three types of t-tests described in this chapter should be employed, the F-test usually is performed first. This will tell us if the variances of the data are approximately equal, which is a requirement for the use of the parametric methods. If the F-test indicates homogeneous variances and the numbers of data within the groups (N) are equal, then the Student's t-test is the appropriate procedure (138). If the F is significant (the data are heterogeneous) and the two groups have equal numbers of data, the modified Student's t-test is applicable (42).

The value of t for Student's t-test is calculated using the formula

$$t = \frac{\bar{X}_1 - \bar{X}_2}{\sum D_1^2 + \sum D_2^2} \sqrt{\frac{N_1 N_2}{N_1 + N_2}(N_1 + N_2 - 2)},$$

where the value of $\Sigma D^2 = [N \Sigma X^2 - (\Sigma X)^2]/N$.

The value of t obtained from the above calculations is compared to the values in a t-distribution table according to the appropriate number of degrees of freedom (df). If the F value is not significant (i.e., variances are homogeneous), the $df = N_1 + N_2 - 2$. If the F was significant and $N_1 = N_2$, then the $df = N - 1$. Although this case indicates a nonrandom distribution, the modified t-test is still valid. If the calculated value is larger than the table value at $p = 0.05$, it may then be compared to the appropriate other table values in order of decreasing probability to determine the degree of significance between the two groups. Example 16 demonstrates this methodology.

Example 16

Suppose we wish to compare two groups (a test and control group) of dog weights following inhalation of a vapor. First, we would test for homogeneity of variance using the F-test. Assuming that this test gave negative (homogeneous) results, we would perform the t-test as follows:

Dog	Test weight (X_1 in kg)	X_1^2	Control weight (X_2 in kg)	X_2^2
1	8.3	68.89	8.4	70.56
2	8.8	77.44	10.2	104.04
3	9.3	86.49	9.6	92.16
4	9.3	86.49	9.4	88.36
Sums	$\Sigma X_1 = 35.7$	ΣX_1^2	$\Sigma X_2 = 37.6$	ΣX_2^2
Means	8.92		9.40	

The difference in means $= 9.40 - 8.92 = 0.48$.

$$\sum D_1^2 = \frac{4(319.31) - (35.7)^2}{4} = \frac{2.75}{4} = 0.6875,$$

$$\sum D_2^2 = \frac{4(355.12) - (37.6)^2}{4} = \frac{6.72}{4} = 1.6800,$$

$$t = \frac{0.48}{\sqrt{0.6875 + 1.6800}} \sqrt{\frac{4(4)}{4 + 4}(4 + 4 - 2)} = 1.08.$$

The table value for t at the 0.05 probability level for (4+4−2), or six degrees of freedom, is 2.447. Therefore, the dog weights are not significantly different at $p = 0.05$.

ASSUMPTIONS AND LIMITATIONS

1. The test assumes that the data are univariate, continuous, and normally distributed.
2. Data are collected by randomly sampling.
3. The test should be used when the assumptions in 1 and 2 are met and there are only two groups to be compared.
4. Do not use when the data are ranked, when the data are not approximately normally distributed, or when there are more than two groups to be compared. Do not use for paired observations.
5. This is the most commonly misused test method, except in those few cases where one is truly only comparing two groups of data and the group sizes are roughly equivalent. Not valid for multiple comparisons (because of resulting additive errors) or where group sizes are very unequal.
6. Test is robust for moderate departures from normality and, when N_1 and N_2 are approximately equal,

robust for moderate departures from homogeneity of variances.
7. The main difference between the Z-test and the t-test is that the Z-statistic is based on a known standard deviation, *a*, whereas the t-statistic uses the sample standard deviation, s, as an estimate of *a*. With the assumption of normally distributed data, the variance σ^2 is more closely estimated by the sample variance s^2 as n gets large. It can be shown that the t-test is equivalent to the Z-test for infinite degrees of freedom. In practice, a "large" sample usually is considered $n \geq 30$.

Cochran t-test

The Cochran test should be used to compare two groups of continuous data when the variances (as indicated by the F-test) are heterogeneous and the numbers of data within the groups are not equal ($N_1 \neq N_2$). This is the situation, for example, when the data, though expected to be randomly distributed, were found not to be (28, pp. 100–102).

Two t values are calculated for this test, the "observed" t (t_{obs}) and the "expected" t (t′) The observed t is obtained by

$$t_{obs} = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{W_1 + W_2}}$$

where W=SEM^2 (standard error of the mean squared),
$=S^2/N$,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_318.html[2010/10/28 18:42:59]

where *S* (variance) can be calculated from

$$S = \frac{\dfrac{N\sum X^2 - \left(\sum X\right)^2}{N}}{N-1}$$

The value for *t′* is obtained from

$$t' = \frac{t'_1 W_1 + t'_2 W_2}{W_1 + W_2}$$

where t'_1 and t'_2 are values for the two groups taken from the t-distribution table corresponding to *N*–1 degrees of freedom (for each group) at the 0.05 probability level (or such level as one may select). The calculated t_{obs} is compared to the calculated t′ value (or values, if t′ values were prepared for more than one probability level). If t_{obs} is smaller than a t′, the groups are not considered to be significantly different at that probability level. This procedure is shown in Example 17.

Example 17

If we wished to compare the red blood cell count (RBC) of rats receiving a test material in their diet with the RBCs of control rats, we might obtain the following results:

Test RBC (X_1)	X_1^2	Control RBC (X_2)	X_2^2
8.23	67.73	7.22	52.13
8.59	73.79	7.55	57.00
7.51	56.40	7.53	56.70
6.60	46.56	7.32	53.58
6.67	44.49		
$\sum X_1 = 37.60$	$\sum X_1^2$ 285.97	$\sum X_2 = 29.62$	$\sum X_2^2$ 219.41

$$\bar{X}_1 = \frac{37.60}{5} = 7.52, \quad W_1 = \frac{0.804}{5} = 0.1608,$$

$$\bar{X}_2 = \frac{29.62}{4} = 7.40, \quad W_2 = \frac{0.025}{4} = 0.0062,$$

(note that S^2 values of 0.804 and 0.025 are calculated in Example 17)

$$t_{obs} = \frac{7.52 - 7.40}{\sqrt{0.1608 + 0.0062}} = 0.29.$$

From the t-distribution table we use t1=2.776 (d*f*=4) and t2=3.182 (d*f*=3) for the 0.05 level of significance; there is no statistical difference at p=0.05 between the two groups.

ASSUMPTIONS AND LIMITATIONS

1. The test assumes that the data are univariate, continuous, normally distributed, and that group sizes are unequal.
2. The test is robust for moderate departures from normality and very robust for departures from equality of variances.

F-Test

This is a test of the homogeneity of variances between two groups of data (138). It is used in two separate cases. The first is when Bartlett's indicates heterogeneity of variances among three or more groups (i.e., it is used to determine which pairs of groups are heterogeneous). Second, the F-test is the initial step in comparing two groups of continuous data that we would expect to be parametric (two groups not usually being compared using ANOVA), the results indicating whether the data are from the same population and whether subsequent parametric comparisons would be valid.

The F is calculated by dividing the larger variance (S_1^2) by the smaller one (S_2^2). S2 is calculated as

$$S^2 = \frac{\dfrac{N\sum X^2 - \left(\sum X\right)^2}{N}}{N-1},$$

where *N* is the number of data in the group and X represents the individual values within the group. Frequently, S2 values may be obtained from ANOVA calculations. Use of this is demonstrated in Example 18.

The calculated F value is compared to the appropriate number in an F value table for the appropriate degrees of freedom (N–1) in the numerator (along the top of the table) and in the denominator (along the side of the table). If the calculated value is smaller, it is not significant and the variances are considered homogeneous (and the Student's t-test would be appropriate for further comparison). If the calculated F value is greater, F is significant and the variances are heterogeneous (and the next test would be modified Student's t-test if N1=N2 or the Cochran t-test if N1≠N2; see Figure 7.2 to review the decision tree).

Example 18

Using the RBC comparison from Example 17 (with N1=5, N2=4), the following results were determined:

$$\text{Variance for } X_1 = S_1^2 = \frac{\dfrac{5(285.97) - (37.60)^2}{5}}{5-1}$$
$$= 0.804,$$

$$\text{Variance for } X_2 = S_3^2 = \frac{\frac{4(219.41)-(29.62)^2}{4}}{4-1}$$

$$= 0.025,$$

$$F = \frac{0.804}{0.025} = 32.16.$$

From a table for F values, for 4 (numerator) versus 3 (denominator) df, we read the limit of 9.12 at the 0.05 level. As our calculated value is larger (and, therefore, significant), the variances are heterogeneous and the Cochran t-test would be appropriate for comparison of the two groups of data.

ASSUMPTIONS AND LIMITATIONS

1. This test could be considered as a two-group equivalent of the Bartlett's test.
2. If the test statistic is close to 1.0, the results are (of course) not significant.
3. The test assumes normality and independence of data.

Analysis of Variance

ANOVA is used for comparison of three or more groups of continuous data when the variances are homogeneous and the data are independent and normally distributed. A series of calculations are required for ANOVA, starting with the values within each group being added (ΣX) and then these sums being added (ΣΣX). Each figure within the groups is squared, and these squares are then summed (ΣX^2) and these sums added ($\Sigma\Sigma X^2$). Next the "correction factor" (CF) can be calculated from the following formula:

$$CF = \frac{\left(\sum_1^K \sum_1^N X\right)^2}{N_1 + N_2 + \ldots N_k},$$

where N is the number of values in each group and K is the number of groups. The total sum of squares (SS) is then determined as follows:

$$SS_{total} = \sum_1^K \sum_1^N X^2 - CF.$$

In turn, the sum of squares between groups (bg) is found from

$$SS_{bg} = \frac{\left(\sum X_1\right)^2}{N_1} + \frac{\left(\sum X_2\right)^2}{N_2} + \cdots \frac{\left(\sum X_k\right)^2}{N_k} - CF.$$

The sum of squares within group (wg) is then the difference between the last two figures, or

$$SS_{wg} = SS_{total} - SS_{bg}.$$

Now there are three types of degrees of freedom to determine. The first, total df, is the total number of data within all groups under analysis minus one ($N_1+N_2+\ldots N_k-1$). The second figure (the df between groups) is the number of groups minus one (K−1). The last figure (the df within groups or "error df") is the difference between the first two figures ($df_{total}-df_{bg}$).

The next set of calculations requires determination of the two mean squares (MD_{bg} and MS_{wg}). These are the respective sum of square values divided by the corresponding df figures (MS=SS/df). The final calculation is that of the F ratio. For this, the MS between groups is divided by the MS within groups ($F=MS_{bg}/MS_{wg}$).

A table of the results of these calculations (using data from Example 19 at the end of this section) would appear as follows:

	df	SS	MS	F
Bg	3	0.04075	0.01358	4.94
Wg	12	0.03305	0.00275	
Total	15	0.07380		

For interpretation, the F ratio value obtained in the ANOVA is compared to a table of F values. If F≤1.0, the results are not significant and comparison with the table values is not necessary. The degrees of freedom (df) for the greater mean square (MS_{bg}) are indicated along the top of the table. Then read

down the side of the table to the line corresponding to the df for the lesser mean square (MSwg). The figure shown at the desired significance level (traditionally 0.05) is compared to the calculated F value. If the calculated number is smaller, there is no significant differences among the groups being compared. If the calculated value is larger, there is some difference, but further (post hoc) testing will be required before we know which groups differ significantly.

Example 19

Suppose we want to compare four groups of dog kidney weights, expressed as percentage of body weights, following an inhalation study. Assuming homogeneity of variance (from Barlett's test), we could complete the following calculations:

	400 ppm	200 ppm	100 ppm	0 ppm
	0.43	0.49	0.34	0.34
	0.52	0.48	0.40	0.32
	0.43	0.40	0.42	0.33
	0.55	0.34	0.40	0.39
ΣX	1.93	1.71	1.56	1.38

$$\Sigma\Sigma X=1.93+1.71+1.56+1.38=6.58.$$

Next, the preceding figures are squared:

	400 ppm	200 ppm	100 ppm	0 ppm
	0.1849	0.2401	0.1156	0.1156
	0.2704	0.2304	0.1600	0.1024
	0.1849	0.1600	0.1764	0.1089
	0.3025	0.1156	0.1600	0.1521
$\Sigma X2$	0.9427	0.7461	0.6120	0.4790

$$\Sigma\Sigma X2=0.9427+0.7461+0.6120+0.4790=2.7798.$$

$$\mathrm{CF}=\frac{(6.58)^2}{4+4+4+4}=2.7060,$$

$$\mathrm{SS}_{\mathrm{total}}=2.7798-2.7060=0.0738,$$

$$\mathrm{SS}_{\mathrm{bg}}=\frac{(1.93)^2}{4}+\frac{(1.71)^2}{4}+\frac{(1.56)^2}{4}+\frac{(1.38)^2}{4}-2.7060$$
$$=0.04075,$$

$$\mathrm{SS}_{\mathrm{wg}}=0.07380-0.04075=0.03305.$$

$$\text{The total degrees of freedom (df)}=4+4+4+4-1=15,$$

$$\mathrm{df}_{\mathrm{bg}}=4-1=3\ \mathrm{df}_{\mathrm{wg}}=15-3=12,$$

$$\mathrm{MS}_{\mathrm{bg}}=\frac{0.4075}{3}=0.01358,$$

$$\mathrm{MS}_{\mathrm{wg}}=\frac{0.03305}{12}=0.00275,$$

$$\mathrm{F}=\frac{0.01358}{0.00275}=4.94.$$

Going to a table of F values, we find that for 3 dfbg (greater mean square) and 12 dfwg (lesser mean square), the 0.05 value of F is 3.49. As our calculated value is greater, there is a difference among groups at the 0.05 probability level. To determine where the difference is, further comparisons by a post hoc test will be necessary.

ASSUMPTIONS AND LIMITATIONS

1. What is presented here is the workhorse of toxicology—the one-way analysis of variance. Many other forms exist for more complicated experimental designs.
2. The test is robust for moderate departures from normality if the sample sizes are large enough. Unfortunately, this is rarely the case in toxicology.
3. ANOVA is robust for moderate departures from equality of variances (as determined by Bartlett's test) if the sample sizes are approximately equal.
4. It is not appropriate to use a t-test (or a 2-groups-at-a-time version of ANOVA) to identify where significant differences are within the design group. A multiple-comparison post hoc method must be used.

Post Hoc Tests

There is a wide variety of post hoc tests available to analyze data after finding significant result in an ANOVA. Each of these tests has advantages and disadvantages, proponents, and critics. Four of the tests are commonly used in toxicology and are presented here. These are Duncan's, Scheffe's, and Dunnett's t-test and Williams' t-test. Two other tests that are available in many statistical packages are Tukey's method and the Student-Newman-Keuls method (171, pp. 151–161).

If ANOVA reveals no significance, it is not appropriate to proceed to perform a post hoc test in hope of finding differences. To do so would only be another form of multiple comparisons, increasing the type I error rate beyond the desired level.

Duncan's Multiple Range Test

Duncan's (44) is used to compare groups of continuous and randomly distributed data (such as body weights, organ weights, etc.). The test normally involves three or more groups taken one pair at a time. It should only follow observation of a significant F value in the ANOVA and can serve to determine which group (or groups) differs significantly from which other group (or groups).

There are two alternative methods of calculation. The selection of the proper one is based on whether the number of data (N) are equal or unequal in the groups.

Groups with Equal Number of Data (N1=N2)

Two sets of calculations must be carried out. First, the determination of the difference between the means of pairs of groups; second, the preparation of a probability rate against which each difference in means is compared (as shown in the first of the two examples in this section).

The means (averages) are determined (or taken from the ANOVA calculation) and ranked in either decreasing or increasing order. If two means are the same, they take up two equal positions (thus, for four means we could have ranks of 1, 2, 2, and 4 rather than 1, 2, 3, and 4). The groups are then taken in pairs and the differences between the means $(\bar{X}_1 - \bar{X}_2)$, expressed as positive numbers, are calculated. Usually, each pair consists of a test group and the control group, though multiple test groups may be intracompared if so desired. The relative rank of the two groups being compared must be consid-

Page 322

ered. If a test group is ranked "2" and the control group is ranked "1," then we say that there are two places between them, whereas if the test group were ranked "3," then there would be three places between it and the control.

To establish the probability table, the standard error of the mean (SEM) must be calculated as presented earlier, or as

$$\sqrt{\frac{\text{error mean square}}{N}} = \sqrt{\frac{\text{mean square within group}}{N}},$$

where N is the number of animals or replications per dose level. The mean square within groups (MSwg) can be calculated from the information given in the ANOVA procedure (refer to the earlier section on ANOVA). The SEM is then multiplied by a series of table values (14,80) to set up a probability table. The table values used for the calculations are chosen according to the probability levels (note that the tables have sections for 0.05, 0.01, and 0.001 levels) and the number of means apart for the groups being compared and the number of "error" degrees of freedom (df). The "error" df is the number of df within the groups. This last figure is determined from the ANOVA calculation and can be taken from ANOVA output. For some values of df, the table values are not given and should thus be interpolated. Example 20 demonstrates this case.

Example 20

Using the data given in Example 19 (4 groups of dogs, with 4 dogs in each group), we can make the following calculations:

Ranks	1	2	3	4
Concentration	0 ppm	100 ppm	200 ppm	400 ppm
Mean kidney weight $(\bar{X})$	0.345	0.390	0.428	0.482

Groups compared	$\bar{X}_1-\bar{X}_2$	No of means apart	Probability
2 vs. 1 (100 vs 0 ppm)	0.045	2	p>0.05
3 vs. 1 (200 vs 0 ppm)	0.083	3	p>0.05
4 vs. 1 (400 vs 0 ppm)	0.137	4	0.01>p>0.001
4 vs. 2 (400 vs 100 ppm)	0.092	3	0.05>p>0.01

The mean square within groups from the ANOVA example was 0.00275. Therefore, the SEM= $\sqrt{0.00275/4}=0.02622$. The "error" d*f*(d*f*wg) was 12, so the following table values are used.

No. of means apart	Probability levels 0.05	0.01	0.001
2	3.082	4.320	6.106
3	3.225	4.504	6.340
4	3.313	4.662	6.494

When these are multiped by the SEM we get the following probability table:

No. of means apart	Probability levels 0.05	0.01	0.001
2	0.0808	0.1133	0.1601
3	0.0846	0.1161	0.1662
4	0.0869	0.1212	0.1703

Groups with Unequal Numbers of Data (N1≠N2)

This procedure is very similar to that discussed above. As before, the means are ranked and the differences between the means are determined $(\bar{X}_1-\bar{X}_2)$. Next, weighing values ("aij" values) are calculated for the pairs of groups being compared in accordance with

$$a_u = \sqrt{\frac{2N_iN_j}{(N_i+N_j)}} = \sqrt{\frac{2N_1N_2}{(N_1+N_2)}}$$

This weighting value for each pair of groups is multiplied by $(\bar{X}_1-\bar{X}_2)$ for each value to arrive at a "t" value. It is the "t" that will later be compared to a probability table.

The probability table is set up as above except that instead of multiplying the appropriate table values by SEM, SEM2 is used. This is equal to $\sqrt{\text{MS}_{\text{wg}}}$.

For the desired comparison of two groups at a time, the $(\bar{X}_1-\bar{X}_2)$. value (if N1=N2) is compared to

the appropriate probability table. Each comparison must be made according to the number of places between the means. If the table value is larger at the 0.05 level, the two groups are not considered to be statistically different. If the table value is smaller, the groups are different and the comparison is repeated at lower levels of significance. Thus, the degree of significance may be determined. We might have significant differences at 0.05 but not at 0.01, in which case the probability would be represented at $0.05>p>0.01$. Example 21 demonstrates this case.

Example 21

Suppose that the 400 ppm level from the above example had only 3 dogs, but that the mean for the group and the mean square within groups were the same. To continue Duncan's we would calculate the weighing factors as follows:

100 ppm vs. 0 ppm,

$$200 \text{ ppm vs. } 0 \text{ ppm } N_1 = 4; N_2 = 4 \; a_{ij} = \sqrt{\frac{2(4)(4)}{4+4}} = 2.00,$$

Page 323

$$400 \text{ ppm vs. } 0 \text{ ppm } N_2 = 3;\ N_4 = 4 a_{ij} = \sqrt{\frac{2(3)(4)}{3+4}} = 1.852,$$

400 ppm vs. 100 ppm.

Using the $\bar{X}_1 - \bar{X}_2$ from the above example we can set up the following tables:

Concentrations ppm	No. of means apart	$\bar{X}_1 - \bar{X}_2$	aij	$(\bar{X}_1 - \bar{X}_2)\cdot$aij
100 versus 0	2	0.045	2.000	2.000(.045)=.090
200 versus 0	3	0.083	2.000	2.000(.083)=.166
400 versus 0	4	0.137	1.852	1.852(.137)=.254
400 versus 100	3	0.092	1.852	1.852(.092)=.170

Next we calculate SEM2 as being $\sqrt{0.00275} = 0.05244$. This is multiplied by the appropriate table values chosen for 11 d*f*(d*f*wg for this example). This gives the following probability table.

	Probability levels		
No. of means apart	0.05	0.01	0.001
2	0.1632	0.2303	0.3291
3	0.1707	0.2401	0.3417
4	0.1753	0.2463	0.3501

Comparing the "t" values with the probability table values we get the following:

Comparison	Probability
100 ppm vs. 0 ppm	p>0.05
200 ppm vs. 0 ppm	p>0.05
400 ppm vs. 0 ppm	0.01>p>0.001
400 ppm vs. 100 ppm	0.05>p>0.01

ASSUMPTIONS AND LIMITATIONS

1. Duncan's assures a set alpha level or type I error rate for all tests when means are separated by no more than ordered step increases. Preserving this alpha level means that the test is less sensitive than some others, such as the Student-Newman-Keuls. The test is inherently conservative and not resistant or robust.

Scheffe's Multiple Comparisons

Scheffe's is another post hoc comparison method for groups of continuous and randomly distributed data. It also normally involved three or more groups (79, 131). It is widely considered a more powerful significance test than Duncan's.

Each post hoc comparison is tested by comparing an obtained test value (Fcontr) with the appropriate critical F value at the selected level of significance (the table F value multiplied by K–1 for an F with K–1 and N-K degrees of freedom2). Fcontr is computed as follows:

(a) Compute the mean for each sample (group);

(b) Denote the residual mean square by MSwg;

(c) Compute the test statistic as

$$F_{contr} = \frac{C_1\bar{X}_1 + C_2\bar{X}_2 + \ldots + C_k\bar{X}_k^2)}{(K-1)MS_{wg}(C_1^2/n_1 + \ldots + C_K^2/n_k},$$

where Ck is the comparison number such that the sum C1, C2…Ck=0 (see Example 22) and

2Where K=the number of groups and N=the total number of data.

Example 22

At the end of a short-term feeding study, the following body weight changes were recorded:

	Group 1	Group 2	Group 3	
		10.2	12.2	9.2
		8.2	10.6	10.5
		8.9	9.9	9.2
		8.0	13.0	8.7
		8.3	8.1	9.0
		8.0	10.8	
			11.5	
Totals	51.6	76.1	46.6	
Means	8.60	10.87	9.32	

$MS_{wg}=1.395$

To avoid logical inconsistencies with pairwise comparisons, we compare the group having the largest sample mean (group 2) with that having the smallest sample mean (group 1), then with the group having the next smallest sample mean, and so on. As soon as we find a nonsignificant comparison in this process (or no group with a smaller sample mean remains), we replace the group having the largest sample mean with that having the second largest sample mean and repeat the comparison process. Accordingly, our first comparison is between groups 2 and 1. We set $C_1=-1$, $C_2=1$, and $C_3=0$ and calculate our test statistic

$$F_{contr} = \frac{(10.87 - 8.60)^2}{(3-1)1.395(1/6+1/7)} = 5.97.$$

The critical region for F at $p \le 0.05$ for 2 and 11 degrees of freedom is 3.98. Therefore, these groups are significantly different at this level. We next compare groups

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_323.html[2010/10/28 18:43:03]

2 and 3, using C1=0, C2=1, and C3=−1:

$$F_{contr} = \frac{(10.87 - 9.32)^2}{(3-1)1.395(1/7+1/5)} = 2.51.$$

This is less than the critical region value, so these groups are not significantly different.

ASSUMPTIONS AND LIMITATIONS

1. The Scheffe procedure is robust to moderate violations of the normality and homogeneity of variance assumptions.
2. It is not formulated on the basis of groups with equal numbers (as one of Duncan's procedures is), and if N1≠N2, there is no separate weighing procedure.
3. It tests all linear contrasts among the population means (the other three methods confine themselves to pairwise comparison, except they use a Bonferroni type correlation procedure).
4. The Scheffe procedure is powerful because of its robustness, yet it is very conservative. Type I error (the false-positive rate) is held constant at the selected test level for each comparison.

Dunnett's t-Test

Dunnett's t-test (45, 46) has as its starting point the assumption that what is desired is a comparison of each of several means with one other mean and only one other mean; in other words, that one wishes to compare each and every treatment group with the control group, but not compare treatment groups with each other. The problem here is that, in toxicology, one is frequently interested in comparing treatment groups with other treatment groups; however, if one does want only to compare treatment groups versus a control group, Dunnett's is a useful approach. In a study with K groups (one of them being the control), we will wish to make K-1 comparisons. In such a situation, we want to have a P level for the entire set of K-1 decisions (not for each individual decision). The Dunnett's distribution is predicated on this assumption. The parameters for using a Dunnett's table, such as found in his original article, are K (as above) and the number of degrees of freedom for mean square with groups (MSwg). The test value is calculated as

$$t = \frac{|T_j - T_i|}{\sqrt{2MS_{wg}/n}}$$

where n is the number of observations in each of the groups. The mean square within group (MSwg) is as we have defined it previously; Tj is the control group mean and Ti is the mean of, in order, each successive test group observation. Note that one uses the absolute value of the positive number resulting from subtracting Ti from Tj. This is to ensure a positive number for our final t.

Example 23 demonstrates this test, again with the data from Example 19.

Example 23

The means, N's, and sums for the groups previously presented in Example 19 are

	Control	100 ppm	200 ppm	400 ppm
Sum (ΣX)	1.38	1.56	1.71	1.93
N	4		44	4
Mean	0.345	0.39	0.4275	0.4825

The MSwg was 0.00275, and our test t for 4 groups and 12 df is 2.41. Substituting in the equation, we calculate our t for the control versus the 400 ppm to be

$$= \frac{|0.345 - 0.4825|}{\sqrt{2(0.00275)/4}}$$

$$= \frac{0.1375}{\sqrt{0.001375}}$$

$$= \frac{0.1375}{0.037081} = 3.708.$$

which exceeds our test value of 2.41, showing that these two groups are significantly different at $p \leq 0.05$. The values for the comparisons of the control versus the 200 and 100 ppm groups are then found to be, respectively, 2.225 and 1.214. Both of these are less than our test value, and therefore the groups are not significantly different.

ASSUMPTIONS AND LIMITATIONS

1. Dunnett's seeks to ensure that the type 1 error rate will be fixed at the desired level by incorporating correction factors into the design of the test value table.
2. Treated group sizes must be approximately equal.

Williams' t-Test

Williams' t-test (164, 165) is also popular, although its use is quite limited in toxicology. It is designed to detect the highest level (in a set of dose/exposure levels) at which there is no significant effect. It assumes that the response of interest (such as change in body weights) occurs at higher levels but not at lower levels and that the responses are monotonically ordered so that $X0 \leq Xi \ldots \leq Xk$. This frequently is not the case, however. The Williams' technique handles the occurrence of such discontinuities in a response series by replacing the offending value and the value immediately preceding it with weighted average values. The test also is adversely affected by any mortality at high dose levels. Such moralities "impose a severe penalty, reducing the power of detecting an effect not only at level K but also at all lower doses" (165, p. 529). Accordingly, it is not generally applicable in toxicology studies.

Page 325

Analysis of Covariance

ANCOVA is a method for comparing sets of data that consist of two variables (treatment and effect, with our effect variable being called the "variate") when a third variable (called the "covariate") exists that can be measured but not controlled and that has a definite affect on the variable of interest. In other words, it provides an indirect type of statistical control, allowing us to increase the precision of a study and to remove a potential source of bias. One common example of this is in the analysis of organ weights in toxicity studies. Our true interest here is the effect of our dose or exposure level on the specific organ weights, but most organ weights also increase (in the young, growing animals most commonly used in such studies) in proportion to increases in animal body weight. As we are not interested in the effect of this covariate (body weight), we measure it to allow for adjustment. We must be careful before using ANCOVA, however, to ensure that the underlying nature of the correspondence between the variate and covariate is such that we can rely on it as a tool for adjustments (3, 97).

Calculation is performed in two steps. The first is a type of linear regression between the variate Y and the covariate X. This regression, performed as described under the linear regression section, gives us the model

$$Y=a1+BX+e,$$

which in turn allows us to define adjusted means ($\bar{Y}$ and $\bar{X}$) such that $\bar{Y}_{1a}=\bar{Y}_1-(\bar{X}_1-X^*)$.

If we consider the case where K treatments are being compared such that K=1,2,...K, and we let Xik and Yik represent the predictor and predicted values for each individual i in group k, we can let Xk and Yk be the means. Then, we define the between-group (for treatment) sum of squares and cross products as

$$T_{xx}=\sum_{k-1}^{K}n_k(\bar{X}_K-\bar{X})^2,$$

$$T_{yy}=\sum_{k-1}^{K}n_k(\bar{Y}_K-\bar{Y})^2,$$

$$Txy=\sum_{k-1}^{K}n_k(\bar{X}_k-\bar{X})(\bar{Y}_k-\bar{Y}_k-\bar{Y}).$$

In a like manner, within-group sums of squares and cross products are calculated as

$$\sum xx=\sum_{k=1}^{k}\sum_{i}(X_{ik}-X_k)^2,$$

$$\sum yy=\sum_{k=1}^{k}\sum_{i}(Y_{ik}-Y_k)^2,$$

$$\sum xy=\sum_{k=1}^{k}\sum_{i}(X_{ik}-X_k)(Y_{ik}-Y_k),$$

where i indicates the sum from all the individuals within each group; f′=total number of subjects minus the number of groups

$$Sxx=Txx+\Sigma xx,$$
$$Syy=Tyy+\Sigma xx,$$
$$Sxy=Txy+\Sigma xy.$$

With these in hand, we can then calculate the residual mean squares of treatments (St2) and error (Se2):

$$St^2 = \frac{T_{yy} - \frac{S_{xy}^2}{S_{xx}} + \frac{\sum_{xy}^2}{\sum_{xx}}}{k-1},$$

$$Se^2 = \frac{\left(\sum_{yy} - \frac{\sum_{y}^{2}}{\sum_{xx}}\right)}{f-1.}$$

These can be used to calculate an F statistic to test the null hypothesis that all treatment effects are equal:

$$\mathrm{F} = \frac{\mathrm{St}^2}{\mathrm{Se}^2}.$$

The estimated regression coefficient of Y or X is

$$B = \frac{\sum_{xy}}{\sum_{xx}}.$$

The estimated standard error for the adjusted difference between two groups is given by

$$Sd = Se\frac{1}{n_i} + \frac{1}{n_j} + \frac{(X_i - X_j)^2}{\sum_{xx}},$$

where ni and nj are the sample sizes of the two groups. A test of the null hypothesis that the adjusted differences between the groups is zero is provided by

$$\mathrm{t} = \frac{\mathrm{Y_i - Y_j - B(X_i - X_j)}}{\mathrm{Sd}}.$$

The test value for the t is then looked up in the t-table with f-1 degrees of freedom. Computation is markedly simplified if all the groups are of equal size, as demonstrated in Example 24.

Example 24

An ionophere was evaluated as a potential blood-pressure-reducing agent. Early studies indicated that there was an adverse effect on blood cholesterol and hemoglobin levels, so a special study was performed

to evaluate this specific effect. The hemoglobin (Hgb) level covariate was measured at study start along with the percentage changes in serum triglycerides between study start and at the end of the 13-week study. Was there a difference in effects of the two ionopheres?

Ionophere A		Ionophere B	
Hgb (X)	Serum Triglyceride, %—Change (Y)	Hgb (X)	Serum Triglyceride, %—Change (Y)
7.0	5	5.1	10
6.0	10	6.0	15
7.1	−5	7.2	−15
8.6	−20	6.4	5
6.3	0	5.5	10
7.5	−15	6.0	−15
6.6	10	5.6	−5
7.4	−10	5.5	−10
5.3	20	6.7	−20
6.5	−15	8.6	−40
6.2	5	6.4	
7.8	0	6.0	−10
8.5	−40	9.3	−40
9.2	−25	8.5	−20
5.0	25	7.9	−35
		5.0	0
		6.5	−10

To apply ANCOVA using Hgb as a covariate, we first obtain some summary results from the data as follows:

	Ionophere A (Group 1)	Ionophere B (Group 2)	Combined
Σx	112.00	119.60	231.60
Σx^2	804.14	821.64	1625.78
Σy	−65.00	−185.00	−250.00
Σy^2	4575.00	6475.00	11050.00
Σxy	−708.50	−1506.50	−2215.00
$\bar{x}$	7.000	6.6444	6.8118
$\bar{y}$	−4.625	−10.2778	−7.3529
n	16	18	34

We compute for the ionophere group (i=1):

$$S_{xx}(1)=804.14-(112)^2/16=20.140,$$
$$S_{yy}(1)=4575.00-(-65)^2/16=4310.938,$$
$$S_{xy}(1)=-708.50-(112)(-65)/16=-253.500.$$

Similarly, for the ionophere B group (i=2), we obtain

$$S_{xx}(2)=26.964,$$
$$S_{yy}(2)=4573.611,$$
$$S_{xy}(2)=-277.278.$$

Finally, for the combined data (ignoring groups), we compute

$$S_{xx}=48.175,$$
$$S_{yy}=9211.765,$$
$$S_{xy}=-512.059.$$

The sums-of-squares can now be obtained as

$$TOT(SS) = 9211.8,$$

$$SSE = (20.140 + 26.964)(4310.938 + 4573.611) \frac{-[-253.500 - 277.28]^2}{(20.140 + 26.964)} = 2903.6,$$

$$SSG = \frac{(48.175)(9211.765) - (-512.059)^2}{48.175} - 2903.6 = 865.4,$$

$$SSX = (4310.938 + 473.611) - 2903.6 = 5980.9,$$

and the ANCOVA summary table can be completed as follows:

SOURCE	*df*	*SS*	*MS*	*F*
TREATMENT	1	865.4	865.4	9.2*
X (Hgb)	1	5980.9	5980.9	63.8
Error	31	2903.7	93.7	
Total	33	9211.8		

*Significant ($p<0.05$); critical F-value=4.16.

The F-statistics are formed as the ratios of effect mean-squares (MS) to the MSE (93.7). Each F-statistic is compared with the critical F value with 1 upper and 31 lower degrees of freedom. The critical F-value for $\alpha=0.05$ is 4.16.

The significant covariate effect (F=63.8) indicates that the triglyceride response has a significant linear relationship with HbAlc. The significant F-value for TREATMENT indicates that the mean triglyceride response adjusted for hemoglobin effect differs between treatment groups.

ASSUMPTIONS AND LIMITATIONS

1. The underlying assumptions for ANCOVA are fairly rigid and restrictive. The assumptions include the following:

a. The slopes of the regression lines of a Y and X are equal from group to group. This can be examined visually or formally (i.e., by a test). If this condition is not met, ANCOVA cannot be used.
b. The relationship between X and y is linear.
c. The covariate X is measured without error. Power of the test declines as error increases.
d. There are no unmeasured confounding variables.
e. The errors inherent in each variable are independent of each other. Lack of independence effectively (but to an immeasurable degree) reduces sample size.
f. The variances of the errors in groups are equivalent between groups.
g. The measured data which form the groups are normally distributed. ANCOVA is generally robust to departures from normality.
2. Of the seven assumptions above, the least robust are the first four.

Modeling

The mathematical modeling of biological systems, restricted even to the field of toxicology, is an extremely large and vigorously growing area. Broadly speaking, modeling is the principal conceptual tool by which toxicology seeks to develop as a mechanistic science. In an iterative process, models are developed or proposed, tested by experiment, reformulated, and so on in a continuous cycle. Such a cycle could also be described as two related types of modeling—explanatory (where the concept is formed) and correlative (where data are organized and relationships derived). An excellent introduction to the broader field of modeling of biological systems can be found in Gold (72).

In toxicology, modeling is of prime interest in seeking to relate a treatment variable with an effect variable and, from the resulting model, predict effects at exact points where no experiment has been done (but in the range where we have performed experiments, such as "determining" LD50s) to estimate how good our prediction is, and occasionally, simply to determine if a pattern of effects is related to a pattern of treatment.

For use in prediction, the techniques of linear regression, probit/logit analysis (a special case of linear regression), moving averages (an efficient approximation method), and nonlinear regression (for doses where data cannot be made to fit a linear pattern) are presented. For evaluating the predictive value of these models, both the correlation coefficient (for parametric data) and Kendall's rank correlation (for nonparametric data) are given. Finally, the concept of trend analysis is introduced and a method presented.

When we are trying to establish a pattern between several data points (whether this pattern is in the form of a line or a curve), what we are doing is interpolating. It is possible for any given set of points to produce an infinite set of lines or curves that pass near (for lines) or through (for curves) the data points. In most cases we cannot actually know the "real" pattern, so we apply a basic principle of science—Occam's razor. We use the simplest explanation (or, in this case, model) that fits the facts (or data). A line is, of course, the simplest pattern to deal with and describe, so fitting the best line (linear regression) is the most common form of model in toxicology.

Linear Regression

Foremost among the methods for interpolating within a known data relationship is regression—the fitting of a line or curve to a set of known data points on a graph and the interpolation ("estimation") of this line or curve in areas where we have no data points. The simplest of these regression models is that of linear regression (valid when increasing the value of one variable changes the value of the related variable in a linear fashion, either positively or negatively). This is the case we will explore here, using the method of least squares.

Given that we have two sets of variables, x (say, mg/kg of test material administered) and y (say, percentage of animals so dosed that die), what is required is solving for a and b in the equation $Y_i=a+bx_i$ (where the uppercase Y_i is the fitted value of y_i at x_i, and we wish to minimize $(y_i-Y_i)^2$). So we solve the equations

$$b=\frac{\sum x_1y_1-nx\bar{y}}{\sum x_1^2-n\bar{x}^2}$$

and

$$a=\bar{y}-b\bar{x},$$

where a is the y intercept, b is the slope of the time, and n is the number of data points. Use of this is demonstrated in Example 25.

Note that in actuality, dose-response relationships often are not linear and instead we must use either a

transform (to linearize the data) or a nonlinear regression method (65).
Note also that we can use the correlation test statistic (to be described in the correlation coefficient section) to determine if the regression is significant (and, therefore, valid) at a defined level of certainty. A more specific test for significance would be the linear regression analysis of variance (119). We start by developing the appropriate ANOVA table, as demonstrated in Example 25, then proceed to perform the linear regression portion of the ANOVA, as shown in Example 26.

Example 25

From a short-term toxicity study we have the following results:

Dose Administered (mg/kg)		% Animals dead	
xi,	x_i^2	yi	xiyi
1	1	10	10
3	9	20	60
4	16	18	72
5	25	20	100
Sums x1=13	$x_i^2 = 51$	yi=68	xiyi−242

$$\bar{x} = 3.25, \quad \bar{y} = 17,$$

$$b = \frac{242 - (4)(3.25)(17)}{51 - (4)(10.5625)} = \frac{21}{8.75} = 2.40,$$

$$a = 17 - (2.4)(3.25) = 9.20.$$

We therefore see that our fitted line is Y=9.2+2.4X.
These ANOVA table data are then used as shown in Example 26.

Linear regression analysis of variance

Source of variation (1)	Sum of squares (2)	Degrees of freedom (3)	Mean square (4) equal to $\frac{2}{3}$)
Regression	$b_1^2(\sum x_1^2 - n\bar{x}^2)$	1	By division
Residual	By difference	n−2	By division
Total	$\sum y_1^2 - n\bar{y}^2$	n−1	

We then calculate

$$F_{1,n-2} = \frac{\text{regression mean square}}{\text{residual mean square}}.$$

Example 26
We desire to test the significance of the regression line in Example 25:

$$\sum y_i^2 = 10^2 + 20^2 + 18^2 + 20^2,$$

Regression $SS=(2.4)^2[51-4(3.25)^2]=50.4$,
Total $SS=1224-4(17^2)=68.0$,
Residual $SS=68.0-50.4=17.6$,
$F_{1,2}=50.4/8.8=5.73$.

This value is not significant at the 0.05 level; therefore, the regression is not significant. A significant F value (as found in an F distribution table for the appropriate degrees of freedom) indicates that the regression line is an accurate prediction of observed values at that confidence level. Note that the portion of the total sum of squares explained by the regression is called the coefficient of correlation, which in the above example is equal to 0.862 (or 0.74). Calculation of the correlation coefficient is described later in this chapter.

Finally, we might wish to determine the confidence intervals for our regression line (i.e., given a regression line with calculated values for Yi given xi, within what limits may we be certain [with say a 95% probability] what the real value of Yi is)?

If we denote the residual mean square in the ANOVA by s^2, the 95% confidence limits for *a* (denoted by A, the notation for the true—as opposed to the estimated—value for this parameter) are calculated as

$$t_{n-2} = \frac{a - A}{\sqrt{\frac{s^2(\sum x^2)}{n\sum x_1^2 - n^2\bar{x}^2}}},$$

$$\frac{9.2 - \mathrm{A}}{\sqrt{\frac{8.8(51)}{4(51) - (16)(10.562)}}} = \frac{9.2 - \mathrm{A}}{\sqrt{\frac{448}{35.008}}}$$

$$= \frac{9.2 - \mathrm{A}}{3.58} = \pm 4.303,$$

$$9.2 - \mathrm{A} = \pm 15.405,$$

$$A = 9.2 \pm 15.405.$$

ASSUMPTIONS AND LIMITATIONS

1. All the regression methods are for interpolation, not extrapolation. That is, they are valid only in the range that we have data—the experimental region—not beyond.
2. The method assumes that the data are independent and normally distributed and it is sensitive to outliers. The x-axis (or horizontal) component plays an extremely important part in developing the least square fit. All points have equal weight in determining the height of a regression line, but extreme x-axis values unduly influence the slope of the line.
3. A good fit between a line and a set of data (i.e., a strong correlation between treatment and response variables) does not imply any casual relationship.
4. It is assumed that the treatment variable can be measured without error, that each data point is independent, that variances are equivalent, and that a linear relationship does not exist between the variables.
5. There are many excellent texts on regression, which is a powerful technique, including (53, 54), which are not overly rigorous mathematically.

Probit/Log Transforms and Regression

As we noted in the preceding section, dose-response problems (among the most common interpolation prob-

lems encountered in toxicology) rarely are straightforward enough to make a valid linear regression directly from the raw data. The most common valid interpolation methods are based on probability ("probit") and logarithmic ("log") value scales, with percentage responses (death, tumor incidence, etc.) being expressed on the probit scale whereas doses (Yi) are expressed on the log scale. There are two strategies for such an approach. The first is based on transforming the data to these scales, then doing a weighted linear regression on the transformed data (if one does not have access to a computer or a high-powered programmable calculator, the only practical strategy is not to assign weights). The second requires the use of algorithms (approximate calculation techniques) for the probit value and regression process and is extremely burdensome to perform manually.

Our approach to the first strategy requires that we construct a table with the pairs of values of xi and yj listed in order of increasing values of Yi (percentage response). Beside each of these columns a set of blank columns should be left so that the transformed values may be listed. We then simply add the columns described in the linear regression procedure. Log and probit values may be taken from any of a number of sets of tables and the rest of the table is then developed from these transformed x_i' and y_i' values (denoted as x_i' and y_i' A standard linear regression is then performed (see Example 27).

The second strategy we discussed has been broached by a number of authors (16, 32, 103, 12). All of these methods, however, are computationally cumbersome. It is possible to approximate the necessary iterative process using the algorithms developed by Abramowitz and Stegun (1), but even this merely reduces the complexity to a point where the procedure may be readily programmed on a small computer or programmable calculator.

Example 27

Percentage of animals killed xi	Probit of xi =xi	Dose of chemical (mg/kg) yi	Log of yi= y_i'	$(x_i')^2$	$x_i'y_i'$
2	2.9463	3	0.4771	8.6806	1.40568
10	3.7184	5	0.6990	13.8264	2.59916
42	4.7981	10	1.0000	23.0217	4.79810
90	6.2816	20	1.3010	39.4585	8.17223
98	7.2537	30	1.4771	52.6162	10.4190
	Σxi=24.9981			$\sum x_i'^2 = 137.6034$	$\sum x_i'y_i' = 27.68974$

Our interpolated log of the LD50 (calculated by using Y=−0.200591−0.240226 x, where x equals 5.000—the probit of 50%—in the regression equation) is 1.000539. When we convert this log value to its linear equivalent, we get an LD50 of 10.0 mg/kg.

Finally, our calculated correlation coefficient is r=0.997. A goodness-of-fit of the data using chi-square may also be calculated.

ASSUMPTIONS AND LIMITATIONS

1. The probit distribution is derived from a common error function, with the midpoint (50% point) moved to a score of 5.00.
2. The underlying frequency distribution becomes asymptotic as it approaches the extremes of the range. That is, in the range of 16%−84%, the corresponding probit values change gradually—the curve is relatively linear, but beyond this range they change ever more rapidly as they approach either 0% or 100%. In fact, there are no values for either of these numbers.
3. A normally distributed population is assumed, and the results are sensitive to outliers.

Moving Averages

An obvious drawback to the interpolation procedures we have examined to date is that they do take a significant amount of time (though they are simple enough to be done manually), especially if the only result we desire is an LD50, LC50, or LT50.

The method of moving averages (144, 161) gives a rapid and reasonable accurate estimate of this "median-effective-dose" (m) and the estimated SD of its logarithm.

Such methodology requires that the same number of animals be used per dosage level and that the spacing between successive dosage exposure levels be geometrically constant (i.e., levels of 1, 2, 4, and 8 mg/kg or 1, 3, 9, and 27 ppm). Given this and access to a table for the computation of moving averages, one can readily calculate the median effective dose with the formula (illustrated for dose):

log m=log D+d(K−1)/2+df, where m=median effective dose or exposure.

D=the lowest dose tested.

$\sum y_i' = 4.9542$

d=the log of the ratio of successivedoses/ exposures.

f=a table value taken from Gad (62) for the proper K (the total number of levels tested minus 1).

Example 28 demonstrates the use of this method.

Example 28

As part of an inhalation study, we exposed groups of 5 rats each to levels of 20,40, 80 and 160 ppm of a chemical vapor. These exposures killed 0, 1, 3, and 5 animals, respectively. From the N=5, K=3 tables on the r value 0, 1, 3, 5 line, we get an f of 0.7 and an σ_f^4 of 0.31623. We can then calculate the LC50 to be

LogLC50=1.30130+0.30103(2)/2+0.30103(0.7)
=1.30103+0.51175
=1.81278,
∴ LC50=65.0 ppm with 95% confidence intervals of
± 2.179 $d\sigma f$ or ±2.179(0.30103)(0.31623)
=±0.20743.

Therefore, the log confidence limits are 1.81278
± 0.20743=1.60535 to 2.02021; on the linear scale
=40.3 to 104.8 ppm

ASSUMPTIONS AND LIMITATIONS

1. A common misconception is that the moving average method cannot be used to determine the slope of the response curve. This is not true. Weil has published a straightforward method for determining slope in conjunction with a moving average determination of the LD50 (161).
2. The method also provides confidence intervals.

Nonlinear Regression

More often than not in toxicology we find that our data demonstrate a relationship between two variables (such as age and body weight) that are not linear. That is, a change in one variable (say age) does not produce a directly proportional change in the other (e.g., body weight), but some form of relationship between the variables is apparent. If understanding such a relationship and being able to predict unknown points is of value, we have a pair of options available to us. The first, which was discussed and reviewed earlier, is to use one or more transformations to linearize our data and then to make use of linear regression. This approach, though most commonly used, has a number of drawbacks. Not all data can be suitably transformed; sometimes the transformations necessary to linearize the data require a cumbersome series of calculations, and the resulting linear regression is not always sufficient to account for the differences among sample values—there are significant deviations around the linear regression line (i.e., a line may still not give us a good fit to the data or do an adequate job of representing the relationship between the data). In such cases we have available a second option—the fitting of data to some nonlinear function such as some form of the curve. This is, in general form, nonlinear regression and may involve fitting data to an infinite number of possible functions, but most often we are interested in fitting curves to a polynomial function of the general form

Y=a+bx+cx2+dx2+...,

where x is the independent variable. As the number of powers of x increases, the curve becomes increasingly complex and will be able to fit a given set of data increasingly well. Generally in toxicology, however, if we plot the log of a response (such as body weight) versus a linear scale of our dose or stimulus, we get one of four types of nonlinear curves. These are (137)

(1) Exponential growth, where
log Y=A(Bx), such as the growth curve for the log phase of a bacterial culture.
(2) Exponential decay, where
log Y=A(B−x), such as a radioactive decay curve.
(3) Asymptotic regression, where
log Y=A−B(px), such as a first-order reaction curve.
(4) Logistic growth curve, where
log Y=A/(1+Bpx), such as a population growth curve.

In all these cases, A and B are constant whereas p is a log transform. These curves are illustrated in Figure 7.7.

All four types of curves are fit by iterative processes (i.e., best guess numbers are initially chosen for each of the constants and, after a fit is attempted, the constants are modified to improve the fit). This process is repeated until an acceptable fit has been generated. Analysis of variance or covariance can be

used to objectively evaluate the acceptability of it. Needless to say, the use of a computer generally accelerates such a curve-fitting process.

ASSUMPTIONS AND LIMITATIONS

1. The principle of using least squares may still be applicable in fitting the best curve if the assumptions of normality, independence, and reasonably error-free measurement of response are valid.
2. Growth curves are best modeled using a nonlinear method.

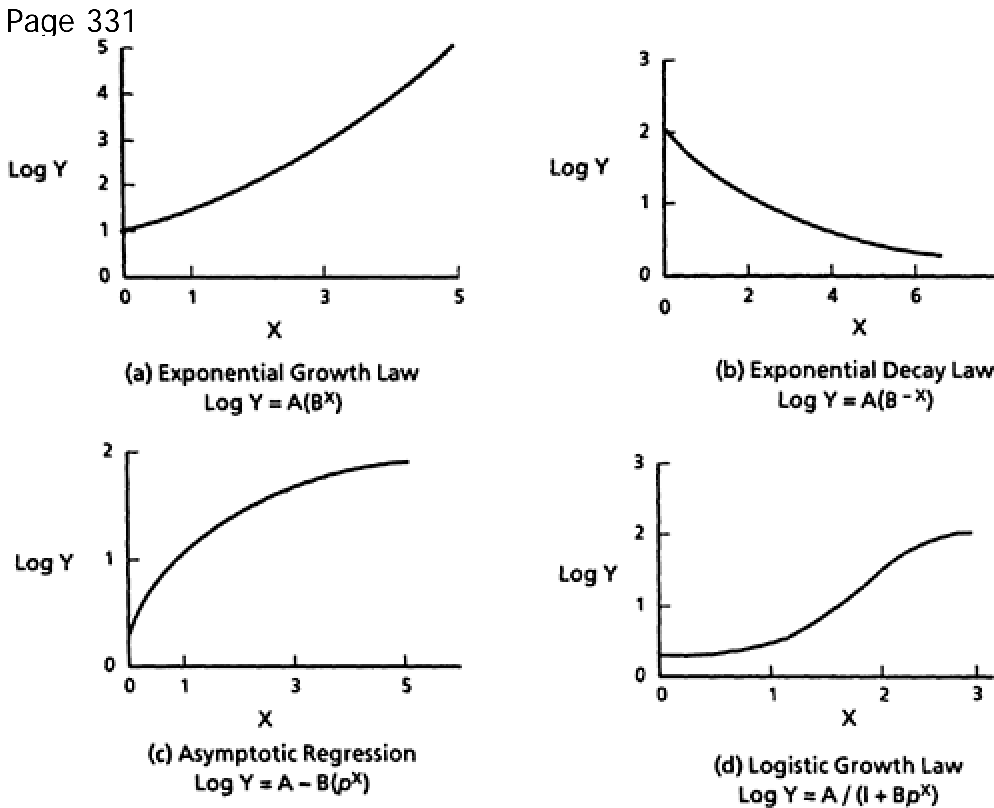

FIG. 7.7. Common curvilinear curves.

Correlation Coefficient

The correlation procedure is used to determine the degree of linear correlation (direct relationship) between two groups of continuous (and normally distributed) variables. It will indicate whether there is any statistical relationship between the variables in the two groups. For example, we may wish to determine if the liver weights of dogs on a feeding study are correlated with their body weights. Thus, we will record the body and liver weights at the time of sacrifice and then calculate the correlation coefficient between these pairs of values to determine if there is some relationship.

A formula for calculating the linear correlation coefficient (rxy) is as follows:

$$r_{xy} = \frac{N\sum XY - (\sum X)(\sum Y)}{\sqrt{N\sum X^2 - (\sum X)^2}\sqrt{N\sum Y^2 - (\sum Y)^2}},$$

where X is each value for one variable (such as the dog body weights in the above example), Y is the matching value for the second variable (the liver weights), and N is the number of pairs of X and Y. Once we have obtained rxy, it is possible to calculate tr, which can be used for more precise examination of the degree of significant linear relationship between the two groups. This value is calculated as follows:

$$t_r = \frac{r_{zy}\sqrt{N-2}}{\sqrt{1 - r_{zy}^2}}.$$

This calculation is also equivalent to r=sample covariance/(SxSy), as was seen earlier under ANCOVA. The value obtained for rxy can be compared to table values (137) for the number of pairs of data involved minus two. If the rxy is smaller (at the selected test probability level, such as 0.05), the correlation is not significantly different from zero (no correlation). If rxy is larger than the table value, there is a positive statistical relationship between the groups. Comparisons are then made at lower levels of probability to determine the degree of relationship (note that if rxy=either 1.0 or −1.0, there is complete correlation between the groups). If rxy is a negative number and the absolute is greater than the table value, there is an inverse relationship between the groups (i.e., a change in one group is associated with a change in the opposite direction in the second group of variables). Both computations are demonstrated in Example 29.

Because the comparison of rxy with the table values may be considered a somewhat weak test, it is perhaps more meaningful to compare the tr value with values in a t-distribution table for N-2 degrees of freedom (df), as is done for the Student's t-test. This will give a more exact determination of the degree of statistical correlation between the two groups.

Note that this method examines only possible linear relationships between sets of continuous, normally distributed data.

Example 29

If we computed the dog body weight versus dog liver weight for a study, we could have the following results:

	Body weight (kgj)		Liver weight (g)		
Dog#	X	X2	Y	Y2	XY
1	8.4	70.56	243	59049	2041.2
2	8.5	72.25	225	50625	1912.5
3	9.3	86.49	241	58081	2241.3
4	9.5	90.25	263	69169	2498.5
5	10.5	110.25	256	65536	2688.0
6	8.6	73.96	266	70756	2287.6
Sums	ΣX=54.8	ΣX2=503.76	ΣY=1494	ΣY2=373216	ΣXY=13669.1

$$r_{xy} = \frac{6(13669.1) - (54.8)(1494)}{\left(\sqrt{6(503.76) - (54.8)^2}\right)\left(\sqrt{6(373216) - (1494)^2}\right)}$$

$$= 0.381.$$

The table value for six pairs of data (read beside the N-2 value, or 6–2=4) is 0.811 at a 0.05 probability level. Thus, there is a lack of statistical correlation (at p=0.05) between the body weights and liver weights for this group of dogs.

The tr value for these data would be calculated as follows:

$$t_r = \frac{0.381\sqrt{6-2}}{\sqrt{1-(0.381)^2}} = 0.824.$$

The value for the t-distribution table for four df at the 0.05 level is 2.776; therefore, this again suggests a lack of significant correlation at p=0.05.

ASSUMPTIONS AND LIMITATIONS

1. A strong correlation does not imply that a treatment causes an effect.
2. The distances of data points from the regression line are the portions of the data not "explained" by the model. These are called residuals. Poor correlation coefficients imply high residuals, which may be due to many small contributions (variations of data from the regression line) or a few large ones. Extreme values (outliers) greatly reduce correlation.
3. X and Y are assumed to be independent.
4. Feinstein (55) has provided a fine discussion of the difference between correlation (or association of variables) and causation.

Kendall's Coefficient of Rank Correlation

Kendall's rank correlation, represented by τ(tau), should be used to evaluate the degree of association between two sets of data when the nature of the data is such that the relationship may not be linear. Most commonly, this is when the data are not continuous and/or normally distributed. An example of such a case is when we are trying to determine if there is a relationship between the length of hydra and their survival time in a test medium in hours, as is presented in Example 30. Both of our variables here are discontinuous, yet we suspect a relationship exists. Another common use is in comparing the subjective scoring done by two different observers.

Tau is calculated at τ=N/n(n−1), where n is the sample size and N is the count of ranks, calculated as N=4(nCi)−n(n−l), with the computing of nCi being demonstrated in the example.

If a second variable Y2 is exactly correlated with the first variable Y1, then the variates Y2 should be in the same order as the Y1 variates; however, if the correlation is less than exact, the order of the variates Y2 will not correspond entirely to that of Y. The quantity N measures how well the second variable corresponds to the order of the first. It has maximum value of n(n−1) and a minimum value of

$-n(n-1)$.

Page 333

A table of data is set up with each of the two variables being ranked separately. Tied ranks are assigned as demonstrated earlier under the Kruskal-Wallis test. From this point, disregard the original variates and deal only with the ranks. Place the ranks of one of the two variables in rank order (from lowest to highest), paired with the rank values assigned for the other variable. If one (but not the other) variable has tied ranks, order the pairs by the variables without ties (138).

The most common way to compute a sum of the counts is also demonstrated in Example 30. The resulting value of tau will range from −1 to+1, as does the familiar parametric correlation coefficient, *r*.

Example 30

During the validation of an in vitro method, it was noticed that larger hydra seem to survive longer in test media than do small individuals. To evaluate this, 15 hydra of random size were measured (mm) and then placed in test media. How many hours each individual survived was recorded over a 24-hour period. These data are presented below, along with ranks for each variable:

Length	Rank(R1)	Survival	Rank(R2)
3	6.5	19	9
4	10	17	7
6	15	11	1
1	1.5	25	15
3	6.5	18	8
3	6.5	22	12
1	1.5	24	14
4	10	16	6
4	10	15	5
2	3.5	21	11
5	13	13	3
5	13	14	4
3	6.5	20	10
2	3.5	23	13
5	13	12	2

We then arrange this based on the order of the rank of survival time (there are no ties here). We then calculate our counts of ranks. The conventional method is to obtain a sum of the counts, Ci, as follows: examine the first value in the column of ranks paired with the ordered column. In the following case this is rank 15. Count all ranks subsequent to it that ranks greater than 15. There are 14 ranks following the 2 and all of them are less than 15. Therefore, we count a score of C1=0. We repeat this process for each subsequent rank of R1, giving us a final score of 1 (by this point it is obvious that our original hypothesis—that larger hydrae live longer in test media than do small individual—was in error).

R2	R1	Following (R2) ranks greater than (R1)	Counts (Ci)
1	15	—	C1=0
2	13	—	C2=0
3	13	—	C3=0
4	13	—	C4=0
5	10	—	C5=0
6	6.5	10	C6=0
7	10	—	C7=0
8	6.5	—	C8=0
9	6.5	—	C9=0
10	6.5	—	C10=0
11	3.5	6.5	C11=0
12	6.5	—	C12=0
13	3.5	—	C13=0
14	1.5	—	C14=0
15	1.5	—	C15=0
			Ci=1

Our count of ranks, N, is then calculated as

$$N=4(1)-15(15-1)$$
$$=4-15(14)$$
$$=-206.$$

We can then calculate tau as

$$= \frac{-206}{15(15-1)}$$

$$= \frac{-206}{210}$$

$$= -0.9810.$$

In other words, there is a strong negative correlation between our variables.

ASSUMPTIONS AND LIMITATIONS

1. A very robust estimator that does not assume normality, linearity, or minimal error of measurement.

Trend Analysis

Trend analysis is a collection of techniques that have been "discovered" by toxicology since the mid-1970s (141). The actual methodology dates back to the mid-1950s (29).

Trend analysis methods are a variation on the theme of regression testing. In the broadcast sense, the methods are used to determine whether a sequence of observations taken over an ordered range of a variable (most commonly time) exhibit some form of pattern of change (either an increase-upward trend) associated with another

variable of interest (in toxicology, some form or measure of dosage or exposure).
Trend corresponds to sustained and systematic variations over a long period of time. It is associated with the structural causes of the phenomenon in question (e.g., population growth, technological progress, new ways of organization, or capital accumulation).
The identification of trend has always posed a serious statistical problem. The problem is not one of mathematical or analytical complexity but of conceptual complexity. This problem exists because the trend, as well as the remaining components of a time series, are latent (nonobservable) variables, and therefore, assumptions must be made on their behavioral pattern. The trend is generally thought of as a smooth and slow movement over a long term. The concept of "long" in this connection is relative, and what is identified as trend for a given series span might well be part of a long cycle once the series is considerably augmented. Often, a portion of a long cycle is treated as a trend because the length of the observed time series is shorter than one complete cycle.
The ways in which data are collected in toxicology studies frequently serve to complicate trend analysis, as the length of time for the phenomena underlying a trend to express themselves is frequently artificially censored. To avoid the complexity of the problem posed by a statistically vague definition, statisticians have resorted to two simple solutions. One consists of estimating trend and cyclical fluctuations together, calling this combined movement *trend-cycle;* the other consists of defining the trend in terms of the series length, denoting it as the longest nonperiodic movement.

Trend Models

Within the large class of models identified for trend, we can distinguish two main categories: deterministic trends and stochastic trends. Deterministic trend models are based on the assumption that the trend of a time series can be approximated closely by simple mathematical functions of time over the entire span of the series. The most common representation of a deterministic trend is by means of polynomials or of transcendental functions. The time series from which the trend is to be identified is assumed to be generated by a nonstationary process where the nonstationarity results from a deterministic trend. A classical model is the regression or error model (4), where the observed series is treated as the sum of a systematic part or trend and a random part or irregular part. This model can be written as

$$Z_t = Y_t + U_t',$$

where U_1 is a purely random process; that is, U_t ~i.i.d. $(0, \sigma_u^2)$ (independent and identically distributed with expected value 0 and variance σ_u^2).
Trend tests generally are described as "k-sample tests of the null hypothesis of identical distribution against an alternative of linear order"; i.e., if sample I has distribution function F1, i= 1, then the null hypothesis

$$H-:F1=F2-\ldots=Fk$$

is tested against the alternative

$$H1:F1>F2>\ldots=Fk$$

(or its reverse); there, at least one of the inequalities is strict. These tests can be thought of as special cases of tests of regression or correlation in which association is sought between the observations and its ordered sample index. They are also related to analysis of variance except that the tests are tailored to be powerful against the subset of alternatives H1, instead of the more general set $\{F1 \neq Fj, \text{some } i \neq j\}$.
Different tests arise from requiring power against specific elements or subsets of this rather extensive set of alternatives. The most popular trend test in toxicology is currently that presented by Tarone (141) in 1975 because it is that used by the National Cancer Institute in the analysis of carcinogenicity data. The Armitage and Doll method also is recommended by UIS and Canadian regulatory agencies. A simple but efficient alternative is the Cox and Stuart test (29) which is a modification of the sign test. For each point at which we have a measure (such as the incidence of animals observed with tumors), we form a pair of observations—one from each of the groups we wish to compare. In a traditional National Cancer Institute (NCI) bioassay this would mean pairing control with low dose and low dose with high dose (to explore a dose-related trend) or each time period observation in a dose group (except the first) with its predecessor (to evaluate time-related trend). When the second observation in a pair exceeds the earlier observation, we record a plus sign for that pair. When the first observation is greater than the second, we record a minus sign for that pair. A preponderance of plus signs suggests a downward trend whereas an excess of minus signs suggests an upward trend. A formal test at a preselected confidence

level can then be performed.

More formally put, after having defined what trend we want to test for, we first match pairs as (X_1-X_{1+c}), (X_2, X_{2+C}),...$(X_{n'-c}, X_{n'})$, where $c=n'/2$ when n' is even and $c=(n'+l)/2$ when n' is odd (where n' is the number of observations in a set). The hypothesis is then tested by comparing the resulting number of excess positive or negative signs against a sign test table such as are found in Beyer.

				Sum of signs Y−X	4+ 4− =0 (No trend)		Sum of signs Z-X	6+ 1− =5

Reference to a sign table is not necessary for the low-dose comparison (where there is no trend), but clearly shows the high dose to be significant at the p≤0.5 level.

We can, of course, combine a number of observations to allow ourselves to actively test for a set of trends, such as the existence of a trend of increasing difference between two groups of animals over a period of time. This is demonstrated in Example 31.

Example 31

In a chronic feeding study in rats, we tested the hypothesis that in the second year of the study there as a dose-responsive increase in tumor incidence associated with the test compound. We utilize below a Cox-Stuart test for trend to address this question. All groups start the second year with an equal number of animals.

ASSUMPTIONS AND LIMITATIONS

1. Trend tests seek to evaluate whether there is monotonic tendency in response to a change in treatment. That is, the dose response direction is absolute—as dose goes up, the incidence of tumors increases. Thus, the test loses power rapidly in response to the occurrences of “reversals”—for example, a low-dose group with a decreased tumor incidence. There are methods (47) that “smooth the bumps” of reversals in long data series. In toxicology, however, most data series are short (i.e., there are only a few dose levels).

Tarone’s trend test is most powerful at detecting dose-related trends when tumor onset hazard functions are proportional to each other. For more power against other dose-related group differences, weighted versions of the statistic are also available (19, 32).

In 1985, the United States *Federal Register* (53) recommended that the analysis of tumor incidence data is carried out with a Cochran-Armitage (8, 27) trend test.

The test statistic of the Cochran-Armitage test is defined as this term:

$$T_{CA} = \sqrt{\frac{N}{((N-r))r} \cdot \frac{\sum_{i=0}^{k}\left(R_1 - \frac{n_1}{N}r\right)d_1}{\sqrt{\sum_{i=0}^{k}\frac{n_i}{N}d_i^2 - \left(\sum_{i=0}^{k}\frac{n_i}{N}d_1\right)^2}}}$$

with dose scores *di.* Armitage’s test statistic is the square of this term (T^2_{CA}). As one-sided tests are carried out for an increase of tumor rates, the square is not considered. Instead, the above-mentioned test statistic, which is presented by Portier and Hoel (120), is used. This test statistic is asymptotically standard normal distributed. The Cochran-Armitage test is asymptotically efficient for all monotone alternatives (141) but this result only

holds asymptotically. Tumors are rare events, so the binominal proportions are small. In this situation approximations may become unreliable. Therefore, exact tests can be performed using two different approaches: conditional and unconditional are considered. In the first case, the total number of tumors *r* is regarded as fixed. As a result, the null distribution of the test statistic is independent of the common probability *p*. The exact conditional null distribution is a multivariate hypergeometric distribution.
The unconditional model treats the sum of all tumors as a random variable. Then the exact unconditional null distribution is a multivariate binomial distribution. The distribution depends on the unknown probability.

METHODS FOR THE REDUCTION OF DIMENSIONALITY

Techniques for the reduction of dimensionality are those that simplify the understanding of data, either visually or numerically, while causing only minimal reductions in the amount of information present. These techniques operate primarily by pooling or combining groups of variables into single variables, but may also entail the identification and elimination of low-information-content (or irrelevant) variables.
Descriptive statistics (calculations of means, SDs, etc.) are the simplest and most familiar form of reduction of dimensionality. Here we first need to address classification, which provides the general conceptual tools for identifying and quantifying similarities and differences between groups of things that have more than a single linear scale of measurement in common (e.g., which have both been determined to have or lack a number of enzyme activities). Then we will consider two collections of methodologies that combine graphic and computational methods, multidimensional/nonmetric scaling, and cluster analysis. Multidimensional scaling (MDS) is a set of techniques for quantitatively analyzing similarities, dissimilarities, and distances between data in a display-like manner. Nonmetric scaling is an analogous set of methods for displaying and relating data when measurements are nonquantitative (the data are described by attributes or ranks). Cluster analysis is a collection of graphic and numerical methodologies for classifying things based on the relationships between the values of the variables that they share.
The final pair of methods for reduction of dimensionality that will be tackled in this chapter are Fourier analysis and the life table analysis. Fourier analysis seeks to identify cyclic patterns in data and then either analyze the patterns or the residuals after the patterns are taken out. Life table analysis techniques are directed to identifying and quantitating the time course of risks (such as death or the occurrence of tumors).

Classification

Classification is both a basic concept and a collection of techniques that are necessary prerequisites for further analysis of data when the members of a set of data are (or can be) each described by several variables. At least some degree of classification (which is broadly defined as the dividing of the members of a group into smaller groups in accordance with a set of decision rules) is necessary prior to any data collection. Whether formally or informally, an investigator has to decide which things are similar enough to be counted as the same and develop rules for governing collection procedures. Such rules can be simple as “measure and record body weights only of live animals on study,” or as complex as that demonstrated by the expanded weighting classification presented in Example 32. Such a classification also demonstrates that the selection of which variables to measure will determine the final classification of data.

Example 32

I.	Is animal of desired species?	Yes/No
II.	Is animal member of study group?	Yes/No
III.	Is animal alive?	Yes/No
IV.	Which group does animal belong to?	
	A. Control	
	B. Low dose	
	C. Intermediate dose	
	D. High dose	
V.	What sex is animal?	Male/Female
VI.	Is the measured weight in acceptable range?	Yes/No

Classifications of data have two purposes (73, 81): data simplification (also called a descriptive function) and prediction. Simplification is necessary because there is a limit to both the volume and complexity of data that the human mind can comprehend and deal with conceptually. Classification allows us to attach a label (or name) to each group of data, to summarize the data (i.e., assign individual elements of data to groups and to characterize the population of the group), and to define the relationships between

groups (i.e., develop a taxonomy).

Prediction, meanwhile, is the use of summaries of data and knowledge of the relationships between groups to develop hypotheses as to what will happen when further data are collected (as when more animals or people are exposed to an agent under defined conditions) and as to the mechanisms which cause such relationships to develop. Indeed, classification is the prime device for the discovery of mechanisms in all of science. A classic example of this was Darwin's realization that there were reasons (the mechanisms of evolution) behind the differences and similarities in species that had caused Linaeus

to earlier develop his initial modern classification scheme (or taxonomy) for animals.
To develop a classification, one first sets bounds wide enough to encompass the entire range of data to be considered but not unnecessarily wide. This is typically done by selecting some global variables (variables every piece of data has in common) and limiting the range of each so that it just encompasses all of the cases on hand. Then one selects a set of local variables (characteristics which only some of the cases have, say, the occurrence of certain tumor types, enzyme activity levels, or dietary preferences) which thus serve to differentiate between groups. Data are then collected, and a system for measuring differences and similarities is developed. Such measurements are based on some form of measurement of distance between two cases (x and y) in terms of each single variable scale. If the variable is a continuous one, then the simplest measure of distance between two pieces of data is the Euclidean distance, (d[x, y]), defined as

$$= \frac{0.1375}{0.037081} = 3.708.$$

For categorical or discontinuous data, the simplest distance measure is the matching distance, defined as:

$$d(x, y) = \text{number of times } x_i \neq y_i.$$

After we have developed a table of such distance measurements for each of the local variables, some weighting factor is assigned to each variable. A weighting factor seeks to give greater importance to those variables that are believed to have more relevance or predictive value. The weighted variables are then used to assign each piece of data to a group. The actual act of developing numerically based classifications and assigning data members to them is the realm of cluster analysis and will be discussed later in this chapter. Classification of biological data based on qualitative factors has been well discussed (70, 73) and does an excellent job of introducing the entire field and mathematical concepts.
Relevant examples of the use of classification techniques range from the simple to the complex. Schaper et al. (130) developed and used a very simple classification of response methodology to identify those airborne chemicals which alter the normal respiratory response induced by CO_2. At the other end of the spectrum, Kowalski and Bender (98) developed a more mathematically based system to classify chemical data (a methodology they termed *pattern recognition*).

Statistical Graphics

The use of graphics in one form or another in statistics is the single most effective and robust statistical tool, and at the same time, one of the most poorly understood and improperly used. Graphs are used in statistics (and in toxicology) for one of four major purposes. Each of the four is a variation on the central theme of making complex data easier to understand and use. These four major functions are exploration, analysis, communication and display of data, and graphical aids. Exploration (which may be simply summarizing data or trying to expose relationships between variables) is determining the characteristics of data sets and deciding on one or more appropriate forms of further analysis, such as the scatter plot. Analysis is the use of graphs to formally evaluate some aspect of the data, such as whether there are outliers present or if an underlying assumption of a population distribution is fulfilled. As long ago as 1960 (5), some 18 graphical methods for analyzing multivariate data relationships were developed and proposed.
Communication and display of data are the most commonly used function of statistical graphics in toxicology, whether used for internal reports, presentations at meetings, or formal publications in the literature. In communicating data, graphs should not be used to duplicate data that are presented in tables, but rather to show important trends and/or relationships in the data. Though such communication is most commonly of a quantitative compilation of actual data, it can also be used to summarize and present the results of statistical analysis. The fourth and final function of graphics is one that is largely becoming outdated as microcomputers become more widely available. Graphical aids to calculation include nomograms (the classic example in toxicology of a nomogram is that presented by Litchfield and Wilcoxon for determining median effective doses) and extrapolating and interpolating data graphically based on plotted data.
There are many forms of statistical graphics (a partial list, classified by function, is presented in Table 7.6), and a number of these (such as scatter plots and histograms) can be used for each of a number of possible functions. Most of these plots are based on a Cartesian system (i.e., they use a set of rectangular coordinates), and our review of construction and use will focus on these forms of graphs.
'Construction of a rectangular graph of any form starts with the selection of the appropriate form of graph followed by the laying out of the coordinates (or axes). Even graphs that are going to encompass

multivariate data (i.e., more than two variables) generally have as their starting point two major coordinates. The vertical axis, or ordinate (also called the Y axis), is used to present an independent variable. Each of these axes is scaled in the units of measure that will most clearly present the trends of interest in the data. The range covered by the scale of each axis is selected to cover the entire region for which data is presented. The actual demarking of

		Weathervane plot
ANALYSIS		
Distribution Assessment	Model Evaluation and Assumption Verification	Decision Making
Probability plot	Average versus standard deviation	Control chart
Q-Q plot	Component-plus-residual plot	Cusum chart
P-P plot	Partial-residual plot	Half-normal plot
Hanging histogram	Residual plots	Ridge trace
Rootagram		Youden plot
Poissonness plot		
COMMUNICATION AND DISPLAY OF DATA		
Quantitative Graphics	Summary of Statistical Analyses	Graphical Aids
Line chart	Means plot	Confidence limits
Pictogram	Sliding reference distribution	Graph paper
Pie chart	Notched box plot	Power curves
Contour plot	Factor space/response	Nomographs
Stereogram	Interaction plot	Sample-size curves
Color Map	Contour plot	Trilinear coordinates
Histogram	Predicted response plot	
	Confidence region plot	

the measurement scale along an axis should allow for easy and accurate assessment of the coordinates of any data point, yet should not be cluttered.

Actual data points should be presented by symbols that present the appropriate indicators of location, and if they represent summaries of data from a normal data population, it would be appropriate to present a symbol for the mean and some indication of the variability (or error) associated with that population, commonly by using “error bars” which present the SD (or standard error) from the mean. If, however, the data are not normal or continuous, it would be more appropriate to indicate location by the median and present the range or semiquartile distance for variability estimates. The symbols that are used to present data points can also be used to present a significant amount of additional information. At the simplest level a set of clearly distinct symbols (circles, triangles, squares, etc.) are very commonly used to provide a third dimension of data (most commonly, treatment group), but by clever use of symbols, all sorts of additional information can be presented. Using a method such as Chernoff faces (79), in which faces are used as symbols of the data points (and various aspects of the faces present additional data, such as the presence or absence of eyes denoting presence or absence of a secondary pathological condition), it is

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_338.html[2010/10/28 18:43:14]

FIG. 7.8. Acquisitions of postnatal development landmarks in rats.

possible to present a large number of different variables on a single graph.

The three other forms of graphs that are commonly used in toxicology are histograms, pie charts, and contour plots. Histograms are graphs of simple frequency distribution. Commonly, the abscissa is the variable of interest (such as lifespan or litter size) and generally is shown as classes or intervals or measurements (such as age ranges of 0 to 10 weeks, 10 to 20 weeks, etc.). The ordinate, meanwhile, is the incidence or frequency of observations. The result is a set of vertical bars, each of which represents the incidence of a particular set of observations. Measures of error or variability about each incidence are reflected by some form of error bar on top of or in the frequency bars, as shown in Figure 7.8. The size of class intervals may be unequal (in effect, one can combine or pool several small class intervals), but it is proper in such cases to vary the width of the bars to indicate differences in interval size.

Pie charts are the only common form of quantitative graphic technique that is not rectangular. Rather, the figure is presented as a circle out of which several "slices" are delimited. The only major use of the pie chart is in presenting a breakdown of the components of a group.

Typically the entire set of data under consideration (such as total body weight) constitutes the pie whereas each slice represents a percentage of the whole (such as the percentages represented by each of several organs). The total number of slices in a pie should be small for the presentation to be effective. Variability or error can be readily presented by having a subslice of each sector shaded and labeled accordingly.
Finally, there is the contour plot, which is used to depict the relationships in a three-variable, continuous data system. That is, a contour plot visually portrays each contour as a locus of the values of two variables associated with a constant value of the third variable. An example would be a relief map that gives both latitude and longitude of constant altitude using contour lines.
The most common misuse of graphs is to either conceal or exaggerate the extent of the difference by using an inappropriately scaled or ranged axis. Tufte (146) has termed a statistic for evaluating the appropriateness of scale size, the lie factor, defined as

$$\text{Lie factor} = \frac{\textit{Size of effect shown in graph}}{\textit{Size of effect in data}}.$$

An acceptable range for the lie factor is from 0.95 to 1.05. A value less than this range means the size of an effect is being understated, more than the effect is being exaggerated.
There are a number of excellent references available for those who would like to pursue statistical graphics more. Anscombe (7) presents an excellent short overview, whereas others (132, 145–147) provide a wealth of information.
Multidimensional and Nonmetric Scaling
Multidimensional scaling (MDS) is a collection of analysis methods for data sets that have three or more variables making up each data point. MDS displays the relationships of three or more dimensional extensions of the methods of statistical graphics.
MDS presents the structure of a set of objects from data that approximate the distances between pairs of the objects. The data, called similarities, dissimilarities, distances, or proximities, must be in such a form that the degree of similarities and differences between the pairs of the objects (each of which represents a real-life data point) can be measured and handled as a distance (remember the discussion of measures of distances under classifications). Similarity is a matter of degree, small differences between objects cause them to be "similar" (a high degree of similarity) whereas large differences cause them to be considered dissimilar (a small degree of similarity).
In addition to the traditional human conceptual or subjective judgments of similarity, data can be an "objective" similarity measure (the difference in weight between a pair of animals) or an index calculated from multivariate data (the proportion of agreement in the results of a number of carcinogenicity studies); however, the data must always represent the degree of similarity of pairs of objects.
Each object or data point is represented by a point in a multidimensional space. These plots or projected points are arranged in this space so that the distances between pairs of points have the strongest possible relation to the degree of similarity among the pairs of objects. That is, two similar objects are represented by two points that are close together, and two dissimilar objects are represented by a pair of points that are far apart. The space is usually a two- or three-dimensional Euclidean space, but may be non-Euclidean and may have more dimensions.
MDS is a general term that includes a number of different types of techniques; however, all seek to allow geometric analysis of multivariate data. The forms of MDS can be classified (170) according to the nature of the similarities in the data. It can be qualitative (nonmetric) or quantitative (metric MDS). The types can also be classified by the number of variables involved and by the nature of the model used—for example, classical MDS (there is only one data matrix, and no weighting factors are used on the data), replicated MDS (more than one matrix and no weighting), and weighted MDS (more than one matrix and at least some of the data being weighted).
MDS can be used in toxicology to analyze the similarities and differences between effects produced by different agents in an attempt to use an understanding of the mechanism underlying the actions of one agent to determine the mechanisms of the other agents. Actual algorithms and a good intermediate level presentation of MDS can be found in Davison (35).
Nonmetric scaling is a set of graphic techniques closely related to MDS, and is definitely useful for the reduction of dimensionality. Its major objective is to arrange a set of objects (each object, for our purposes, consisting of a number of related observations) graphically in a few dimensions while retaining the maximum possible fidelity to the original relationships between members (i.e., values that are most

different are portrayed as most distant). It is not a linear technique and it does not preserve linear relationships (i.e., A is not shown as twice as far from C as B, even though its "value difference" may be twice as much). The spacings (interpoint distances) are kept such that if the distance of the original scale between members A and B is greater than that between C and D, the distances on the model scale shall likewise be greater between A and B than between C

and D. Figure 7.5 uses a form of this technique in adding a third dimension by using letters to present degrees of effect on the skin.

This technique functions by taking observed measures of similarity or dissimilarity between every pair of M objects and then finding a representation of the objects as points in Euclidean space that the interpoint distances in some sense "match" the observed similarities or dissimilarities by means of weighting constants.

Cluster Analysis

Cluster analysis is a quantitative form of classification. It serves to help develop decision rules and then use these rules to assign a heterogeneous collection of objects to a series of sets. This is almost entirely an applied methodology (as opposed to theoretical). The final result of cluster analysis is one of several forms of graphic displays and a methodology (set of decision-classifying rules) for the assignment of new members into the classifications.

The classification procedures used are based on either density of population or distance between members. These methods can serve to generate a basis for the classification of large numbers of dissimilar variables, such as behavioral observations and compounds with distinct but related structures and mechanisms (63, 64), or to separate tumor patterns caused by treatment from those caused by old age (14).

There are five types of clustering techniques (52):

a. Hierarchical techniques: Classes are subclassified into groups, with the process being repeated at several levels to produce a tree that gives sufficient definition to groups.

b. Optimizing techniques: Clusters are formed by optimization of a clustering criterion. The resulting classes are mutually exclusive; the objects are partitioned clearly into sets.

c. Density- or mode-seeking techniques: Clusters are identified and formed by locating regions in a graphic representation that contains concentrations of data points.

d. Clumping techniques: A variation of density-seeking techniques in which assignment to a cluster is weighted on some variables so that clusters may overlap in graphic projections.

e. Others: Methods that do not clearly fall into classes a-d.

Romesburg (124) provides an excellent step-by-step guide to cluster analysis.

Fourier or Time Analysis

Fourier analysis (16) is most frequently a univariate method used for either simplifying data (which is the basis for its inclusion in this chapter) or for modeling. It can, however, also be a multivariate technique for data analysis. In a sense it is like trend analysis; it looks at the relationship of sets of data from a different perspective. In the case of Fourier analysis, the approach is by resolving the time dimension variable in the data set. At the most simple level it assumes that many events are periodic in nature, and if we can remove the variation in other variables because of this periodicity (by using Fourier transforms), we can better analyze the remaining variation from other variables. The complications to this are (a) there may be several overlying cyclic time-based periodicities, and (b) we may be interested in the time cycle events for their own sake.

Fourier analysis allows one to identify, quantitate, and (if we wish) remove the time-based cycles in data (with their amplitudes, phases, and frequencies) by use of the Fourier transform:

$$nJi=xiexp(-iwit),$$

where

n=length

J=The discrete Fourier transform for that case,

x=actual data,

i=increment in the series,

w=frequency,

t=time.

A graphic example of the use of Fourier analysis in toxicology is provided in Figure 7.9.

Life Tables

Chronic in vivo toxicity studies generally are the most complex and expensive studies conducted by a toxicologist. Answers to a number of questions are sought in such a study—notably if a material results in a significant increase in mortality or in the incidence of tumors in those animals exposed to it, but we are also interested in the time course of these adverse effects (or risks). The classic approach to assessing these age-specific hazard rates is by the use of life tables (also called survivorship tables).

It may readily be seen that during any selected period of time (ti) we have a number of risks competing to affect an animal. There are risks of (a) "natural death," (b) death induced by a direct or indirect

action of the test compound, and (c) death due to such occurrences of interest as tumors (77). We are indeed interested in determining if (and when) the last two of these risks become significantly different than the "natural" risks (defined as what is seen to happen in the control group). Life table methods enable us to make such determinations as the duration of survival (or time until tumors develop) and the probabil

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_341.html[2010/10/28 18:43:15]

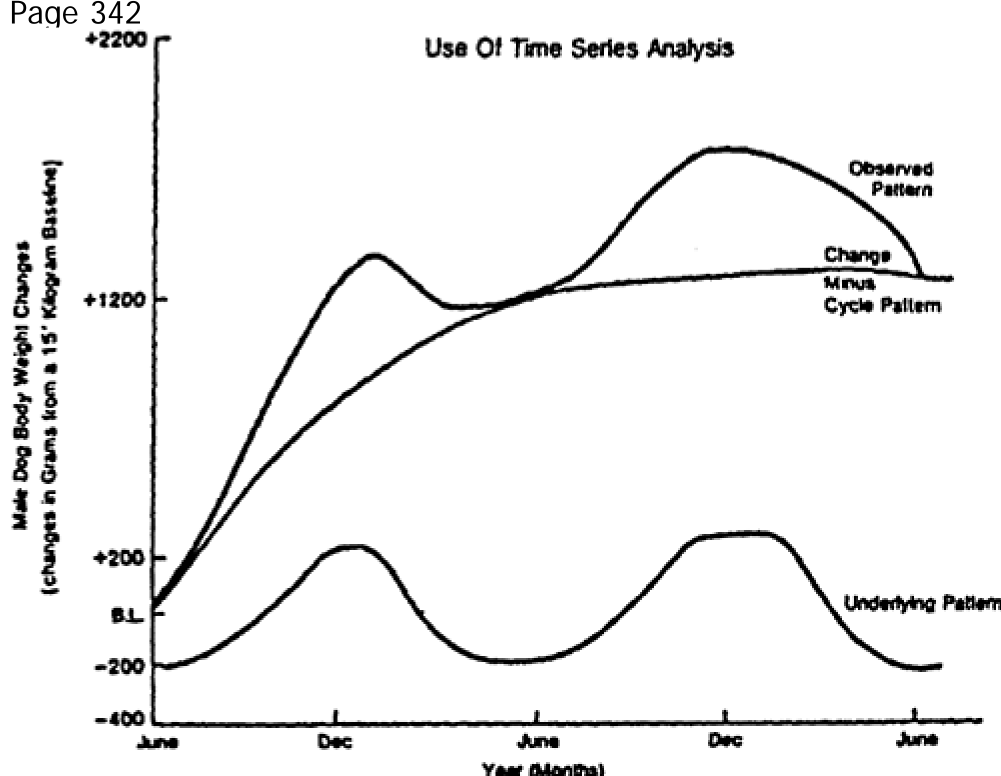

FIG. 7.9. Use of time series analysis.

ity of survival (or of developing a tumor) during any period of time.

We start by deciding the interval length (t_i) we wish to examine within the study. The information we gain becomes more exact as the interval is shortened, but as interval length is decreased, the number of intervals increases and calculations become more cumbersome and less indicative of time-related trends because random fluctuations become more apparent. For a 2-year or lifetime rodent study, an interval length of a month is commonly employed. Some life table methods, such as the Kaplan-Meyer, have each new event (such as a death) define the start of a new interval.

Having established the interval length, we can tabulate our data (33). We start by establishing the following columns in each table (a separate table being established for each group of animals—i.e., by sex and dose level):

(a) The interval of time selected (t_i).
(b) The number of animals in the group that entered that interval of the study alive (l_i).
(c) The number of animals withdrawn from study during the interval (such as those taken for an interim sacrifice or that may have been killed by a technician error) (ω_i).
(d) The number of animals that died during the interval (d_i).
(e) The number of animals at risk during the interval, $l_i = l_i - 1/2\omega I$, or the number on study at the start of the interval minus one half of the number withdrawn during the interval.
(f) The proportion of animals that died $= D_i = d_i / l_i$.
(g) The cumulative probability of an animal surviving until the end of that interval of study, $P_i = 1 - D_i$, or one minus the number of animals that died during that interval divided by the number of animals at risk.
(h) The number of animals dying until that interval (M_i).
(i) Animals found to have died during the interval (m_i).
(j) The probability of dying during the interval of the study $c_i = 1 - (M_i + m_i / l_i)$, or the total number of animals dead until that interval plus the animals discovered to have died during that interval divided by the number of animals at risk through the end of that interval.
(k) The cumulative proportion surviving, p_i, is equivalent to the cumulative product of the interval probabilities of survival (i.e., $P_i = p_1 \cdot p_2 \cdot p_3 \ldots P_x$).
(l) The cumulative probability of dying, C_i, equal to the cumulative product of the interval probabilities to that point (i.e., $C_i = c_1 \cdot c_2 \cdot c_3 \ldots c_x$).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_342.html[2010/10/28 18:43:16]

With such tables established for each group in a study (as shown in Example 33), we may now proceed to test the hypotheses that each of the treated groups has a significantly shorter duration of survival or that the treated groups died more quickly (note that plots of total animals dead and total animals surviving will give one an appreciation of the data, but can lead to no statistical conclusions).

Now, for these two groups, we wish to determine effective sample size and to compare survival probabilities in the interval months 14 to 15.

For the exposure group we compute sample size as

$$\ell_{E14-15}=\frac{0.8400(1-0.8400)}{(0.0367)^2}=99.7854$$

Likewise, we get a sample size of 98.1720 for the control group.

The standard error of difference for the two groups here is

$$SD=\sqrt{0.0367^2+0.0173^2}=0.040573$$

The probability of survival differences is PD= 0.9697–0.8400=0.1297. Our test statistic is then 0.1297/0.040573=3.196. From our z value table we see that the critical values are

$p\leq 0.05=1.960$

$p\leq 0.01=2.575$

$p\leq 0.001=3.270$

As our calculated value is larger than all but the last of these, we find our groups to be significantly different at the 0.01 level (0.01>p>0.001).

There are a multiplicity of methods for testing significance in life tables, with (as is often the case) the power of the tests increasing as does the difficulty of computation (30, 83, 126, 141).

We begin our method of statistical comparison of survival at any point in the study by determining the standard error of the K interval survival rate as (66)

$$S_K=P_k\sqrt{\sum_1^k\left(\frac{D_i}{1'_x-d_x}\right)}.$$

We may also determine the effective sample size (11) in accordance with

$$1_1=\frac{P(1-P)}{S^2}.$$

Example 33

Interval (months)	Alive at Beginning of interval	Animals withdrawn	Died during interval	Animals at risk	Proportion of animals dead	Probability of survival	Cumulative proportion surviving	Standard error of survival
				Test level 1

We may now compute the standard error of difference for any two groups (1 and 2) as

$$S_D = \sqrt{S_1^2 + S_2^2}.$$

The difference in survival probabilities for the two groups is then calculated as

$$PD=P1-P2.$$

We can then calculate a test statistic as

$$t' = \frac{P_D}{S_D}.$$

This is then compared to a z distribution table. If t'>z at the desired probability level, it is significant at that level. Example 33 illustrates the life table technique for mortality data. With increasing recognition of the effects of time (both as age and length of exposure to unmeasured background risks), life table analysis has become a mainstay in chronic toxicology. An example is the reassessment of the ED01 study (139), which radically changed interpretation of the results and understanding of underlying methods when adjustment for time on study was made.

Now, for these two groups, we wish to determine effective sample size and to compare survival probabilities in the interval months 14–15.

For the exposure group we compute sample size as

$$S_{xx} = T_{xx} + \sum_{xx}.$$

Likewise, we get a sample size of 98.1720 for the control group.

The standard error of difference for the two groups here is

$$SD = \sqrt{0.0367^2 + 0.0173^2} = 0.040573.$$

The probability of survival differences is PD=0.9697–0.8400=0.1297. Our test statistic is then 0.1297/0.040573=3.196. From our *z* value table we see that the critical values are

$$p \le 0.05 = 1.960,$$
$$p \le 0.01 = 2.575,$$
$$p \le 0.001 = 3.270.$$

As our calculated value is larger than all but the last of these, we find our groups to be significantly different at the 0.01 level (0.01>p>0.001).

The increased importance and interest in the analysis of survival data has not been restricted to toxicology, but rather has encompassed all of the life sciences. Those with further interest should consult Lee (101) or Elandt Johnson and Johnson (49), both general in their approach to the subject.

Multivariate Methods

In a chapter of this kind, an in-depth explanation of the available multivariate statistical techniques is an impossibility; however, as the complexity of problems in toxicology increases, we can expect to confront more frequently data that are not univariate but rather multivariate (or multidimensional). For example, a multidimensional study might be one in which the animals are being dosed with two materials that interact. Suppose we measure body weight, tumor incidence, and two clinical chemistry values for test material effects and interaction. Our dimensions, or variables, are now A=dose "x," B=dose "y," W=body weight, C=tumor incidence, D and E=levels of clinical chemistry parameters, and possibly also t (length of dosing).

These situations are particularly common in chronic studies (129). Though we can continue to use multiple sets of univariate techniques as we have in the past, there are significant losses of power, efficiency, and information when this is done, as well as an increased possibility of error (34).

Here we will also look briefly at the workings and uses of each of the most commonly employed multivariate techniques, together with several examples from the literature of their employment in toxicology and the other biological sciences. We shall group the methods according to their primary function: hypothesis testing (are these significant or not?), model fitting (what is the relationship between these variables, or what would happen if a population would be exposed to x?), and reduction of dimensionality (which variables are most meaningful?). It should be noted (and will soon be obvious), however, that most multivariate techniques actually combine several of these functions.

The most fundamental concept in multivariate analysis is that of a multivariate population distribution. By this point it is assumed that the reader is familiar with the univariate random variable and with such standard distributions as the normal distribution. Here we extend these to the multivariate normal distribution.

Multivariate data are virtually never processed and analyzed other than by computer. One must first set up an appropriate database file and then enter the data, coding some of them to meet the requirements of the software being used (e.g., if only numerical data are analyzed, sex may have to be coded as 1 for male and 2 for females).

Having recorded the data, it is then essential to review for suspect values and errors of various kinds. There

are many different types of suspect values, and it is helpful to distinguish among them:

(a) Outliers: These are defined to be observations that appear to be inconsistent with the rest of the data. They may be caused by gross recording or entering errors, but it is important to realize that an apparent outlier may occasionally be genuine and indicate a non-normal distribution or valuable data point.

(b) Inversions: A common type of error occurs when two consecutive digits are interchanged at the recording, coding, or entering stage. The error may be trivial if, for example, 56.74 appears as 56.47, but it may generate an outlier if 56.74 appears as 65.74.

(c) Repetitions: At the coding or entering stage, it is quite easy to repeat an entire number in two successive rows or columns of a table, thereby omitting one number completely.

(d) Values in the wrong column: It is easy to get numbers into the wrong columns.

(e) Other errors and suspect values: There are many other types of error, including possible misrecording of data of a minor nature.

The general term used to denote procedures for detecting and correcting errors is *data editing*. This includes checks for completeness, consistency, and credibility. Some editing can be done at the end of the data entry stage. In addition, many routine checks can be made by the computer itself, particularly those for gross outliers. An important class of such checks are range tests. For each variable an allowable range of possible values is specified and the computer checks that all observed values lie within the given range. Bivariate and multivariate checks are also possible. For example, one may specify an allowable range for some functions of two or more variables. A set of checks called "if-then" checks are also possible. For example, if both age and date of birth are recorded for each animal, then one can check that the answers are consistent. If the date of birth is given, then one can deduce the corresponding age. In fact, in this example the age observation is redundant. It is sometimes a good idea to include one or two redundant variables as a check on accuracy. Various other general procedures for detecting outliers are described by Barnett and Lewis (10).

When a questionable value or error is detected, the toxicologist must decide what to do about it. One may be able to go back to the original data source and check the observation. Inversions, repetitions, and values in the wrong column can often be corrected in this way. Outliers are more difficult to handle, particularly when they are impossible to check or have been misrecorded in the first place. It may be sensible to treat them as missing values and try to insert a value "guessed" in an appropriate way (e.g., by interpolation or by prediction from other variables). Alternatively, the value may have to be left as unrecorded and then either all observations for the given individual will have to be discarded or one will have to accept unequal numbers of observations for the different variables. With a univariate set of observations, the analysis usually begins with the calculation of two summary statistics, namely the mean and standard deviation. In the multivariate case, the analysis usually begins with the calculation of the mean and standard deviation for each variable, and, in addition, the correlation coefficient for each pair of variables is usually calculated. Their summary statistics are vital in having a preliminary look at the data.

The sample mean of the jth variable is given by

$$\bar{x}_j = \sum_{r=1}^{n} x_{rj}/n,$$

and the sample mean vector, x, is given by XT=[x1, x2, xn, ..., xn]. If the observations are a random sample from a population with mean $\bar{x}$, then the sample mean vector x is usually the point estimate of x, and this estimate can easily be shown to be unbiased.

The SD of the jth variable is given by

$$Sj = \sqrt{\left[\sum_{r=1}^{n} (x_{rj} - \bar{x}_j^2)/(n-1)\right]}.$$

The correlation coefficient of variables i and j is given by

$$r_{ij} = \sum_{r=1}^{n} (x_{ri} - \bar{x}_j)(x_{rj} - \bar{x}_j)/(n-1)S_i s_j.$$

These coefficients can be conveniently assembled in the sample correlation matrix, R, which is given by

$$R = \begin{bmatrix} 1 & r_{12} & \dots & r_{1n} \\ r_{21} & 1 & \dots & r_{2n} \\ \vdots & & & \\ r_n^1 & r_n^2 & \dots & 1 \end{bmatrix}.$$

Note that the diagonal terms are all unity.

The interpretation of mean and standard deviations is straightforward. It is worth looking to see if, for example, some variables have much higher scatter than others. It is also worth looking at the form of the distribution of each variable and considering whether any of the variables need to be transformed. For example, the logarithmic transformation is often used to reduce positive skewness and produce a distribution that is closer to normal.

One may also consider the removal of outliers at this stage.

There are three significant multivariate techniques that have hypothesis testing as their primary function: MANOVA, MANCOVA, and factor analysis.

MANOVA (multivariate analysis of variance) is the multidimensional extension of the ANOVA process we explored before. It can be shown to have grown out of Hotelling's T2 (88), which provides a means of testing the overall null hypothesis that two groups do not differ in their means on any of p measures. MANOVA accomplishes its comparison of two (or more) groups by reducing the set of p measures on each group to a simple number applying the linear combining rule Wi=WjXij (where Wj is a weighting factor) and then computing a univariate F-ratio on the combined variables. New sets of weights (wj) are selected in turn until that set which maximizes the F-ratio is found. The final resulting maximum F-ratio (based on the multiple discriminant functions) is then the basis of the significance test. As with ANOVA, MANOVA can be one way or higher order, and MANOVA has as a basic assumption a multivariate normal distribution.

Gray and Laskey (75) used MANOVA to analyze the reproductive effects of manganese in the mouse, allowing identification of significant effects at multiple sites. Witten et al. (167) utilized MANOVA to determine the significance of the effects of dose, time, and cell division in the action of abrin on the lymphocytes.

Multivariate analysis of covariance (MANCOVA) is the multivariate analog of analysis of covariance. As with MANOVA, it is based on the assumption that the data being analyzed are from a multivariate normal population. The MANCOVA test uses the two residual matrices using the statistic and is an extension of ANCOVA with two or more uncontrolled variables (or covariables). A detailed discussion can be found in Tatsuoka (142).

Factor analysis is not just a technique for hypothesis testing; it can also serve a reduction of dimensionality function. It seeks to separate the variance unique to particular sets of values from that common to all members in that variable system and is based on the assumption that the intercorrelations among the n original variables are the result of there being some smaller number of variables ("factors") that explain the bulk of variation seen in the variables. There are several approaches to achieving the end results, but they all seek a determination of what percentage of the variance of each variable is explained by each factor (a factor being one variable or a combination of variables). The model in factor analysis is y=Af xz, where

y=n dimensional vector of observable responses;

A=factor loading an n×q matrix of unknown parameters;

f=q dimensional vector of common factor;

z=n dimensional vector of unique factor.

Used for the reduction of dimensionality, factor analysis is said to be a linear technique because it does not change the linear relationships between the variables being examined.

Joung et al. (92) used factor analysis to develop a generalized water quality index that promises suitability across the United States, with appropriate weightings for 10 parameters. Factor analysis promises great utility as a tool for developing models in risk analysis, where a number of parameters act and interact.

Now we move on to two multivariate modeling techniques: multiple regression and discriminant analysis. Multiple regression and correlation seeks to predict one (or a few) variable from several others. It assumes that the available variables can be logically divided into two (or more) sets and serves to establish maximal linear (or some other scale) relationships among the sets;

The linear model for the regression is simply

$$Y=b_0+b_1X_1+b_2X_2+\ldots+b_pX_p,$$

where Y=the predicted value, b=values set to maximize correlations between X and Y, and X and Y=the actual observations (with X's being independent of predictor variables and Y's being dependent variables or outcome measures). One of the outputs from the process will be the coefficient of multiple correlation, which is simply the multivariate equivalent of the correlation coefficient *(r)*.

Schaeffer et al. (128) have neatly demonstrated the utilization of multiple regression in studying the contribution of two components of a mixture to its toxicologic action, using quantitative results from an Ames test as an end point. Paintz et al. (116) similarly used multiple regression to model the quantitative structure-activity relationships of a series of 14 l-benzoyl-3-methyl-pyrazole derivatives.

Discriminant analysis has for its main purpose finding linear combinations of variables that maximize the differences between the populations being studied, with the objective of establishing a model to sort objects into their appropriate populations with minimal error. At least four major questions are, in a

sense, being asked of the data:

1. Are there significant differences among the K groups?
2. If the groups do exhibit statistical differences, how do the central masses (or centroids, the multivariate equivalent of means) of the populations differ?
3. What are the relative distances among the K groups?

4. How are known (or at this point unknown) members allocated to *establish* groups? How do you predict the set of responses of characteristics of an as yet untried exposure case?

The discriminant functions used to produce the linear combinations are of the form

$$Di=di1Xi+di2Z2\ldots+dipZp,$$

where

D1=the score on the discriminant function I,

d's=weighing coefficients,

Z's=standardized values of the discriminating variables used in the analysis.

It should be noted that discriminant analysis can also be used for the hypothesis testing function by the expedient of evaluating how well it correctly classifies members into proper groups (say, control, treatment 1, treatment 2, etc.) Taketomo et al. (140) used discriminant analysis in a retrospective study of gentamycin nephrotoxicity to identify patient risk factors (i.e., variables which contributed to a prediction of a patient being at risk).

Finally, we introduce four techniques whose primary function is the reduction of dimensionality: canonical correlation analysis, principal components analysis, biplot analysis, and correspondence analysis.

Canonical correlation analysis provides the canonical R, an overall measure of the relationship between two sets of variables (one set consisting of several outcome measures, the other of several predictor variables). The canonical R is calculated on two numbers for each subject:

$$Wi=\Sigma wjXij \text{ and } Vi=\Sigma viYij,$$

where

X's=predictor variables,

Y's=outcome measures,

Wj and Vj=canonical coefficients.

MANOVA can be considered a special case of canonical correlation analysis. Canonical correlation can be used in hypothesis testing also for testing the association of pairs of sets of weights, each with a corresponding coefficient of canonical correlation, each uncorrelated with any of the preceding sets of weights, and each accounting for successively less of the variation shared by the two sets of variables. For example, Young and Matthews (169) used canonical correlation analysis to evaluate the relationship between plant growth and environmental factors at 12 different sites.

The main purpose of principal components analysis is to describe as economically as possible the total variance in a sample in a few dimensions: one wishes to reduce the dimensionality of the original data while minimizing the loss of information. It seeks to resolve the total variation of a set of variables into linearly independent composite variables that successively account for the maximum possible variability in the data. The fundamental equation is Y=AZ, where

A=matrix of scales eigenvectors,

Z=original data matrice,

Y=principal components.

The concentration here, as in factor analysis, is on relationships within a single set of variables. Note that the results of principal components analysis are affected by linear transformations.

Cremer and Seville (31) used principal components to compare the difference in blood parameters resulting from each of two separate pyrethroids. Henry and Hidy (84), meanwhile, used principal components to identify the most significant contributors to air quality problems.

The biplot display (58) of multivariate data is a relatively new technique but promises wide applicability to problems in toxicology. It is, in a sense, a form of exploratory data analysis, used for data summarization and description.

The biplot is a graphical display of a matrix Ynmx of N rows and M columns by means of row and column marker. The display carries one marker for each row and each column. The "bi" in biplot refers to the joint display of rows and columns. Such plots are used primarily for inspection of data and for data diagnostics when such data are in the form of matrices.

Shy-Modjeska et al. (135) illustrated this usage in the analysis of aminoglycoside renal data from beagle dogs, allowing the simultaneous display of relationships among different observed variables and presentation of the relationship of both individuals and treatment groups to these variables.

Correspondence analysis is a technique for displaying the rows and columns of a two-way contingency table as points in a corresponding low-dimensional vector space. As such, it is equivalent to simultaneous linear regression (for contingency table data, such as tumor incidences, which is a very common data form in toxicology). As such, it can be considered a special case of canonical correlation

analysis. The data are defined, described, and analyzed in a geometric framework. This is particularly attractive to such sets of observations in toxicology as multiple end point behavioral scores and scored multiple tissue lesions.

There are a number of good surveys of multivariate techniques available (9, 21, 133) that are not excessively mathematical. More rigorous mathematical treatments on an introductory level are also available (71). Most of the techniques we have described are available in the better computer statistical packages.

Table 7.7 Classification of Data Commonly Encountered in Toxicology, by Type

Continuous normal:	Body weights
	Food consumption
	Organ weights: Absolute and relative
	Mouse Ear Swelling Test (MEST) measurements
	Pregnancy rates
	Survival rates
	Crown-Rump lengths
	Hematology (some)
	Clinical chemistry (some)
Continuous but not normal:	Hematology (some—WBC)
	Clinical chemistry (some)
	Urinalysis
Scalar data:	Neurobehavioral signs (some)
	PDI scores
	Histopathology (some)
Count data:	Resorption sites
	Implantation sites
	Stillborns
	Hematology (some—reticulocyte counts//Howel-Jolly//WBC differentials)
Categorical data	Clinical signs
	Neurobehavioral signs (some)
	Ocular scores
	GP sensitization scores
	Mouse ear swelling tests (MEST) sensitization
	Counts
	Fetal abnormalities
	Dose/mortality data
	Sex ratios
	Histopathology data (most)

DATA ANALYSIS APPLICATIONS IN TOXICOLOGY

Having reviewed basic principles and provided a set of methods for statistical handling of data, the remainder of this book will address the practical aspects and difficulties encountered in day-to-day toxicological work. As a starting point, we present in Table 7.7 an overview of data types actually encountered in toxicology, classified by type (as presented at the beginning of this book). It should be stressed, however, that this classification is of the most frequent measure of each sort of observation (such as body weight) and will not always be an accurate classification.

There are now common practices in the analysis of toxicology data, though they are not necessarily the best. These are discussed in the remainder of this chapter, which seeks to review statistical methods on a use-by-use basis and to provide a foundation for the selection of alternatives in specific situations.

Median Lethal and Effective Doses

For many years, the starting point for evaluating the toxicity of an agent was to determine its LD50 or LC50, which are the dose or concentration of a material at which half of a population of animals would be expected to die. These figures are analogous to the ED50 (effective dose for half a population) used in pharmacologic activities, and are derived by the same means. It is important to keep in mind the three dimensions of dose response.

As the dose increases,

Incidence of responders in an exposed population increases.

Severity of response in effected individuals increases.

Time to occurrence of response or of progressive stage of response decreases.

To calculate either the LD50 or LC50, we need, at each of several dosage (or exposure) levels, the number of animals dosed and the number that died. If we seek only to establish the median effective dose in a range-finding test, then 4 or 5 animals per dose level, using Thompson's method of moving averages, is the most efficient methodology and will give a sufficiently accurate solution. With two dose levels, if the ratio between the high and low dose is two or less, even total or no mortality at these two dose levels will yield an acceptably accurate medial lethal dose, although a partial mortality is desirable. If, however, we wish to estimate a number of toxicity levels (LD10, LD90) and are interested in more

precisely establishing the slope of the dose/lethality curve, the use of at least 10 animals per dosage level with the log/probit regression technique is the most common approach. Note that in the equation $Y_i=a+bx_1$, b is the slope of the regression line and that our method already allows us to calculate 95% confidence intervals about any point on this line. Note that the confidence interval at any one point will be different from the interval at other points and must be calculated separately. Additionally, the nature of the probit transform is such that toward the extremes—LD10 and LD90, for example—the confidence intervals will "balloon" (i.e., they become very wide). Because the slope of the fitted line in these assays has a very large uncertainty, in relation to the uncertainty of the LD50 itself (the midpoint of the distribution), much caution must be used with calculated Ldxs other than LD50s. The imprecision of the LD35, a value close to the LD50, is discussed by Weil (153), as is that of the slope of the log dose-probit line (152). Debanne and Haller (37) recently reviewed the statistical aspects of different methodologies for estimating a median effective dose.

There have been questions for years as to the value of LD50 and the efficiency of the current study design (which uses large numbers of animals) in determining it. As long ago as 1953, Weil et al. (154) presented forceful

arguments that an estimate having only minimally reduced precision could be made using significantly fewer animals. More recently, the last few years have seen an increased level of concern over the numbers and uses of animals in research and testing and have produced additional arguments against existing methodologies for determining the LD50 or even the need to make the determination at all (172). In response, a number of suggestions for alternative methodologies have been advanced (20, 38, 59).

Body and Organ Weights

Among the sets of data commonly collected in studies where animals are dosed with (or exposed to) a chemical are body weight and the weights of selected organs. In fact, body weight is frequently the most sensitive indication of an adverse effect. How to best analyze this and in what form to analyze the organ weight data (as absolute weights, weight changes, or percentages of body weight) have been the subject of a number of articles (90, 155, 156, 162).

Both absolute body weights and rates of body weight change (calculated as changes from a baseline measurement value that is traditionally the animal's weight immediately prior to the first dosing with or exposure to test material) are almost universally best analyzed by ANOVA followed by a post hoc test, if called for. Even if the groups were randomized properly at the beginning of a study (no group being significantly different in mean body weight from any other group, and all animals in all groups within two SDs of the overall mean body weight), there is an advantage to performing the computationally, slightly more cumbersome (compared to absolute body weights) analysis of changes in body weight. The advantage is an increase in sensitivity because the adjustment of starting points (the setting of initial weights as a "zero" value) acts to reduce the amount of initial variability. In this case, Bartlett's test is performed first to ensure homogeneity of variance, and the appropriate sequence of analysis follows.

With smaller sample sizes, the normality of the data becomes increasingly uncertain, and nonparametric methods, such as Kruskal-Wallis, may be more appropriate (171).

The analysis of relative (to body weight) organ weights is a valuable tool for identifying possible target organs (59). How to perform this analysis is still a matter of some disagreement, however.

Weil (155) presented evidence that organ weight data expressed as percentages of body weight should be analyzed separately for each sex. Furthermore, because the conclusions from organ weight data of males differed so often from those of females, data from animals of each sex should be used in this measurement. Others (17, 18, 157, 162) have discussed in detail other factors that influence organ weights and must be taken into account.

The two competing approaches to analyzing relative organ weights call for either

(1) calculating organ weights as a percentage of total body weight (at the time of necropsy) and analyzing the results by ANOVA, or

(2) analyzing results by ANCOVA, with body weights as the covariates, as discussed previously by the author (156).

A number of considerations should be kept in mind when these questions are addressed. First, one must keep a firm grasp on the difference between biological significance and statistical significance. In this particular case, we are especially interested in examining organ weights when an organ weight change is not proportional to changes in whole body weights. Second, we are now required to detect smaller and smaller changes while still retaining a similar sensitivity (i.e., the $p<0.05$ level).

There are several devices to attain the desired increase in power. One is to use larger and larger sample sizes (number of animals) and the other is to use the most powerful test we can; however, the use of even currently employed numbers of animals is being vigorously questioned and the power of statistical tests must, therefore, now assume an increased importance in our considerations.

The biological rationale behind analyzing both absolute body weight and the organ weight to body weight ratio (this latter as opposed to a covariance analysis of organ weights) is that in the majority of cases, except for the brain, the organs of interest in the body change weight (except in extreme cases of obesity or starvation) in proportion to total body weight. We are particularly interested in detecting cases where this is not so. Analysis of actual data from several hundred studies (unpublished data) has shown no significant difference in rates of weight change of target organs (other than the brain), compared to total body weight for healthy animals in those species commonly used for repeated dose studies (rats, mice, rabbits, dogs). Furthermore, it should be noted that analysis of covariance is of questionable validity in analyzing body weight and related organ weight changes, as a primary assumption is the independence of treatment—that the relationship of the two variables is the same for all treatments (123). Plainly, in toxicology this is not true.

In cases where the differences between the error mean squares are much greater, the ratio of F-ratios will diverge in precision from the result of the efficiency of covariance adjustment. These cases are where either sample sizes are much larger or where the differences between means themselves are much larger. This latter case is one that

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_349.html[2010/10/28 18:43:21]

page_350

does not occur in the designs under discussion in any manner that would leave analysis of covariance as a valid approach because group means start out being very similar and cannot diverge markedly unless there is a treatment effect. As we have discussed earlier, a treatment effect invalidates a prime underpinning assumption of analysis of covariance.
Shirley and Newnham (134) have argued the case for ANCOVA but without providing answers to arguments presented above.
Clinical Chemistry
A number of clinical chemistry parameters are commonly determined on the blood and urine collected from animals in chronic, subchronic, and, occasionally, acute toxicity studies. In the past, and still in some places, the accepted practice has been to evaluate these data using univariate-parametric methods (primarily t-tests and/or ANOVA); however, this can be shown to be not the best approach on a number of grounds.
First, such biochemical parameters are rarely independent of each other. Neither is our interest often focused on just one of the parameters. Rather, there are batteries of the parameters associated with toxic actions at particular target organs. For example, increases in creatinine phosphokinase (CPK), γ-hydroxybutyrate dehydrogenase (γ-HBDH), and lactate dehydrogenase (LDH), occurring together, are strongly indicative of myocardial damage. In such cases we are not just interested in a significant increase in one of these, but in all three. Table 7.8 gives a brief overview of the association of various parameters with actions at particular target organs. A more detailed coverage of the interpretation of such clinical laboratory tests can be found in other references (65, 78, 103, 105).
Similarly, the serum electrolytes (sodium, potassium, calcium) interact with each other; a decrease in one is frequently tied, for instance, to an increase in one of the others. Furthermore, the nature of the data (in the case of some parameters), either because of the biological nature of the parameter or the way in which it is measured, is frequently either not normally distributed (particularly because of being markedly skewed) or not continuous in nature. This can be seen in some of the reference data for experimental animals in Mitruka and Rawnsley (109) or Weil (158) in, for example, creatinine, sodium, potassium, chloride, calcium, and blood.
Hematology
Much of what we said about clinical chemistry parameters is also true for the hematologic measurements made in toxicology studies. Which test to perform should be evaluated by use of a decision tree until one becomes confident as to the most appropriate methods. Keep in mind that sets of values and (in some cases) population distribution vary not only between species, but also between the commonly used strains of species, and that "control" or "standard" values will "drift" over the course of only a few years.
Again, the majority of these parameters are interrelated and highly dependent on the method used to determine them. RBC, platelet counts, and mean corpuscular volume (MCV) may be determined using a device such as a Coulter counter to take direct measurements, and the resulting data are usually stable for parametric methods. The hematocrit, however, may actually be a value calculated from the RBC and MCV values, and if so, is dependent on them. If the hematocrit is measured directly, instead of being calculated from the RBC and MCV, it may be compared by parametric methods.
Hemoglobin is directly measured and is an independent and continuous variable; however, and probably because at any one time a number of forms and conformations (oxyhemoglobin, deoxyhemoglobin, methemoglobin, etc.) of hemoglobin are actually present, the distribution seen is not typically a normal one, but rather may be a multimodal one. Here a nonparametric technique such as the Wilcoxon or multiple Rank-Sum is called for.
Consideration of the white blood cell (WBC) and differential counts leads to another problem. The total WBC is, typically, a normal population amenable to parametric analysis, but differential counts are normally determined by counting, manually, one or more sets of 100 cells each. The resulting relative percentages of neutrophils are then reported as either percentages or are multiplied by the total WBC count with the resulting "count" being reported as the "absolute" differential WBC. Such data, particularly in the case of eosinophils (where the distribution does not approach normality) should usually be analyzed by nonparametric methods. It is widely believed that "relative" (percentage) differential data should not be reported because they are likely to be misleading.
Lastly, it should always be kept in mind that it is rare for a change in any single hematologic parameter to be meaningful. Rather, because these parameters are so interrelated, patterns of changes in parameters should be expected if a real effect is present, and analysis and interpretation of results should focus on such patterns of changes. Classification analysis techniques often provide the basis for a
file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_350.html[2010/10/28 18:43:21]

useful approach to such problems.

Histopathologic Lesion Incidence

The last 30 years have seen increasing emphasis placed on histopathological examination of tissues collected

Page 351

Table 7.8 Association of changes in biochemical parameters with actions at particular target organs

PARAMETER	ORGAN SYSTEM								NOTES
	BLOOD	HEART	LUNG	KIDNEY	LIVER	BONE	INTESTINE	PANCREAS	
Albumin				↓	↓				Produced by the liver. Very significant reductions indicate extensive liver damage.
ALP (alkaline phosphatase)					↑	↑	↑		Elevations usually are associated with cholestasis. Bone alkaline phosphatase tends to be higher in young animals.
Bilirubin (total)	↑				↑				Usually elevated due to cholestasis—either due to obstruction or hepatopathy.
BUN (blood urea nitrogen)				↑	↓				Estimates blood filtering capacity of the kidneys. Doesn't become significantly elevated until kidney function is reduced 60%–75%.
Calcium				↑					Can be life threatening and result in acute death.
Cholinesterase				↑	↓				Found in plasma, brain and RBC.
CPK (creatinine phosphokinase)		↑							Most often elevated due to skeletal muscle damage but can also be produced by cardiac muscle damage. Can be more sensitive than histopathology.
Creatinine				↑					Also estimates blood filtering

PARAMETER	BLOOD	HEART	LUNG	ORGAN SYSTEM KIDNEY	LIVER	BONE	INTESTINE	PANCREAS	NOTES
									capacity of kidney as BUN does More specific than BUN.
Glucose								↑	Alterations other than those associated with stress are uncommon and reflect an effect on the pancreatic islets or anorexia.
GGT (gamma glutamyl transferase)					↑				Elevated in cholestasis. This is a microsomal enzyme and levels often increase in response to microsomal enzyme induction.
HBDH (hydroxybutyric dehydrogenase)		↑			↑				
LDH (lactic dehydrogenase		↑	↑	↑	↑				Increase usually due to skeletal muscle, cardiac muscle and liver damage. Not very specific.
Protein (total)				↓	↓				Absolute alterations are usually associated with decreased production (liver) or increased loss (kidney). Can see increase in case of muscle "wasting" (catabolism).

PARAMETER	BLOOD	HEART	LUNG	ORGAN SYSTEM KIDNEY	LIVER	BONE	INTESTINE	PANCREAS	NOTES
SGOT (serum glutamic-oxaloacetic transaminase); also called AST (aspartate amino transferase)		↑		↑	↑			↑	Present in skeletal muscle and heart and most commonly associated with damage to these
SGPT (serum glutamic-pyruvic transaminase); also called ALT (alanine amino transferase)					↑				Elevations usually associated with hepatic damage or disease.
SDH (sorbitol dehydrogenase)					↑ or ↓				Liver enzyme that can be quite sensitive but is fairly unstable. Samples should be processed as soon as possible.

Arrow indicates increase (↑) or decrease (↓).

from animals in subchronic and chronic toxicity studies. Whereas it is not true that only those lesions that occur at a statistically significant increased rate in treated/ exposed animals are of concern (for there are the cases where a lesion may be of such a rare type that the occurrence of only one or a few such in treated animals "raises a flag"), it is true that, in most cases, a statistical evaluation is the only way to determine if what we see in treated animals is significantly worse than what has been seen in control animals. Although cancer is not our only concern, this category of lesions is of greatest interest.

Typically, comparison of incidences of any one type of lesion between controls and treated animals are made using the multiple 2×2 chi-square test or Fisher's exact test with a modification of the numbers of animals as the denominators. Too often, experimenters exclude from consideration all those animals (in both groups) that died prior to the first animals being found with a lesion at that site. The special case of carcinogenicity bioassays will be discussed in detail later in this chapter.

An option that should be kept in mind is that frequently a pathologist cannot only identify a lesion as present, but also grade those present as to severity. This represents a significant increase in the information content of the data that should not be given up by performing an analysis based only on the perceived quantal nature (present/absent) of the data. Quantal data, analyzed by chi-square or Fisher's exact tests, are a subset (the 2×2 case) of categorical or contingency table data. In this case it also becomes ranked (or "ordinal") data—the categories are naturally ordered (e.g., no effect<mild lesion<moderate lesion<severe lesion). This gives a 2×R table if there are only one treatment and one control group, or an N×R ("multiway") table if there are three or more groups of animals.

The traditional method of analyzing multiple, crossclassified data has been to collapse the N×R contingency table over all but two of the variables and to follow this with the computation of some measure of association between these variables. For an N-dimensional table, this results in N (N−1)/2 separate analyses. The result is crude, "giving away" information and even (by inappropriate pooling of data) yielding a faulty understanding of the meaning of data. Though computationally more laborious, a multiway (N×R table) analysis should be used.

Reproduction

The reproductive implications of the toxic effects of chemicals are becoming increasingly important. Because of this, reproduction studies, together with other closely related types of studies (such as teratogenesis, dominant lethal, and mutagenesis studies, which are discussed later

in this chapter), are now a common companion to chronic toxicity studies.
One point that must be kept in mind with all reproduction-related studies is the nature of the appropriate sampling unit. What is the appropriate N in such a study? The number of individual pups, the number of litters, pregnant females? Fortunately, it is now fairly well accepted that the first case (using the number of offspring as the N) is inappropriate (162). The real effects in such studies actually occur in the female that was exposed to the chemical or that is mated to a male that was exposed. What happens to her and to the development of the litter she is carrying is biologically independent of what happens to every other female/litter in the stud. This cannot be said for each offspring in each litter (e.g., the death of one member of a litter can and will be related to what happens to every other member). The effect on all of the offspring might be similar for all of those from one female and different or lacking for those from another.
As defined by Oser and Oser (115), there are four primary variables of interest in a reproduction study. First, there is the fertility index (FI), which may be defined as the percentage of attempted matings (i.e., each female housed with a male) that resulted in pregnancy, with pregnancy being determined by a method such as the presence of implantation sites in the female. Second, there is the gestation index (GI), which is defined as the percentage of mated females, as evidenced by a vaginal plug being dropped or a positive vaginal smear, which deliver viable litters (i.e., litters with at least one live pup). Two related variables that may also be studied are the mean number of pups born per litter and the percentage of total pups per litter that are stillborn. Third, there is the viability index (VI), which is defined as the percentage of offspring born that survive at least 4 days after birth. Finally (in this four-variable system) there is the lactation index (LI), which is the percentage of animals per litter that survive 4 days and also survive to weaning. In rats and mice, this is classically taken to be 21 days after birth. An additional variable that may reasonably be included in such a study is the mean weight gain per pup per litter.
Given that our N is at least 10 pregnant animals, we may test each of these variables for significance using a method such as the Wilcoxon-Mann-Whitney U test, or the Kruskal-Wallis nonparametric ANOVA. If N is less than 10, we cannot expect the central limit theorem to be operative and should use the Wilcoxon sum of ranks (for two groups) or the Kruskal-Wallis nonparametric ANOVA (for three or more groups) to compare groups.

Developmental Toxicology

When the primary concern of a reproductive/developmental study is the occurrence of birth defects or deformations (terata, either structural or functional) in the offspring of exposed animals, the study is one of developmental toxicology (teratology). In the analysis of the data from such a study, we must consider several points.
First is sample size. Earlier a method to estimate sufficient sample size was presented previously. The difficulties with applying these methods here revolve around two points: (1) selecting a sufficient level of sensitivity for detecting an effect, and (2) factoring in how many animals will be removed from study (without contributing a datum) by either not becoming pregnant or not surviving to a sufficiently late stage of pregnancy. Experience generally dictates that one should attempt to have 20 pregnant animals per study group if a pilot study has provided some confidence that the pregnant test animals will survive the dose levels selected. Again, it is essential to recognize that the litter, not the fetus, is the basic independent unit for each variable.
A more fundamental consideration, alluded to in the section on reproduction, is that as we use more animals, the mean of means (each variable will be such in a mathematical sense) will approach normality in its distribution. This is one of the implications of the Central Limit Theorem: even when the individual data are not normally distributed, their means will approach normality in their distribution. At a sample size of 10 or greater, the approximation of normality is such that we may use a parametric test (such as a t-test or ANOVA) to evaluate results. At sample sizes less than 10, a nonparametric test (Wilcoxon rank-sum or Kruskal-Wallis nonparametric ANOVA) is more appropriate. Other methodologies have been suggested (100, 112) but do not offer any prospect of widespread usage. One nonparametric method that is widely used is the Mann-Whitney U test, which was described earlier. Williams and Buschbom (163) further discuss some of the available statistical options and their consequences, and Rai and Ryzin (22) have recommended a dose-responsive model.

Dominant Lethal Assay

The dominant lethal study is essentially a reproduction study that seeks to study the end point of lethality to the fetuses after implantation and before delivery. The proper identification of the sampling unit (the pregnant female) and the design of an experiment so that a sufficiently large sample is

available for analysis are the prime statistical considerations. The question of sampling unit has been adequately addressed in earlier sections. Sample size is of concern here because the hypothesis-testing techniques that are appropriate with small samples are of relatively low power, as the variability about the mean in such cases is relatively large. With sufficient sample size (e.g., from 30–50 pregnant females per dose level per week (11)),

variability about the mean and the nature of the distribution allow sensitive statistical techniques to be employed.
The variables that are typically recorded and included in analysis (for each level/week) are as follows: (a) the number of pregnant females, (b) live fetuses/pregnancy, (c) total implants/pregnancy, (d) early fetal deaths (early resorptions)/pregnancy, and (e) late fetal deaths/pregnancy.
A wide variety of techniques for analysis of these data have been (and are) used. Most common is the use of ANOVA after the data have been transformed by the arc sine transform (111).
Beta binomial (2, 151) and Poisson distributions (36) have also been attributed to these data, and transforms and appropriate tests have been proposed for use in each of these cases (in each case with the note that the transforms serve to "stabilize the variance" of the data). With sufficient sample size, as defined earlier in this section, the Mann-Whitney U test is recommended for use here. Smaller sample sizes necessitate the use of the Wilcoxon rank-sum test.
Diet and Chamber Analysis
Earlier we presented the basic principles and methods for sampling. Sampling is important in many aspects of toxicology, and here we address its application to diet preparation and the analysis of atmospheres from inhalation chambers.
In feeding studies we seek to deliver doses of a material to animals by mixing the material with their diet. Similarly, in an inhalation study we mix a material with the air the test animals breathe. In both cases we must then sample the medium (food or atmosphere) and analyze these samples to determine what levels or concentrations of material were actually present and to assure ourselves that the test material is homogeneously distributed. Having an accurate picture of these delivered concentrations and how they varied over the course of time is essential on a number of grounds:
1. The regulatory agencies and sound scientific practice require that analyzed diet and mean daily inhalation atmosphere levels be ±10% of the target level.
2. Excessive peak concentrations, because of the overloading of metabolic repair systems, could result in extreme acute effects that would lead to results in a chronic study that are not truly indicative of the chronic low-level effects of the compound, but rather of periods of metabolic and physiologic overload. Such results could be misinterpreted if true exposure or diet levels were not maintained at a relatively constant level.
Sampling strategies are not just a matter of numbers (for statistical aspects), but of geometry, so that the contents of a container or the entire atmosphere in a chamber is truly sampled, and of time, in accordance with the stability of the test compound. The samples must be both randomly collected and representative of the entire mass of what one is trying to characterize. In the special case of sampling and characterizing the physical properties of aerosols in an inhalation study, some special considerations and terminology apply. Because of the physiologic characteristics of the respiration of humans and of test animals, our concern is very largely limited to those particles or droplets that are of a respirable size. Unfortunately, "respirable size" is a complex characteristic based on aerodynamic diameter, density, and physiological characteristics. Unfortunately, while those particles with an aerodynamic diameter of less than 10 µm are generally agreed to be respirable in humans (i.e., they can be drawn down to the deep portions of the lungs), 3 µm in aerodynamic diameter is a more realistical value. Typically, it then becomes a matter of the calculation of measures of central tendency and dispersion statistics, with the identification of those values that are beyond acceptable limits (15).
Genotoxicity
Over the last 25 years a wide variety of tests (see ref. 96 for an overview of those available) for genotoxicity have been developed and brought into use. These tests give us a quicker and cheaper (though not as conclusive) way of predicting whether a material of interest is a mutagen, and possibly a carcinogen, than do longer-term, whole-animal studies.
How to analyze the results of the multitude of tests (Ames, DNA repair, micronucleus, chromosome abberation, cell transformation, and sister chromatid exchange, to name a few) is an extremely important question. Some workers in the field hold that it is not possible (or necessary) to perform statistical analysis and that the tests can simply be judged to be positive or not positive on the basis of whether or not they achieve a particular increase in the incidence of mutations in the test organism. Quantitations of potency are complicated by the fact that we are dealing with a nonlinear phenomenon, and although low dose of most genotoxins produce a linear response curve with increasing dose, the curve will flatten out (and even turn into a declining curve) as the higher doses provoke an acute response.
Several concepts different from those we have previously discussed need to be examined, for our

concern has now shifted from how a multicellular organism acts in response to one of a number of complex actions to how a mutational event is expressed, most frequently by a single cell. Given that we can handle much larger

numbers of experimental units in systems that use smaller test organisms, we can seek to detect both weak and strong mutagens.

Conducting the appropriate statistical analysis and using the results of such an analysis properly must start with an understanding of the biological system involved and, from this understanding, developing the correct model and hypothesis. We start such a process by considering each of five interacting factors (74, 150):

1. α, which is the probability of our committing a type I error (saying an agent is mutagenic when it is not, equivalent to our p in such earlier considered designs as the Fisher's exact test); false-positive.
2. β, which is the probability of our committing a type II error (saying an agent is not mutagenic when it is); false-negative.
3. Δ, our desired sensitivity in an assay system (such as being able to detect an increase of 10% in mutations in a population).
4. σ, the variability of the biological system and the effects of chance errors.
5. n, the single necessary sample size to achieve each of these (we can, by our actions, change only this portion of the equation) as n is proportional to

$$\frac{\sigma}{\alpha, \beta, \text{and } \Delta}$$

The implications of this are, therefore, that (a) the greater σ is, the larger n must be to achieve the desired levels of α, β, and Δ; (b) the smaller the desired levels of α, β, and/or Δ, if n is constant, the larger our σ is.

What is the background mutation level and the variability in our technique? As any good genetic or general toxicologist will acknowledge, matched concurrent control groups are essential. Fortunately, with these test systems, large n's are readily attainable, though there are other complications to this problem, which we shall consider later. An example of the confusion that would otherwise result is illustrated in the intralaboratory comparisons on some of these methods done to date, such as that reviewed by Weil (159).

New statistical tests based on these assumptions and on the underlying population distributions have been proposed, along with the necessary computational background, to allow one to alter one of the input variables (α, β, or Δ). A set that shows particular promise is that proposed by Katz (94, 95) in his two articles. He described two separate test statistics: Φ for when we can accurately estimate the number of individuals in both the experimental and control groups, and *θ* for when we do not actually estimate the number of surviving individuals in each group, we can assume that the test material is only mildly toxic in terms of killing the test organisms. Each of these two test statistics is also formulated on the basis of only a single exposure of the organisms to the test chemicals. Given this, then we may compute

$$\phi = \frac{a(M_E - 0.5) - Kb(M_C + 0.5)}{\sqrt{Kab(M_E + M_C)}},$$

where a and b are the number of groups of control (c) and experimental (e) organisms, respectively. N_C and N_E are the numbers of surviving microorganisms:

$$[K = N_E/N_C].$$

M_E and M_C are the numbers of mutations in experimental and control groups; μ_e and μ_c are the true (but unknown) mutation rates (as μ_c gets smaller, N's must increase).

We may compute the second case as

$$\theta = \frac{a(M_E - 0.5) + (M_C + 0.5)}{ab(M_E + M_C)}$$

with the same constituents.

In both cases, at a confidence level for I of 0.05, we accept that $\mu_c = \mu_e$ if the test statistic (either Φ or *θ*) is less than 1.64. If it is equal to or greater than 1.64, we may conclude that we have a mutagenic effect (at α=0.05).

In the second case (*θ*, where we do not have separate estimates of population sizes for the control and experimental groups), if K deviates widely from 1.0 (if the material is markedly toxic), we should use more containers of control organisms (tables for the proportions of each to use given different survival frequencies may be found in ref. 96). If different levels are desired, tables for *θ* and Φ may be found in Kastenbaum and Bowman (94).

An outgrowth of this is that the mutation rate per surviving cells (μc and μe) can be determined. It must be remembered that if the control mutation rate is so high that a reduction in mutation rates can be achieved by the test compound, these test statistics must be adjusted to allow for a two-sided hypothesis (48). The α levels may likewise be adjusted in each case, or tested for, if we want to assure ourselves that a mutagenic effect exists at a certain level of confidence (note that this is different from disproving the null hypothesis).

It should be noted that there are numerous specific recommendations for statistical methods designed for individual mutagenicity techniques, such as that of Bernstein et al. (13) for the Ames test.

Behavioral Toxicity

A brief review of the types of studies/experiments conducted in the area of behavioral toxicology and a classi

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_356.html[2010/10/28 18:43:25]

fication of these into groups is in order. Although there are a small number of studies that do not fit into the following classification, the great majority may be fitted into one of the following four groups. Many of these points were first covered in earlier articles (61, 63).

The first type of study is observational. Observational score-type studies are based on observing and grading the response of an animal to its normal environment or to a stimulus that is imprecisely controlled. This type of result is generated by one of two major sorts of studies. Open-field studies involve placing an animal in the center of a flat, open area and counting each occurrence of several types of activities (grooming, moving outside a designated central area, rearing, etc.) or timing until the first occurrence of each type of activity. The data generated are scalar of either a continuous or discontinuous nature but frequently are not of a normal distribution. Tilson et al. (144) presented some examples of this sort.

Observational screen studies involve a combination of observing behavior and evoking a response to a simple stimulus, the resulting observation being graded as normal or as deviating from normal on a graded scale. Most of the data so generated are rank in nature, with some portions being quantal or interval. Irwin (89) and Gad (61) have presented schemes for the conduct of such studies, which became the basis of the commonly used functional observational battery. Table 7.9 gives an example of the nature (and of one form of statistical analysis) of such data generated after exposure to one material.

The second type of study is one that generates rates of response as data. The studies are based on the number of responses to a discrete controlled stimulus or are free of direct connection to a stimulus. The three most frequently measured parameters are licking of a liquid (milk, sugar water, ethanol, or a psychoactive agent in water), gross locomotor activity (measured by a photocell or elec tromagnetic device), or level pulling. Examples of such studies have been published by Annau (6) and Norton (114). The data generated are most often of a discontinuous or continuous scalar nature and are often complicated by underlying patterns of biological rhythm.

The third type of study generates a variety of data that are classified as error rate. These are studies based on animals learning a response to a stimulus or memorizing a simple task (such as running a maze or a Skinner box-type shock avoidance system). These tests or trials are structured so that animals can pass or fail on each of a number of successive trials. The resulting data are quantal, though frequently expressed as a percentage.

The final major type of study is that which results in data that are measures of the time to an endpoint. They are based on animals being exposed to or dosed with a toxicant and the time taken for an effect to be observed is measured. Usually the endpoint is failure to continue to be able to perform a task and can, therefore, be death, incapacitation, or the learning of a response to a discrete stimulus. Burt (22) and Johnson et al. (91) present data of this form. The data are always of a censored nature (i.e., the period of observation is always artificially limited, as in measuring time-to-incapacitation in combustion toxicology data, where animals are exposed to the thermal decomposition gases to test materials for a period of 30 minutes). If incapacitation is not observed during these 30 minutes, it is judged not to occur. The data generated by these studies are continuous, discontinuous, or rank in nature. They are discontinuous because the researcher may check, or may be restricted to checking for the occurrence of the endpoint only at certain discrete points in time. On the other hand, they are rank if the periods to check for occurrence of the endpoint are far enough apart, in which case one may actually only know that the endpoint occurred during a broad period of time, but not where in that period.

Table 7.9 Functional Observational Battery parameters showing significant differences between treated and control groups

	Rats (18-crown-6 animals given 40 mg/kg i.p.)				
Parameter	Control sum of ranks	Nc	18-crown-6 treated sum or ranks	NT	Observed difference in treated animals (as compared to controls)
Twitches	55.0	10	270.0	15	Involuntary muscle twitches
Visual placing	55.0	10	270.0	15	Less aware of visual stimuli
Grip strength	120.0	10	205.0	15	Considerable loss of strength, especially in hind limbs
Respiration	55.0	10	270.0	15	Increased rate of respiration
Tremors	55.0	10	270.0	15	Marked tremors

All parameters above are significant at $p<0.05$.

Page 358

There is a special class of test that should also be considered at this point—the behavioral teratology or reproduction study. These studies are based on dosing or exposing either parental animals during selected periods in the mating and gestation process or pregnant females at selected periods during gestation. The resulting offspring are then tested for developmental defects of a neurological and behavioral nature. Analysis is complicated by a number of facts:

(1) The parental animals are the actual targets for toxic effects, but observations are made on offspring.
(2) The toxic effects in the parental generation may alter the performance of the mother in rearing its offspring, which in turn can lead to a confusion of prenatal and postnatal effects.
(3) Different capabilities and behaviors develop at different times (discussed further later).

A researcher can, by varying the selection of the animal model (species, strain, sex), modify the nature of the data generated and the degree of dispersion of these data. In behavioral studies particularly, limiting the within-group variability of data is a significant problem and generally should be a highly desirable goal.

Most, if not all, behavioral toxicology studies depend on at least some instrumentation. Very frequently overlooked here (and, indeed, in most research) is that instrumentation, by its operating characteristics and limitations, goes a long way toward determining the nature of the data generated by it. An activity monitor measures motor activity in discrete segments. If it is a "jiggle cage"-type monitor, these segments are restricted so that only a distinctly limited number of counts can be achieved in a given period of time and then only if they are of the appropriate magnitude. Likewise, technique can also readily determine the nature of the data. In measuring response to pain, for example, one could record it as a quantal measure (present or absent), a rank score (on a scale of 1–5 for decreased to increased responsiveness, with 3 being "normal"), or as scalar data (by using an analgesia meter, which determines either how much pressure or heat is required to evoke a response).

Study design factors are probably the most widely recognized of the factors that influence the type of data resulting from a study. Number of animals used, frequency of measures, and length of period of observation are three obvious design factors that are readily under the control of the researcher and which directly help to determine the nature of the data.

Finally, it is appropriate to review each of the types of studies presently seen in behavioral toxicology, according to the classification presented at the beginning of this section, in terms of which statistical methods are used now and what procedures are recommended for use. The recommendations, of course, should be viewed with a critical eye. They are intended with current experimental design and technique in mind and can only claim to be the best when one is limited to addressing the most common problems from a library of readily and commonly available and understood tests.

Table 7.10 summarizes this review and recommendation process.

Carcinogenesis

The experimental evaluation of potentially carcinogenic substances is generally based on the exposure of nonhuman species to some relatively high dose and an attempt is made to predict the occurrence and level of

Table 7.10 Overview of statistical testing in behavioral toxicology: Those tests commonly used[a] as opposed to those recommended

Type of observation	Most commonly used procedures	Suggested procedures
Observational scores	Either Student's t-test or one-way ANOVA	Kruskal-Wallis nonparametric ANOVA or Wilcoxon Rank sum
Response rates	Either Student's t-test or one-way ANOVA	Kruskal-Wallis ANOVA or one way ANOVA
Error rates	ANOVA followed by a post-hoc test	Fisher's exact, or R×C chi-square, or Mann-Whitney U-test
Times to endpoint	Either Student's t-test or one-way ANOVA	ANOVA then a post-hoc test or Kruskal-Wallis ANOVA
Teratology and reproduction	ANOVA followed by a post-hoc test	Fisher's exact test, Kruskal-Wallis ANOVA, or Mann-Whitney U-test

[a]These are the most commonly used procedures. The reader need only look at the example articles cited in this chapter to verify this fact.

aP=Power for each comparison of treatment group with background tumor incidence.

tumorogenesis in humans at much lower levels. This topic is addressed in Chapter 8 as well as in Gad (62).

The single most important statistical consideration in the design of carcinogenicity bioassays in the past was based on the point of view that what was being observed and evaluated was a simple quantal response (cancer occurred or it didn't) and that a sufficient number of animals needed to be used to have reasonable expectations of detecting such an effect. Though the single fact of whether or not the simple incidence of neoplastic tumors is increased due to an agent of concern is of interest, a much more complex model must now be considered. The time to tumor, patterns of tumor incidence, effects on survival rate, and age at first tumor all must now be included in a model.

Bioassay Design

As presented earlier in the section on experimental design, the first step that must be taken is to clearly state the objective of the study to be undertaken. Carcinogenicity bioassays have two possible objectives.

The first objective is to detect possible carcinogens. Compounds are evaluated to determine if they can or cannot induce a statistically detectable increase in tumor rates over background levels, and only by happenstance is information generated that is useful in risk assessment. Most older studies have such detection as their objective. Current belief is that at least two species must be used for detection, though the necessity of a second species (the mouse) is increasingly questioned.

The second objective for a bioassay is to provide a range of dose response information (with tumor incidence being the response) so that a risk assessment may be performed. Unlike detection, which requires only one treatment group with adequate survival times (to allow expression of tumors), dose response requires at least three treatment groups with adequate survival. We will shortly look at the selection of dose levels for this case; however, given that the species is known to be responsive, only one species of animal need be used for this objective.

To address either or both of these objectives, three major types of study designs have evolved. First is the classical skin painting study, usually performed in mice. A single, easily detected endpoint (the formation of skin tumors) is evaluated during the course of the study. Though dose response can be evaluated in such a study (dose usually being varied by using different concentrations of test material in volatile solvent), most often detection is the objective of such a study. Though others have used different frequencies of application of test material to vary dose, there are data to suggest that this only serves to introduce an additional variable (166). Traditionally, both test and control groups in such a test consist of 50 to 100 mice of one sex (males being preferred because of their very low spontaneous tumor rate). This design is also used in tumor initiation/promotion studies.

The second common type of design is the original National Cancer Institute (NCI) bioassay. The announced objective of these studies was detection of moderate to strong carcinogens, though the results have also been used in attempts at risk assessment. Both mice and rats were used in parallel studies. Each study used 50 males and 50 females at each of two dose levels (high and low) plus an equal-sized control group. The National Toxicology Program (NTP) has subsequently moved away from this design because of a recognition of its inherent limitations. More animals per group and more dose groups are now used.

Table 7.12 Average number of animals needed to detect a significant increase in the incidence of an event (tumors, anomalies, etc.) over the background incidence (control) at several expected incidence levels using the Fisher exact probability test (p=0.05)

Background incidence, %	Expected Increase in Incidence, %					
	0.01	0.1	1	3	5	10
0	46,000,000a	460,000	4,600	511	164	46
0.01	46,000,000	460,000	4,600	511	164	46
0.1	47,000,000	470,000	4,700	520	168	47
1	51,000,000	510,000	5,100	570	204	51
5	77,000,000	770,000	7,700	856	304	77
10	100,000,000	1,000,000	10,000	1,100	400	100
20	148,000,000	1,480,000	14,800	1,644	592	148
25	160,000,000	1,600,000	16,000	1,840	664	166

aNumber of animals needed in each group, controls as well as treated.

Finally, there is the standard industrial toxicology design, which uses at least two species (usually rats and mice) in groups of no fewer that 100 males and females each. Each study has three dose groups and at least one control. Frequently, additional numbers of animals are included to allow for interim terminations and histopathological evaluations. In both this and the NCI design, a long list of organs and tissues are collected, processed, and examined microscopically. This design seeks to address both the detection and dose response objectives with a moderate degree of success.

Selecting the number of animals to use for dose groups in a study requires consideration of both biological (expected survival rates, background tumor rates, etc.) and statistical factors. The prime statistical consideration is reflected in Table 7.11. It can be seen in this table that if, for example, we were studying a compound that caused liver tumors and were using mice (with a background or control incidence of 30%), we would have to use 389 animals per sex per group to be able to demonstrate that an incidence rate of 40% in treatment animals was significant compared to the controls at the p=0.05 level.

Perhaps the most difficult aspect of designing a good carcinogenicity study is the selection of the dose levels to be used. At the start it is necessary to consider the first underlying assumption in the design and use of animal cancer bioassays—the need to test at the highest possible dose for the longest practical period.

The rationale behind this assumption is that though humans may be exposed at very low levels, detecting the resulting small increase (over background) in the incidence of tumors would require the use of an impractically large number of test animals per group. This point is illustrated by Table 7.11, where, for instance, while only 46 animals (per group) are needed to show a 10% increase over a zero background (i.e., a rarely occurring tumor type), 770,000 animals (per group) would be needed to detect a tenth of a percent increase above a 5% background. As we increase dose, however, the incidence of tumors (the response) will also increase until it reaches the point where a modest increase (say, 10% over a reasonably small background level (say, 1%)) could be detected using an acceptably small-sized group of test animals (in Table 7.12 we see that 51 animals would be needed for this example case). There are, however, at least two real limitations to the highest dose level. First, the test rodent population must have a sufficient survival rate after receiving a lifetime (or two years) of regular doses to allow for meaningful statistical analysis. Second, we really want the metabolism and mechanism of action of the chemical at the highest level tested to be the same as at the low levels, where human exposure would occur. Unfortunately, toxicologists usually must select the high dose level based only on the information provided by a subchronic or range-finding study (usually 90 days in length), but selection of either too low or too high a dose will make the study invalid for detection of carcinogenicity and may seriously impair the use of the results for risk assessment.

There are several solutions to this problem. One of these solutions has been the rather simplistic approach of the NTP Bioassay Program, which is to conduct a 3-month range-finding study with sufficient dose levels to establish a level that significantly (10%) decreases the rate of body weight gain. This dose is defined as the maximum tolerated dose (MTD) and is selected as the highest dose. Two other levels, generally one half MTD and one quarter MTD, are selected for testing as the intermediate and low-dose levels. In many earlier NCI studies, only one other level was used.

The dose range-finding study is necessary in most cases, but the suppression of body weight gain is a

scientifically questionable bench mark when dealing with establishment of safety factors. Physiologic, pharmacologic, or metabolic markers generally serve as better indicators of systemic response than body weight. A series of well-defined acute and subchronic studies designed to determine the "chronicity factor" and to study onset of pathology can be more predictive for dose setting than body weight suppression.

Also, the NTP's MTD may well be at a level where the metabolic mechanisms for handling a compound at real-life exposure levels have been saturated or overwhelmed, bringing into play entirely artifactual metabolic and physiologic mechanisms (68). The regulatory response to questioning the appropriateness of the MTD as a high-dose level (82) has been to acknowledge that occasionally an excessively high dose is selected, but to counter by saying that using lower doses would seriously decrease the sensitivity of detection.

QUESTIONS

1. If the results of an analysis of variance establish that differences between groups is significant at the $p \leq 0.05$ level, what are the chances that the two groups are not different?

a) 5% or less. That is, one in twenty or less.

2. If a set of 17 measured values are ranked in ascending order, the median value is which value in order?

a) The 9th value.

3. Analysis of variance assumes that the data it is evaluating is from a normally distributed population. The test is robust for deviation from this assumption if what?

a) The sample size is large enough.

4. In what manner does a lag profit transformation of a dose response curve alter its shape?

a) It linearizes it.

5. Does the occurrence of outliers in a sample increase or decrease the sensitivity of any hypothesis testing (such as ANOVA)?

a) Decreases Sensitivity.

Groups of incidence data are usually compared by contingency table tests (such as Fishers Extract Test) of ANOVA?

a) Contingency table analysis.

The purpose of this chapter is to describe the scientific basis for extrapolation of toxicity findings in laboratory animals to predict outcomes in human populations. Such extrapolation is often said to comprise two components, one qualitative in nature, the second quantitative. Qualitative extrapolations generally concern the nature of the toxic response (are the specific toxicity endpoints observed in test animals also expected in similarly exposed human beings?), while quantitative extrapolations concern issues such as the magnitude and duration of the dose at which human beings and test animals are expected to be at equal risk of toxicity. Although both types of extrapolation are important, scientific understanding of the basis for quantitative extrapolations across species is more limited than is the basis for qualitative extrapolations. At the same time, because results from animal toxicity studies have become such important determinants of regulatory and other public health protection activities, and because the latter typically require the establishment of quantitative limits on human exposure, questions regarding quantitative extrapola tions have come to be seen as ultimately of greater significance than those that are purely qualitative in character. Thus, as in many other areas in which science plays a significant role in the development of social policies, the questions that are of most importance tend to be those about which science has the least clear answers. It is therefore no surprise that there is so much public skepticism about the predictions of toxicologists and risk assessors.

The scientific basis for quantitative extrapolations across species is not, however, as feeble as it is sometimes made out to be by those who would minimize the importance of toxicology, and science in general, in regulatory and public health decisions. The principal purpose of this chapter is to describe that basis as it is understood today, and to point to the many active areas of research that are devoted to furthering that understanding. As has been the case in the evolution of other areas of science, the greatest understanding comes with the ability to provide quantitatively accurate, empirical descriptions

of physical and biological phenomena, and to build from these gen

erally applicable, predictive models of those phenomena. It is true, of course, that quantitative understanding never provides a complete description of these phenomena—the qualitative aspects will always be necessary to complete the picture.

Following brief discussions of the historical context of and need for interspecies extrapolation, and a description of the problem, the chapter continues with five sections on different aspects of the problem of extrapolation (these are outlined in the section on the need for extrapolation), and concludes with a discussion of the overall strategy for scientifically based, interspecies extrapolation.

HISTORICAL CONTEXT

The use of experimental animals to study biological phenomena arose in the mid 19th century, but their modern use in toxicology had its origin during the third decade of the 20th century, when several investigators began to study the effects of vitamins, minerals, and other food constituents. At about the same time, efforts were initiated to identify and breed species and strains of laboratory animals whose genetic and physiological characteristics, and nutritional requirements, could be sufficiently well defined that they could be reliably used in controlled experiments. By the mid-1930s a number of government and industrial laboratories in the United States, Europe, and Japan had begun the fairly routine use of laboratory animals to study occupational chemicals, and soon thereafter, reports of studies of food additives, pesticides, and pharmaceutical agents began to appear in the literature. These early efforts to use laboratory animals to investigate chemical toxicity were no doubt motivated by the belief that responses in animals were useful indicators of potential human responses, but there was little explicit discussion of how data from these studies should be used for that purpose.

Two FDA scientists, Arnold Lehman and O.Garth Fitzhugh, were perhaps the first toxicologists to deal explicitly with the issue. In a short but famous paper published in 1954 (39), the two scientists described the basis for the belief that results from animal studies could be used qualitatively to predict responses in humans, but that quantitative predictions were more problematic. To deal with this problem, Lehmann and Fitzhugh postulated that "average" humans would likely respond to a chemical exposure at a lower dose than would a group of experimental animals, and that within the human population, some individuals would respond at lower doses than would the "average" person. In modern parlance, these authors recognized that the *variability* in response at a given dose was likely to be much greater in a highly diverse human population than it is in a group of inbred, and otherwise homogeneous and healthy, experimental animals. They further recognized that if toxicology data from experimental animals were to be used to establish protective limits1 (what Lehman and Fitzhugh called "safe levels") for humans, it would be necessary to "adjust" the experimental results. From their discussion and review arose the concept of "safety factors": a factor of 10 was proposed to adjust (downward) the animal dose (specifically the no-observed-adverse-effect level, NOAEL) to estimate the NOAEL for the "average" human, and another factor of 10 to estimate the NOAEL for the "most sensitive" members of the human population. They offered the term *acceptable daily intake* (ADI) as their notion of a "safe level" of chronic chemical exposure for the general population, and the ADI was to be obtained by dividing experimental NOAELs from chronic animal toxicology studies by a factor of 100 (10×10). This system, though modified in several significant ways, remains in place today. It is used to establish various protective limits for chemical exposures in the general population. It is interesting that in the 1954 Lehman-Fitzhugh paper, an attempt is made to find an empirical basis for the two factors of 10, but the authors recognized that the database available for such an analysis was extremely limited (39).

Although the Lehman-Fitzhugh approach to quantitative extrapolation recognized the phenomena of inter-and intraspecies variability, it assumed implicitly that no toxic response was likely to occur in any individual unless exposures exceeded some threshold dose. The problem was to define that threshold for a large and diverse human population when the only significant data available arose from experimental studies. During the 1940s and 1950s an influential body of scientists working in the area of experimental carcinogenesis espoused the view that this particular class of toxic agents behaved biologically in ways that called into question the viability of the threshold concept (45). Government policies incorporated this view, which was until the 1970s captured by the phrase *no safe level*. By that time regulators saw that such a policy provided little useful guidance for decision making, and turned to the scientific literature to identify specific methodologies that could be applied to animal carcinogenicity data to estimate low-dose risks to humans for substances that might act by "no-threshold" mechanisms (45). The concept of safety also took a turn at this time, as scientists and decision makers recognized

1*Protective limits* is our term, used through the chapter as a description of any quantitative measure that is derived from toxicology or epidemiology data and that is intended to establish the upper limit on

exposure that is thought to be without significant risk of toxicity to humans. It is recognized that it is not possible to provide absolute assurance that such limits will protect every person in a population; moreover, exposures greater than these limits may pose no risk to many persons. The term is used here as a simple, one-phrase description of a concept that has in practice unfortunately attracted many different names (described later).

that safety could be defined only in relative terms. In an influential 1983 study issued by the National Research Council, the notion arose that decisions regarding levels of risk that were sufficiently small to ensure protection of the public health properly fell within the domain of *risk management:* Scientists have the task of assessing toxic risks and describing how their magnitudes change with exposure, but policymakers have the task of deciding how much risk reduction is needed to protect public health, and of how any needed risk reduction is to be achieved (45, 48).

As these developments regarding the uses of toxicology data in decision making evolved, so did the work of experimental toxicologists. Since the 1950s, animal studies have provided increasingly complete data on the effects of chemical exposures. Thus, increasing amounts of information have developed on the influences of dose, duration, and routes of exposure, on the roles of chemical kinetics and metabolism, and on the biological and molecular mechanisms underlying the production of toxicity. Experimentalists continue to find useful ways to examine the influences of exogenous compounds on a greater variety of targets, including complex systems of the body. Alongside the work of toxicologists must now be placed developments in the field of epidemiology, because these offer increased possibilities for testing hypotheses generated in the toxicology laboratory.

These various developments, which emerge more completely in the discussions to follow, place greater demands on the risk managers who must use the results of risk assessments in the formulation of health protection policies. At the same time, they provide better tools for risk assessment—of which interspecies extrapolation is a highly important component—and are proving to be of value in improving the scientific basis for risk-based decision making. This is, after all, what toxicology is about.

THE NEED FOR EXTRAPOLATION

Experimental and Epidemiological Methods and Their Limits

In the best of all possible worlds there would be no need for any form of extrapolation. Second best would be a world in which well-founded predictive models were available to extrapolate from one set of conditions to another. In the area of predictive toxicology, we now live in a third-best world, and perhaps our goal is to achieve the second best. The "best" world is probably not within our reach.

Why is extrapolation necessary? The answer to this question may seem so obvious that it is unnecessary to offer an explicit discussion. But because so many observers see science as a purely empirical subject in which all forms of extrapolation are merely speculative (a highly naive view of science), or as a subject in which extrapolation is justified only when well-supported predictive models have come to be available (a more credible and, indeed, a proper view of science), the question of "why engage in extrapolation?" is not as easy to answer as it might appear to be.

Given that there is a social need, expressed in many federal and state laws, to protect people from the toxic properties of chemicals in the environment, in foods, consumer products, medicines, and so on, it is necessary to rely upon one or both of the two basic methods available for acquiring toxicological data —the epidemiological and the experimental. Both have strengths and limits (Table 8.1), but neither method is capable of providing direct measurements of toxic risks that are applicable in all situations of potential interest. Animal studies allow us to understand toxicity characteristics of a chemical before human exposure is allowed to occur, whereas the epidemiological method generally does not. They also allow much more thorough examination of the effects of chemical exposure, under a much wider variety of conditions, than do the methods of epidemiology. They usually provide better information on dose-response characteristics, and also allow causal relations to be more readily established. They suffer, of course, one large disadvantage, in that they do not reveal responses directly in the species of interest. Thus, extrapolation from animal data is necessary in many if not most cases if anything at all is to be said about potential human risk and protection of human populations.

Both methods, experimental and epidemiological, suffer from additional limitations. Most importantly, the information they yield, even under the best conditions, is restricted to that portion of the dose-response curve that is within the detection power of the method used; in both cases the size of the population that can be studied, along with some other aspects of that population, is the principal determinant of detection power. Thus, empirical dose-response data will be limited to the relatively "high dose-high risk" portion of the dose-response curve. Most conditions about which toxicity dose-response data are sought concern exposures and doses that fall outside of (well below) the observable range, and therefore outside of the area of direct measurement.

It is also important to emphasize that although epidemiological data derive from studies in humans, there always remains the question of the representativeness of the studied population for the population whose risk is being assessed. The typical problem concerns the use of information obtained in occupational cohorts for assessing toxic risk in the general population.

Other extrapolation issues arise and cannot be avoided, because it is often necessary to reach decisions in the absence of complete data. The most common problems

page_368

Table 8.1 Comparison of epidemiology and animal studies for identifying toxic properties

	Epidemiology studies	Animal studies
Opportunity to conduct study	Often not possible	Generally possible
Opportunity to obtain information prior to human exposure	No	Yes
Time requirements	Years to decades	Weeks to years
Species of interest	Yes[a]	No
Cause-effect determination	Difficult	Not as difficult
Opportunity to obtain quantitative dose-response data	Not frequently	Always

[a]Note that epidemiology studies may not provide data on both sexes or on all relevant subgroups of the human population.

arise when it is necessary to assess risk for a given route of exposure when data are available only for another route, and when the assessment concerns risks associated with chronic exposures when only relatively short-term data on toxicity are available.

Thus, if toxicity and epidemiology data are to be used at all to assess human risk and to establish protective limits, extrapolations will be necessary, sometimes several types.

Using Epidemiological and Experimental Data: Distinguishing "Prudence" From "Science"

When engaging in any form of extrapolation for which a reliable, well-established model or empirical basis is not available, judgments must be made that, strictly speaking, go beyond the realm of pure science (45). If such judgments are not introduced, then, as described earlier, no useful conclusions can be reached. Because of the social need to provide conclusions, however tentative and uncertain, judgments must be introduced, whether they concern qualitative or quantitative issues. The National Research Council (NRC), in its 1983 report on risk assessment in the federal government (45) and also in its 1994 report on the same subject (48) recommended that regulatory agencies use the best available science, but that the agencies also adopt guidelines that would specify what judgements they would make (these have come to be loosely called "defaults") to fill knowledge and data gaps. The NRC notion was that these defaults would be specified in advance, in the form of guidelines, and that they would be applied consistently, in specific risk assessments, to avoid case-by-case "manipulations" and to ensure explicitness in the assessment. The NRC also recommended flexibility in the use of defaults, so that chemical-specific data, if reliable, could be used in specific cases to replace one or more generic defaults.

The choice of defaults is a difficult topic, having both scientific and policy components. The U.S. Environmen tal Protection Agency (EPA) guidelines for carcinogen risk assessment can be consulted for information on the choice of defaults (73). The emphasis in this chapter is on the scientific basis for extrapolation and its limits, and the regulatory defaults are discussed only in passing. It is important, however, to attempt to distinguish what is in the area of well-established science from what is a "science-policy" choice. The truth is that all science is accompanied by uncertainty, and that there is no sharp distinction between what is known with such high certainty that little or no judgment is called for, and that which is insufficiently certain to stand on its own. (It would be interesting to poll the community of toxicologists on how much of any decision to extrapolate from experimental animals to humans they may think is based upon "science," and what part is based on "prudence"—"I'm not sure of its relevance to people but I'll use it anyway, because I want to be careful.")

DESCRIPTION OF THE PROBLEM

The several types of extrapolations necessary to assess risks of toxicity in human populations from data obtained in experimental animals are described in the next five sections of this chapter, along with what are called the empirical and biological bases for each. Both qualitative and quantitative aspects are described, with emphasis on the latter.

Cross-species extrapolations are those pertaining to the attempt to describe expected toxic responses and their relationship to dose in human populations based on responses and their relationship to dose observed experimentally in animals.

Within-species extrapolations are those pertaining to the attempt to describe the expected variability in response within human populations, based either on observations in limited segments of that

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_368.html[2010/10/28 18:43:32]

population, or on responses predicted for limited segments of that population from observations in experimental animals.

Cross-dose extrapolations are those pertaining to the attempt to describe toxic responses and their relationship to dose for the range of the dose-response relationship that falls below the range that is subject to direct measurement, and within the range expected to be experienced by the population that is the subject of the risk assessment.

Cross-route extrapolations are those pertaining to the attempt to describe expected toxic responses and their relationships to dose in populations exposed by one route, based on responses and their relations to dose observed when exposure occurs by another route.

Cross-time extrapolations are those pertaining to the attempt to describe toxic responses and their relationships to dose for various exposure durations, based on responses and their relationships to dose observed over more limited exposure durations.

In each case the empirical and biological bases for such extrapolations are summarized. By *empirical* is meant an analysis based upon comparisons made in more limited circumstances of actual observations relevant to the extrapolation being considered. Thus, for example, compilations and comparisons of human and animal dose-response data for several carcinogens are available, and these comparisons allow at least limited generalizations to be made regarding cross-species extrapolations. By *biological* bases is meant the use of basic knowledge in biology to provide support for particular forms of extrapolation. Both the empirical and biological bases are limited, but often inferences drawn from them converge and thus may provide support for some aspects of extrapolation.

The emphasis in this chapter is on quantitative extrapolations and on the types of scientific data and theories that are regarded as the basis for such extrapolations. As noted in the concluding sections, practical applications of many of the issues discussed in the following are not yet generally available; the thrust of the discussion thus concerns the directions necessary to improve the scientific basis for human risk assessment.

CROSS-SPECIES EXTRAPOLATION

Defining the Problem

When extrapolating toxicological data from one species to another, it is necessary to consider the various factors that may differentially affect the response of dif ferent species to the exposure of interest. As a first approximation, of course, for both cross-species and within-species extrapolation, it is common to normalize the toxicant dose to the body weight, and express it as milligrams per kilogram body weight per day. This approach assumes that it is the concentration of the toxicant in the body or at the target site (or some measure directly proportional to it) that determines the magnitude of the toxic effect. Although this appears to address at least one of the differences between species (body size), there are many examples in the literature showing that direct extrapolation simply on the basis of body weight is not accurate. Other aspects of differences among species need to be considered.

Two broad, overlapping classes of factors may affect differential responses: those related to the "effective dose" of the toxicant (determined in part by its pharmacokinetic and metabolic behavior), and those related to the inherent sensitivity of different species. In the absence of differences in inherent sensitivity (often called pharmacodynamic2 differences), it is generally assumed that different species will show similar responses when exposed to the same effective dose of the toxicant. The effective dose may in turn be influenced by species differences in body size, life span, anatomy and physiology, and pharmacokinetics and metabolism. For a direct-acting toxicant that follows first-order kinetics, the effective dose may be simply proportional to the administered dose. For a chemical with a more complex pattern of kinetics and metabolism to generate a reactive metabolite, pharmacokinetic modeling may be needed to accurately predict the effective dose.

Two general approaches have been used to evaluate methods for interspecies extrapolation: empirical, and biologically based. Empirical approaches rely on collection of data from multiple species exposed to the same substances under comparable conditions, and evaluation of the data to identify consistent relationships among species that permit the prediction of the magnitude of the response in one species (typically humans) based on data from another species. This approach has the advantage of simplicity, but does not readily allow consideration of chemical-specific factors that may affect interspecies scaling. Biologically based approaches make use of scientific knowledge of factors that may influence interspecies scaling, such as anatomical and physiological parameters and especially pharmacokinetics, metabolism, and mechanism of action.

2 The terms *pharmacokinetic* and *pharmacodynamic* derive from the pharmacological sciences. They have been retained by many toxicologists to describe the behavior of substances having toxic effects.

Some have advocated the terms *toxicokinetics* and *toxicodynamics*, but, though those terms seem more descriptive, they have not become widespread in use.

Page 370
Empirical Approaches
Empirical approaches to cross-species scaling have been studied since the end of the nineteenth century, when Rubner (62) noted that oxygen utilization and caloric expenditure scaled among dogs of different sizes approximately on the basis of body surface area more closely than simply on body mass. Subsequently, this work was extended to other species and other parameters, including the development of criteria for selecting doses for cancer chemotherapeutic drugs (26, 53). These authors noted that, for a number of chemotherapeutic drugs, the repeat-dose LD10 in mice, rats, and hamsters (treated daily for 5 days), the maximum tolerated dose in dogs and monkeys (the highest daily dose that killed no animals), and the maximum tolerated dose used clinically in humans were more closely comparable when the doses were expressed on a milligrams per square meter body surface area basis than when expressed on the basis of body weight. Because of the difficulty in accurately measuring body surface area, as an approximation based on the relationship between the mass and surface area of a sphere, this surface-area scaling is generally approximated as (body weight)$^{2/3}$.
A more recent reevaluation of these and other repeat toxicity data by Travis and White (69), however, suggested that (body weight)$^{3/4}$ scaling gave a better correlation. Travis and White (69) reanalyzed the repeat toxicity data in mouse, rat, dog, rhesus monkey, and human with 14 chemotherapeutic drugs described by Freireich et al. (26), and similar data in mouse, hamster, rat, dog, monkey, and human for an additional 13 chemotherapeutic drugs. Based on all of these data sets, and the use of a multiple linear regression model, the exponent of body weight giving the best correlation (r^2=.96) among species was 0.73, with 95% confidence bounds of .69 to 0.77.
Recently, Rhomberg and Wolff (59) reported an analysis of cross-species scaling for acute oral LD50 values covering ten mammalian species and a wide range of chemical types. They used data from the NIOSH Registry of Toxic Effects of Chemical Substances (RTECS) database, which contains information on over 135,000 substances. Several thousand of these had oral LD50 data from at least two species to permit comparisons. Overall, based on the log-log scatter plots of LD50 values in pairs of species (e.g., rat vs. mouse; mouse vs. rabbit), and log-log plots of mean ratio of LD50 values versus body weight for all species-pair comparisons, body-weight scaling appeared to give a better correlation among species than did body surface area, (body weight)$^{2/3}$ or (body weight)$^{3/4}$. The authors suggested that the difference between the apparent optimal scaling procedure for acute lethality (mg/kg) and that for repeat-dose lethality [(mg/kg$^{2/3}$) or (mg/kg$^{3/4}$)] may be related to differences in the mechanism of lethality. With single acute doses, the lethal dose may depend upon the level of defense capacities or reserves, proportional to body mass; with repeated exposure, survival may, to a larger extent, be a function of repair or replacement rate, which may show scaling patterns more like those for basal metabolic rate or other rates. As discussed later, these rates tend to scale across species as a function of body surface area or (body weight)$^{3/4}$.
Empirical approaches have also been used extensively in attempts to identify the most appropriate approach for scaling of cancer data between species (2, 15, 28). In one of the most extensive of these studies, Allen et al. (2) evaluated 23 chemicals for which data permitted quantitative estimation of cancer potency in humans and animals. As their measure of "potency," Allen et al. (2) calculated "risk-related doses" (RRDs), defined as the average daily dose per kilogram body weight that would be expected to result in an extra cancer risk of 25% over a lifetime. Allen et al. examined several different ways of expressing the dose, different scaling procedures, different subsets of animal data (restricted by experimental design, route of exposure, species, sex, tumor types), different statistical measures (maximum likelihood estimates and lower confidence limits on RRD), and different ways of considering results from multiple studies of the same chemicals (median response, most sensitive species/sex combination). When the logarithms of the RRDs derived from epidemiological studies were plotted against the logarithms of the predicted RRDs from animal studies, the scaling procedure giving the strongest correlation (by a slight margin) between humans and animals was scaling on the basis of body weight. However, there were wide variations in the apparent relative potency for individual chemicals, and given the uncertainties in the experimental and epidemiological data, it was not possible to rule out surface-area scaling [(body weight)$^{2/3}$], or some intermediate procedure, such as (body weight)$^{3/4}$, as being appropriate. Wide variations in apparent relative potency were also reported in the other comparisons (14, 15, 28). These studies considered mostly potency comparisons between rats and mice. On average in these studies, rats appeared to be slightly more sensitive than mice when compared on a body-weight basis, as would be expected if the "correct" scaling was on the basis of (body weight)$^{2/3}$ or (body weight)$^{3/4}$. Because of the small sample sizes and wide variation for individual chemicals, however, these comparisons are of limited predictive value.

The U.S. Environmental Protection Agency (72) published an extensive discussion on the selection of a default scaling procedure for cancer risk assessment based on these and other considerations. Its conclusion was that, although there was considerable uncertainty in the

Page 371

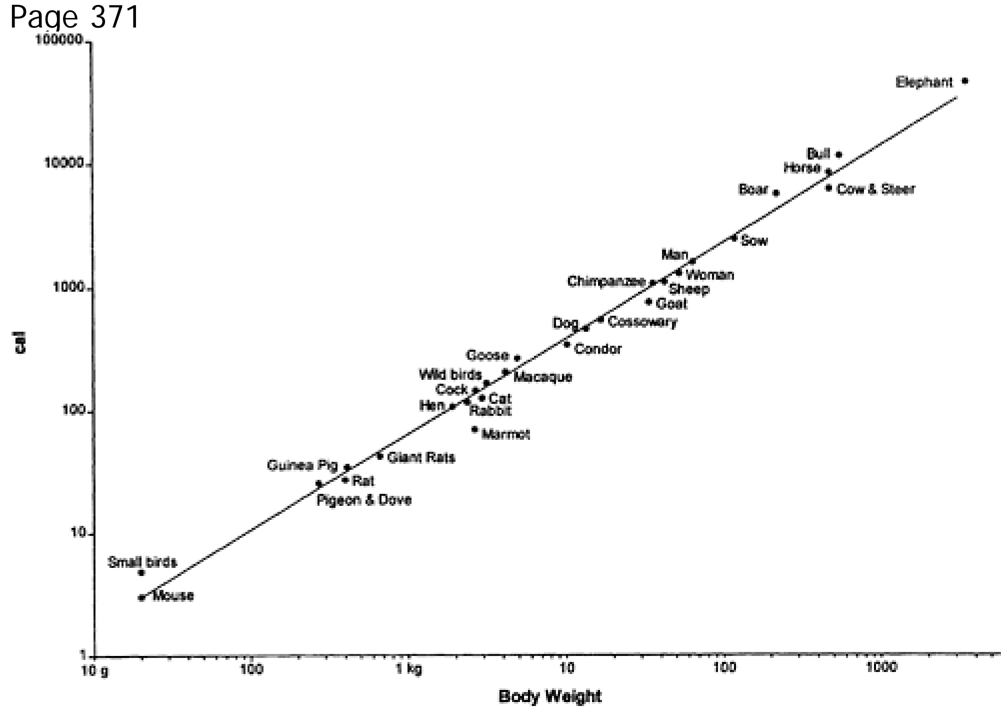

FIG. 8.1. Benedict's (7) mouse-to-elephant graph showing the relationship between species body weight and basal metabolic rate.

selection of any generic scaling procedure, the balance of evidence supported the use of (body weight)3/4 as a general procedure when no chemical-specific data provided support for an alternative procedure.

Biologically Based Approaches

Allometry

The work of Rubner (62) and others (e.g., refs. 1, 34, 35) on the relationship between body size and metabolism, mentioned previously, led to the study of allometry, the relationships between body weight and various biological and physiological parameters. A large number of biological and physiological parameters have been found to show a relation to body weight of the form:

$$Y=aWb$$

where *Y* is the biological parameter of interest (organ size, blood flow rate, basal metabolic rate, etc.), and *a* and *b* are constants relating *Y* to body weight *(W)*.

When the exponent *b* in the allometric equation is 1.0, cross-species scaling is based on relative body-weights. When it is 0.67, the biological or physiological measure is said to scale on the basis of relative surface areas.

In examining a wide number of measurements, measures of size (organ weights, blood volumes, etc.) tended to show an exponent *(b)* of approximately 1.0, while measures of rates (ventilation rate, basal metabolic rate, drug clearance rate, etc.) typically showed values closer to 0.67 (1). There was considerable variation in the best estimate of the exponent, *b,* for different parameters, and other authors have suggested that the value of *b* for metabolic and other rates falls closer to 0.75 (11, 54, 64). Figure 8.1, for example, shows a plot of basal metabolic rate versus body weight for warm blooded animals, ranging from mouse to elephant (7). The slope of this line corresponds to a *b* value of 0.76 (see ref. 19a).

Pharmacokinetics

Parameters affecting pharmacokinetic differences across species (organ sizes, physiological and metabolic

rates) are also subject to allometric scaling. As a result, provided a chemical follows the same pharmacokinetic pathways in different species, pharmacokinetic scaling will also tend to follow allometric scaling. Travis et al. (70) have suggested that for toxicants that are metabolically inactivated, scaling on the basis of (body weight)$^{3/4}$ provides the most accurate scaling across species. For reactive chemicals that are spontaneously inactivated, body weight scaling may provide a more accurate scaling metric.

All of the preceding discussion has centered on determining a generic procedure for extrapolating among species. As noted earlier, one of the most critical factors in cross-species extrapolation is the effective dose of the toxicant at the site of action. This is the purview of pharmacokinetic modeling. The use of pharmacokinetic modeling, particularly physiologically based pharmacokinetic (PBPK) modeling, in exposure estimation for risk assessment has been extensively discussed (46, 69a, 70) and is continually being updated and improved. For example, a series of increasingly comprehensive PBPK models have been applied to trichloroethylene over the past 10–15 years (see refs. 32, 66).

As discussed in Chapter 5, PBPK modeling uses physiological parameters, such as breathing rates, blood flow rates, and tissue volumes, to describe metabolic processes in physiologically realistic tissue groups (compartments), such as liver, lung, fat muscle, and other organs that are connected by venous and arterial blood flow. Each compartment is described mathematically by a set of differential equations. Such models can be used to relate exposure concentrations—for example, in air, water, or food—to concentrations of the parent compound or its metabolites in different tissues, including the target tissue. A major strength of PBPK models is that one can use the same model developed for a chemical in one species to predict chemical transport and metabolism in other species (including humans) by substituting species- specific physiological, biochemical, and metabolic parameters in the model.

Pharmacodynamics

Pharmacokinetics deals with the movement of chemicals in the body. Pharmacodynamics examines the interactions of chemicals and their metabolites with tissue constituents, their biological and physiological effects, and mechanisms of action. Even if one uses allometric scaling or pharmacokinetic modeling to identify an "equivalent" dose of a chemical at a target site, there may be differences in response in different species because of differences in pharmacodynamics or susceptibility. Thus, for example, a diverse group of chemicals, including unleaded gasoline, decalin, and d-limonene, cause nephrotoxicity and renal tumors in male rats by a species- and sex-specific mechanism involving binding to α2*u*-globulin (10, 68). This phenomenon does not occur in female rats, or in other species (including humans) that do not produce α2*u*-globulin. Nor does it occur in male Black Reiter rats, which also lack α2*u*-globulin (20).

A number of chemicals interact with glutathione and cause toxic effects when tissue glutathione levels are depleted. Knowledge of differences among species in the constitutive levels of glutathione in different tissue and its rate of synthesis can assist in predicting differences among species in sensitivity to such chemicals.

In some cases, data from in vitro studies can be used to assist in interspecies extrapolation. For example, chemicals that cause peroxisome proliferation in rodent liver have been studied in isolated hepatocytes to investigate differences among species in susceptibility (23, 50). Use of data from studies in isolated cells to predict effects in vivo, however, adds its own set of uncertainties, including those related to the representativeness of the cell or tissue samples used for the studies (49).

Application of Allometric Scaling

To apply allometric scaling in practice for converting a specific animal dose (in mg/kg body weight) to an equivalent human dose (also in mg/kg) the animal dose is multiplied by the ratio of animal to human body weight to the $(1-b)$ power. Thus, for scaling on the basis of (body weight)$^{3/4}$, the equivalent human dose is calculated as:

$$\text{Human dose (mg/kg)} = \text{animal dose (mg/kg)} \times \left(\frac{\text{animal body weight}}{\text{human body weight}}\right)^{1/4}$$

This scaling factor is derived as follows. For (body weight)^b scaling:

$$\frac{D_h}{(W_h)^b} = \frac{D_a}{(W_a)^b}$$

where D_h is the human dose (mg), D_a is the animal dose (mg), W_h is the human body weight (kg), and

Wa is the animal body weight. Rearranging this equation and dividing both sides by the human body weight gives:

$$\frac{D_{\mathrm{h}}}{W_{\mathrm{h}}}=\frac{D_{\mathrm{a}}}{W_{\mathrm{h}}}\times\left(\frac{W_{\mathrm{h}}}{W_{\mathrm{a}}}\right)^{b}$$

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_372.html[2010/10/28 18:43:34]

Table 8.2 Cross-species scaling factors based on allometric scaling (based on equations described in text)

Allometric scaling	Mouse-human scaling factor	Rat-human scaling factor
W1.0	(0.035/70)0=1.0	(0.3 770)0=1.0
*W*0.75	(0.035/70)0.25=0.1 50	(0.3/70)0.25=0.256
*W*0.67	(0.035/70)0.33= 0.0794	(0.3/70)0.33=0.162

Note. Assumes human body weight of 70 kg, mouse body weight of 35 g, and rat body weight of 300 g. The scaling factor indicates the dose for a human (mg/kg/day) that is equivalent to 1 mg/kg/day for a mouse or rat. For example with *W*0.75 scaling, a dose of 1 mg/kg/day in a mouse is equivalent to 0.150 mg/kg/day for a 70-kg human.

Multiplying the top and bottom of the right side by the animal body weight *Wa* gives:

$$\frac{D_h}{W_h} = \frac{D_a}{W_a} \times \frac{(W_h)^b \times W_a}{(W_a)^b \times W_h}$$
$$= \frac{D_a}{W_a} \times \frac{(W_a)^{1-b}}{(W_h)^{1-b}}$$
$$= \frac{D_a}{W_a} \times \left(\frac{W_a}{W_h}\right)^{1-b}$$

Examples of the application of these relationships are illustrated in Table 8.2.

Current Trends

At the present time there is extensive work under way aimed at improving our ability to perform cross-species extrapolation, particularly in the areas of pharmacokinetic and pharmacodynamic modeling. As with other types of extrapolation, cross-species extrapolation is aided by an understanding of the mechanism of action of the toxicant under consideration. Because of the limitations of studying toxicants in humans, efforts are also underway to use isolated human cells to address some pharmacodynamic questions and, hence, improve the accuracy of extrapolation.

WITHIN-SPECIES EXTRAPOLATION—VARIABILITY IN HUMAN RESPONSE

Defining the Problem

The term *extrapolation* is, in this context, used somewhat differently than it is in the four other areas discussed in this chapter. The human population is without question highly *heterogeneous* with respect to all of the many differences that affect response to a given dose of a given chemical. If the distribution of toxic responses at a specified dose were known with accuracy, it would be possible to specify a dose at which a specified fraction of the population would be at a given risk of toxicity. Moreover, if the distribution of threshold doses for the population were known, it would be possible to specify the dose at which, for example, the vast majority of individuals would not be at risk; the specific fraction at the tail of the distribution that might remain at risk would be selected as a matter of policy (such a selection would be necessary on the assumption that any plausible distribution of population thresholds would not include an identifiable dose at which there were absolutely zero responders).

In practice such population distributions are not available, and the traditional "default" approach has been, first, to estimate a threshold dose for some hypothetical person described as "average" with respect to responsiveness, and, second, to divide this threshold estimate by a factor, usually 10, that is thought to lead to an estimate of the threshold dose somewhere near the tail of the underlying, but unknown, distribution at which the "most sensitive" members of the population are expected to be found. This estimate is usually considered protective for the "most sensitive" individuals and, necessarily, for all less sensitive individuals. Factors other than 10 have been used if there is some reason to believe that the data supporting a threshold represent individuals more or less sensitive than the hypothetical "average." This relatively crude procedure thus involves extrapolation from so-called "average" to "sensitive" individuals. Interestingly, there is no methodological tradition within the realm of carcinogen risk assessment that is specifically designed to account for population variability (48).

The traditional approach to deriving protective doses offers no insight into the degree of population protection provided. Whether it is underprotective or extraordinarily overprotective depends upon where on the true (but unknowable) distribution of threshold doses the protective dose happens to lie.

Movement away from the "default" approach toward a more scientifically rigorous one that provides some insight into the degree of protection from toxic risk provided at various doses depends upon the

development and incorporation of scientific information relevant to the question of population variability. The factors known to influence variability are described in the next subsection, and this is followed by a review of some empirical data on this question.

Biological Bases for Interindividual Variability

Three major sources of interindividual variability in response to a chemical exposure can be described. First,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_373.html[2010/10/28 18:43:35]

Table 8.3 Major sources of interindividual variability in responses to chemical exposures

Source	Cause of variability	Some major influences
Uptake	Differences in contact with and absorption of chemical from its environmental sources	Age Diet Smoking Health status of skin, respiratory tract, and gastrointestinal tract
Pharmacokinetics and metabolism	Differences in distribution, metabolism, and elimination, leading to different target site concentrations	Age Gender Health status Other exposures (dietary, drug, chemicals) Genetic polymorphisms Pregnancy
Response at target site(s) (pharmacodynamics)	Differences in biological response at a given target site concentration	Age Gender Health status Nutritional status Hormonal status Pregnancy Immune status Genetic polymorphisms

individuals vary in uptake of a chemical from the environment. Second, pharmacokinetic and metabolic behaviors of chemicals vary among individuals; and third, interindividual variability exists with respect to the response at the target site to a given dose (concentration×time) of a toxicologically active compound (pharmacodynamic differences). These three influences lead to variability in the size of the dose (concentration×time) of active compound (administered compound or, more often, a metabolite thereof) that reaches the target site, and the magnitude of the response to that dose, even when all individuals are exposed to identical concentrations of a chemical in their environment. In addition, variability exists with respect to the intake of a chemical because of differences in the nature and extent of human contacts with the environmental media in which the chemical is present. In Table 8.3 are listed some of the major contributors to interindividual variability in toxic response.

Although there is substantial empirical support for the fact of human variability, there is large uncertainty regarding its magnitude. In any given exposure situation, some factors may serve to increase the relative responsiveness of some individuals, while in other exposure situations these same individuals may be at less relative risk. Thus, for example, infants lacking metabolic capacity, which does not fully develop until about 1 year of age, may be less susceptible to substances requiring metabolic activation, yet be more sensitive to other substances because of their less than fully functional immune systems. The number of factors influencing responsiveness is so large and variable within the human population, and the cumulative direction of their effects (to increase or decrease sensitivity) so unpredictable in any given exposure situation, that no attempt to derive a generally applicable model of variability based on biological understanding of each of the factors known to influence it has proved successful. Instead, empirical evidence that captures the cumulative effects of all important influences has been generally regarded as of more value (48).

Empirical Approaches to Understanding Interindividual Variability

Little empirical data supported Lehmann and Fitzhugh's original 1954 proposal to extrapolate from "average" to "sensitive" individuals by the incorporation of the assumption of a 10-fold difference in sensitivity, and this assumption has become the standard "default" uncertainty factor, typically used by regulators when there is no known basis for another factor. Although it has never been explicitly described, the adoption of the 10-fold factor suggests that the total variability in response in the human population ranges over about 100-fold, assuming a symmetrical distribution of

responses about the average. Of course, the location of the "least" and "most" sensitive individuals on the actual distribution is unknown, so it is not possible to describe the actual range.

By the early 1980s, sufficient empirical information had accumulated to allow limited analysis of variability (21). Dourson and Stara's 1983 review of a number of data sets (21) concluded that a 10-fold factor was likely to reflect a wider range of interindividual variability than could be documented for the vast majority of chemicals. This analysis suggested that the 10-fold factor was adequately protective. Review of differences in human metabolism of chemicals (12) has found that a 10-fold factor covered the total range of variability for 80–95% of the population; this finding suggests that the range from "average" to "sensitive" is significantly less than 10-fold. LD50 ratios of adults to newborns for 238 chemicals have been evaluated (65) as a measure of intraspecies variability. Although it was found that the median ratio reflected only a 2.6-fold variability, and that 86% of the ratios were less than 10, the fact that most of the data derived from experimental animal studies casts some doubt on its applicability to humans.

In a review published in 1996, Dourson et al. (22) concluded, based on evaluations of the type just described, that:

In general, the default value of 10 for interhuman variability appears to be protective when starting from a median response, or by inference, from a NOAEL assumed to be from an average group of humans. However, when NOAEL's are available in a known sensitive human subpopulation, or if human toxicokinetics or toxicodynamics are known with some certainty, this default value should be adjusted or replaced accordingly. (p.111)

Some authors have proposed to examine variability separately for factors influencing delivery of target site dose (uptake, pharmacokinetics, metabolism) and those affecting response. One reviewer suggested that variability in the former factor was generally larger than it was for the latter, and he proposed that the 10-fold factor be subdivided into factors of 4 (pharmacokinetics) and 2.5 (pharmacodynamics) (58).

The limited empirical analysis supporting the factor of 10, or its subfactors, is perhaps reassuring. Little effort has been devoted to developing more complete descriptions of variability distributions. Heterogeneity in response might be derived by treating human data, where available, as animal data are often treated (56). Probit plots have, for example, been developed using data derived from studies in Iraq of neurobehavioral outcomes in humans exposed in utero to methylmercury. A probit plot is one useful way of describing the variability in thresholds among individuals in a population. If it is assumed that the distribution is lognormal in character, then a plot of probit against log dose yields a straight line, the slope of which reflects variability; steep slopes reveal less variability than do shallower ones. (Lognormal distributions arise when the factors contributing to variability act multiplicatively—addition of the logarithms of variables is identical to multiplying the variables themselves.) It has been suggested that some responses to methylmercury show a probit slope as low as 1, corresponding to a geometric standard deviation of 10 (56). It is inferred from this that 95% of the population would have thresholds spread over a range of 10,000-fold in dosage—from 100-fold lower to 100-fold higher than the threshold dose for individuals at the median. Such estimates provide the type of description of variability that could increase the level of risk information provided to decision makers, because they allow more explicit analysis of the areas of the distribution that might be selected as the focus of regulation. At the same time, numerous difficulties attend the use of such statistical methods, not the least of which is its failure to incorporate data on biological mechanisms. It nevertheless suggests the possibility of a more quantitative direction for this aspect of risk assessment.

QUANTITATIVE STRATEGIES FOR HIGH- TO LOW-DOSE EXTRAPOLATION

In the production and use of chemicals, it is necessary to consider the health risks and benefits. Both the degree of risks and benefits depend upon the amount of chemical present. For some chemicals, such as genotoxic carcinogens, trace amounts may pose a small risk. For other relatively nontoxic chemicals, large doses may be required before adverse health effects result. In either case, the goal is to eliminate or at least minimize the occurrence of adverse health effects. This generally entails establishing a dose-response curve that relates the incidence of disease, that is, the proportion of individuals that develop a disease, to the dose of a chemical. This provides a method for estimating doses associated with low probability of disease.

In the case of cancer, regulatory decisions regarding exposures to carcinogens are generally made to limit the estimated lifetime probability of cancer (risk) to less than 1 in 10,000 and often to less than 1 in 1,000,000 (60). This creates a difficult problem. For studies conducted in laboratory animals, it would require tens of thousands of animals to estimate the incidence of cancer with precision at doses producing cancer risks below 1 in 10,000. Resources simply are not available to conduct such studies.

Instead, experiments are conducted in animals at doses high enough to elicit potential toxic effects that can be observed in a moderate number, generally 50 or less, of animals per dose group. Such studies generally must produce incidence rates in excess of 10% in order to achieve statistical significance; this limit is 1,000 to

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_375.html[2010/10/28 18:43:36]

100,000 times greater than the risks that are the subject of regulation. Often, these studies require doses that are tens, hundreds, or even thousands of times higher than human doses. In cancer studies, the highest dose generally is selected that is anticipated not to cause death, other than due to tumors, and does not cause average body weight losses greater than 10% compared to control animals. The use of high doses necessitates extrapolation to estimate the incidence of adverse health effects at human dose levels.
Occasionally, human data are available to access risk. Often these studies are based on occupational exposures that are higher than those experienced by the general public. Hence, extrapolation to lower doses is required, albeit much less than from animal studies.
Toxicity studies for drugs often are conducted from near human dose levels up to perhaps 100 times higher. In such studies, some extrapolation to lower dose levels may be required.
A question almost always arises from toxicological studies about extrapolating the results from high doses to lower doses experienced by humans. In the following sections the biological and empirical basis for low-dose extrapolation is summarized. Finally, the uncertainties and future directions for low-dose extrapolation are discussed.

Biologically Based Models for Low-Dose Extrapolation

Very few biological processes are understood well enough to make quantitative predictions of outcomes based on toxic insults. When we speak of biologically based dose-response models, it usually only means that some general principles are accepted that dictate to some extent the shape of the dose-response model. For example, it may be reasonable to assume that a threshold dose exists below which adverse health effects do not occur. Or, arguments may be presented that suggest no threshold dose exists. Arguments may be presented that support the saturation of toxic or detoxification pathways leading to asymptotic curves that flatten at high or low doses, respectively. Even if the general shape of a dose-response model can be established from knowledge of the biological mode of action or mechanisms, considerable variation may exist in available experimental data, resulting in imprecise estimates of risk particularly at doses below the experimental dose range. However, such estimates are generally considered more reliable than estimates based solely on empirical fits to data from an array of plausible dose-response models.

Threshold Doses

For noncancer endpoints, it generally is assumed that small doses of chemicals can be tolerated without any adverse health effects. Experimental data often are compatible with the existence of a threshold dose. However, experimental data can only demonstrate that an effect is likely to be within certain limits. For example, with no adverse effect in 100 animals, it can be stated with 95% confidence that the true incidence is likely to be less than 3%. Threshold doses generally cannot be estimated with precision even in animal studies with homogeneous animals. Estimation of threshold doses for a heterogeneous human population is even more problematic.
The general approach to safety assessment for noncancer effects is to establish an acceptable daily intake (reference dose) based on dividing an experimental no-observed-adverse-effect level (NOAEL) by a series of safety (uncertainty) factors up to 10 for each to allow for extrapolation from animals to humans, when necessary, and to allow for sensitive individuals in a population (6). Hopefully, this results in a reference dose (RfD) that is below the threshold dose for most individuals, resulting in negligible risks. Since the RfD based on animal data is generally a factor of 100 or more below doses that produce adverse effects in bioassays, it is presumed that risks are negligible at these lower doses. There generally is no dose-response modeling attempted to estimate the risk at or below the reference dose.
There is no explicit use of a dose-response curve in the safety assessment process described earlier. There is no estimate of the risk at the NOAEL and no extrapolation to lower risks at lower doses. Gaylor (27) demonstrated that estimated risks of embryo/fetal death and malformations at the NOAEL varied from 0 to 4.5% for typical bioassays. Leisenring and Ryan (40) show that risks at the NOAEL could be as high as 20% for quantal (incidence) data from typical bioassays. Recognizing the wide variation in risks at the NOAEL and the fact that smaller sample sizes result in larger NOAELs, Crump (16) suggested that rather than the NOAEL, the point of departure for RfDs should be a benchmark dose (BD) corresponding to a specified low level (1 to 10%) of risk. A lower confidence limit for the BD is used to allow for experimental variation, and an additional uncertainty factor is introduced to account for the point of departure being associated with a low level of risk.
The whole concept of threshold doses is challenged by the additivity-to-background argument. Obviously, all adverse health effects of concern occur in the human population. For those health effects

that may be the result of chemical exposure, either endogenous and/or exogenous, threshold doses have been surpassed for some individuals. Hence, the addition of any chemical dose, no matter how small, will have an additional effect if it augments an existing toxic chemical pathway (19). At low doses, the relationship between added health risk and dose is approximately linear (19). For this to be true,

the added chemical dose must not be a toxic effect that has a mechanism of action independent of existing mechanisms.

U-Shaped Dose-Response

For some essential vitamins and minerals, a U-shaped dose-response curve may occur. At deficient levels health risks increase, but health risks may also occur at excessive levels, such as for vitamin A and iron. Hence, there is an optimum dose or range that minimizes risk with risk increasing below and above the optimum level. If the dose-response can be modeled for both the deficient and excessive dose risks, assuming these two processes are independent, the overall risk can be estimated by adding the risk from the two components.

There is some evidence for hormetic effects. For example, low doses of a chemical may induce a detoxification process that actually lower risks, but becomes overwhelmed at higher doses. Such a process also may produce a U-shaped dose-response for risk.

Clearly, U-shaped dose-response curves require special attention. Risk assessment procedures that only consider high-dose risk may result in recommended doses that produce risks at low doses, particularly for essential or beneficial nutrients.

Noncancer Effects

The Michaelis-Menten equation is used widely in enzyme kinetics to relate the velocity (V) of an enzyme-mediated reaction to the substrate dose *(d)*, where *V* increases rapidly for small doses and then levels off, approaching a maximum rate (V max) at high doses:

$$V = \frac{V_{\max} d}{K + d}$$

where *K* is the dose at which *V* equals one-half of the maximum value (V_{max}). V_{max} and *K* are generally estimated by a double-reciprocal plot of 1/*V* versus 1/*d* that gives a linear relationship with an intercept of 1/V_{max} and slope of *K* times the intercept:

$$\frac{1}{V} = \frac{1}{V_{\max}} + \frac{K}{V_{\max}} \left(\frac{1}{d}\right)$$

In the event that an endogenous dose is present that is equivalent to d_e, then

$$V = \frac{V_{\max}(d + d_e)}{K + (d + d_e)}$$

Now nonlinear regression procedures are required to estimate the parameters.

The Hill equation is a generalization where

$$V = \frac{V_{\max}(d + d_e)^n}{K + (d + d_e)^n}$$

If $n>1$, the relationship between *V* and *d* is sigmoidal. If risk is proportional to the amount of V present, then

$$\text{Risk} = \frac{B(d + d_e)^n}{K + (d + d_e)^n}$$

where $B \leq 1$ when risk is expressed as a probability on the scale of 0 to 1. Even though there may be a biological basis for this dose-response curve, estimates of *B*, *K*, d_e, and *n* may be quite imprecise unless there are adequate numbers of animals over a wide range of doses. Also, the relationship between risk and *V* is crucial.

For developmental effects, Gaylor and Chen (29) proposed that birth defects may be related to decreased fetal weight. It was assumed that fetal growth was exponential and that the growth rate constant was effected by chemical exposure during gestation. Gaylor and Chen (29) suggested two models that fit a number of dose-response data about equally well for predicting the incidence *(P)* of a variety of structural malformations.

$$p=1-\exp[-b_0+b_1 d^k)]$$

and

$$P=1-\exp[-(b_0+b_1 d+b_2 d^2+\ldots+b_k d^k)]$$

where the *d* is the daily dose and the *b* terms and *k* are estimated from the data.

Leroux et al. (41) developed a mathematical model to describe aspects of the dynamic process of organogenesis, based on branching models of cell kinetics. The biological information incorporated in the model includes timing and rates of dynamic cell processes such as differentiation, migration, growth,

and replication. The dose-response models produced can explain patterns of malformation rates as a function of both dose and time of exposure.

Cancer

More attention has been devoted to dose-response modeling for cancer than to noncancer effects for risk assessment. For a genotoxic carcinogen, theoretically one molecule interacting with DNA at the right place and time could result in a mutation that initiates a carcinogenic process. Even though the probability that this event occurs is infinitesimally small, it argues against absolute threshold doses for genotoxic carcinogens. Further, the probability of an initiated cell is a stochastic process that is proportional to the number of molecules available to interact with DNA. This argues for low-dose linearity at the target site. As discussed earlier, additivity

of doses to background processes also argues for linear, nonthreshold dose-response for risk. The question is not, does low-dose linearity exist for genotoxic carcinogens; rather, the question is, over what dose range does linearity hold? High-dose studies may alter metabolic pathways and saturate detoxification processes. Nonlinear kinetics will result in nonlinear dose-response curves for risk, at least at high doses.

The most widely used model for estimating tumor risk is the multistage model of carcinogenesis. This model assumes that cancer is a progression of mutagenic or mutageniclike events that transform a normal cell into a malignant cell. These events may be the formation of DNA adducts, activation of oncogenes, deactivation of tumor suppressor genes, or mutations. The probability *(p)* of a tumor appearing within a specified period of time (t) is expressed in a simplified form as:

$$P=1-\exp[-(q_0+q_1d+q_2d^2+\ldots+q_kd^k)]t^k$$

where the *q* terms generally are restricted to be nonnegative and are estimated from tumor incidence data, and *d* is the active dose at the target tissue site. In practice, the term t^k is dropped and absorbed into the estimates of the *q* terms. In the absence of information to the contrary, it often is assumed that the target tissue dose is proportional to the administered dose. This model does not explicitly take into account pharmacokinetics, or the rates of cell proliferation, apoptosis, or DNA repair. Clearly, these factors may influence tumor incidence. However, the polynomial form of the model is flexible enough to provide an adequate fit to most data.

The value of *k* is the number of stages affected by the chemical. It is generally believed from the examination of data that *k* often ranges from 3 to 6. If only one stage is effected, a one-hit supralinear model is obtained:

$$P= 1-\exp[-(q_0+q_1d)]$$

This produces a concave dose-response that rises approximately linearly at low doses and then levels off.

At low doses the multistage model is approximately linear up to doses that double the background tumor incidence (19). The extra risk is approximately linear versus dose:

$$(P-P_0)/(1-P_0)\approx q_1d$$

where P_0 is the background tumor incidence. The upper confidence limit on the estimate of q1 is denoted as q_1^* When the dose-response has a sigmoid shape, $k\geq2$, at low doses the dose-response curves upward. Linear extrapolation tends to overestimate the risk in this range. The upper bound estimate of extra risk at low doses is given by

$$\text{Risk} \leq q_1^* \times d$$

which is the so-called linearized multistage estimate.

Crude tumor incidence rates (number of animals with tumors divided by the number of animals examined for a dose group) may provide poor fits for dose-response models. Animals may die at some doses before late occurring tumors appear, often resulting in lower crude incidence rates at higher doses than lower doses. To account for different noncancer mortality across dose groups, Peto et al. (51) proposed a dose-response trend test consisting of two parts: nonfatal tumors that are incidentally discovered when an animal dies from a cause other than the tumor type of concern or is sacrificed, and fatal tumors that cause the death of the animal. Bailer and Portier (4) and Bieler and Williams (9) provided a dose-response trend test that does not require knowledge of the cause of death but does utilize the age of death of the animal.

Moolgavkar and Venzon (44) and Moolgavkar and Knudson (43) introduced a two-stage model that included initiated cell cloning. This model considers the rate that normal cells are initiated, the birth and death rates of initiated cells, and the mutation rate of initiated cells to malignant cells. The exact solution that provides the probability of tumor by age t is given in a NRC report (47) as

$$P(t) = 1 - \left[\frac{2Ce^{-(\beta-\delta-\mu+C)t/2}}{(\beta-\delta-\mu+C)e^{-Ct}-(\beta-\delta-\mu-C}\right]^{v/\beta}$$

where $C=[(\beta+\delta+\mu)^2-4\beta\delta]^{1/2}$ and the parameters *v, β, δ,* and *μ* are defined as follows. It is assumed that the number of normal cells that are dividing per day remains relatively constant resulting in an average number, *v* of new initiated cells per day, β is the probability that an initiated cell undergoes division in a day, *δ* is the daily probability that an initiated cell is removed, and *μ* is the daily probability that an initiated cell divides into another initiated cell and a mutated cancer cell. In general, the values of these parameters as a function of dose are not known. However, changes in the tumor incidence can be calculated for changes in the parameters. For example, Gaylor and Zheng (30) showed that a

sustained increase of 20% in the net cell proliferation rate ($\beta-\delta$) can double the lifetime tumor incidence. Zheng et al. (74) extended the model to describe a sequence of mutational changes that constitute the G: C-A: T base substitution.

Empirical Models for Low-Dose Extrapolation

All empirical models must be biologically plausible if they are to fit bioassay data. The models described next do not arise from specific biologically based mechanisms, but generally accommodate saturation of detoxification and toxic processes. Unfortunately, several different

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_378.html[2010/10/28 18:43:38]

models may fit bioassay data about equally well in the experimental dose range but unfortunately may result in widely different estimates of risk at low doses of interest (25). For this reason, linear extrapolation often is used to provide an upper bound on the risk for low doses of convex dose-responses that curve upward. Linear extrapolation does not mean that a linear model is fit to curvilinear dose-response data. A curvilinear model is still fit to the data and linear extrapolation is only used from the low end of the experimental dose range to an excess risk of zero at zero dose.

Statistical Models

The simplest model is linear where y is a response and d is dose:

$$y=b_0+b_1d$$

The intercept (b_0) representing the background response and b_1, the slope, are estimated from the data. A linear model often is used to approximate a dose-response curve over a limited range of doses. The response may be the incidence of risk of an adverse effect. A linear approximation may be adequate at low doses, but obviously must level off as the incidence (probability of risk) approaches 1.

The linear-quadratic model allows for some curvature, either up or down, in the dose-response curve:

$$y=b_0+b_1d+b_2d^2$$

This model often will fit data adequately up to the inflection point where the response curvature changes from convex to concave or concave to convex.

The probit model has a long history in biology (24). It belongs to a class of tolerance distributions. The probit model is based on the Gaussian (normal) bell-shaped distribution. The tolerance distribution describes the relative probability that an individual will respond—suffer an adverse health effect—at a dose d. If there is a large number of factors that act in an additive manner to determine the dose at which an individual responds, then by the Central Limit Theorem a normal distribution is obtained. Integrating (summing the relative probabilities) up to a dose d gives the proportion (probability) of individuals that develop an adverse effect at or below the dose d. The normal distribution is defined by the mean (μ) and standard deviation (σ). At the mean dose, 50% of the individuals are affected. Special probability (probit) graph paper is available such that plotting the proportion of effected individuals versus dose gives a straight line. The slope of the line is the reciprocal of the standard deviation.

Often, a probit model describes experimental data better when the logarithm of dose is used. This distribution could arise when a number of factors multiplicatively determine the dose at which an individual responds. The log-probit model has been used extensively for the analysis of dichotomous bioassay data (24). This model assumes that the distribution of log-dose thresholds is normal. For the log-probit model, the probability of a tumor induced by an exposure to a dose d of a chemical is given by

$$P(d)=\phi(b_0+b_1\log d)$$

where ϕ denotes the standard cumulative normal distribution.

Another model that has been used extensively in the analysis of dichotomous bioassay data is the log-logistic model (8):

$$P(d)=[1+\exp(b_0+b_1\ \log\ d)]^{-1}$$

where $P(d)$ is the probability (incidence) of an adverse effect by a specified time at a dose d, and b_0 and b_1 are estimated from the data.

Data from reproductive/developmental studies pose special problems where pregnant animals are dosed and the results are measured in the offspring/fetuses. Correlation of results among offspring/fetuses within a litter must be considered. Kodell et al. (37) assumed that the incidence of adverse effects for the offspring/fetuses of a litter behaves according to a binomial distribution and that the probability of adverse effects varies among litters according to a beta distribution. Further, it is assumed that the probability of an adverse effect may be a function of the size s (number of offspring/fetuses in a litter). The expected probability of an adverse effect for an offspring/fetus in a litter of size s at dose d is

$$P(d,s)=1-\exp\{-[b_0+b_1(s-\bar{s})]\}$$

for d less than or equal to a threshold dose of d_0 and s is the average litter size across all dose groups in a bioassay. For doses above the threshold dose of d_0,

$$P(d,s)=1-\exp(-\{b_0+b_1(s-\bar{s}) + [b_3+b_4(s-\bar{s})](d-d_0)^k\})$$

where the $b \geq 0$ and $k \geq 1$ are estimated from the data, and where $[b_0+b_1(s-\bar{s})]\geq 0$ and $[b_3+b_4(s-\bar{s})]\geq 0$ for all s

Kupper et al. (38) proposed a model for reproductive/developmental data of the form

$$P(d, s)=b0+b1s+[1-b0-b1s]/\ [1+\exp[b3+b4s-b5\log(d-d0)]$$

Ryan (63) discussed multivariate models that simultaneously consider two or more biological effects, such

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_379.html[2010/10/28 18:43:38]

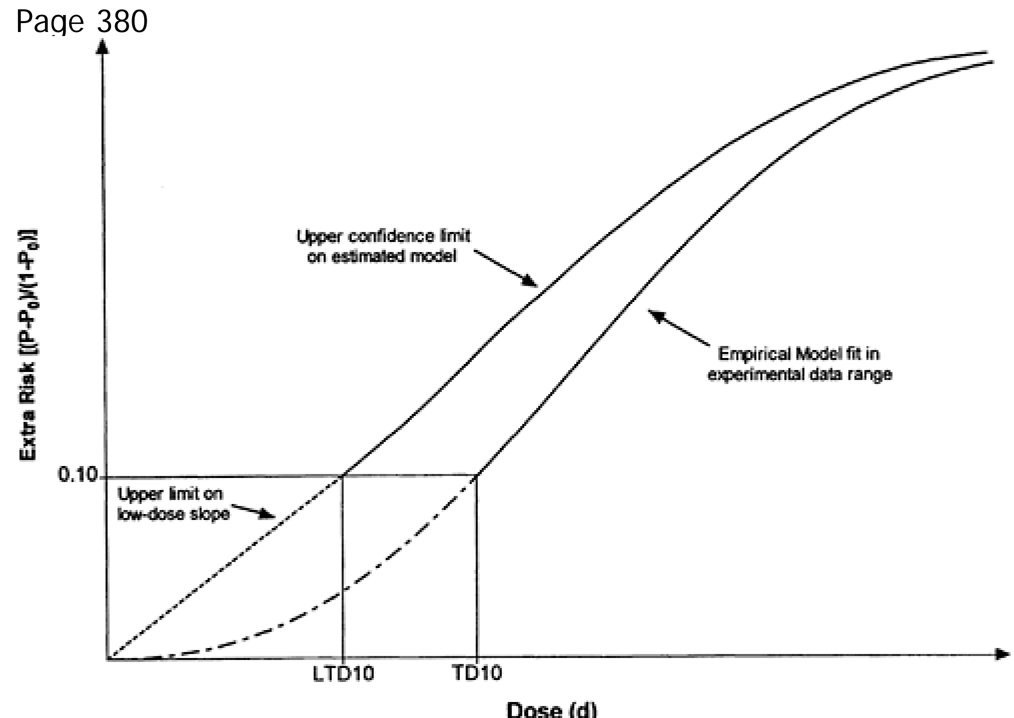

FIG. 8.2. Illustration of the low-dose extrapolation of the empirical model and likely overestimation of low-dose risk.

as the proportion of malformed fetuses in a litter and the proportion of dead/resorbed fetuses in a litter.

Microbial risk assessment is an area currently receiving more attention than in the past. Haas (33) proposed that the probability of infection could be described as a function of the number *N* of colony-forming-units by

$$P=1-[1+(N/\beta)]^{-\alpha}$$

where α and β are estimated from dose-response data.

Low-dose extrapolation using empirical models is suspect. The model may fit adequately in the experimental dose range, but there is little assurance of accuracy below the experimental dose range. However, linear extrapolation can serve as an upper bound estimate of risk for dose-responses that are convex (curve upward).

Recognizing that current methodology generally does not permit precise estimates of cancer risks below 10%, the proposed U.S. Environmental Protection Agency (73) carcinogen cancer risk assessment guidelines suggest estimating the dose associated with a 10% tumor risk (TD10) as a point of departure for low-dose extrapolation. In order to account for experimental variation, a lower confidence limit (LTD10) is calculated for this benchmark dose. If a nonlinear (thresholdlike) dose-response is likely below this benchmark dose, the LTD10 is divided by appropriate uncertainty (safety) factors to arrive at a reference dose that is not likely to cause an appreciable cancer risk. If a nonlinear dose-response below the benchmark dose cannot be justified, the regulatory default is linear extrapolation from the LTD10 to zero (Figure 8.2). This gives a low-dose cancer potency slope factor of 0.10/LTD10. This often is similar to the value of q_1^*, discussed earlier, which is estimated from the multistage model of carcinogenesis. If data are adequate, a benchmark dose below a 10% level of estimated cancer risk may be used as a point of departure for low-dose cancer risk assessment (73).

Uncertainties and Future Directions

There is a tremendous amount of research being conducted to examine the mechanisms of toxicity. Presumably this will provide better information to develop biologically based dose-response models that can facilitate low-dose extrapolation. In order to employ the

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_380.html[2010/10/28 18:43:39]

Moolgavkar-Venzon-Knudson two-stage clonal model of carcinogenesis to estimate cancer risk, for example, it is necessary to identify directly or indirectly initiated cells and to obtain a measure of the rate at which initiated cells arise from normal cells, divide, and are removed, all as a function of dose of the carcinogen. Further, the mutation rate of an initiated cell to a malignant state is needed as a function of dose. Seldom will all of this information be available. Hence, assumptions regarding some of these rates generally will be needed in order to use this model. Currently, there are relatively large uncertainties, up to a factor of 100, for cancer risk estimates based on animal data (31). Many scientists have questioned the validity of long-term bioassays conducted at the maximum tolerated dose. Several authors (17, 55) have suggested that in the absence of extrapolatable data which can be extrapolated to low doses the same approach to safety assessment should be used for carcinogens as for noncancer effects. That is, establish a relatively safe dose and divide by a series of uncertainty factors to account for extrapolation from animals to humans, sensitive individuals, and other uncertainties to arrive at a relatively safe dose without any numerical estimates of risk. Several publications in recent years have addressed the size of uncertainty factors needed to provide adequate safety. Baird et al. (5) have shown that the products of current default values of 10 appear to provide adequate coverage for these uncertainties. Doubtless, research will continue to explore mechanisms of toxicity that will lead to better predictive models. Hopefully, the development of biomarkers of exposure will expand the use of human data for dose-response modeling.

CROSS-ROUTE EXTRAPOLATION

It is often necessary, particularly in the regulatory setting, to make some estimate of the likely toxic effect associated with exposure to a chemical by one route of exposure (e.g., inhalation) when toxicity data only from studies of exposure by a different route (e.g., oral) are available. Such extrapolation is subject to considerable uncertainty, and often is not attempted. In particular, chemicals quite frequently show route-specific toxic effects, especially at or near the site of administration (in the respiratory tract by inhalation, in the upper gastrointestinal tract by oral administration, or on the skin by dermal exposure). Such local effects may be indicative of a potential effect at a local site by another route of administration (e.g., a chemical that causes local dermal irritation when applied to the skin will very likely also cause local irritation when inhaled or ingested). However, quantitative extrapolation of such effects is generally not possible because of difficulties in identifying the effective dose of the toxicant at the target site and particularly because of differences in sensitivity of different tissues.

For systemic effects at distant sites, a crude cross-route adjustment can be performed (if absorption data are available) by simply normalizing the dose to a body-weight basis, and adjusting for relative absorption by the different routes of exposure. This procedure can be quite misleading, however. For example, if the chemical is subject to a significant first-pass effect in the liver (either activating a protoxicant, or inactivating a direct-acting toxicant), the ingestion and inhalation routes may show substantially different responses even with the same total absorbed dose. Clearly, if relevant metabolic and pharmacokinetic data are available, a preferred approach would be the development of a pharmacokinetic model that would take these factors into consideration (see Chapter 4).

CROSS-TIME EXTRAPOLATION: QUANTITATIVE STRATEGIES FOR ADJUSTING FOR DIFFERENCES IN EXPOSURE DURATIONS

Dosing animals with chemicals in toxicological studies may vary from a single administration to continuous exposure over the lifetime of the animal. Likewise, human exposure may vary from a single episode to continuous lifetime exposure. Often, a 2-year rodent lifetime is considered equivalent to a 70-year human lifetime. Hence, an exposure of an animal for 1 year is assumed to be equivalent to a 35-year exposure in humans. Generally, the durations of animal studies are chosen to mimic likely human exposure conditions. However, resources are not available to test chemicals at all of the possible human exposure conditions. Hence, statistical techniques have been devised to estimate the effects of short-term exposures from studies conducted with long-term exposures and vice versa.

Biological Models

Generally, estimates of cancer risk are based on the average daily lifetime exposure. That is, the total dose is divided by the number of days in a lifetime. This is a plausible approach for a genotoxic carcinogen where it is assumed that carcinogenesis is a stochastic process. In such a case, the probability of a biological event is proportional to the number of molecules of the chemical available to interact with biological matter. In order to predict biological effects for different durations of exposures, it is necessary that dose-response models contain a time or age element.

As discussed earlier, the multistage model of carcinogenesis does contain an element of time. Crump and Howe (18) provided estimates of risk as a function

of age and duration of exposure. Kodell et al. (36) showed that the use of the average daily lifetime dose may overestimate risk but never underestimates the cancer risk by more than a factor of *k* (generally 3 to 6) for a k-stage model. For example, based on the average daily lifetime dose, the estimated risk for exposure for one-tenth of a lifetime would be one-tenth of the risk for continuous lifetime exposure at that daily dose. According to Kodell et al. (36), this estimated risk should be multiplied by a factor of 3 to 6 to allow for exposure during a sensitive age.

For the Moolgavkar-Venson-Knudson two-stage clonal expansion model of carcinogenesis, Chen et al. (13) showed that the use of the average daily lifetime dose generally does not underestimate risk by more than a factor of ten. For exposures longer than one-tenth of a lifetime, the estimated risk would be the same as for a continuous lifetime exposure. For exposures for a fraction *(f)* less than one-tenth of a lifetime, the estimated risk is taken to be less than 10 times the upper limit on the estimated lifetime risk with continuous exposure. For the extreme case of only a single exposure to *N* milligrams of a carcinogen, the average daily lifetime (75-year) dose for a 70-kg person is $N/(70\times75\times365)=5\times10^{-7}\times N$ mg/kg. If q_1^* is the estimated upper bound of the cancer risk per milligram per kilogram body weight per lifetime daily exposure, the estimated risk from a single exposure is $5\times10^{-6}\times q_1^*$ where a factor of 10 is included to allow for exposure at a sensitive age.

Empirical Models

For noncancer effects, extrapolation of subchronic to chronic exposures is generally accompanied by an uncertainty factor of 10 (6). That is, it is assumed that an effect observed with a subchronic exposure is not likely to occur at less than one-tenth that dose for a chronic exposure. Swartout (67) compared NOAELs and LOAELs for subchronic and chronic exposures for about 100 cases. The median ratio of subchronic to chronic doses producing equivalent effects was 2 with a 95th percentile of 17. On the average, a chronic exposure to one-half of the dose for a subchronic exposure produced the same biological effect. For 5% of the cases, the chronic dose was less than 1/17th of the subchronic dose for the same biological effect. The convention default factor of 10 for subchronic to chronic extrapolation covered about 89% of the cases. Pieters et al. (52) conducted a similar study for 149 cases and obtained median ratio of subchronic to chronic doses for similar effects of 1.7 with a 95th percentile of 29.

Haber's Rule has been used extensively to make small extrapolations between durations of exposure. Haber's Rule states that equal biological effects are expected for equal exposures of concentration *(c)* times duration *(t)*. That is, equal values of $c\times t$ are expected to produce equal biological effects. For example, if the exposure duration is doubled, the concentration would need to be halved to obtain the same biological effect. A generalization of Haber's Rule is given by tenBerge et al. (71) where values of $c^n\times t$ are expected to produce equal biological effects. Estimation of the exponent *n* requires dose-response data collected for different durations of exposure. For several data sets, tenBerge et al. (71) observed that *n* varied from about 1 to 3 and tended to center around $n=2$. In the absence of duration-dose-response data, the recommended extrapolation to different durations of exposure is calculated on the basis of $c^2\times t$. For example, if the exposure time is increased by a factor of 4, the concentration needs to be halved to obtain an equivalent biological effect. In order to be conservative, it is recommended that $c^3\times t$ be used when extrapolating from long to shorter exposure times and $c\times t$ be used when extrapolating from short to longer exposure durations.

AN OVERALL STRATEGY FOR SCIENTIFICALLY BASED INTERSPECIES EXTRAPOLATION

Assessing risks to human populations from exposures to potentially toxic substances, based upon data from experimental studies, always requires cross-species and within-species extrapolations, almost always requires cross-dose extrapolations, and often requires cross-route and cross-time extrapolations. The need for specific types of extrapolation depends upon (a) the specific risk situation under assessment and (b) the nature of the data available for that assessment. Embarking upon a risk assessment thus requires, at the outset, a careful delineation of the problem to be evaluated. Once this is accomplished, efforts are made to collect all data that might be relevant to the risk question at hand. A matching of the data available with the problem to be assessed allows identification of the types of extrapolation that will have to be undertaken.

At the present stage of development of the toxicological sciences, most extrapolations are undertaken using the so-called "default" approaches discussed earlier. Increasingly, however, attempts are being made to search for the types of information needed to avoid resorting to such defaults, and to use approaches with more fully developed scientific bases.

Table 8.4 describes the types of inquiries that might be made to move toward a more purely science-based approach. It is assumed that the risk assessment problem to be addressed requires the use of

animal toxicology data (there is no significant epidemiology data available), and that all five forms of extrapolation will be required. Thus, for example, the assessment might involve chronic, gen

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_382.html[2010/10/28 18:43:40]

Table 8.4 Overall strategy for science-based interspecies extrapolation: The search for information necessary to improve the scientific basis for human risk assessment based upon experimental data

Type of extrapolation	Type of inquiry
Cross-species	Can data be found for quantitative cross-species comparisons of target site doses and their relationships to administered doses?
	Can PBPK models be developed to accomplish above?
	Can mechanistic data be developed to estimate differences in target-site responsiveness across species?
Within species	Can quantitative estimates be developed, on a chemical-specific basis, of the ranges of human variability in uptake, pharmacokinetic and metabolic handing, and target-site responsiveness?
	Can methods be developed to integrate these sources of variability?
Cross-dose	Can the data necessary to apply biologically based models for low-dose extrapolation be identified or developed?
Cross-route	Can pharmacokinetic data be developed to permit accurate assessment of interroute differences?
Cross-time	Can empirical data be found to support extrapolations from one exposure duration to another? Are there biologically based mechanistic considerations to guide such extrapolations?

eral population exposure to a drinking-water or food contaminant for which the only available toxicity data involves gavage or even inhalation exposure over 90 days in one or more species of experimental animals. Before resorting to the usual defaults for each of these types of required extrapolation, and assuming that they are simply scientific uncertainties that cannot be overcome, it is now expected that toxicologists will inquire more fully, along the lines outlined in Table 8.4, into the possibility that alternative, data-based approaches can be developed. At the same time, it must be recognized that development of the data necesary for science-based extrapolations will necessarily introduce new uncertainties that have to be accommodated. Thus, while most would agree that reliable pharmacokinetic data can provide useful information on interspecies differences, it is likely that scientists will disagree on just how complete such data need to be before they can be used in risk assessment. Regulators typically display a high degree of skepticism about the incorporation of such data, and tend to remain close to the usual defaults, not because they dispute their relevance, but because they question their completeness. Thus, risk assessors must work to reach consensus not only on the types of data needed to improve risk assessments, but also on the difficult question of how complete they must be before they can be used for important public health decisions.

QUESTIONS

1. Why is it necessary to extrapolate?
2. How is a dose-response curve selected?
3. Does a threshold dose always exist? Ever exist?
4. Is the risk zero at the no-observed-adverse-effect level? Explain.
5. When does linear extrapolation to lower doses overestimate risk?
6. Describe the basis for a probit model.
7. Construct a numerical example that illustrates Haber's Rule.
8. When is a safety factor not an uncertainty factor?
9. What factors affect interspecies differences in response?
10. What factors account for variability in response within species?
11. What is the difference between variability and uncertainty?
12. What is the difference between a biologically based extrapolation and an empirically based extrapolation? Is one more reliable than the other?
13. How does science develop *general* explanations for phenomena such as interspecies differences in response?
14. Under what circumstances would cross-route extrapolation not be appropriate?

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_383.html[2010/10/28 18:43:41]

INTRODUCTION

Health risk assessment is the process wherein toxicology data from animal studies and human epidemiology are evaluated, a mathematical formula is applied to predict the response al low doses, and then information about the degree of exposure is used to predict quantitatively the likelihood that a particular adverse response will be seen in a specific human population (229, 257). More simply, risk assessment is a process by which scientists evaluate the potential for adverse health effects from exposure to naturally occurring or synthetic agents (335). Regulatory agencies have used the risk assessment process for nearly 50 years, most notably the U.S. Food and Drug Administration (U.S. FDA) (189). However, the difference between assessments performed in the 1950s and 1960s and those performed in the 1980s and 1990s is that dose-extrapolation models, quantitative

exposure assessments, and quantitative descriptions of uncertainty have been added to the process (63). Because of increased understanding of many relevant issues, the availability of desktop computers, and better quantitative methods for predicting the low-dose response (such as physiologically based pharmacokinetic ([PBPK] models), risk assessments conducted today provide more accurate risk estimates than in the past (257).

Since 1980, most environmental regulations and some occupational health standards have, at least in part, been based on health risk assessments (61, 390). They include standards for pesticide residues in crops, drinking water, ambient air, and food additives, as well as exposure limits for chemicals found in indoor air, consumer products, and other media. Risk managers increasingly rely on risk assessment to decide whether a broad array of risks are significant or trivial: an important task since, for example, more than 400 of the about 2000 chemicals routinely used in industry have been labeled carcinogens in various animal studies (234). In theory, the results of risk assessments in the United States should influence virtually all regulatory decisions involving so-called “toxic agents” (238, 278, 279).

The risk assessment process has four parts: hazard identification, dose-response assessment, exposure assessment, and risk characterization (234). Although progress has been made over the past 20 years in how to conduct and interpret toxicology and epidemiology studies (e.g., hazard identification), and scientists believe that they are doing a better job of dose-response extrapolation than in the past, most significant advances in the risk assessment process have occurred in the field of exposure assessment (405).

In recent years, an increasing number of environmental scientists have embraced the view that “toxicology data are important, but they do not mean much without quantitative information about human exposure.” For this reason, each year since about 1990, the toxicology community has shown increasing interest in understanding the exposure assessment field (246, 247). Fortunately, a significant amount of research has been conducted to identify better values for many exposure parameters, and major improvements have been made in applying these exposure factors to various scenarios. This chapter is intended to familiarize toxicologists, risk assessors, and others with this evolving field.

BASIC CONCEPTS

Description of Exposure Assessment

Exposure assessment is the step in the risk assessment process that quantifies the uptake of an agent resulting from contact with various environmental media (e.g., air, water, soil, food) (1, 257, 375). Exposure assessments can address past, current, or future anticipated exposures, although uncertainties can become significant when attempting to anticipate what might happen or estimate what happened long ago (98, 130, 262, 263, 294, 345).

Exposure assessment in various forms dates back at least to the early twentieth century, and perhaps earlier, particularly in the fields of epidemiology (106, 204), industrial hygiene (212, 256), and health physics (360). Epidemiology is the study of disease occurrence and the causes of disease. Exposure assessment combines elements of industrial hygiene, radiological health, and air pollution and relies upon aspects of statistics, biochemical toxicology, large-animal toxicology, atmospheric sciences, analytical chemistry, food sciences, physiology, environmental modeling, and others (377).

Fundamentally, an exposure assessment describes the nature and size of the various populations exposed to a chemical agent and the magnitude and duration of their exposures (371, 382). It determines the degree of contact a person has with a chemical and estimates the magnitude of the absorbed dose (69). Several factors need to be considered when estimating the absorbed dose, including exposure duration, exposure route, chemical bioavailability from the contaminated media (e.g., soil), and, sometimes, the unique characteristics of the exposed population (e.g., hairless mice absorb a greater percent of chemical than other mice). By definition, “duration” is the period of time over which the person is exposed.

Knowledge of the chemical concentration in an environmental medium is essential to determine the magnitude of the absorbed dose. This information is usually obtained by analytical measurements of samples of the contaminated medium (air, water, soil, sediment, food, or dust). Estimates can also be made using mathematical models, such as models relating air concentrations at various distances from a point of release (e.g., a smoke stack) to factors including release rate, weather conditions, distance, and stability of the agent (312, 430). Needless to say, a significant number of factors need to be considered to quantitatively evaluate a typical contaminated site (Figure 9.1).

In general, since about 1995, our ability to perform exposure assessments has matured to a degree that they will usually possess less uncertainty than other steps in the risk assessment. Admittedly, many factors should be considered when estimating exposure; for example, it is a complicated procedure to

understand the transport and distribution of a chemical that has been released into the environment. Nonetheless, available data indicate that scientists can now do an adequate job of quantifying chemical concentrations in various media, and the resulting uptake by exposed persons, if they account for the majority of factors that should be considered (268).

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_388.html[2010/10/28 18:43:44]

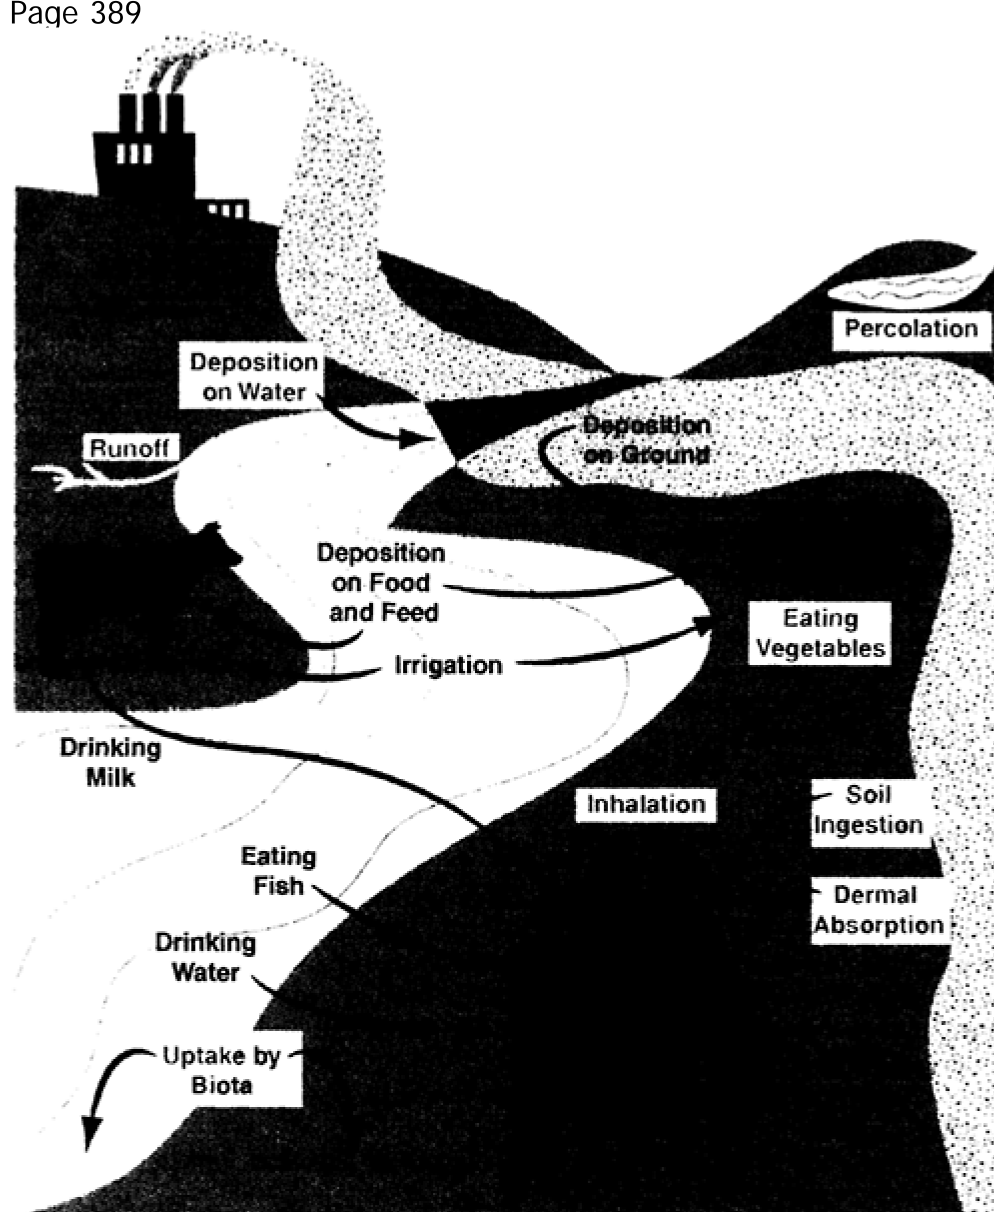

FIG. 9.1. Exposure pathways.

For those who wish to question this assertion, consider our level of confidence in animal bioassays which label a chemical a possible human carcinogen even though tumors were observed in a mouse liver only at the maximum tolerated dose (MTD). Similarly, consider our confidence in dose-extrapolation when three equally valid models yield risk estimates that are 1000-fold different at a typical environmental dose.

The primary routes of human exposure to chemicals in the ambient environment are dust and vapor inhalation, dermal contact with contaminated soils or dusts, and ingestion of contaminated food, water, dust, or soil. In the workplace, the predominant exposure route usually is inhalation, followed by dermal uptake and, to a lesser extent, dust ingestion due to hand-to-mouth contact (269). Uncertainty in environmental exposure assessment is usually less than in an occupational exposure assessment. In many workplaces, there can be large fluctuations in airborne concentrations, a significant difference in work practices of different persons, and there is real difficulty in measuring dermal uptake and incidental ingestion (166, 256, 259).

Scientists in the field of radiological health were the first to quantitatively estimate human uptake of environmental contaminants (301); health physics publications can be a source of valuable information when conducting assessments of chemical contaminants (20). This work, which was conducted after World War II, provided numerous methodologies for estimating human uptake of environmental contaminants. These have been refined

Page 390

over the past decade (161, 125, 218). The availability of information on the degree of exposure associated with various scenarios has increased dramatically over the past 15 years, as evidenced by the size of the recent *EPA Exposure Factors Handbook*, a four-volume document containing nearly 1000 pages of information on exposure assessment (382–384, 386).

The practice of exposure assessment, at least for regulatory purposes, has changed over time. For example, beginning in the late 1970s, regulatory policy in the United States encouraged or mandated the use of conservative approaches when conducting exposure assessments. This was codified in the U.S. EPA original document entitled *Risk Assessment Guidance for Superfund,* called RAGS (372). At that time, standardization of exposure assessments used to satisfy regulatory agencies was considered prudent because it guaranteed that risks would not be underestimated in order to ensure protection of public health. Beginning about 1985, concern evolved that repeated use of conservative exposure factor assumptions was producing unrealistically high estimates of exposure (81, 209, 242, 254, 259) and that the cost of achieving the recommended cleanup levels was becoming enormous. Thus, to improve the accuracy of many of the factors used in these assessments, a significant amount of new research was initiated.

Around 1990, risk assessors learned how to apply Monte Carlo techniques to evaluate both typical and highly exposed persons. Application of Monte Carlo techniques to exposure assessment has dramatically improved our understanding of the certainty of our estimates, and has decreased the problems associated with the repeated use of conservative assumptions, thereby altering the field permanently (44, 117, 353, 354). The U.S. EPA and other agencies have now embraced this approach, which is well described in the recent document called RAGS3A (a process for conducting probabilistic risk assessment) (392).

What Is Exposure?

Because there has been no agreed-upon definition of where or when exposure takes place, terminology used in published exposure assessment literature has been inconsistent. Although there is reasonable agreement that human exposure means contact with the chemical or the agent (4, 372, 375), there has not yet been widespread agreement as to whether this means contact with (1) the visible exterior of the person (e.g., an aluminum strip touches the skin but can't be absorbed), or (2) the so-called exchange boundaries where absorption takes place (skin, lungs, gastrointestinal tract) (377). The differing definitions have led to some ambiguity in the use of terms and units for quantifying exposure.

Some scientists find it helpful to think of the human body as having a hypothetical outer boundary that separates the inside of the body from the outside (377). The outer boundary of the body consists of the skin and openings into the body, such as the mouth, nostrils, or punctures and lesions in the skin. In most exposure assessments, chemical exposure is defined as contact of the chemical with some part of this boundary. An exposure assessment is the quantitative or qualitative evaluation of that contact. It describes the intensity, frequency, and duration of contact, the route of the chemical across the boundary (exposure route, e.g., dermal, oral, or respiratory), the resulting amount of chemical actually crossing the boundary (dose), and the amount of chemical absorbed (internal dose) (192, 375). These categories can be further refined as described below; however, a very workable quantitative definition of exposure is to think of it as "the product of (concentration), (time), and (duration), or rate of transport of toxicant (mg/cm2-min)" (166).

Depending on the purpose of the exposure assessment, the numerical output of these analyses may be an estimate of either exposure or dose. If an exposure assessment is being done as part of a risk assessment in support of an epidemiologic study, for example, sometimes only qualitative exposure levels are all that can be provided. In these situations, categories like low-, medium-, and high-level exposure may be used. In contrast, most assessments of environmental or occupational exposure conducted in recent years attempt to quantitatively predict the absorbed dose (mg/kg-d) and, occasionally, the circulating blood level or the concentration of the toxicant in the target organ (260, 292).

Concepts of Exposure, Intake, Uptake, and Dose

The process of a chemical entering the body can be described in two steps—contact (exposure), followed by actual entry (crossing the boundary). Absorption, either upon crossing the boundary or subsequently, leads to the availability of an amount of chemical to biologically significant sites within the body (target tissue dose). Although the description of contact with the outer boundary is simple conceptually (e.g., mg benzene/cm2 skin), estimating the degree to which a chemical crosses this boundary is somewhat more complex.

In the early 1990s, some scientists described the transport of chemicals into the body as involving two

separate steps: intake and uptake. Intake involved physically moving the chemical in question through an opening in the outer boundary (usually the mouth or nose), typically via inhalation, eating, or drinking. Normally, the chemical was contained in a medium such as air, food, water, or dust/soil. Here, the key question was the mass inhaled

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_390.html[2010/10/28 18:43:45]

or ingested. Uptake, in contrast to intake, involved absorption of the chemical through the skin or across other barriers.

Today, most persons tend to lump intake and uptake together, simply calling the amount of chemical entering the body "uptake." In some cases, chemicals are absorbed completely, so systemic absorption (uptake) is the same as that eaten or in contact with the skin (intake). In other cases, the chemical is often contained in a carrier medium, and the medium itself typically is not absorbed at the same rate as the "contaminant of interest," so estimates of the amount of chemical crossing the boundary cannot be made directly. For example, benzene on the surface of a contaminated soil particle will move quickly through the skin, but benzene in the center of the soil particle may never completely reach the surface, and therefore it is not bioavailable and will not enter the bloodstream. Of course, for many inorganic chemicals like arsenic or lead in soil, oral and dermal bioavailability can be very low since the chemical is bound to the interstices of the soil particle and, therefore, uptake is very low. In short, if a chemical cannot be released from a media, it has no bioavailability and, consequently, since there is no uptake the chemical does not pose a risk.

Dermal absorption is an example of direct uptake across the outer boundary of the body. A chemical uptake rate is the amount of chemical absorbed per unit of time. In this process, mass transfer occurs by diffusion, so uptake will depend on the concentration gradient across the boundary, permeability of the barrier, and other factors (192, 214, 215). Chemical uptake rates can be expressed as a function of the exposure concentration, permeability coefficient, and surface area exposed, or as flux (269).

Bioavailability

The study of the bioavailability of chemicals in various media began around 1980 and continues to be an important topic (305).

Most studies are of oral bioavailability, although the dermal and inhalation bioavailability of chemicals have also been evaluated. This area of research has been a bit confusing due to a lack of standard terminology (159). A recent review paper by Ruby et al. (305) is probably the most authoritative one on this topic. The following definitions should be used in future assessments:

Bioavailability: Oral bioavailability is defined as the fraction of an administered dose that reaches the central (blood) compartment from the gastrointestinal tract. Bioavailability defined in this manner is commonly referred to as *absolute bioavailability*, and is equal to the oral absorption fraction.

Relative bioavailability: Relative bioavailability refers to comparative bioavailabilities of different forms of a substance or for different exposure media containing the substance (e.g., bioavailability of a metal from soil relative to its bioavailability from water), expressed in this document as a relative absorption factor (RAF).

Relative absorption factor: The RAF describes the ratio of the absorbed fraction of a substance from a particular exposure medium relative to the fraction absorbed from the dosing vehicle used in the toxicity study for that substance (the term *relative bioavailability adjustment*, RBA, is also used to describe this factor).

Bioaccessibility: The oral bioaccessibility of a substance is the fraction that is soluble in the gastrointestinal environment and is available for absorption. It is imortant to note that the bioaccessible fraction is not necessarily equal to the RAF (or RBA) but depends on the relation between results from a particular in vitro test system and an appropriate in vivo model.

There are both in vitro and in vivo tests for evaluating bioavailability, and many different approaches have been suggested over the past 20 years (159, 165, 321, 358).

As noted by Ruby et al. (305), a number of in vitro tests are available. Simple extraction tests have been used for several years to assess the degree of metals dissolution in a simulated gastrointestinal-tract environment. The predecessor of these systems was developed originally to assess the bioavailability of iron from food, for studies of nutrition. In these systems, various metal salts or soils containing metals are incubated in low-pH solution for a period intended to mimic residence time in the stomach. The pH is then increased to near neutral, and incubation continues for a period intended to mimic residence time in the small intestine. Enzymes and organic acids are added to simulate gastric and small-intestinal fluids. The fraction of lead, arsenic, or other metals that dissolves during the stomach and small-intestinal incubations represents the fraction that is bioaccessible (i.e., is soluble and available for absorption).

A number of in vivo tests have also been used with varying success. For example, gastrointestinal absorption of lead in humans varies with the age, diet, and nutritional status of the subject as well as with the chemical species and the particle size of lead that is administered. For example, age is a well-established determinant of lead absorption; adults typically absorb 5–7% of lead ingested from dietary

sources, while estimates of lead absorption from dietary sources in infants and children range from 40 to 53%. For the purpose of modeling exposure to lead in soil, the U.S. EPA currently assumes that the absolute bioavailability of lead in diet and water is 50% and that

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_391.html[2010/10/28 18:43:46]

the absolute bioavailability of lead in soil is 30% for children. This corresponds to a soil RAF of 0.60 (60%) for the bioavailability of soil lead relative to lead in water (i.e., RAF=0.3/0.5) (305).
The results of bioavailability studies need to be considered in virtually all assessments involving human exposure. Often the effects in uptake will be minor, while in other cases one may find that insignificant quantities of a chemical are absorbed even though the applied dose or exposure is quite high (358, 396).

Applied Dose or Potential Dose

Applied dose has been defined as the amount of chemical available at the absorption barrier (skin, lung, gastrointestinal tract) (377). It is useful to know the applied dose if a relationship can be established between the applied dose and the internal dose, a relationship that can sometimes be established experimentally. This relationship can be estimated either through modeling or by direct measurement. For example, some researchers have analyzed phenol concentrations in the blood of volunteers over time after placing their hands in a bucket of nitrobenzene in an attempt to quantify the flux rate (273, 275). Usually it is difficult to measure the applied dose directly, as many of the absorption barriers are internal to the human, and not localized in such a way to make measurement easy. An approximation of applied dose can be made, however, using the concept of potential dose (377).
Potential dose is simply the amount of chemical that is ingested or inhaled, or the amount of chemical contained in material applied to the skin. It is a useful term or concept in those instances when there is a measurable amount of chemical or transport medium. The potential dose for ingestion and inhalation is analogous to the administered dose in a dose-response experiment.
For the dermal route, potential dose is the amount of chemical applied, or the amount of chemical in the medium applied (for example, as a small amount of soil deposited on the skin). Note that because all of the chemical in the soil particulate is not contacting the skin, this differs from exposure (the concentration in the particulate times the duration of contact) and applied dose (the amount in the layer actually touching the skin) (377).
As previously noted, the amount of chemical that reaches the exchange boundaries of the skin, lungs, or gastrointestinal tract may often be less than the potential dose if the material is only partly bioavailable. For example, only about 0.001% to 1.0% of dioxins or polycyclic aromatic hydrocarbons (PAHs) on fly ash in contact with the skin are likely to penetrate (321). When bioavailability data are known, adjustments to the potential dose should be made to convert it to the absorbed or internal dose (159, 321).

Internal Dose

The amount of chemical that has been absorbed and is available for interaction with biologically significant receptors (e.g., target organs) is called the *internal dose.* Estimating internal dose is the first objective of a good exposure assessment (288, 381).
Transport models are available to assist in this process (219). Once absorbed, the chemical can be metabolized, stored, excreted, or transported within the body. The amount transported to an individual organ, tissue, or fluid of interest is termed the *delivered dose* (68). The delivered dose may be only a small part of the total internal dose. For example, although 1 mg of PCB may be absorbed into the body, at any given time the amount in the liver (the target organ) may only be 0.001 mg. Work to refine the techniques used to estimate delivered dose has been among the most exciting areas of exposure assessment research over the past 15 years. Currently, the best approach to estimate delivered dose is to directly measure blood or to use physiologically based pharmacokinetic (PBPK) models (12, 194).
The *biologically effective dose* (BED), or the amount that actually reaches cells, sites, or membranes where adverse effects occur (235), may represent only a fraction of the delivered dose, but it is obviously the best one for predicting adverse effects. To understand BED is the ultimate goal of exposure assessment. Thus far, toxicologists have rarely been able to estimate BED or measure it for most chemicals (377), but models allow us to estimate it.
Currently, most risk assessments dealing with environmental chemicals (as opposed to pharmaceutical assessments) rely upon dose-response relationships based on the potential (administered) dose or the internal dose, because our understanding of how to estimate the delivered dose or the biologically effective dose is insufficient for most chemicals. In general, the best method currently available for estimating the dose to the target organ is to use PBPK models. These have been developed for about 60 high-volume industrial chemicals (193) (Table 9.1).
Often it is more convenient in risk assessment to refer to dose rates, or the amount of a chemical dose (applied or internal) per unit time (e.g., mg/d), or as dose rates on a per unit body weight basis (e.g., mg/kg-d). Most exposure data found in the various editions of the U.S. EPA *Exposure Factors Handbook*

and other guidance documents are presented as dose rates (e.g., grams of fish consumed each day) rather than as dose (8, 382–384).

Exposure and Dose Relationships

Depending on the purpose of the exposure assessment, different estimates of exposure and dose may require

Table 9.1 Examples of PBPK models for toxic substances

Benzene	Lead
Benzo[a]pyrene	Methanol
Butoxyethanol	Methoxyethanol (2-ME)
Carbon tetrachloride	Methyl ethyl ketone (MEK)
Chlorfenvinphos	Nickel
Chloralkanes	Nicotine
Chloroform	Parathion
Chloropentafluorobenzene	Physostigmine
cis-Dichlorodiammine platinum	PBB
Dichloroethane	PCBs
Dichloroethylene	Styrene
Dichloromethane	Toluene
Dieldrin	TCDF
Diisopropylfluorophosphate	TCDD (Dioxin)
Dimethyloxazolidine dione	Tetrachloroethylene
Dioxane	Trichloroethane
Ethylene oxide	Trichloroethylene
Ethyoxy ethanol (2-EE)	Trichlorotribluoroethane
Formaldehyde	Vinyl chloride
Hexane Hexavalent chromium	Vinylidene fluoride Xylene
Kepone	

Note. This table is an expansion of one presented in a paper by Leung and Paustenbach (193).

calculation. Often, estimates of uptake will be presented in units used in the toxicology study which may not be useful for exposure calculations.

When risk is a function of time of exposure, exposure or dose profiles can be very useful. In these profiles, the exposure concentration or dose is plotted as a function of time (19). Concentration and time are used to depict exposure, while amount and time characterize dose.

Such profiles are important for use in risk assessment where the severity of the effect depends on the pattern by which the exposure occurs, rather than on the total (integrated) exposure. For example, a developmental toxicant may only produce effects if exposure occurs during a particular stage of development. As shown in Figure 9.2, during the time above a certain dose rate (the shaded portion), there was an increased risk to the fetus of certain birth defects. Similarly, a single acute exposure to very high dose may induce adverse effects, even if the average is much lower than apparent no-effect levels. To understand the probability of an adverse effect, one must generally consider the pharmacokinetics of the specific chemical. For example, for a chemical that has a long biologic half-life, internal exposure continues long after the chemical is ingested because blood levels remain high until the substance is completely released from poorly perfused tissues like adipose, and then is metabolized and/or eliminated.

In general, there is a need to consider the time elements of exposure assessment. Specifically, it is useful to understand the relationship between the biological half-lives of toxicants and the subsequent critical time element of their exposure. Indeed, the appropriate consideration of these elements should drive the specified averaging times for both toxicant exposure limits and exposure assessment (258, 295).

If a chemical or agent causes its biological damage quickly and is gone from the body in a short time, then how we test its toxicity is critical. For example, consider

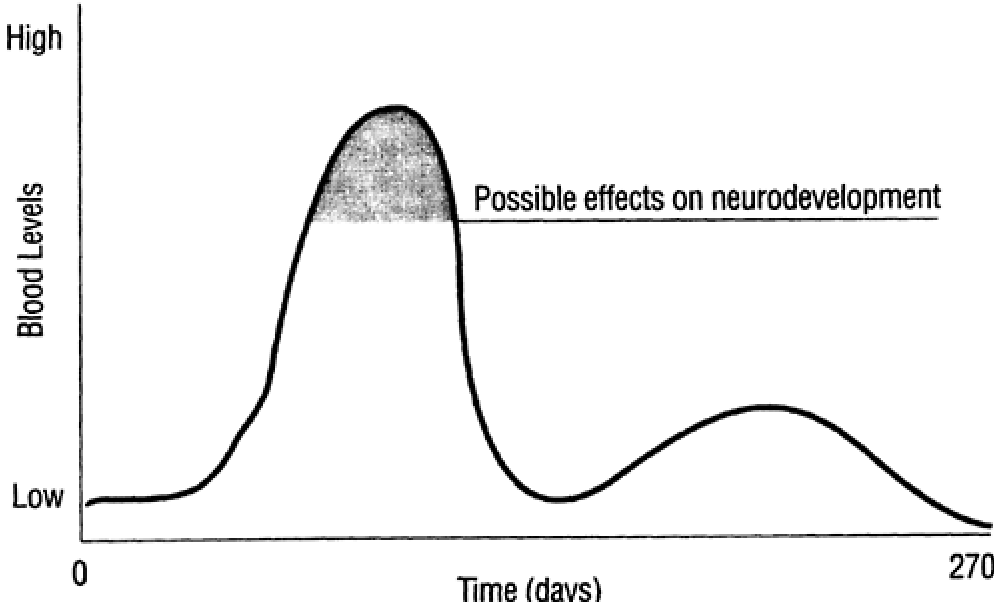

FIG. 9.2. Time course of exposure to a developmental toxicant. Note that the shaded portion represents the blood concentration of toxicant which is necessary to offer some probability that an inverse effect might occur.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_393.html[2010/10/28 18:43:47]

a material with a half-life of a few minutes in the body. If we were to test it by spreading or apportioning the daily dose of this material over 24 h via inhalation, it will produce a different toxicity than if the animal got the same amount in a couple of 1-h inhalation exposures. The same dose of this quick-acting material would do much more damage amassed in a bolus dose of a few minutes or even an hour or two than spread over 24 h.

Thus, dosing times in toxicological studies should be commensurate with the biological half-life for the relatively quick-acting chemicals. We often need to measure the exposure over an appropriately short period of time where the worst-case exposure may occur. The same logic also holds for the dermal (topically applied) and oral (normally ingested) exposures in that they should occur in time frames that are comparable to what we would expect in use. Bolus dosing by gavage or injection would, of course, be worst case.

On the other hand, if the biological half-life of the compound is longer than a few days, then relatively high spikes of exposure over a day or two are not particularly significant from a health impact perspective. What is important from a chronic toxicity perspective for these types of compounds is, of course, the weighted average over a significantly longer time period.

As such, it would only seem appropriate to use an annual average exposure when you are dealing with a compound with a very long (greater than 90 d) half-life in the body and no evidence of acute toxicity at high short-term dose rates (289, 291, 295).

Aggregate exposure is the sum total of exposure to a chemical via all routes of exposure (and all media). It is now commonplace to add as many as 6 to 10 different exposure sources per route (e.g., DDT in different fruits and vegetables) and 3 exposure routes (e.g., DDT via food, air, and dermal contact). The units of aggregate exposure are concentration times duration. Aggregate exposure has been considered in complex assessments of the past 10 yr, such as for incinerators, but it came to the fore with the passage of the Food Quality Protection Act (FQPA) in 1996. At least one major symposium and the resulting publication tackle this subject. Ample guidance from regulatory agencies and examples of how to perform these assessments will undoubtedly be published over the next 5 yr (161).

Integrated exposure is the total "area under the blood concentration vs. time curve" (AUC) of the exposure profile. An exposure profile (a picture of the exposure concentration over time) is particularly useful when trying to understand occupational exposure because it contains more information than a numerical estimate of the integrated exposure, including the duration and periodicity of exposure, the peak exposure, and the shape of the area under the time-concentration curve (Figure 9.2). The risk posed by most systemic toxicants with chronic effects are often best understood by evaluating the blood concentration versus time relationship.

The last way to characterize exposure is the time-weighted average (TWA). This is particularly relevant when conducting a carcinogen risk assessment. In cancer risk assessments, the time over which exposure is integrated is usually 70 yr (377). A TWA dose rate is the total dose divided by the time period of dosing, usually expressed in units of mass per unit time, or mass/time normalized to body weight (e.g., mg/kg-d). TWA dose rates such as the lifetime average daily dose (LADD) are used in dose-response equations to estimate lifetime risk.

Measures of Dose

For risk assessment purposes, dose estimates should be expressed in a manner that can be compared with available dose-response data from animal or human studies. For example, if data on human exposure are in milligrams of lead per deciliter of blood (mg/d1), it would be best to use the blood concentrations in an animal or human study to predict the risk. Frequently, dose-response relationships are based on potential dose (called administered dose in animal studies), although dose-response relationships are sometimes based on internal dose. These differences need to be accounted for. The measure of dose selected should be based on the mode of action of the adverse effect (10, 13, 19, 375, 381). For example, to assess a nasal irritant, the airborne concentration of the chemical is a relevant dose, and an even better dose metric would be mg of chemical contacting a square centimeter of nasal mucosa.

Doses may be expressed in several different ways. Solving Eq. (1), for example, gives the dose rate over the time period of interest. The dose per unit time is the dose rate, which has units of mass per time. The most common dose measure is average daily dose (ADD), which is used to predict or assess the noncarcinogenic effects of a chemical.

$$\mathrm{ADD}=(C\cdot \mathrm{IR}\cdot \mathrm{B})/(\mathrm{BW}\cdot \mathrm{AT}) \qquad (1)$$

where ADD is the potential average daily dose, BW the body weight, *B* the bioavailability, AT the time period over which the dose is averaged (days), C the mean exposure concentration, and IR the

ingestion rate.

The following presents a typical calculation.

Example Calculation 1: Determining the Average Daily Dose

A typical American eats a certain amount of lettuce over a lifetime (about 2000 kg). Assume that on any given week, the maximum quantity ingested is 0.5 kg, and the maximum on any one day is 0.04 kg/d. Assume that

the typical aldrin residue is 4 mg/kg on all lettuce ingested over the person's lifetime. What is the ADD of aldrin for the maximum week? Assume the oral bioavailability of aldrin in lettuce is 90%.

Given:

$$C=4\text{mg/kg(aldrin)}$$
$$\text{BW}=70\text{kg}$$
$$\text{AT}=7\text{d}$$
$$\text{IR}=0.5\text{kg}$$
$$\text{B}=0.9$$

Therefore:

$$\text{ADD}=(C\cdot \text{IR}\cdot \text{B})/(\text{BW}\cdot \text{AT})$$
$$\text{ADD}=(4\ \text{mg/kg})(0.5\ \text{kg})(0.9)/(70\ \text{kg})(7\ \text{d})$$
$$\text{ADD}=0.004\ \text{mg/kg-d}$$

When the primary health risk posed by a chemical is cancer or another chronic effect, then the biological response is usually described in terms of lifetime probabilities (e.g., the increased risk of developing cancer during a 70-yr lifetime is 2 in 100,000). In these circumstances, even though exposure may not occur over the entire lifetime, doses are usually presented as LADDs (377). The LADD takes the form of Eq. (2), with lifetime (LT) replacing the averaging time (AT):

$$\text{LADD}=(\text{C}\cdot \text{IR}\cdot \text{B})/(\text{BW}\cdot \text{LT}) \qquad (2)$$

Example Calculation 2: Determining the Lifetime Average Daily Dose

Assume that the reasonable maximum ingestion lifetime uptake of lettuce over a 70-yr lifetime (99% person) is 14,000 kg and that it contains 4mg/kg of aldrin. What is the LADD? Given:

$$C=4\ \text{mg/kg (aldrin in lettuce)}$$
$$\text{IR}=14,000\ \text{kg}$$
$$B=0.9$$
$$\text{BW}=70\text{kg}$$
$$\text{LT}=70\ \text{yr}=25,550\ \text{d}$$

where

$$\text{LADD}=(\text{C}\cdot \text{IR}\cdot \text{B})/(\text{BW}\cdot \text{LT})$$

Then

$$\text{LADD}=(4)(14,000)(0.9)/(70)(25,550)$$
$$\text{LADD}=0.028\ \text{mg/kg-d}$$

Although other measures of chronic dose may be more appropriate for predicting the hazard posed by specific chronic toxicants, such as an area under the blood concentration (AUC) curve or the peak target tissue concentration, the LADD is the most common dose metric used in carcinogen risk assessment (Figure 9.3).

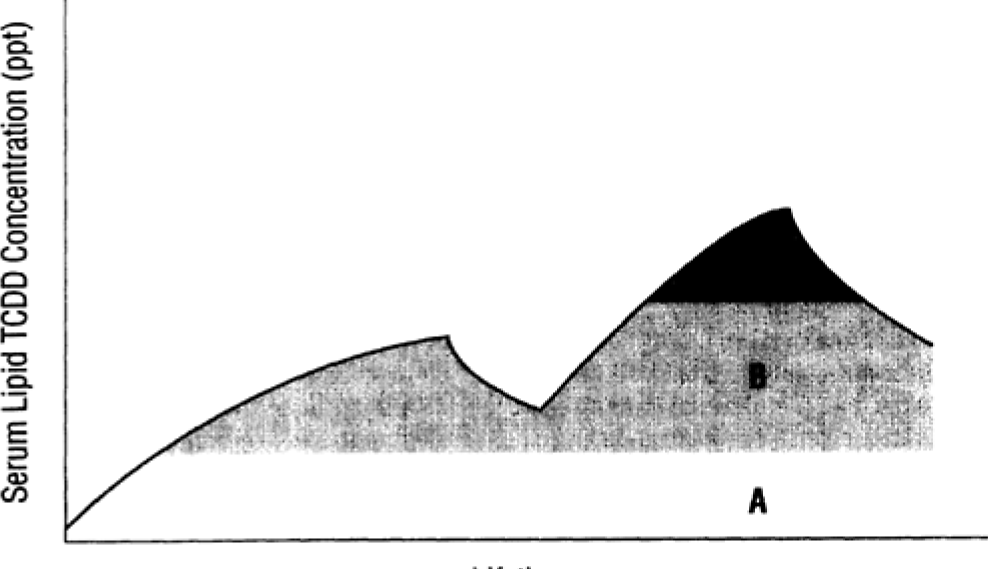

FIG. 9.3. Theoretical concentration versus time curve for TCDD illustrating one possible relationship between AUC and response. This figure illustrates the possible combination of AUC and thresholds for production of various responses: area A, no effect; area B, enzyme induction occurs; area C, significant

increased cell proliferation. From Reference 19.

CONCEPTUAL APPROACHES TO EXPOSURE ASSESSMENT

Quantifying Exposure

Although exposure assessments are conducted for a variety of reasons, the process of estimating exposure can be approached using one of the following three methods (377):

1. Direct measurement: The exposure can be measured at the point of contact (the outer boundary of the body) while it is taking place, measuring the exposure concentration and time of contact and integrating them (point-of-contact measurement). An example is the measurement of the amount of contaminated soil on an exposed hand of someone digging a hole to plant a tree. The relevant exposure information would be contaminant concentration in soil (μg/g), surface area of the hand in contact with the soil (100 m2), and time of exposure (2 h).
2. Exposure scenario: Sometimes one is concerned about an exposure that may or may not occur, so a hypothetical exposure scenario is developed. In these assessments, specific data cannot actually be collected, but relevant information can be found. For example, if an incinerator were built, it would not be known today how much of each chemical in the airborne emissions would reach the various compartments in the environment (food, soil, sediment, surface water), but one can describe what would be likely to occur (a scenario).
3. Biomonitoring: Sometimes historical exposure can be estimated based on the amount of chemical in the body or being eliminated in breath, urine, or feces. In recent years, doses have been reconstructed through internal indicators (biomarkers, body burden, excretion levels) for persistent organics and several metals. Among the best examples are lead in blood, phenol in urine, volatile hydrocarbons in the breath, and dioxins in blood fat.

These three approaches to exposure quantification (or dose) are independent because each is based on different assumptions and/or data. The fact that they are independent measures is useful in verifying or validating the results of the various approaches. Each of the three has strengths and weaknesses; using them in combination can considerably strengthen the credibility of an exposure assessment (236, 375, 395). For example, results of the exposure assessment would be validated if one could mathematically predict the absorbed dose per day of a chemical, estimate the resulting blood concentrations, and confirm these estimates by sampling the blood of the exposed population (268).

Estimates Based on Direct Measurement

Point-of-contact or direct exposure assessment evaluates the exposure as it occurs. Measuring chemical concentrations at the interface between the person and the environment as a function of time yields an exposure profile. The best known example of point-of-contact measurement is the output of a radiation dosimeter. This small badgelike device measures radiation exposure as it occurs and provides an integrated exposure estimate for the period of time over which the measurement has been taken (377). The Total Exposure Assessment Methodology (TEAM) studies (369) conducted by the U.S. EPA made use of direct measurements. In the TEAM studies, a small pump with a collector and an absorbent was attached to a person's clothing to measure his or her exposure to airborne solvents or other pollutants as it occurred, just as has been done in industrial hygiene studies of the past 60 yr (7). In both of these examples, the measurements are taken at the interface between the person and the environment while exposure is occurring.

The area of exposure assessment known as agricultural hygiene has developed very sophisticated techniques for estimating the uptake (absorption) of chemicals during the mixing and application of pesticides. These have been described in numerous articles (179, 180). A recent paper by Kissel and Fenske (175) is also useful.

Providing that the measurement devices are accurate, the direct measurement method likely gives the best exposure value for the period of time over which the measurement was taken. It is often expensive, however, to use these techniques to evaluate persons in the community, and measurement devices and techniques do not currently exist for all chemicals (at least at ambient concentrations).

Estimates Based on Exposure Scenarios

Using the exposure scenario approach, the assessor attempts to estimate or predict chemical concentrations in a medium or location and link this information with the time that individuals or populations are in contact with the chemical. An exposure scenario is the set of assumptions describing how this contact takes place. This is, by far, the most common approach to exposure assessment. Such an approach is necessary when trying to predict the impact of events that may occur in the future, such as building a new manufacturing facility or introducing a new pesticide or herbicide (239, 261, 262, 284).

The first step to building a scenario is to determine the concentration of the contaminated media. This is

typically accomplished indirectly by measuring,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_396.html[2010/10/28 18:43:49]

modeling, or using existing data on concentrations in the media of concern, rather than at the point of contact (for example, pesticide residues on food or metal emissions on residential soils). Often, we assume that the concentration in the bulk medium is the same as the concentration at the point of exposure. This can be a source of potential error and should be discussed in the uncertainty analysis. For example, over the past 20 yr, most assessments of the hazard posed by contaminated soil were based on soil samples collected in the top 6 in of soil, even though most persons were exposed routinely to the surface soil (usually the top 2½ in). Arguments can be made in either direction about the appropriateness of this assumption.

The next step in conducting an exposure scenario is to estimate the contact time, identify who is likely to be exposed, and then develop estimates of the exposure frequency and duration. Like chemical concentration characterization, this is usually done indirectly using demographic data, survey statistics, behavior observation, activity diaries, activity models, or, in the absence of more substantive information, assumptions about behavior (386, 387).

Chemical concentration and population characterizations are ultimately combined in an exposure scenario. One of the major problems in evaluating dose equations is that the limiting assumptions used to derive them (e.g., steady-state assumptions) do not always hold true. Two approaches to this problem are available: (1) to evaluate the exposure or dose equation under conditions when the limiting assumptions do hold true, or (2) to build a dynamic model that accounts for both accumulation and degradation. The microenvironment method, which is usually used to evaluate air exposures, is an example of the first approach. This method evaluates segments of time and location when the assumption of constant concentration is approximately true, and then sums the time segments to determine the total exposure for the respiratory route, effectively removing some of the uncertainty (282). In occupational hygiene, this is done by combining time-motion data with short-term air concentration data. While exposure concentration and time of contact may be estimated in some situations, the concentration and time of contact can be measured for each microenvironment. This avoids much of the error due to summing average values in cases where concentration and time of contact vary widely.

In the second approach, a computer model can efficiently predict dose if enough data are available (51, 204, 430). When conducting modeling, there are various tools used to describe parameter variation, such as Monte Carlo analysis, and these may be necessary in some assessments.

Estimating Exposure Using Biological Monitoring

Exposure can often be estimated after it has taken place. The key factor is whether the biological half-life of the chemical is sufficiently long to allow for accurate measurement. If a total dose is known or can be reconstructed, and information about intake and uptake rates is available, an average past exposure rate can be estimated (19, 276, 309, 333, 346). Dose reconstruction relies on measuring biological fluids (blood, urine), hair, nails, or feces after exposure, intake, and uptake have already occurred, and using these measurements to back-calculate dose (19). However, data on body burden levels or biomarkers cannot be used directly unless a relationship can be established between these levels (or biomarker indications) and internal dose.

Biological monitoring can be used to evaluate the amount of a chemical in the body by measuring one or more parameters (Table 9.2). In general, if these measurements can be made and the biologic half-life is acceptable, then past exposure estimates can be reasonably accurate. Not all of these can be measured for every chemical (377). Following is a list of possible measurements:

- The concentration of the chemical itself in biological tissues or sera (blood, urine, breath, hair, adipose tissue, etc.).
- The concentration of the chemical's metabolite(s).
- The biological effect that occurs as a result of human exposure to the chemical (e.g., alkylated hemoglobin or changes in enzyme induction).
- The amount of a chemical or its metabolites bound to target molecules.

The results of biomonitoring can be used to estimate chemical uptake during a specific interval, if background levels do not mask the marker and the relationship between uptake and the selected marker is known (89). The sampling time for biomarkers is often critical. Establishing a correlation between exposure and measurement of the marker, including pharmacokinetics, is necessary to properly back-calculate historical exposure (377).

The strengths of this method are that it demonstrates that exposure and absorption of the chemical has actually taken place, and theoretically it can give a good indication of past exposure. The drawbacks are that (1) it will not work for every chemical because of interferences or the reactive nature of the

chemical, or because the biological half-life of the agent is too short; (2) that the approach has been applied to only a few chemicals; (3) that data relating internal dose to exposure are needed; and (4) that it may be expensive.

Page 398

Table 9.2

Examples of types of measurements to characterize exposure-related media and parameters

Type of measurement (sample)	Usually attempts to characterize (whole)	Examples	Typical information needed to characterize exposure
Breath	Total internal dose for individuals or population (usually indicative of relatively recent exposures).	Measurement of volatile organic compounds (VOCs), alcohol. (Usually limited to volatile compounds.)	1. Relationship between individuals and population; exposure history (i.e., steady-state or not) pharmacokinetics (chemical half-life), possible storage reservoirs within the body. 2. Relationship between breath content and body burden.
Blood	Total internal dose for individuals or population (may be indicative of either relatively recent exposures to fat-soluble organics or longterm body burden for metals).	Lead studies, pesticides, heavy metals (usually best for soluble compounds, although blood lipid analysis may reveal lipophilic compounds).	1. Same as for breath. 2. Relationship between blood content and body burden.
Adipose	Total internal dose for individuals or population (usually indicative of longterm averages for fat-soluble organics).	NHATS, dioxin studies, PCBs (usually limited to lipophilic compounds).	1. Same as for breath. 2. Relationship between adipose content and body burden.
Nails, hair	Total internal dose for individuals or population (usually indicative of past exposure in weeks to months range; can sometimes be used to evaluate exposure patterns).	Heavy metal studies (usually limited to metals).	1. Same as for breath. 2. Relationship between nails, hair content and body burden.
Urine	Total internal dose for individuals or population (usually indicative of elimination rates); time from exposure to appearance in urine may vary, depending on chemical.	Studies of tetrachloroethylene and trichloroethylene.	1. Same as for breath. 2. Relationship between urine content and body burden.

Note. From Reference 385.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_398.html[2010/10/28 18:43:50]

For those chemicals where biological monitoring can be used to estimate past exposure, the information obtained can be invaluable for conducting retrospective exposure assessments that can be used in epidemiology studies. Some examples of chemicals for which past exposure can reliably be estimated include several metals, as well as numerous large organic chemicals (e.g., DDT, chlordane, dioxin, polybrominated biphenyl [PBB], PCB) (19).

INFORMATION UPON WHICH EXPOSURE ASSESSMENTS ARE BASED

Comprehensive exposure assessment of a complex scenario may require several hundred exposure factors to estimate the various chemical concentrations in one of several dozen different media. Among the most complex exposure assessments are those that address the risks posed by airborne emissions from combustors (125, 281, 388) (Figure 9.4). To estimate the concentration, numerous dispersion models, as well as fate and transport models, may be required. In addition, the assessor may need to search the literature to identify relevant studies from as many as 10 related fields of research. Sometimes, hundreds of published papers and government guidance documents need to be evaluated, used, and cited. In short, the exercise can be formidable, especially for assessments involving food chain contamination. Equally difficult and highly complex exposure assessments are those that attempt to estimate the uptake of fish by various members of the angling public (428).

Obtaining Data on Intake and Uptake

The numerous editions of the *Exposure Factors Handbook* (382–384, 386) present statistical data on many of the factors used to assess exposure, including intake rates, and these provide citations for primary references. Today, this series of publications represents the most comprehensive, single source of exposure assessment information. Some of the many intake factors in the various volumes include:

- Drinking water consumption rates.
- Breast milk ingestion rates for infants.
- Consumption rates for homegrown fruits, vegetables, beef, and dairy products.

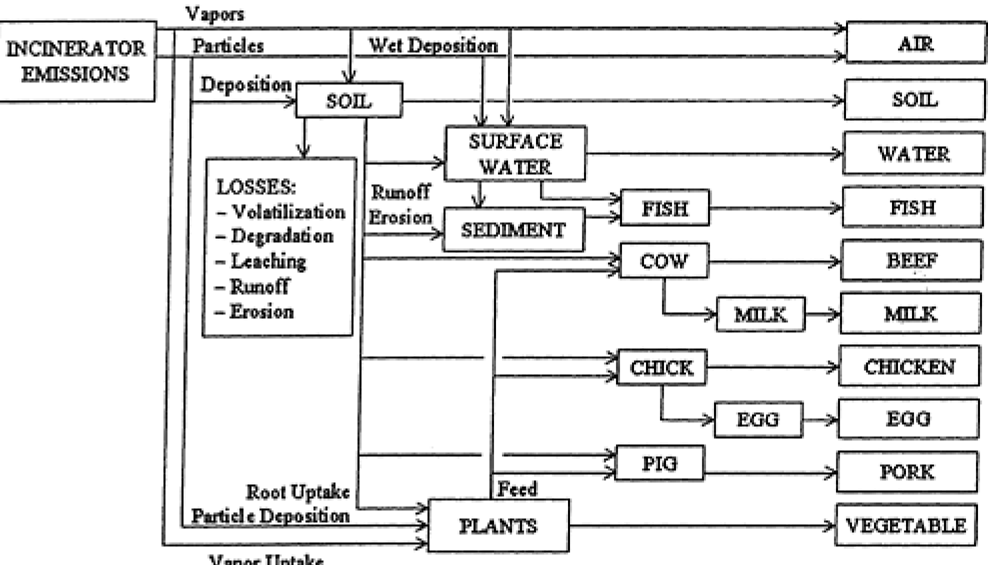

FIG. 9.4. EPA's conceptual approach to dealing with direct and indirect exposure pathways as illustrated by assessments of incinerator emissions.

- Consumption rates for recreationally caught fish and shellfish.
- Incidental soil ingestion rates.
- Pulmonary ventilation rates.
- Surface area of various parts of the human body.
- Body weight for various age groups.

Table 9.3 presents examples of some of the standard or default exposure factors used in risk assessment.

The *Exposure Factors Handbook* is updated routinely to include additional factors and to include new research data on previously discussed factors. It also provides default parameter values, which can be used when site-specific data are not available. Obviously, general default values should not be used in place of known, valid data that are more relevant to the assessment being conducted. The U.S. EPA handbook, though substantial, may not contain all available information on exposure factors or relevant studies, so a supplemental literature search should be conducted to ensure that pertinent literature has been identified. As discussed later, if a probabilistic or Monte Carlo assessment is to be conducted, the document titled *Risk Assessment Guidance for Superfund: Process for Conducting Probabilistic Risk Assessment* (392) and other publications should be consulted.

Concentration Measurements in Environmental Media

Sometimes the existing chemical concentration data are inadequate to conduct a proper site-specific assessment. In these cases, concentration data can be gathered by conducting a new field study, or by evaluating data from past field studies and using them to estimate concentrations. Media measurements taken close to the point of contact are preferable to measurements far removed geographically or temporally. As the distance from the point of contact increases, the certainty of the data at the point of contact usually decreases, and the obligation for the assessor to show relevance of the data to the assessment at hand becomes greater. For example, an outdoor air measurement, no matter how close it is taken to the point of contact, cannot by itself adequately characterize indoor exposure (267). Concentrations often vary considerably from place to place, seasonally and over time due to changing emission and use patterns (259, 312, 313). This needs to be considered not only when designing studies to collect new data, but also when evaluating the applicability of existing measurements as estimates of exposure concentrations in a new assessment. It is of particular concern when the measurement data will be used to extrapolate to long time periods, such as lifetimes. Transport and dis

Table 9.3 Some standard regulatory default assumptions used i in exposure assessment

Variable	Assumption
Drinking water	2 L/d (RME adult)
	1.4 L/d (adult ave.)
	1.0 L/d(child)
	0.1 L/d (incidental ingestion during swimming)
Soil (ingestion)	200 mg/d (child ave.)
	800 mg/d (child 90th percentile)
	100 mg/d (adult)
Food	2000 g/d (adult total)
Beef (home-grown)	44 g/d (ave.)
	75 g/d (RME) 100 g/d (all sources)
Dairy (home-grown)	160 g/d (ave.)
	300 g/d (RME)
	400 g/d (all sources)
Fruit (home-grown)	28 g/d (ave.)
	42 g/d (RME)
	140 g/d (all sources)
Vegetables (home-grown)	50 g/d (ave.)
	80 g/d (RME)
	200 g/d (all sources)
Sport fish	30 g/d (ave.)
	140 g/d (RME)
Inhalation	10 m3/d (ave. 8-h shift.)
	20 m3/d (adult ave.)
	30 m3/d (RME)

	20.8 kg (6 yr)
	70 kg (adult ave.)
Lifespan	70 yr
Exposed skin area	0.2 m2 (adult ave.)
	0.53 m2 (adult RME)
	1.94 m2 (male bathing)
	1.69 m2 (female bathing)
Showering	7 min (ave.)
	(5-min. shower uses 40 gal)
	12 min (90th percentile)
Residence time	9 yr (ave.)
	30 yr (RME)

Note. RME, reasonable maximum exposure; ave., average.

persion models are frequently used to help answer these questions (51).

The exposure assessor is likely to encounter several different types of measurements. One type often used to understand concentration trends is outdoor fixed-location monitoring. This measurement is used by the U.S. EPA and other groups to provide a record of pollutant concentration at one place over time. Nationwide air and water monitoring programs have been established so that baseline values in these environmental media can be documented. Although it is not practical to set up a national monitoring network to gather data for a particular exposure assessment, data from existing

networks can be evaluated for relevance to an exposure assessment. These data are often far removed from the point of contact. Adapting data from previous studies usually presents specific challenges. Indoor air contaminant concentrations can vary as much as or more than those in outdoor air (298, 410—413). Consequently, indoor exposure is best represented by measurements taken at the point of contact. However, because pollutants such as carbon monoxide can exhibit substantial outdoor penetration, indoor exposure estimates should consider potential outdoor, as well as indoor, sources of the contaminant(s) under evaluation (247, 377).

Contaminant concentrations in food and drinkingwater measurements can also be measured. General characterization of these media, such as market basket studies (where representative diets are characterized), shelf studies (where foodstuffs are taken from store shelves and analyzed), or drinking-water quality surveys, are usually far removed from the point of contact for an individual, but may be useful in evaluating exposure concentrations for a large population. Measurements of tap water or foodstuffs in a home and how they are used are closer to the point of contact. In evaluating the relevance of data from previous studies, variation in the distribution systems must be considered, as well as the space-time proximity (377).

Consumer or industrial product analysis is sometimes done to characterize the chemical concentrations in products. Product formulations can change substantially over time, similar products do not necessarily have similar formulations, and regional differences in product formulation can also occur. These should be considered when determining the relevance of existing data and when setting up sampling plans to gather new data (377).

Another type of concentration measurement is the microenvironmental measurement. Rather than using measurements to characterize the entire medium, this approach defines specific zones in which the concentration in the medium of interest is thought to be relatively homogeneous, and then characterizes the concentration in that zone (283, 375). Typical microenvironments include the home or parts of the home, office, automobile, or other indoor settings. Microenvironments can also be divided into time segments (e.g., kitchen during the day, kitchen during the night). This approach can produce measurements that are closely linked with the point of contact, both in location and time, especially when new data are generated for a particular exposure assessment. The more specific the microenvironment, however, the greater is the burden on the exposure assessor to establish that the measurements are representative of the population of interest.

The concentration measurement that provides the closest link to the actual point of contact is personal monitoring. In virtually all cases, if available, this information should be the basis of exposure assessments of individuals. An obvious exception is the work environment where lapel sampling is conducted while the person is wearing a respirator; in this case, personal sampling would not reflect genuine exposure.

Models and Their Role

Often the most critical element in an exposure assessment is estimating pollutant concentrations at exposure points. This is usually carried out by combining field data and modeling results. In the absence of field data, this process often relies on the results of mathematical models of aerial dispersion, such as ISCLT, or of water movement, such as MODFLOW (107, 364, 366–368). The U.S. EPA Science Advisory Board and others have recommended that modeling ideally should be linked with monitoring data in regulatory assessments, although this is not always possible.

A modeling strategy has several aspects, including setting objectives, model selection, obtaining and installing the code, calibrating and running the computer model, and validation and verification. Many of these aspects are analogous to the quality assurance and quality control measures applied to measurements.

Regardless of whether models are extensively used in an assessment or whether a formal modeling strategy is documented in the exposure assessment plan, when computer simulation models such as fate and transport models and exposure models are used in exposure assessments, the assessor must be aware of the performance characteristics of the model and state how the exposure assessment requirements are satisfied by the model (51).

The site must be characterized if models are to be used to simulate pollutant behavior at a specific site. Site characterization for any modeling study includes examining all data on the site, such as source characterization, dimensions and topography of the site, location of receptor populations, meteorology, soils, geohydrology, and ranges and distributions of chemical concentrations. For exposure models that simulate both chemical concentration and time of exposure (through behavior patterns), data on these two parameters must be evaluated (262, 264, 375).

Criteria are provided by the U.S. EPA (368) for selecting surface water models and groundwater models, respectively; the reader is referred to this document for details. Similar selection criteria exist for air dispersion models.

A primary consideration in selecting a model is whether to perform a screening study or a detailed evaluation. A screening study makes a preliminary evaluation of a site

or a general comparison between several sites. It may be generic to a type of site (i.e., an industrial segment or a climatic region) or may pertain to a specific site for which sufficient data are not available to properly characterize the site. Screening studies can help direct data collection at the site by, for example, providing an indication of the level of detection and quantification that would be required and the distances and directions from a point of release where chemical concentrations might be expected to be highest.

An example of a screening-level modeling effort would be to estimate the amount of lead deposited by an incinerator onto local crops using a basic air dispersion model, without considering local geographical or weather conditions. The next level of complexity would consider the presence of mountains, their proximity to the stack, the local weather patterns, and the number of atmospheric inversions per year. A higher level of analysis could incorporate yet other, more subtle factors.

The value of the screening-level analysis is that it is simple to perform and may indicate that no significant contamination exists. Screening-level models are frequently used to get a first approximation of the concentrations that may be present. Often these models use very conservative assumptions; that is, they tend to overpredict concentrations or exposures. If the results of the conservative screening procedure predict concentrations or exposures at less than a predetermined no-concern level, then more detailed analysis is probably not necessary. If the screening estimates are above that level, refinement of the assumptions or a more sophisticated model are necessary to generate a more realistic estimate (377).

Screening-level models also help the user conceptualize the physical system, identify important processes, and locate available data. The assumptions used in the preliminary analysis should represent conservative conditions, such that the predicted results overestimate potential conditions, limiting false negatives. If the limited field measurements or screening analyses indicate that a contamination problem may exist, then a detailed modeling study may be useful.

In contrast, the purpose of the detailed evaluation is to use the best data available to make the best estimate of spatial and temporal chemical distributions of a specific site. Detailed studies typically require higher quality data and more sophisticated models.

Accounting for Background Concentrations

Background exposure to so-called "toxic" or industrial chemicals, especially environmentally persistent ones, can occur due to natural or anthropogenic sources (355). In most exposure assessments, background soil concen trations are the focus of attention, but the same issue can be relevant when evaluating sediments, ambient air, groundwater, and vegetation (foodstuffs). At some sites, it is important that these so-called "background" concentrations be accounted for because removing the quantity of toxicant due to humans may, in fact, not appreciably change the concentrations or be sufficient to reduce the risk to acceptable levels. For example, naturally occurring concentrations of lead, arsenic, and cadmium, in some locations, may be higher than cleanup levels established by various regulatory agencies (94, 95). The exposure assessor should try to determine local background concentrations by gathering data from nearby locations clearly unaffected by the site under investigation, or by referring to published works that have assessed this issue. Statistical approaches are applicable to address this issue (245).

Description of Background Levels

When assessing soils, background levels can be viewed in at least four different ways (107):

• "Pristine" levels—Some would like to equate background levels with those associated with the "pristine" state, that is, soils or landscapes unaffected by human activity. This rather idealistic situation probably no longer exists; even in Antarctica, mercury and dioxin concentrations can be detected in some media. Toxic elements mainly associated with the solid phase of some natural material (such as soil dust, plant or volcanic ash, vegetable matter) are relatively mobile in a global sense. For example, Nriagu (243) has suggested that about 40 million tons of heavy metals have been dispersed atmospherically over the many centuries of human activity.

Increases in pollutant metal concentrations have been measured up to 60 km from smelters, and automotive lead (fine particles) has been measured in soils and rainfall up to about 50 km downwind from major cities. Soil contamination up to 50–100m from highways by automotive lead (coarser particles) is an example of short-range transport, and contrasts with transport of toxic metals on a continental or global scale (e.g., contamination of the Greenland ice sheets from the northern United States, mercury in the Florida Everglades due to aerial releases in South America, the snows of the New Zealand Alps by soil dust from inland Australia) (107).

• "Normal" levels—The question could be asked: Are soils contaminated at farms in the higher rainfall

areas of the Appalachians, which used to receive automotive exhaust particulates from

the New York metropolitan area 200 km away? These soils are not pristine, but the chemical concentrations are perfectly safe for growing food, raising farm animals, and residential living. Soils from such areas would have a range of what is often called "normal" background values. To most exposure assessors, this mosaic of normal soils, which is only affected by the minor pollution of everyday activities associated with modern rural and urban life, should be the basis for defining background values. Statistically, this range of normal background values would constitute a single lognormally distributed population. Obviously, one needs to exclude the outliers or "hot" spots due to a geochemical anomaly, or localized pollution arising from either industrial emissions, disposal of waste products, or intensive (excessive) use of farm chemicals (107).

• Historically polluted regions—Local community and regulatory policies often affect what are defined as background levels. A community with highly developed environmental consciousness may insist on very low, possibly unreasonable, reference values. Some densely populated areas with historically derived pollution, perhaps from former mining activities, may sustain apparently healthy populations who pragmatically must accept higher "background" level values. The cities of Philadelphia, Baltimore, and New York, and parts of Japan, for example, may fit in this category.

• Geochemical variation—Background levels of some potentially toxic elements may vary among geographical regions because of differences in soil type. The resulting concentrations are often called naturally occurring levels.

An important factor is the composition of rocks and sediments that weather from soils. Some extreme examples are high concentrations of nickel, cobalt, and chromium in igneous rocks such as basalts that cover extensive areas in western Victoria and Tasmania, Australia; and high concentrations of boron in soils on marine sediments in the Riverina, Mallee, and Wimmera districts of South Australia, and in Victoria, Eyre Peninsula and parts of western Australia.

Some regulatory agencies have provided written guidance describing how to select soil or sediment cleanup values that account for background chemical concentrations. In past years, these have varied significantly, but within the past 5 yr, there appears to be some convergence regarding the definition of background, how to measure it, and how it should affect exposure assessment calculations.

ESTIMATING UPTAKE VIA THE SKIN

When attempting to predict chemical risks in the environmental or occupational setting, the dermal exposure route can vary in its importance from negligible to significant. In most evaluations of hazardous waste sites and ambient air or water contaminants, this is not a major route of exposure. Although the uptake of chemicals via the skin has generally been overlooked in most workplace exposure assessments, it probably represents a substantial portion of the exposure for many occupations. Even though gloves are more frequently used than in years past and training has increased on the possible hazards of dermal exposure, there is still ample evidence to indicate that, in order to conduct a complete exposure assessment, this route deserves attention (192, 253, 265).

In addition to the risks associated with systemic toxicity due to uptake via the skin, it is sometimes necessary to evaluate the allergic contact dermatitis hazard (ACD). In recent years, techniques have been developed to quantitatively predict the likelihood of elicitation and induction of ACD (164, 240). Some regulatory agencies are concerned with ACD and have developed cleanup standards based on this health endpoint.

In the workplace, a worker's skin frequently comes into contact with solvents or chemicals mixed in water (aqueous materials). In most environmental settings where persons can be exposed to contaminated soil or contaminated water, dermal uptake must be assessed. Fortunately, a good deal of research has been conducted to understand the rate at which chemicals pass through the skin.

Percutaneous absorption of neat chemicals (i.e., the pure liquid) was often studied in humans until the late 1970s (100, 101, 113, 184, 225, 274, 275, 347). Because of the potential toxicity of many chemicals and improved laboratory techniques, in vivo human studies have been largely supplanted by experiments with laboratory animals, in vitro studies, or athymic rodents grafted with human skin (178). Historical research has shown that, in general, chemical penetration of the human skin is similar to that of a pig or monkey, and much slower than that of the rat and rabbit (26). Thus, for many chemicals, there is some level of confidence that the rate of dermal uptake of a chemical by humans can be inferred from animal data.

Starting in the 1980s, in vitro studies using human skin began to be conducted on a more routine basis. In these studies, a piece of excised skin is attached to a diffusion apparatus with a top chamber to hold the applied chemical and a temperature-controlled bottom chamber containing saline or other fluids (plus a sampling port to withdraw fractions for analysis) (123). Although human forearm skin is optimal,

it is difficult to obtain, so abdominal or breast skin is commonly used. Generally,

a properly conducted in vitro test can be a reasonably good predictor of the absorption rate in vivo (34). However, due to the fragile nature of the technique, these studies must be carefully interpreted (22). Often, depending on the conditions of the test, the results are not applicable to humans.

Aside from neat liquids and exposure to contaminated water, dermal exposures can also occur through contact with dust or dirt on surfaces, and by way of contact with soil or dust-bound contaminants (267). Few studies (96, 119, 156, 169, 177, 191, 286, 300, 317) have directly estimated soil loading on human skin, and only one of them attempted to measure dermal contact of contaminated equipment by workers (206). The available studies probably provide sufficient data to generate point estimates of soil adherence and perhaps can provide a reasonable probability density function (PDF) for most persons exposed to contaminated soils. The degree of representativeness of the data to the general population is difficult to assess (48).

Recently, a few studies measured the adherence of soil to multiple skin surfaces (hands, forearms, lower legs, faces, and feet) under ambient and recreational conditions (156, 177). Dermal loading on the hands was found to vary over five orders of magnitude and to be dependent on the type of activity. Differences between pre- and postactivity adherence demonstrated the episodic nature of dermal contact with soil. However, due to the activity-dependent nature of soil exposure, data from these studies must be interpreted for their relevance to the type of activity, frequency, duration, and otherwise site-specific nature of exposure. The various studies involving contaminated soil are informative for providing an estimate of exposure; however, they are probably a couple orders of magnitude greater than what might be expected in an occupational setting. Nonetheless, this work is a "starting point" for bracketing potential exposure to dusts in the workplace.

Recently, there has been a reasonable level of research investigating exposure to house dust. The basis for this concern has been increasing evidence that controlling exposure to house dust, especially in homes located near sites with considerable surface soil contamination, is more important for reducing the health hazard than remediating the soil (267). Numerous papers in recent years have shown that in-house exposure to toxics is much greater than that encountered due to ambient (so-called environmental) contamination (247, 405).

Along these lines, and of particular interest to those who study indoor exposure, is the recent work to develop standardized approaches for collecting wipe samples and estimating the amount of dust loading on the palm of the hand (197, 198). Although dermal absorption of toxicants in house dust will almost always pose a relatively low dermal uptake hazard, the uptake of toxicants due to hand-to-mouth contact can be substantial (267).

Quantitative Description of Dermal Absorption

For the purposes of risk assessment, percutaneous absorption is defined as transport of externally applied chemicals through cutaneous structures and the extracellular medium to the bloodstream (375, 391). In many settings, such as for agricultural workers, platers, mechanics, and others, dermal uptake is the primary route of exposure. The simplest way to describe the rate of skin absorption is to apply Fick's first law of diffusion at steady state (349, 418):

$$J = dQ/dt = KC/e \approx K_p C \qquad (3)$$

where J $(=dQ/dt)$ is the chemical flux or rate of chemical absorbed (mg/cm2-h), D is the diffusivity in the stratum corneum (cm2/h), K the stratum corneum/vehicle partition coefficient of the chemical (unitless), ∇C the concentration gradient (mg/cm3), e the thickness of the stratum corneum (cm), K_p the permeability coefficient (cm/h), and C the applied chemical concentration (mg/cm3). The concentration gradient is equal to the difference between the concentration above and below the stratum corneum. Because the concentration below is small compared to the concentration above, ∇C can be approximated as equal to the applied chemical concentration. From the preceding equation, it can be seen that the rate of absorption is directly proportional to the applied concentration. The diffusivity represents the rate of migration of the chemical through the stratum corneum. Since the stratum corneum has a nonnegligible thickness, there is a period of transient diffusion (lag time), during which the transfer rate rises to reach a steady state. In these studies, the steady state is maintained indefinitely, provided the system remains constant. Depending on the type of chemical, the lag time can range from minutes to days (192). From an exposure assessment standpoint, if the exposure duration is shorter than the lag time, it is unlikely that there will be any significant systemic absorption (142, 349). The partition coefficient (K_p) is one of the key parameters that influences the degree to which a chemical penetrates the skin (14, 122, 128, 142, 349). Fatty chemicals tend to accumulate in the stratum corneum. Conversely, the stratum coraeum is an effective barrier for hydrophilic substances, which tend to have low skin absorption rates. Because stratum corneum/vehicle partition coefficients are

difficult to measure, the three parameters (*D*, *k*, and *e*) are combined to give an overall permeability coefficient *(Kp)*. It is noteworthy that Eq. (3) only approximates most in vivo exposure situations

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_404.html[2010/10/28 18:43:53]

in which true steady-state conditions are rarely attained. In spite of its limitations, this equation has yielded satisfactory estimations of the actual absorption rates of chemicals for many situations (Table 9.4).

Pharmacokinetic Models for Estimating the Uptake of Chemicals in Aqueous Solution

Pharmacokinetic models predict the uptake of a chemical through the skin based on fundamental thermodynamics. Several different models have been proposed. For example, a four-compartment pharmacokinetic model was developed in 1982 (128). This model, which uses first-order rate constants, describes chemical movement through the compartments representing the various skin structures. It has been used successfully to predict the chemical disposition in the skin and plasma as a function of their physicochemical properties, and when an input rate constant to the skin surface is added to the model, it can be used to assess vehicle effects. A similar model that treats the barrier membrane as a series of spaces filled with immiscible liquids has also been developed (14); its advantage is that it allows examination of non-steady-state conditions where Fick's law does not apply.

Under an infinite-dose situation where the amount of a chemical lost by penetration is too small to alter the applied concentration (e.g., where one is swimming), the rate of absorption is essentially linear once steady-state has been reached. In the finite-dose system, however, the chemical solution is applied as a thin film and the concentration decreases as penetration proceeds (e.g., a splash). All other model parameters being the same, penetration is reduced under finite-dose conditions. This is because the chemical concentration is continuously reduced over time, resulting in a decrease in the gradient across the stratum corneum. These modeling results indicate that the mechanism by which fluxes are affected must be considered when extrapolating to non-steady-state conditions.

Although classic pharmacokinetic modeling like that described by Guy et al. (42) can provide a good mathematical description of the disposition of chemicals, it does not depict exactly the biological processes in the intact animal. Fortunately, due to recent improvements in available computer hardware and software, pharmacokinetic methods based on physiological principles are now feasible alternatives for analysis of in vivo skin penetration studies. These so-called PBPK models realistically describe the disposition of the chemical in the intact animal in terms of rates of blood flow, permeability of membranes, and partitioning of chemicals into tissues (12, 14). Characterizing dermal absorption in terms of actual anatomical, physiological, and biochemical parameters facilitates extrapolations to the real species of interest, humans.

In 1991, a PBPK model was developed to describe percutaneous absorption of volatile organic contaminants in dilute aqueous solutions (316). The exposure scenario modeled was either hand or full-body immersion into a vessel of solute-contaminated water. Modeling results suggested that chemical uptake in aqueous solutions is most markedly influenced by epidermal blood flow rates, followed by epidermal thickness and lipid content of the stratum corneum. In general, thicker and fattier skin provides a better barrier to dermal penetration of chemicals. These are precisely the principles under which barrier creams offer their protection for increasing the effective thickness and lipophilicity of the skin. This model also predicted that the dose of some volatile organic chemicals in water absorbed through the skin during a 20-min bath may be equivalent to the amount inhaled (316).

Among the most complex and best validated of the various models for dermal uptake of liquids is that developed by McDougal (213). This team has successfully predicted dermal uptake rates for humans for more than a dozen chemicals based on animal data. One advantage of dermal PBPK models over traditional in vivo methods is their ability to accurately describe nonlinear biochemical and physical processes. For example, describing skin penetration based on blood concentrations or excretion rates as "percent absorbed" assumes that all processes have a simple linear relationship with the exposure concentration. This is often not the case. The kinetics become nonlinear when the absorption, distribution, metabolism, or elimination of a chemical is saturated at high exposure concentrations. This model and models developed since then address this phenomenon in a reasonable manner.

Factors Used to Estimate Dermal Uptake

Many factors need to be quantitatively accounted for in order to estimate the likely systemic uptake of a chemical that comes into contact with the skin, either as a liquid or when present in soil or dust (269, 376).

Dermal Bioavailability

The typical media of concern for assessing cutaneous contact to environmental chemicals, in contrast with occupational exposure, are house dust, soil, fly ash, and sediment. In the workplace, dermal uptake is due to direct contact with liquids and contact with surfaces contaminated with dirt or liquids. A number of parameters can influence the degree of cutaneous bioavailability of chemicals in complex

matrices. These may include aging (time following contamination), soil type (e.g., silt, clay, and sand), type and concentration

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_406.html[2010/10/28 18:43:54]

of cocontaminants (e.g., oil and other organics), and the concentration of the chemical contaminant in the media (321). The bioavailability of a chemical in soil will usually be affected by its physicochemical properties. High-molecular-weight chemicals tend to bind to soil/dust and be less water soluble, while smaller molecules will frequently be water soluble, less tightly bound, and relatively bioavailable (159, 215). The cutaneous bioavailability of perhaps 20 to 30 chemicals in soils has been determined in animals (159, 321, 326, 358, 359, 420). These studies show that different media and different chemicals can yield dramatically different cutaneous bioavailabilities. The results of these studies, for example, produce values of bioavailability for different chemicals that range from 0.001 to 3% for chemicals in soil.

Skin Surface Area

There is an abundance of information about the surface area of different portions of the body. One simple approach is to use the "rule of nines" for estimating the surface area of the human body (334): the head and neck are 9%, upper limbs are each 9%, lower limbs are each 18%, and the front or back of the trunk is 18% (254). The U.S. EPA has estimated an exposed surface area (arms, hands, legs, and feet) of 2900 cm2 for children 0 to 2 yr old; 3400 cm2 for children 2 to 6 yr old; and 2940 cm2 for adults (an adult is assumed to wear pants, an open-neck short-sleeve shirt, shoes, and no hat or gloves) (377). When assessing chemical exposure in the ambient environment, most of the necessary surface area information can be found in the U.S. EPA *Exposure Factors Handbook* (386). Table 9.5 presents the skin surface areas commonly used when conducting exposure assessments (334). A distribution plot of skin area versus body weight has been developed (42).

Soil Loading on the Skin

A key factor to consider when estimating dermal uptake via soil is the soil-to-skin adherence rate. Values of 0.5 to 0.6mg/cm2 and 0.2 to 2.8 mg/cm2 have been reported for adults and children, respectively (59, 96, 259, 286). Recent works by Finley et al. (119), Kissel et al. (177), and Holmes et al. (156) have built on prior studies to show that dermal loading can vary significantly among different activities and different people. Based on data collected in past studies, in 1992 the U.S. EPA suggested a default soil-to-skin adherence rate of 0.2mg/cm2 (median) and 1.0mg/cm2 (95th percentile) for an adult. The recent edition of the *Exposure Factors Handbook* gives considerable attention to this topic (382, 384). One approach to improving dermal uptake calculations is to use area-weighted adherence factors as recently suggested by the U.S. EPA.

Table 9.5 Representative surface areas of the human body (Adult male)

Body portion	Area (cm2)
Whole body	18,000

Interpreting Wipe Samples

In some workplaces, wipe sampling has been conducted historically to assess the degree of surface contamination. Hospitals were among the first occupational settings, as long ago as 1940, to rely on this method to determine microbial levels in operating rooms. In pharmaceutical manufacturing, wipe sampling has been used as an indicator of hygienic conditions since the 1960s. The health physics profession has utilized wipe samples extensively as an indicator of the need for better housekeeping and decontamination; this group performed most of the early work in quantifying the relationship of wipe sample concentrations to dermal and oral uptake.

Over the years, few papers have discussed how to collect and interpret wipe samples (60, 109, 110, 114, 176, 210). When the primary effect of a chemical is skin discoloration, allergic contact dermatitis (ACD), or

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_407.html[2010/10/28 18:43:55]

chloracne, wipe sampling was nearly always the preferred approach for assessing the acceptability of the workplace (rather than relying on air samples). Beginning in the 1980s, a substantial number of wipe samples were collected in office buildings contaminated with dioxins and furans after electrical transformer fires to estimate the potential human exposure (222). The interpretation of these data was often mishandled and, as a result, a number of decisions by risk managers were less than optimal, resulting in significant unnecessary expenses. Today, better approaches are available.

Although wipe sampling data have generally been used as an indicator of cleanliness (60), these data can also be used to estimate systemic uptake of a contaminant if the degree of skin contact with the contaminated surfaces is known. While historical wipe sampling methods were rather imprecise, they were useful for obtaining a rough estimate of the possible exposure, which could be refined later by other means, such as biological monitoring.

If one knows that wipe sampling results are representative of what comes into contact with the hands (i.e., actually able to be absorbed), then the procedures for converting wipe sample data to estimates of systemic uptake are straightforward (35). For example, if one knows the number of times a surface (e.g., valve handle, instrument controller, or drum) is touched, the surface area of the hand touching these items (usually the palm), and the percutaneous chemical absorption rate, then the uptake can be estimated using wipe sample information. The best wipe sampling data were those collected in a reliable and consistent manner, with a focus on the mass per unit area. Hand wash sampling is often more representative than wipe samples (115).

Until recently, no standardized approaches existed for conducting wipe sampling. Differences in the use of wetting agent (acetone, methylene chloride, water, saline, isopropanol, and ethanol) and sampling media (paper, cotton, and synthetic fibers) produced drastically different results. In some procedures, especially those that used methylene chloride (in which the paint was concurrently stripped by the solvent), the chemical in the paint matrix was assumed to be bioavailable (a completely unreasonable assumption). Clearly, much of the previous work, which measured the amount of chemical released following aggressive scrubbing of the contaminated surfaces with detergent or solvent, did not reflect a realistic exposure scenario. Thus, there has been a need for standard techniques that attempt to mimic the conditions in which a hand comes into contact with a contaminated surface (210). Some of the techniques have been developed by hygienists involved in agricultural exposure assessment (179, 187, 188, 277).

In an attempt to fill this need, fairly sophisticated work to standardize these procedures has been conducted by researchers at Rutgers University. In fact, some of their wipe sampling procedures and devices have been patented (197). They have also developed a dry contact sampling device (198) that offers promise for understanding the hazard from surface dusts. The implications from recent wipe sampling research are that: (1) a minimum number of samples is needed to have statistical confidence; (2) the pressure applied to the cloth during sample collection should be standardized; (3) neat solvent should not be used as a collection media; (4) the size of the sample area needs to be sufficient to collect enough contaminant for quantification; and (5) the technique should be validated by using glove analyses.

Estimating the Dermal Uptake of Chemicals in Soil

One of the most frequently occurring exposure scenarios involving environmental exposures is that of contaminated soil (259). Unfortunately, dermal uptake of chemicals found on soil has rarely been evaluated experimentally (192). A model to estimate the amount of an organic chemical in soil that crosses the stratum corneum into the underlying tissue layer has been developed (215). To differentiate this absorptive process from bioavailability, which also includes transport into blood, McKone refers to the percentage of available chemical as an uptake fraction. The approach is based on the fugacity concept, which measures the tendency of a chemical to move from one phase to another. Because the skin has a fat content of about 10% and soil has an organic carbon content on the order of 1 to 4%, an organic chemical in soil placed on the skin will move from the soil to the underlying adipose layers of the skin. However, this transfer depends on the period of time between deposition on the skin and removal by evaporative processes. The mass-transfer coefficients of the soil-to-skin layer and the soil-to-air layer define the rate at which these competing processes occur.

Results of this model suggest that the chemical uptake fraction in soil varies with the exposure duration, soil deposition rate, and physical properties of the chemical, and is particularly sensitive to the values of Kow, as well as the mass or depth of soil deposited on the skin. When the amount of soil on the skin is low (<1 mg/cm2), a high uptake fraction, approaching unity in some cases, is predicted. With higher soil loading (20 mg/cm2), an uptake of only 0.5% is predicted. Because of the diverse variations of the

uptake fraction with soil loading, results obtained from experiments with a single soil loading should be applied with caution to human soil-exposure scenarios.

The dermal uptake of chemicals in soil is a complex process, but its behavior is predictable if the controlling factors are accounted for and quantified (192, 215). In

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_408.html[2010/10/28 18:43:55]

situations involving a relatively thin layer of a chemical on the skin for purposes of screening assessments, a few generalizations can be made. First, for chemicals with a high *K*ow and a low air:water partition coefficient, it is reasonable to assume 100% uptake in 12 h. Second, for chemicals with an air:water partition coefficient greater than 0.01, the uptake fraction is unlikely to exceed 40% in 12 h. Third, for chemicals with an air:water partition coefficient greater than 0.1, one can expect less than 3% uptake in 12 h. In most occupational settings, contaminated soil will rarely be in contact with the skin for greater than 4 h before it is washed off. Consequently, this should be accounted for when attempting to predict systemic uptake.

Dermal Uptake of Contaminants in Soil

To estimate chemical uptake, one needs to know the percutaneous absorption rate, the exposed skin area, the chemical concentration, and the exposure duration. One scenario would be a thin film of chemical on the skin. For this finite-dose scenario, Eq. (5) is useful:

$$\text{Uptake (mg)} = (C)(A)(x)(f)(t) \qquad (5)$$

where *C* is the concentration of the chemical (mg/cm2), *A* the skin surface area (cm2), *x* the thickness of the film layer (cm), *f* the absorption rate (percent per hour), and *f* the duration of exposure (h).

Another scenario would be an excess amount of a chemical on the skin (i.e., infinite dose). In this case, the thickness of the chemical layer is not calculated and steady-state kinetics are assumed. For a chemical in an aqueous or gaseous media:

$$\text{Uptake (mg)} = (C)(A)(Kp)(t)(d) \qquad (6)$$

where *K*p is the permeability coefficient (cm/h) and *d* is the distribution factor.

For a neat liquid chemical,

$$\text{Uptake (mg)} = (A)(J)(t) \qquad (7)$$

where *J* is the flux of chemical (mg/cm2-h).

The U.S. EPA has suggested using the following equation for estimating percutaneous absorption of chemicals in soil (376):

$$\text{Uptake (mg)} = (C)(A)(r)(B) \qquad (8)$$

where *C* is the concentration of the chemical in soil (mg/g), *A* the skin surface area (cm2), *r* the soil-to-skin adherence rate (g/cm2), and *B* the cutaneous bioavailability (unitless).

Example Calculation 3: Skin Uptake of a Chemical in Soil

A person gardens with soil contaminated on average with 250 ng dioxin/soil (250 ppb). Assuming that the person's hands and lower arms are in contact with the soil, the soil loading is equal to 0.2mg/cm2, and the cutaneous bioavailability of dioxin in soil is 1% (321), what is the plausible uptake of dioxin by this person [using Eq. (8)]? Assume that the person washes his or her hands every 4 h and the exposed area of skin is 1800 cm2.

$$\text{Uptake (ng)} = (C)(A)(r)(B)$$

where:

$$C = 250 \text{ ng/g}$$
$$A = 1800 \text{ cm2}$$
$$r = 0.2 \text{ mg/cm2}$$
$$B = 0.01$$

By substitution:

$$\text{Uptake} = \left(\frac{250\,\text{ng TCDD}}{1\,\text{g soil}}\right)\left(\frac{0.2\,\text{mg soil}}{\text{cm}^2\,\text{skin}}\right)\left(\frac{1\,\text{g}}{10^3\,\text{mg}}\right) \times (1800\,\text{cm}^2\,\text{skin})(0.01) = 0.9\,\text{ng TCDD}$$

Note: A preferred method for performing this calculation, if data are available, is to use a flux rate (ng/cm2-h) for the chemical. Assume that rate is 500 ng/cm2-h:

$$\text{Uptake (ng)} = (C)(J)(A)(t)$$

where

$$J = 500 \text{ ng/cm2-h}$$
$$t = 4\text{h}$$

By substitution:

$$\text{Update} = \left(\frac{250\,\text{ng TCDD}}{1\,\text{g soil}}\right)\left(\frac{1\,\text{g}}{10^9\,\text{ng}}\right)(1800\,\text{cm}^2\,\text{skin})(4\text{h}) \times \left(\frac{500\,\text{ng}}{\text{cm}^2 - \text{h}}\right) = 0.9\,\text{ng TCDD}$$

Uptake of Chemicals in an Aqueous Matrix

Published estimates of dermal uptake of chemicals in water have generally focused on evaluating workplace or environmental exposure. A number of different scenarios have been evaluated (50, 117a, 168, 173, 314). If interested in the possible uptake of a chemical present in water, the amount of chlordane absorbed through the skin by a man swimming for 4 h in water containing 1 ppb chloroform has been estimated (168). This is useful to compare various approaches. For example, the amount of chloroform absorbed by a boy swimming for 3 h in

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_409.html[2010/10/28 18:43:56]

water has been calculated (277). Some have compared the amounts absorbed through the skin during a 10-min shower versus a 20-min bath with water containing 1 ppb 1,1,1-trichlorethane (171).

About 10 yr ago, it was recognized that in the indoor environment, oral exposure to volatile chemicals present in drinking water may not necessarily represent the vast majority of the risk. Specifically, it was found that inhalation exposure due to the release of vapors from liquids to which people were in close contact could be relatively high. For example, comparisons have been made of the chloroform concentration in exhaled breath after a shower to that after an inhalation-only exposure (168). The concentration after showering was about twice that after the inhalation-only exposure, indicating that the absorbed dose from the skin is approximately equivalent to that from inhalation absorption.

Example Calculation 4: Skin Uptake of a Chemical From Water

A person has filled his swimming pool with shallow well water contaminated with 0.002mg/ml (2 ppb) toluene. What is the plausible dermal uptake of toluene while swimming in the contaminated water for half an hour? Assume that 18,000cm2 of skin is exposed and the Kp is 1.01 cm/h. From Eq. (6):

$$\text{Uptake} = (C)(A)(Kp)(t)(d)$$

where

C= 0.002 mg/ml
A=18,000 cm2
Kp=1.01 cm/h
t=0.5h
d=distribution factor (1 ml of water covers 1 cm3)

By substitution:

$$\text{Uptake} = (0.002\ \text{mg/ml})(l8{,}000\ \text{cm2})(l.01\ \text{cm/h})(0.5\text{h}) \times (1\ \text{ml water}/1\ \text{cm3}) = 18\text{mg}$$

Percutaneous Absorption of Liquid Solvents

While the percutaneous absorption of chemical solutes generally proceeds by simple diffusion, the skin uptake of neat chemical liquids is not necessarily exclusively governed by Fick's law. Consequently, the uptake of neat liquid through the skin needs to be estimated using direct in vivo skin contact techniques. Table 9.6 presents the percutaneous absorption rates of some neat industrial liquid solvents that have been determined in human volunteer studies.

Table 9.6 Absorption rates of some neat industrial liquid chemicals in human skin in vivo

Chemical	Absorption rate (mg/cm2-h)
Aniline	0.2–0.7
Benzene	0.24–0.4
2-Butoxyethanol	0.05–0.68
2-(2-Butoxyethoxy)ethanol	0.035
Carbon disulfide	9.7
Dimethylformamide	9.4
Ethylbenzene	22–23
2-Ethoxyethanol	0.796
2-(2-Ethyoxyethoxy)ethanol	0.125
Methanol	11.5
2-Methoxyethanol	2.82
2-(2-Methoxyethoxy)ethanol	0.206
Methyl butyl ketone	0.25–0.48
Nitrobenzene	2
Styrene	9–15
Toluene	14–23
Xylene (mixed)	4.5–9.6
m-Xylene	0.12–0.15

Note. From Reference 192.

Example Calculation 5: Skin Uptake of a Neat Liquid Chemical

Due to carelessness or a leak, the inside of a glove becomes contaminated with 2-methoxyethanol. How much can be absorbed if a worker wears the contaminated glove on one hand for half an hour? Assume the surface area of exposed skin is 360 cm2 and the flux rate is 2.82 mg/cm2-h. From Eq. (7),

$$\text{Uptake} = (A)(J)(t)$$

where

A=360 cm2
J=2.82mg/cm2-h

$t=0.5\text{h}$

By substitution,

$$\text{Uptake}=(360\ \text{cm}^2)(2.82\ \text{mg/cm}^2\text{-h})(0.5\text{h})=508\ \text{mg}$$

To understand the relative hazard from skin exposure versus inhalation exposure, the dose of 2-methoxyethanol absorbed by the same worker via inhalation for 8 h (10 m^3

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_410.html[2010/10/28 18:43:57]

Page 411

Table 9.7 Percutaneous absorption rates for chemical vapors in vivo

Chemical	Skin update in combined exposure (%)[a]	Permeability coefficient *K*p (cm/h) Rat	Human
Styrene	9.4	1.75	0.35–1.42
m-Xylene	3.9	0.72	0.24–0.26
Toluene	3.7	0.72	0.18
Perchloroethylene	3.5	0.67	0.17
Benzene	0.8	0.15	0.08
Halothane	0.2	0.05	
Hexane	0.1	0.03	
Isoflurane	0.1	0.03	
Methylene chloride		0.28	
Dibromomethane		1.32	
Bromochloromethane		0.79	
Phenol			15.74–17.59
Nitrobenzene			11.1
1,1,1-Trichloroethane			0.01

Note. Rat data from Reference 214.

[a]In combined exposure, rats are simultaneously absorbing chemical vapors by inhalation and by whole-body absorption through the skin.

of air inhaled), assuming a threshold limit value (TLV) of 16mg/cm3, can be estimated and compared to the dose due to inhalation exposure. Assume an 80% inhalation uptake efficiency.

$$\text{Inhalation uptake} = (16\text{mg/m}^3)(10\text{m}^3)(0.8) = 128 \text{ mg}$$

Thus, the uptake of 2-methoxyethanol following 30 min of skin exposure of a single hand can be as much as 4 times that from inhalation for 8 h at the TLV concentration, a presumably safe level of exposure. From this example, it is clear that the cutaneous route of entry can, in some situations, significantly contribute to the total absorbed dose, especially in the occupational setting.

Percutaneous Absorption of Chemicals in the Vapor Phase

Until the 1990s, it was generally assumed that the plausible dose resulting from vapors absorbed through the skin was too low to pose a hazard. Only a few studies have examined this issue (173, 184, 391). A few clinical reports have encouraged some limited in vivo research to evaluate the absorption of several chemicals in the gaseous phase through the human skin (Table 9.7). A chamber system to measure the whole-body percutaneous absorption of chemical vapors in rats has been described by McDougal et al. (214), and this approach has produced some interesting results (208). In this system, chemical flux across the skin is determined from the chemical concentration in blood during exposure by using a PBPK model. In most cases, vapor absorption through the skin amounts to less than 10% of the total dose received from a combined skin and inhalation exposure. While there is good agreement between the rat and human in the relative ranking of the permeability coefficients among the chemicals studied, for an individual chemical the rat skin appears to be two to four times more permeable than the human skin. These observations are consistent with previously reported data (22, 34, 274, 275, 321).

It is generally not necessary to account for the contribution from percutaneous uptake of vapors when the occupational exposure limit (OEL) is used as a guideline for acceptable exposure, because uptake of vapors through the skin is usually inherent in the data; that is, the studies of animals or humans from which data were collected were usually exposed via inhalation (whole body) so dermal uptake of the vapor occurred. However, although good work practices and the law require that situations where persons are placed in atmospheres that are life-threatening, sometimes in emergency situations,

Page 412

airline (supplied air) respirators or self-contained breathing apparatus (SCBA) are worn in environments containing chemical concentrations 10-fold to 1000-fold greater than the TLV. In these cases, it is important to account for vapor uptake through either exposed or covered skin.

Although nearly all data on vapor absorption involve bare skin, the role of clothing in preventing skin uptake has occasionally been evaluated. For example, a study of workers wearing denim clothing indicated no decreased uptake of phenol vapors (274), but found a 20% and 40% reduction in uptake of nitrobenzene (273) and aniline vapors, respectively (100). Although standard clothing may slightly decrease the amount of a chemical transferred from air through the skin, it can be a significant source of continuous exposure if the clothing has been contaminated.

Example Calculation 6: Skin Uptake of a Chemical Vapor

Assume that a person needs to repair a leaking pump, so he enters a room wearing an airline respirator. Assume the room contains 500 mg/m3 nitrobenzene (100 times the current TLV) and it takes 30 min to repair the pump. How much nitrobenzene might be absorbed through the skin?

The head, neck, and upper limbs are assumed to be exposed (surface area=4860 cm2), and the rest of the body (surface area=13,140 cm2) is covered with clothing. Assume the percutaneous *K*p of nitrobenzene is 11.1cm/h, and that the clothing has reduced the skin uptake rate of vapors by about 20% (273). From Example 5.

$$\text{Uptake} = (C)(A)(K_p)(t)$$

$$\text{Uptake through exposed skin} = (500\,\text{mg/m}^3)(4860\,\text{cm}^2) \times (11.1\,\text{cm/h})(0.5\,\text{h}) \times (1\,\text{m}^3/10^6\,\text{cm}^3) = 13.5\,\text{mg}$$

$$\text{Uptake through clothing} = (500\,\text{mg/m}^3)(13{,}140\,\text{cm}^2) \times (11.1\,\text{cm/h})(0.8)(0.5\,\text{h}) \times (1\,\text{m}^3/10^6\,\text{cm}^3) = 29\,\text{mg}$$

$$\text{Total uptake} = 13.5 + 29 = 42.5\,\text{mg}$$

From this example, it is clear that if one enters an environment containing a high concentration of an airborne contaminant, even if a supplied-air respirator is worn, the degree of skin uptake of the vapor may be worthy of evaluation to ensure that the worker is protected. These kinds of calculations sometimes have to be conducted in difficult work environments that are in a state of alert (e.g., submarines, chemical plants during emergency situations, etc.).

ESTIMATING INTAKE VIA INGESTION

If the appropriate information is available, estimating the intake of various chemicals due to ingestion is a relatively straightforward exercise. In general, one is concerned with the ingestion of the following media: drinking water, other liquids, food, soil, and house dust. Drinking-water contamination may occur because of soil contamination from leaking underground storage tanks, landfills, or hazardous waste sites, as well as discharges from contaminated streams or water transport systems. Nearly all foods in Western society contain a number of intentional and unintentional chemicals, including pesticide residues, naturally occurring chemicals, and food additives that serve as preservatives or enhancers of taste or visual appeal. Soils are ingested as a result of eating incompletely washed vegetables, hand-to-mouth contact, and through direct ingestion by children. Soils are also ingested when particles too large to reach the lower respiratory tract are inhaled (and then are swallowed). House dust contaminated with a number of chemicals can be ingested due to contact with foods and hand-to-mouth activities (267).

Estimating Intake of Chemicals in Drinking Water

Estimating the magnitude of the potential dose of toxics from drinking water requires knowledge of the amount of water ingested, the chemical concentrations in the water, and the chemical bioavailability in the gastrointestinal tract. The amount of water ingested per day varies with each person and is usually related to the amount of physical activity. A good deal of literature has addressed the amount of water ingested by persons engaged in different kinds of activities (364, 366, 386).

Currently, the U.S. EPA suggests that when little is known about the specifics of exposure, a value of 2 L/d for adults and 1 L/d for infants (body weight of less than 10 kg) should be used as the default value. These rates include drinking water consumed in the form of juices and other beverages.

Numerous studies cited in the U.S. EPA *Exposure Factors Handbook* (383, 384) have generated data on drinking-water intake rates. In general, these sources support the U.S. EPA use of 2 L/d for adults and 1 L/d for children as upper percentile tap-water intake rates. Many of the studies have reported fluid intake rates for both total fluids and tap water. Total fluid intake is defined as consumption of all types of fluids including tap water, milk, soft drinks, alcoholic beverages, and water intrinsic to purchased foods. Total tap water is defined as water consumed directly from the tap as a bev-

Page 413

Table 9.8 Summary of tap-water intake by age

Age group	Intake (ml/d)		Intake (ml/kg-d)	
	Mean	10th–90th Percentiles	Mean	10th–90th Percentiles
Infants (<1 yr)	302	0–649	43.5	0–100
Children (1-10 yr)	736	286–1,294	35.5	12.5–64.4
Teens (11-19 yr)	965	353–1,701	18.2	6.5–32.3
Adults (20-64 yr)	1,366	559–2,268	19.9	8.0–33.7
Adults (65+yr)	1,459	751–2, 287	21.8	10.9–34.7

erage or used to prepare foods and beverages (i.e., coffee, tea, frozen juices, soups, etc.). Data for both consumption categories are presented in numerous publications. Table 9.8 presents typical information reported from these studies (377).

All currently available studies on drinking water intake are based on short-term survey data. Although short-term data may be suitable for obtaining mean intake values that are representative of both shortand long-term consumption patterns, upper percentile values may be different for short-term and long-term data because there is generally more variability in short-term surveys. It should also be noted that most of the currently available drinking water surveys are based on recall. This may be a source of uncertainty in the estimated intake rates because of the subjective nature of this type of survey technique (377).

To estimate the intake of toxics via direct ingestion of drinking water, the calculation is straightforward:

$$\text{Intake}=(V)(C)(B)$$

where *V* is the volume of water (L/d), *C* the concentration of chemical in water (μg/L), and *B* the bioavailability (unitless).

One of the more interesting observations of the past 15 yr is that ingestion of contaminated drinking water is sometimes not the primary route of exposure to the toxicant in drinking water. Uptake of volatile chemicals via inhalation can be nearly as great in some homes as ingestion, which is the result of the presence of these chemicals in air due to showering, off-gases from the dishwasher, and other opportunities for volatilization of the chemical (168, 171, 173, 208, 391).

The Importance of Soil Ingestion When Estimating Human Exposure

Between 1980 and 1995, predicted risks associated with the ingestion of contaminated soil were the primary drivers for remediating many (if not most) hazardous waste sites. As discussed by Paustenbach et al. (259), there was no better example than the site in Times Beach, MO. Hundreds of millions of dollars can be needed to clean up these kinds of sites to levels that would not pose a significant risk if children actually ate significant quantities of contaminated soil. Because of the expense of remediation, a good deal of research has been conducted over the past 15 yr to attempt to quantitatively understand this route of exposure.

Clearly, the ingestion of soil and house dust is a potential source of human exposure to toxicants (296–298). The potential for contaminant exposure via this source is greater for children because they are more likely to ingest greater quantities of soil than adults. Inadvertent soil ingestion among children may occur through the mouthing of objects or hands. Mouthing behavior is considered to be a normal phase of childhood development. Adults may also ingest soil or dust particles that adhere to food, cigarettes, or their hands. Deliberate soil ingestion is defined as pica and is considered to be relatively uncommon. Because normal, inadvertent soil ingestion is more prevalent and data for individuals with pica behavior are limited, the focus of most exposure assessments is on normal levels of soil ingestion that occur as a result of mouthing or unintentional hand-to-mouth activity (73, 174, 259, 377).

Mouthing activities by children, which are generally accepted as normal and commonplace [e.g., Barltrop (23) estimated that almost 80% of all children at age

1 yr exhibited mouthing tendencies], are potential exposure routes to trace amounts of soil and/or dust adhering to fingers, hands, and objects placed in the mouth. The available data indicate that soil exposure occurs through several indirect routes:

1. Soil contributes to house dust (e.g., by local dust deposition, and mud and dirt carried in by shoes and pets, etc.).
2. House dust (fine particles) adheres to objects and to children's hands.
3. Children ingest dust particles when sucking and mouthing objects and fingers.

Obviously, in some situations, exposure may be direct (a child playing outdoors may eat dirt directly). In other situations, oral exposure to chemicals in soil may occur via contamination of domestic water supplies or contamination of fruit and vegetable produce grown onsite. However, the content and concentration of dusts in the indoor environment, which may represent the most important source of indirect exposure to soil, need to be better understood (107, 267).

Many studies have been conducted to estimate the amount of soil ingested by children. Most of the early studies attempted to quantify the amount of soil ingested by measuring the amount of dirt present on children's hands and making generalizations based on behavior. More recently, soil intake studies have been conducted using a methodology that measures trace elements in feces and soil that are believed to be poorly absorbed in the gut. These measurements are used to estimate the amount of soil ingested over a specified period of time.

Studies off Soil Ingestion

In light of the importance of soil ingestion for estimating human exposure to contaminated soil, several literature surveys have been undertaken to identify the typical amount of soil consumed by children and adults (107, 174, 259, 377, 382). Research evaluating lead uptake by children from ingestion of contaminated soil, paint chips, dust, and plaster provides the best source of information. Walter et al. (417) estimated that a normal child typically ingests very small quantities of dust or dirt between the ages of 0 to 2 yr, the largest quantities between 2 to 7 yr, and nearly insignificant amounts thereafter. In the classic text by Cooper (71), it was noted that the desire of children to eat dirt or place inedible objects in their mouths becomes established in the second year of life and disappears more or less spontaneously by the age of 4 to 5 yr. A study by Charney et al. (65) also indicated that mouthing tends to begin at about 18 mo and continues through 72 mo, depending on several factors such as nutritional and economic status, as well as race. Work by Sayre et al. (310) indicated that ages 2 to 6 yr are the important years, but that "intensive mouthing diminishes after 2 to 3 years of age."

An important distinction that is often blurred is the difference between the ingestion of very small quantities of dirt due to mouthing tendencies and the disease known as pica. Children who intentionally eat large quantities of dirt, plaster, or paint chips (1 to 10 g/d), and consequently are at greater risk of developing health problems, can be said to suffer from the disease known as pica. This disease is known as geophagia if the craving is for dirt alone. Geophagia, rather than pica, is generally of greatest concern in areas with contaminated soil.

Duggan and Williams (99) have summarized the literature on the amount of lead ingested through dust and dirt. In their opinion, a quantity of 50 mg lead was the best estimate for daily ingestion of dust by children. Lepow et al. (191) estimated an ingestion rate equal to 100 to 250 mg/d (specifically, 10 mg ingested 10 to 25 times a day). Barltrop (23) and Barltrop et al. (25) also estimated that the potential uptake of soils and dusts by a toddler is about 100 mg/d. In a Dutch study, the amount of lead on hands ranged from 4 to 12ng. By assuming maximum lead concentrations of 500 ng/g (concentrations were typically lower) and complete ingestion of the contents adsorbed to a child's hand on 10 separate occasions, the amount of ingested dirt would equal 240 mg. Thus, in order to eat 10,000 mg soil/d, the rate once suggested by the Centers for Disease Control (174), children would have to place their hands into their mouths 410 times a day, a rate that seems improbable (232, 252).

A report by the National Research Council (232) addressing the hazards of lead suggested a rate of 40 mg/d. Day et al. (88) measured the amount of dirt transferred from children's hands (age range from 1 to 3 yr) to a sticky sweet, and estimated a daily intake of 2 to 20 sweets would lead to dirt intake of 10 to 1000 mg/d. Bryce-Smith (36) estimated 33 mg/d. In its document addressing lead in air, the U.S. EPA assumed that children ate 50 mg/d of household dust, 40 mg/d of street dust, and 10 mg/d of dust derived from their parents' clothing (i.e., a total of 100 mg/d).

Kimbrough et al. (174) used a series of assumptions about soil exposure when estimating the possible risks of contaminated soil at Times Beach, MO, based upon unpublished observations about children's behavior and hand-mouth activity. A few years later, Kimbrough noted that their estimate of up to 10,000 mg/d was clearly an exaggeration and her personal estimate would be nearer 50 mg/d (107).

La Goy (186) based his soil ingestion estimates upon a review of the literature, in particular using empirical data

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_414.html[2010/10/28 18:43:59]

derived by Binder et al. (28) and Van Wijnen et al. (397). Similarly, Paustenbach et al. (264) based their estimates upon a review of the literature, including the mass-balance quantitative study conducted by Calabrese et al. (55).

De Silva (90, 91) adopted a different approach that may overcome some of the uncertainties inherent in the assumptions of the above indirect studies. She applied a "slope factor" increase of 0.6mg/dl in children's blood lead levels for each 1000 ppm increase in soil lead [this factor was developed by Barltrop et al. (25) following his work on blood lead levels in children from villages on old mining sites]. De Silva then deduced that an increase of 0.6mg/dl in blood indicates an extra oral intake of 3.75 mg lead/d, based upon a U.S. EPA (367) calculation that an increase of 1.0 mg lead/d in children's diets produces an increase of 0.16 in the blood lead level. With a soil lead value of 1000 ppm, 3.75 mg soil would contain 3.75 mg lead, suggesting that 3.75 mg/d (say 4mg) of soil was ingested by the children. However, the slope factor used here may not be the most appropriate, since mining soil wastes typically have larger sized particles, which tends to decrease lead bioavailability compared with soil contaminated by lead smelter activity, and therefore reduces the slope factor.

A major step forward beyond estimating soil ingestion using indirect measurements has been the attempt to study tracer elements found in soil with elements measured in the urine and feces of children. Several studies have been conducted thus far that have used this approach (28, 53, 55–57, 90, 91, 336–339). One early tracer study evaluated the amount of soil eaten by 24 hospitalized and nursery-school children. They analyzed the amount of aluminum, titanium, and acid-soluble residue in the feces of children aged 2 to 4 yr. The data were normally distributed. They found an average of 105 mg/d of soil in the feces of nursery children, and 49 mg/d in hospitalized children. Even with the limited number of children in the study, the difference between the two groups was significant ($p<.01$). If the value for the hospitalized children is assumed to be the background level because these substances are taken in from nonsoil sources (e.g., diet and toothpastes), the estimated average amount of soil ingested by the nursery school children would be 56 mg/d. This value is in the lower range of estimates in the literature and supports the use of 100 mg/d as a conservative uptake of soil by toddlers (ages 2 to 4 yr).

There have been two major studies completed by Calabrese et al. (53, 55–57; 52, 58, 336, 341). In the first, they quantitatively evaluated 6 different tracer elements in the stools of 65 school children aged 2 to 4 yr. They attempted to evaluate children from diverse socioeconomic backgrounds. This study, conducted in Massachusetts, was more definitive than prior investigations because they analyzed the children's diets, assayed for the presence of tracers in the diapers, assayed house dust and surrounding soil, and corrected for the pharmacokinetics of the tracer materials.

In the second study, soil ingestion estimates were obtained from a stratified, simple random sample of 64 children aged 1–4 years residing on a superfund site in Montana. The study was conducted during the month of September for 7 consecutive days (58). Soil ingestion was estimated by each soil tracer via traditional methods as well as by an improved approach using five trace elements (A1, Si, Ti, Y, and Zr), called the Best Tracer Method (BTM), which substantially corrects for error due to misalignment of tracer input and output as well as error occurring from ingestion of tracers from nonfood, nonsoil sources, while being insensitive to the particle size of the soil/dust ingested. According to the BTM, the median soil ingestion was less than 1 mg/day while the upper 95% was 160mg/day. No significant age (1 year vs. 2, vs. 3) or sex-related differences in soil ingestion were observed. These estimates are lower than estimates observed in the first study, which was conducted in New England during September and October.

Based on the series of papers by the researchers at the University of Massachusetts (53, 55–57; 52, 336), a few generalizations can be made. These studies were difficult to conduct and interpret. Second, only children from a single climate were studied, and it can be expected that rates vary with the amount of time spent indoors and outdoors. Third, only a handful of children have been studied (less than 500), so it is not possible to characterize the percentage of children who might tend to ingest large quantities of soil or house dust. Fourth, the relevant amount of soil or house dust ingested indoors versus outdoors is not known yet. In most cases, the contaminant concentrations in dust can be quite different when found in a carpet versus the yard (267). Fifth, although there is some degree of uncertainty in the results of the various studies, it appears that a best estimate of soil intake for most children resides in the area of 10 to 25 mg/d. It appears that perhaps 1 to 5% of the children may ingest much larger amounts during certain days or weeks (e.g., 2000 mg/d), but these tendencies do not occur on a chronic basis.

It has been proposed that one can estimate uptake over the period of one year and they have proposed

lifetime values (337). Recent work by Calabrese and Stanek (52) suggests that prior work yielded reasonable results for purposes of risk assessment. Most of the values discussed here are presented in Table 9.9. As mentioned previously, another area of research impacting exposure assessments of contaminated soil, which has been and continues to be actively pursued, is the bioavailability of the contaminant in the soil matrix (159).

Table 9.9 Values for childhood and adult soil ingestion rates that have been used in health risk assessments conducted between 1984 and 2000

Author	Age	Soil and dust (mg/d)
Barltrop (24)	2–6 yr	100
Lepow et al. (190)	2–6 yr	100–250
Day et al. (88)	2–6 yr	10–1000
Kimbrough et al. (174) (CDC)	0–9 mo	0
	9–18 mo	1000
	1.5–3.5 yr	10,000
	3.5–5 yr	1000
	5+ yr	100
Hawley (149)	0–2 yr	Negligible
	2–6 yr	90
	6–18 yr	21
	18–70 yr	57
La Goy (186)	1–6 yr	500 (max.)
	1–6 yr	100 (ave.)
Calabrese et al. (55)	1–4 yr	27–85 (mean)
		9–16 (median)
Paustenbach (262)	2–4 yr	25–50
	Adults	2–5
De Silva (91)	Children	~4
U.S. EPA (386)	Children	200
Calabrese & Stanek (52)	Children	30–60 (best estimate)

What is the Significance of Pica?

There appears to be some confusion in the literature over what constitutes "pica." Pica can be defined as "the habitual ingestion of substances not normally regarded as edible," but some authors have included mouthing and sucking activities in their definitions (201). Others appear to assume that all children with pica necessarily must be habitual soil eaters. In fact, pica behavior may be generalized to the ingestion of many different (nonfood) substances, or may be specific to one substance such as paper, soap, or earth. It is likely that repetitive pica behavior specifically for dirt, or habitual "geophagia," rarely occurs in the general population in most industrialized countries (84, 350).

Pica should, therefore, be considered a "normal" temporary phenomenon in some children. In the general population, the prevalence of both mouthing and pica, and the range of articles ingested, has been shown to decrease with age (23). In the 1-yr-old age group, 78% of children mouthed objects and 35% ingested them; this behavior decreased at the age of 4 yr, when 33% were mouthing and only 6% had pica.

It is also relevant to note that in certain circumstances, pica for soil may be culturally determined (such as eating clay, high in silicon and aluminum, for its medicinal properties in the relief of stomach discomfort and diarrhea by some Aborigines; or the custom of eating earth during pregnancy in certain cultures) (107). For example, some women in the southern portions of the United States report a craving for and eat certain clays during pregnancy.

Pica may be associated with physical disorders, including iron deficiency. However, it has been debated whether pica represents a cause or an effect of these deficiencies. Pica can also be associated with mental illness. It has also been reported that 25% of institutionalized mentally handicapped adults indulged in pica of one kind or another (including bizarre objects ranging from rags and string to rocks, insects, and feces) (84).

Calabrese and Stanek (52) have indicated that in their studies, they have observed great variability in soil ingestion by children. They have noted, for example, that some children are highly variable in their soil ingestion activities, displaying little propensity for soil ingestion on one day while ingesting copious amounts the next day. While there has not been any concerted focus on the soil pica child, the available data indicate that some children ingest over 50 g of soil on particular days. They note that while it is true that some children will ingest large amounts of soil, it is far from certain whether soil pica is behavior that only a small subgroup displays over a limited number of years (e.g., one to six) or whether most children, on occasion, display this behavior or some combination of both behavioral patterns. Clearly, additional work is needed to understand this topic.

Soil Ingestion by Adults

For most persons beyond the ages of 5 to 6 yr, the daily uptake of dirt due to intentional ingestion is generally thought to be quite low. With the exception of some lower income persons who eat clays due to tradition or mineral deficiency, adults will not usually intentionally ingest dirt or soil. However, there are two other important ways in which adults eat dirt—incidental hand-to-mouth contact and through dust on vegetables. It has been shown that most soil ingested from crops comes from leafy vegetables. Interestingly, investigations at nuclear weapons trials have shown that particles exceeding 45 μm are seldom retained on leaves. Further, superficial contamination by smaller particles is readily lost from leaves, usually by mechanical processes or rain, and certainly by washing (308). As a result, unless the soil contaminant is absorbed into the plant, superficial contamination of plants by dirt will rarely present a health hazard (207, 259).

The estimated deposition rate of dust from ambient air in rural environments is about 0.012 mg/cm2-d, assuming that rural dust contains about 300 mg/g of lead (the substance for which these data were obtained). The U.S. EPA has estimated that even at very high air concentrations (0.45 mg/m3 total dust), it is unlikely that surface deposition alone can account for more than 0.6 to 1.5mg lead/g dust (2 to 5 μg/g lettuce) on the surface of lettuce during a 21-d growing period (252). These data suggest that daily ingestion of dirt and dust by adults due to eating vegetables is unlikely to exceed about 0 to 5 mg/d even if all of the 137 g of leafy and root vegetables, sweet corn, and potatoes consumed by adult males each day were replaced by family garden products.

In its document on lead, the U.S. EPA used worst-case assumptions to estimate that persons could ingest up to 100 mg of lead each day due to unwashed vegetables. The actual uptake by adults from vegetables should actually be much less, and is probably negligible, because the U.S. EPA estimate assumed that all of the suspended dust is contaminated; persons do not wash the vegetables; garden vegetables are eaten throughout the year, rather than only during the growing season; and persons actually replace most vegetables with their own garden products.

With respect to the second route—incidental ingestion—only a very limited amount of work has been conducted which addresses dust ingestion via this route. It has been suggested that the primary route of uptake will be through accidental ingestion of dirt on the hands, which may be of special concern to smokers, who tend to have more frequent hand-to-mouth contact. It is true that before the importance of this route of entry was recognized, persons who worked in lead factories between 1890 and 1920 probably received a large portion of their body burden of lead due to poor hygiene and ingestion of dust; however, such conditions are now rare in the United States and most developed countries.

Some persons have evaluated the exposure experience of agricultural workers who apply or work with pesticide dusts. Due to the frequency and degree of pesticide exposure during its manufacture or application, these data do not appear to be appropriate surrogates for estimating soil uptake from the hands of persons who live on or near sites having contaminated soil. In addition, most of the published studies on pesticides involve liquids such as the organophosphates, rather than "soil-like" particles. Exposure studies of persons who apply granular pesticides might be more useful for defining upper bound estimates of dermal exposure than estimates based on dusty workplaces (181).

At least one study has been conducted to specifically address soil uptake by adults involved in remediating waste sites (52, 284, 339: also see ref. 431). The results suggest that the amount of soil eaten by these workers is much less than the default value of 100 mg/d suggested by the U.S. EPA in a number of guidance documents and risk assessments. Based on all the available data, it appears that a value of 5–25 mg/day for soil ingestion by most adults is a reasonable one.

Estimating the Intake of Chemicals Via Food

Without question, the information necessary to accurately estimate the ingestion of xenobiotics via foods is one the most complex of all exposure calculations. The hundreds of different possible foods and dozens of different chemicals that can be present as a pesticide residue, coupled with the background concentrations of various chemicals in soil, make this a formidable task.

The methodology for estimating uptake via ingestion must account for the quantity of food ingested each day, the concentration of contaminant in the ingested material, and the bioavailability of the contaminant in the media. Over the past 20 yr, a significant amount of work has been directed at understanding these exposure factors. Specifically, an entire volume of the U.S. EPA *Exposure Factors Handbook* (Volume II) is devoted to this topic (386).

The approach to estimating uptake via foods was first applied in the late 1940s by the Food and Drug Administration (361) and had not changed appreciably through 2000. However, because of the passage of the Food Quality Protection Act of 1996 (FQPA), the methodology for estimating uptake of chemicals from foods will be changing dramatically over the next 5–10 yr. Specifically, the FQPA requires that all pesticide residues from foods be added together, in a prescribed manner based on target organ, with the goal of understanding the total daily dose of all residual pesticides in the diet. Then, if necessary, the pesticide manufacturers are expected to calculate the necessary residue level that their chemical may have in a particular food so that the total dose does not exceed a fraction of the acceptable daily intake (ADI). Since there are hundreds of foods and dozens of residues, this presents a formidable challenge.

Ingestion of contaminated fruits and vegetables is a potential pathway of human exposure to chemicals. Fruits and vegetables may become contaminated by several different pathways. Ambient air pollutants may be deposited on or absorbed by plants, or dissolved in rainfall or irrigation waters that contact the plants. Plant roots may also absorb pollutants from contaminated soil and groundwater. The addition of

pesticides, soil additives, and fertilizers may also result in food contamination (386). Formulas are available to predict the concentration of chemicals from the soil, which have deposited from the air, and remain after treatment with a pesticide.

The primary information source on consumption rates of fruits and vegetables among the U.S. population is the U.S. Department of Agriculture (USDA) Nationwide Food Consumption Survey (NFCS) and the USDA Continuing Survey of Food Intakes by Individuals (CSFII). Data from the NFCS have been used in various studies to generate consumer-only and per-capita intake rates for individual fruits and vegetables, as well as total fruits and total vegetables. CSFII data from the 1989–1991 survey have been analyzed by the U.S. EPA to generate per-capita intake rates for various food items and food groups (362, 365, 386).

Consumer-only intake is defined as the quantity of fruits and vegetables consumed by individuals who ate these food items during the survey period. Per-capita intake rates are generated by averaging consumer-only intakes over the entire population of users and nonusers. In general, per-capita intake rates are appropriate for use in exposure assessment for which average dose estimates for the general population are of interest, because they represent both individuals who ate the foods during the survey period and individuals who may eat the food items at some time but did not consume them during the survey period. Total fruit intake refers to the sum of all fruits consumed in a day, including canned, dried, frozen, and fresh fruits. Likewise, total vegetable intake refers to the sum of all vegetables consumed in a day, including canned, dried, frozen, and fresh vegetables.

Intake rates may be presented on either an as-consumed or a dry-weight basis. As-consumed intake rates (g/d) are based on the weight of food in the form in which it is consumed. In contrast, dry-weight intake rates are based on the weight of food consumed after the moisture content has been removed. In calculating exposures based on ingestion, the unit of weight used to measure the contaminant concentration in the produce will vary. Intake data from the individual NFCS and CSFII components are based on "as eaten" (i.e., cooked or prepared) forms of the food items or groups. Thus, no corrections are required to account for changes in portion sizes from cooking losses (249, 363).

Estimating source-specific exposures to chemicals in fruits and vegetables may also require information on the amount of fruits and vegetables exposed to or protected from contamination as a result of cultivation practices, the physical nature of the food product itself (i.e., those having protective coverings that are removed before eating would be considered protected), or the amount grown beneath the soil (i.e., most root crops such as potatoes). The percentages of foods grown above and below ground will be useful when the contaminant concentrations in foods are estimated from concentrations in soil, water, and air. For example, vegetables grown below ground would more likely be contaminated by soil pollutants, but leafy above-ground vegetables would more likely be contaminated by deposition of air pollutants on plant surfaces. Some examples of various exposure factors and confidence ratings for liquids and food are presented in Table 9.10 (386).

Individual average daily intake rates calculated from NFCS and CSFII data are based on averages of reported individual intakes over 1 d or 3 consecutive days. Such short-term data are marginally suitable for estimating mean average daily intake rates representative of both short-term and long-term consumption. However, the distribution of average daily intake rates generated using short-term data (e.g., 3 day) does not necessarily reflect the long-term distribution of average daily intake rates. The distributions generated from short-term and long-term data will differ to the extent that each individual's intake varies from day to day; the distributions will be similar to the extent that individuals' intakes are constant from day to day (386).

Day-to-day intake variation among individuals will be greatest for food items or groups that are highly seasonal, and for items or groups that are eaten year-round but are not typically eaten every day. For these foods, the intake distribution generated from short-term data will not reflect long-term distribution. On the other hand, for broad categories of foods (e.g., vegetables), which are eaten on a daily basis throughout the year with minimal seasonality, the short-term distribution may be a reasonable approximation of the true long-term distribution, although it will show somewhat more variability.

Other relevant fruits and vegetables intake studies include the U.S. EPA Dietary Risk Evaluation System (DRES), Office of Pesticide Programs (OPP). The OPP uses the DRES (formerly the Tolerance Assessment System) to assess the dietary risk of pesticide use as part of the pesticide registration process (249, 363). The OPP sets tolerances for specific pesticides on raw agricultural commodities based on estimates of dietary risk. These estimates are calculated using pesticide residue data for the food item of concern and relevant consumption data. Intake rates are based primarily on the USDA 1977–1978 NFCS, although intake rates for some food items are based on estimations from production volumes or other data (i.e., some items were assigned an arbitrary value of 0.000001 g/kg-d) (386). The OPP has calculated per-capita intake rates of individual fruits and vegetables for 22 subgroups of the population (age, regional, and seasonal) by determining the composition of NFCS food items and disaggregating

complex food dishes into their component raw agricultural commodities (RACs) (386, 422). The advantage of using these data is that complex food dishes have been disaggregated to provide intake rates for a very large number of fruits and vegetables. These data are also based on the individual body weights of the respondents. Therefore, using these data to calculate

Page 419

Table 9.10 Summary of default exposure factor recommendations and confidence ratings for citizens of United States

Exposure factor	Recommendation	Confidence rating
Drinking-water intake	21 ml/kg-d or 1.4 L/d (average)	Medium
rate	34 ml/kg-d or 2.3 L/d (90th percentile) Percentiles and distribution also included	Medium
	Means and percentiles also included for pregnant and lactating women	
Total fruit intake rate	3.4 g/kg-d (per capita average)	Medium
	12.4 g/kg-d (per capita 95th percentile) Percentiles also included	Low
	Means presented for individual fruits	
Total vegetable intake	4.3 g/kg-d (per capita average)	Medium
rate	10 g/kg-d (per capita 95th percentile) Percentiles also included	Low
	Means presented for individual vegetables	
Total meat intake rate	2.1 g/kg-d (per capita average)	Medium
	5.1 g/kg-d (per capita 95th percentile) Percentiles also included	Low
	Percentiles also presented for individual meats	
Total dairy intake rate	8.0 kg-d (per capita average)	Medium
	29.7 g/kg-d (per capita 95th percentile) Percentiles also included	Low
	Means presented for individual dairy products	
Grain intake	4.1 g/kg-d (per capita average)	High
	10.8 g/kg-d (per capita 95th percentile) Percentiles also included	Low in long-term upper percentiles
Breast-milk intake rate	742 ml/d (average)	Medium
	1,033 ml/d (upper percentile)	Medium
Fish intake rate	General population	
	20.1 g/d (total fish) average	High
	14.1 g/d (marine) average	High
	6.0 g/d (freshwater/estuarine) average	High
	63 g/d (total fish) 95th percentile long-term Percentiles also included	Medium
	Serving size	
	129 g (average)	High
	326 g (95th percentile)	High
	Recreational marine anglers	
	27 g/d (finfish only)	Medium
	Recreational freshwater	
	8 g/d (average)	Medium
	25 g/d (95th percentile)	Medium
	Native American subsistence population	
	70 g/d (average)	Medium
	170 g/d (95th percentile)	Low

chemical exposure may provide more representative estimates of potential dose per unit body weight. However, because the data are based on the NFCS short-term dietary recall, the same limitations discussed previously for other NFCS data sets also apply here. In addition, consumption patterns may have changed since the data were collected in 1977–1978. The OPP is in the process of translating consumption information from the USDA CSFII 1989–1991 survey to be used in DRES (386).

The USDA has also conducted a study entitled *Food and Nutrient Intakes of Individuals in One Day in the U.S.* (362, 386). The USDA calculated mean intake rates for total fruits and total vegetables using NFCS data from 1977–1978 and 1987–1988, and CSFII data from 1994–1995 (362, 386). Mean per-capita total intake rates are based on intake data for 1 d from the 1977–1978 and 1987–1988 USDA and NFCS, respectively. Data from both surveys are presented in the *Exposure Factors Handbook* to demonstrate that although the 1987–1988 survey had fewer respondents, the mean per-capita intake rates for all individuals agree with the earlier survey. Also, slightly different age classifications were used in the two surveys, providing a wider range of age categories from which exposure assessors may select appropriate intake rates. The age groups used in this data set are the same as those used in the 1987–1988 NFCS. Information for per-capita intake rates and consumer-only intake rates for various ages of individuals is also available. Intake rates for consumers-only were calculated by dividing the per-capita consumption rate by the fraction of the population using vegetables or fruits in a day (386).

The advantages of using these data are that they provide intake estimates for all fruits, all vegetables, or all fats combined. Again, these estimates are based on 1-d dietary data which may not reflect usual consumption patterns (386).

Intake of Fish and Shellfish

Contaminated finfish and shellfish are potential sources of human exposure to persistent chemicals and metals. Pollutants are carried in surface waters, but also may be stored and accumulated in sediments as a result of complex physical and chemical processes. Consequently, various aquatic species can be exposed to pollutants and may become sources of contaminated food (386).

Accurately estimating exposure to various chemicals in a population that consumes fish from a polluted water body requires an estimation of caught-fish intake rates by fishermen and their families. Commercially caught fish are marketed widely, making the prediction of an individual's consumption from a particular commercial source difficult. Because the catch of recreational and subsistence fishermen is generally not diluted in this way, these individuals and their families represent the population that is most vulnerable to exposure by intake of contaminated fish from a specific location (386).

Over the years, fish consumption survey data have been collected using a number of different approaches, which need to be considered when interpreting the survey results. Generally, surveys are either "creel" studies in which fishermen are interviewed while fishing, or broader population surveys (using mailed questionnaires or phone interviews). Both data types can be useful for exposure assessment purposes, but somewhat different applications and interpretations are needed. In fact, creel study results have often been misinterpreted because of inadequate knowledge of survey principles (280, 285, 386).

The typical survey seeks to draw inferences about a larger population from a smaller sample of that population. The larger population from which the survey sample is taken and to which the survey results are generalized describes the target population of the survey. In order to generalize from the sample to the target population, the probability of being sampled must be known for each member of the target population. This probability is reflected in weights assigned to each survey respondent, with weights being inversely proportional to sampling probability. When all members of the target population have the same probability of being sampled, all weights can be set to 1 and essentially ignored (102, 306).

In a mail or phone study of licensed anglers, the target population generally involves all licensed anglers in a particular area, and in these studies, the sampling probability is essentially equal for all target population members. In a creel study, the target population is anyone who fishes at the locations being studied; generally in a creel study, the probability of being sampled is not the same for all members of the target population. For instance, if the survey is conducted for 1 d at a site, then it will include all persons who fish there daily, but only about 1/7 of the people who fish there weekly, 1/30 of the people who fish there monthly, etc. In this example, the probability of being sampled (or inverse weight) is seen to be proportional to the frequency of fishing. However, if the survey involves interviewers who revisit the same site on multiple days, and persons who are only interviewed once for the survey, then the probability of being in the survey is not proportional to frequency; in fact, it increases less proportionally with greater frequency of fishing. If the same site is surveyed every day of the survey period with no

reinterviewing, all members of the target population would have the same probability of being sampled, regardless of fishing frequency, implying that the survey weights should all equal 1 (102, 302).
On the other hand, if the survey protocol calls for individuals to be interviewed each time an interviewer

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_420.html[2010/10/28 18:44:02]

encounters them (i.e., without regard to whether they were previously interviewed), then the inverse weights will again be proportional to fishing frequency, no matter how many times interviewers revisit the same site. Note that when individuals can be interviewed multiple times, the results of each interview are included as separate records in the database, and the survey weights should be inversely proportional to the expected number of times that an individual's interviews are included in the database (102, 302, 386).

Fish and shellfish exposure assessments are among the most complicated of all assessments (227). A significant portion of the *Exposure Factors Handbook* addresses this topic (386). Recently, fairly complex Monte Carlo methods have been applied to resolve many of the difficulties estimating exposure of anglers and their families (428).

Aggregate Exposure and FQPA

Pesticides are regulated under both the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Federal Food, Drug, and Cosmetics Act (FFDCA). In 1996, Congress passed the Food Quality Protection Act (FQPA) that amended both FIFRA and FFDCA. These laws mandated the U.S. EPA to register pesticides and set tolerances based on a safety determination, a reasonable certainty that use of a given pesticide or consumption of raw agricultural commodity of processed foods that contain the pesticide and its residues will cause no harm to human health or the environment. The U.S. EPA evaluates risks posed by the use and usage of each pesticide to make a determination of safety. Based upon this determination, the agency regulates pesticides to ensure that use of the chemical is not unsafe.

In the past, the U.S. EPA evaluated the safety of pesticides based on a single-chemical, single-exposurepathway scenario. However, FQPA requires that the agency consider aggregate exposure in its decisionmaking process. Section 408(a)(4)(b)(2)(ii) of FFDCA specifies with respect to a tolerance that there must be a determination "that there is a reasonable certainty that no harm will result from aggregate exposure to the pesticide chemical residue, including all anticipated dietary exposures and all other exposures for which there is reliable information." Section (b)(2)(C)(ii)(I) states that "there is a reasonable certainty that no harm will result to infants and children from aggregate exposure to the pesticide chemical residues" *Aggregate dose* is defined as the amount of a single substance available for interaction with metabolic processes or biologically significant receptors from multiple routes of exposure. *Aggregate risk* is defined as the likelihood of the occurrence of an adverse health effect resulting from all routes of exposure to a single substance. Conversely, *cumulative risk* is defined as the likelihood of the occurrence of an adverse health effect resulting from all routes of exposure to a group of substances sharing a common mechanism of toxicity.

As shown in Figure 9.5, the most basic concept underlying all aggregate exposure assessments is that exposure occurs to an individual. The integrity of the data concerning this exposed individual must be maintained throughout the aggregate exposure assessment. In other words, each of the individual "subassessments" must be linked back to the same person (394). Because exposures are based on that received by a single individual, aggregate exposure assessments must agree in time, place, and demographic characteristics. Each of these parameters have imbedded attributes that must be matched to create a reasonable assessment. Some of these imbedded attributes include:

• Time (duration, daily, seasonally).
• Place (location and type of home, urbanization, watersheds, region).
• Demographics (age, gender, reproductive status, ethnicity, personal preference).

To develop realistic aggregate exposure and risk assessments requires that the appropriate temporal, spatial, and demographic exposure factors be correctly assigned. Examples of some of these factors include sexand age-specific body weights, regional specific drinking-water concentrations of the pesticide being considered, seasonally based pesticide residues in food, and frequency of residential pest control representative of housing type. Once an aggregate exposure and risk assessment is completed for one individual, population and subpopulation distributions of exposures and risk may be constructed by probabilistic techniques (161).

An aggregate exposure and risk assessment is distinct from a cumulative risk assessment. Cumulative risk is defined as "the measure or estimate of distributions of exposures (doses) for a set of chemicals that act by a common mechanism of toxicity" (390). Cumulative risk assessment evaluates risks from multiple chemicals via all routes and pathways of exposure. The cumulative risk assessment considers the combined toxicological effect of a group of chemicals with a common mechanism of toxicity. The definition of a common mechanism of toxicity is "two or more pesticide chemicals that produce an adverse effect(s) to human health by the same, or essentially the same, sequence of major biochemical

events. The underlying basis of the toxicity is the same, or essentially the same, for each chemical" (390). Specific guidance concerning conducting a cumulative risk assessment is currently being developed (161).

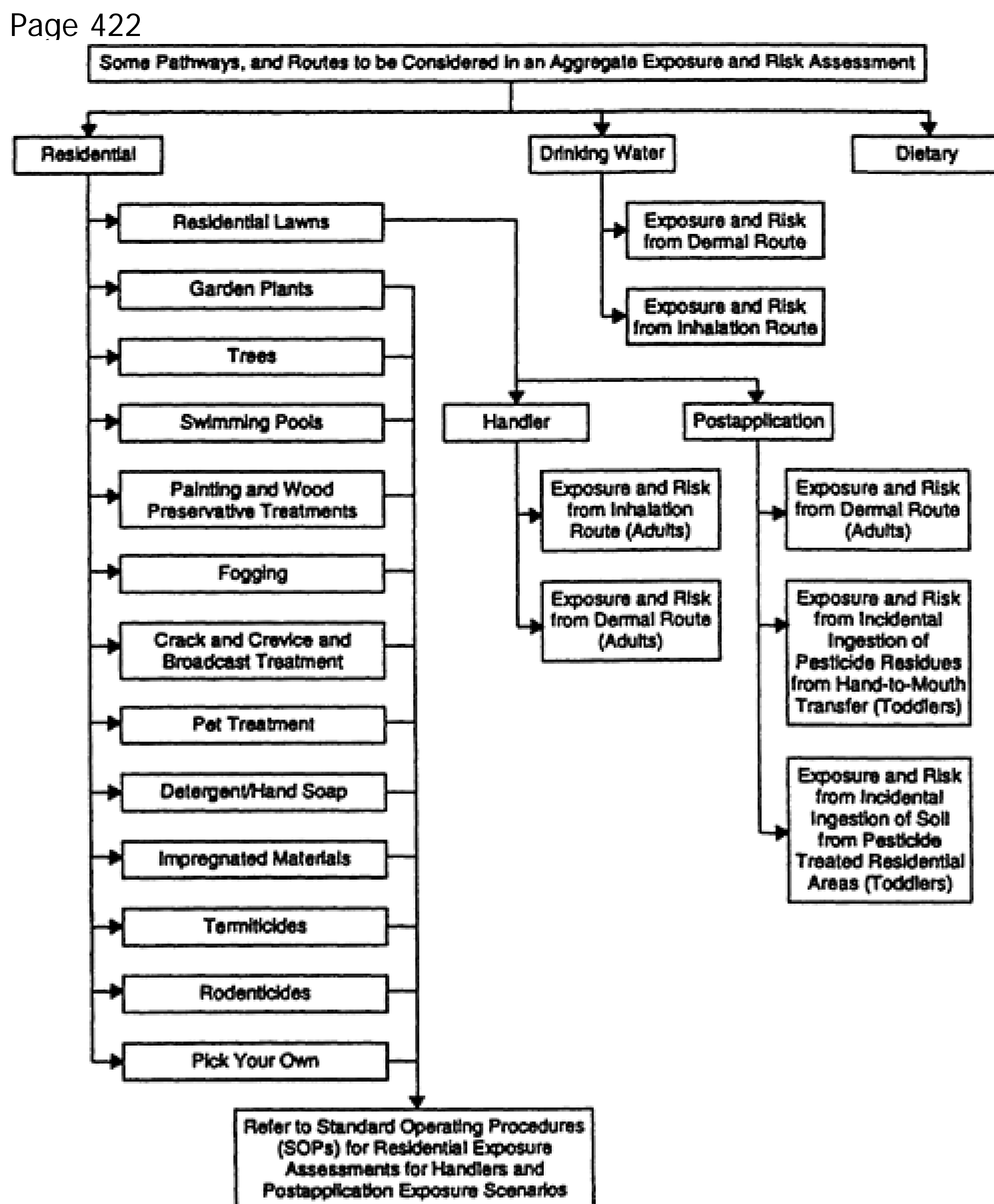

FIG. 9.5. Factors to consider in an aggregate exposure assessment of a pesticide. From Reference 394.

Breast Milk

Breast milk is a potential source of exposure to toxic substances for nursing infants. Lipid-soluble chemical compounds accumulate in body fat and may be transferred to breastfed infants in the lipid portion of breast milk. Because nursing infants obtain most (if not all) of their dietary intake from breast milk, they are especially vulnerable to exposures to these compounds. In fact, some models predict that the peak body burdens of certain chemicals (like dioxin) can reach their lifetime peak (μg/kg) on the last day of nursing at age 12–24 mo. Estimating the magnitude of the potential dose to infants from breast milk and the resulting body burdens of blood levels is quite complicated. It requires information on the quantity of breast milk consumed per day and the duration (months) over which breastfeeding occurs. Information on the fat content of breast milk is also needed for estimating dose from breast-milk residue concentrations that have been indexed to lipid con

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_422.html[2010/10/28 18:44:03]

Page 423

Table 9.11 Default values for daily intakes of breast milk

Age	Number of infants surveyed at each time period	Mean intake (ml/d)	Range of daily intake (ml/d)
Completely breast-fed			
1 mo		11600 ±159	426–989
3 mo		2833	645–1000
6 mo		1682	616–786
Partially breast-fed			
1 mo		4485 ±79	398–655
3 mo		11467 ±100	242–698
6 mo		6395 ±175	147–684
9 mo		3<554	451–732

Note. From Reference 249. Data expressed as mean ± standard deviation.

tent (331, 386). Until recently, these were considered the key parameters but it is now clear that one must account for the quickly increasing body weight of the infant, the differences in the blood perfusion of the fat compartments in the infant versus the mother, and other factors (172, 185).

Several studies have generated data on breast-milk intake (182, 230, 241, 332). Typically, breast-milk intake has been measured over a 24-h period by weighing the infant before and after each feeding without changing its clothing (test weighing). The sum of the difference between the measured weights over the 24-h period is assumed to be equivalent to the amount of breast milk consumed daily. Intakes measured using this procedure are often corrected for evaporative water losses (insensible water losses) between infant weighings (230). Neville et al. (241) evaluated the validity of the test-weight approach among bottle-fed infants by comparing the weight of milk taken from bottles with the difference between the before and after feeding weights of infants. Once corrected for insensible water loss, test-weight data were not significantly different from bottle weights. Conversions between weight and volume of breast milk consumed are made using the density of human milk (approximately 1.03 g/ml) (230). Recently, techniques for measuring breast-milk intake using stable isotopes have been developed; however, few data based on this new technique have been published (230).

Studies among nursing mothers in industrialized countries have shown that infant intake averages approximately 750 to 800 g/d (728 to 777 ml/d) during the first 4 to 5 mo of life, with a range of 450 to 1200 g/d (437 to 1165 ml/d) (230, 386). Similar intakes have also been reported for developing countries (230, 386). Infant birth weight and nursing frequency have been shown to influence the rate of intake (230, 386). Infants who are larger at birth and/or nurse more frequently have been shown to have higher intake rates. Also, breast-milk production among nursing mothers has been reported to be somewhat higher than the amount actually consumed by the infant (102, 386).

Like exposure assessments of fishes, techniques for estimating chemical uptake by children of breast milk continue to evolve. One of the more interesting papers on this topic was recently presented by Kerger et al. (172), which put into question most of the prior calculation approaches for estimating dose to nursing infants based, in part, on work conducted by Kreuzer et al. (185). A portion of the U.S. EPA *Exposure Factors Handbook* addresses this topic, and a few published papers have offered some novel approaches (331, 386, 387). Some examples of breast-milk intake rates are presented in Table 9.11. A distribution for breast-milk consumption has been suggested by Kerger et al. (1999).

ESTIMATING UPTAKE VIA INHALATION

Estimating intake via inhalation depends on only a few exposure factors, such as inhalation rate; airborne chemical concentration; bioavailability; and, if it is a particle, particle size. In general, uncertainty in estimates of intake via inhalation is among the smallest for all exposure calculations.

Inhalation rates are known to vary directly with the amount of physical activity of the persons being evaluated. The default value used by the U.S. EPA and others is 20 m3/d. When conducting occupational exposure assessments, it is common to assume that workers inhale about 10 m3 in an 8-h workday (377).

Airborne chemical concentrations are obtained through either direct measurement or modeling. The form of the chemicals in the air will be a gas (includes vapors) or particles (dusts or fumes). Generally, it is assumed that virtually all of the vapors or gases will be absorbed if inhaled (9, 184, 377). This may not be the case for volatile chemicals, if the concentration in the blood is approaching steady state. In those cases, a significant fraction of the inhaled vapors will be present in the exhaled breath and, therefore, not absorbed (275).

It is usually assumed that if particles enter the lower respiratory tract, they will eventually be absorbed unless the chemical is highly insoluble. Generally, it is assumed that particles less than 150 *μ*m in diameter are inhalable, but virtually all particles greater than 10 μm will be captured in the upper respiratory tract (nose and throat) and then ingested. It has often been assumed that particles less than 10 μm in diameter will be captured in the lower respiratory tract and the majority of these (by mass rather than particle number) will eventually be absorbed. Notably, for some chemicals, the adverse effect is related to the particle size, so this must be taken into account. For example, it is thought that beryllium particles should be collected in several different size fractions and that the severity of the adverse effect varies according to particle size.

Various Inhalation Rates

A significant amount of research has been done to correlate various inhalation rates with different tasks and body weights. Most studies on this subject have been summarized in the most recent U.S. EPA *Exposure Factors Handbook* (382). Data are available for dozens of different levels of physical activity and the distributions for several populations are presented.

A number of equations have been proposed for predicting the inhalation rate based on body weight (386). The *Exposure Factors Handbook* and other sources provide a number of tables that relate physical activity with inhalation rate (see Table 9.12).

Bioavailability of Airborne Chemicals

Because the mass of particles inhaled is usually quite small, and because most particles less than 10 μm in diameter are thought to be fairly easily absorbed, it is generally assumed that particles are 100% bioavailable after they

Table 9.12 Daily inhalation rates estimated from daily activities

	Inhalation rate (IR)		Daily inhalation rate (DIR)a (m3/d)
Subject	Resting (m3/h)	Light activity (m3/h)	
Adult man	0.45	1.2	22.8
Adult woman	0.36	1.14	21.1
Child (10 yr)	0.29	0.78	14.8
Infant (1 yr)	0.09	0.25	3.76
Newborn	0.03	0.09	0.78

Note. From Reference 334. Assumptions made were based on 8 h resting and 16 h light activity for adults and children (10 yr); 14 h resting and 10 h light activity for infants (1 yr); 23 h resting and 1 h light activity for newborns.

$$^{a}\mathrm{DIR} = \frac{1}{T}\sum_{i=1}^{k} \mathrm{IR}_i t_i$$

where IRi is corresponding inhalation rate at ith activity, ti, is hours spent during the ith activity, *k* is number of activity periods, and *T* is total time of the exposure period (i.e., a day).

are trapped in the lower lung. Likewise, it is generally assumed that most vapors and gases are completely absorbed (100% bioavailable) if they reach the lower respiratory tract. Both are conservative assumptions that should be reassessed on a case-by-case basis.

ROLE OF UNCERTAINTY ANALYSIS

Exposure assessment uses a wide array of information sources and techniques. Even when actual exposurerelated measurements exist, assumptions or inferences will still be required. Most likely, data will not be available for all aspects of the exposure assessment and these data may be of questionable or unknown quality. In these situations, the exposure assessor will have to rely on a combination of professional judgment, inferences based on analogy with similar chemicals and conditions, estimation techniques, and the like. The net result is that the exposure assessment will be based on a number

assumptions with varying degrees of uncertainty (377).

The decision analysis literature has focused on the importance of explicitly incorporating and quantifying scientific uncertainty in risk assessments (227, 302). Reasons for addressing uncertainties in exposure assessments include (377):

- Uncertainty information from different sources and of different quality must be combined.
- A decision must be made about whether and how to expend resources to acquire additional information (e.g., production, use, and emissions data; environmental fate information; monitoring data; population data) to reduce the uncertainty.

• So much empirical evidence exists that biases may occur, resulting in so-called best estimates that are not very accurate. Even when all that is needed is a best-estimate answer, the quality of the answer may be improved by incorporating a frank discussion of uncertainty into the analysis.
• Exposure assessment is an iterative process. The search for an adequate and robust methodology to handle the problem at hand may proceed more effectively, and to a more certain conclusion, if the associated uncertainty is explicitly included and it can be used as a guide in the process of refinement.
• A decision is rarely made on the basis of a single piece of analysis. Further, it is rare for there to be one discrete decision; a process of multiple decisions spread over time is the more common occurrence. Chemicals of concern may go through several levels of risk assessment before a final decision is made. During this process, decisions may be made based on exposure considerations. An exposure analysis that attempts to characterize the associated uncertainty allows the user or decision maker to conduct a better evaluation in the context of the other factors being considered.
• Exposure assessors have a responsibility to present not just numbers, but also a clear and explicit explanation of the implications and limitations of their analyses. Uncertainty characterization helps to achieve this.

Essentially, constructing scientifically sound exposure assessments and analyzing uncertainty go hand-in-hand. The reward for analyzing uncertainties is knowing that the results have integrity or that significant gaps exist in available information that can make decision making a tenuous process.

Variability Versus Uncertainty

While some authors treat variability as a specific component of uncertainty, the U.S. EPA (62) and others advise risk assessors (and, by analogy, the exposure assessor) to distinguish between variability and uncertainty (236). Specifically, uncertainty represents a lack of knowledge about factors affecting exposure or risk, whereas variability arises from true heterogeneity across people, places, or time. In other words, uncertainty can lead to inaccurate or biased estimates, whereas variability can affect the precision of the estimates and the degree to which they can be generalized.

Variability and uncertainty can complement or confound one another. The National Research Council (236) has drawn an instructive analogy based on estimating the distance between the earth and the moon. Prior to fairly recent technological developments, it was difficult to accurately measure this distance, resulting in measurement uncertainty. Because the moon's orbit is elliptical, the distance is a variable quantity. If only a few measurements were taken without knowledge of the elliptical pattern, then either of the following incorrect conclusions might be reached:
• The measurements were faulty, thereby ascribing to uncertainty what was actually caused by variability; or
• The moon's orbit was random, thereby not allowing uncertainty to shed light on seemingly unexplainable differences that are in fact variable and predictable.

A more fundamental error in this situation might be to incorrectly estimate the true distance and assume that a few observations were sufficient. This latter pitfall—treating a highly variable quantity as if it were invariant or only uncertain—is most relevant to the exposure or risk assessor (377).

Now consider a situation that relates to exposure, such as estimating the average daily dose by one exposure route—ingestion of contaminated drinking water. Suppose that it is possible to measure an individual's daily water consumption (and concentration of the contaminant) exactly, thereby eliminating uncertainty in the measured daily dose. The daily dose still has an inherent day-to-day variability, however, because of changes in the individual's daily water intake or concentration of the contaminant in the water (377).

Clearly, it is impractical to measure the individual's dose every day. For this reason, the exposure assessor may estimate the average daily dose (ADD) based on a finite number of measurements, in an attempt to "average out" the day-to-day variability. The individual has a true (but unknown) ADD, which has now been estimated based on a sample of measurements. Because the individual's true average is unknown, it is uncertain how close the estimate is to the true value. Thus, the variability across daily doses has been translated into uncertainty in the ADD. Although the individual's true ADD has no variability, the estimate of the ADD has some uncertainty (377).

The preceding discussion pertains to the ADD for one person. Now consider a distribution of ADDs across individuals in a defined population (e.g., the general U.S. population). In this case, variability refers to the range and distribution of ADDs across individuals in the population. By comparison, uncertainty refers to the exposure assessor's state of knowledge about that distribution, or about parameters describing the distribution

(e.g., mean, standard deviation, general shape, various percentiles) (377).

As noted by the National Research Council (1994), the realms of variability and uncertainty have fundamentally different ramifications for science and judgment. For example, uncertainty may force decision makers to judge how probable it is that exposures have been overestimated or underestimated for every member of the exposed population, whereas variability forces them to cope with the certainty that different individuals are subject to exposures both above and below any of the exposure levels chosen as a reference point (377).

Types of Variability

Variability in exposure is related to an individual's location, activity, and behavior or preferences at a particular point in time, as well as pollutant emission rates and physical/chemical processes that affect concentrations in various media (e.g., air, soil, food, and water). The variations in pollutant-specific emissions or processes, and in individual locations, activities, or behaviors are not necessarily independent of one another. For example, both personal activities and pollutant concentrations at a specific location might vary in response to weather conditions, or between weekdays and weekends (377).

At a more fundamental level, three types of variability can be distinguished:

- Variability across locations (spatial variability).
- Variability over time (temporal variability).
- Variability among individuals (inter-individual variability).

Spatial variability can occur both at regional (macroscale) and local (microscale) levels. For example, fish intake rates can vary depending on the region of the country. Higher consumption may occur among populations located near large bodies of water such as the Great Lakes or coastal areas. As another example, outdoor pollutant levels can be affected at the regional level by industrial activities and at the local level by activities of individuals. In general, higher exposures tend to be associated with closer proximity to the pollutant source, whether it be an industrial plant or related to a personal activity such as showering or gardening. In the context of exposure to airborne pollutants, the concept of a "microenvironment" has been introduced to denote a specific locality (e.g., a residential lot or a room in a specific building) where the airborne concentration can be treated as homogeneous (i.e., invariant) at a particular point in time.

Temporal variability refers to variations over time, whether long or short term. Seasonal fluctuations in weather, pesticide applications, use of woodburning appliances, and fraction of time spent outdoors are examples of longer term variability. Examples of shorter term variability are differences in industrial or personal activities on weekdays versus weekends or at different times of the day.

Interindividual variability can be either of two types: (1) human characteristics such as age or body weight, and (2) human behaviors such as location and activity patterns. Each of these variabilities, in turn, may be related to several underlying phenomena that vary. For example, the natural variability in human weight is due to a combination of genetic, nutritional, and other lifestyle or environmental factors. Variability arising from independent factors that combine multiplicatively generally will lead to an approximately lognormal distribution across the population, or across spatial/temporal dimensions (377; 153, 154).

Monte Carlo Analysis

Among the most promising and exciting techniques to emerge in the area of exposure assessment in recent years is the application of Monte Carlo or other probabilistic analyses to environmental health issues (98, 223, 379). Monte Carlo analysis has existed as an engineering analytical tool for many years, but the development of the personal computer and software [e.g., Crystal Ball (Decisioneering, Boulder, CO), @RISK (Palisades Corp., Newfield, NY)] has allowed its application to new areas. As discussed previously, one criticism of many exposure assessments has been a reliance on overly conservative assumptions about exposure, as well as the problem of how to properly account for the highly exposed (but usually small) populations that do exist (44,242). The Monte Carlo technique offers an approach to addressing this issue.

The probabilistic or Monte Carlo model accounts for the uncertainty in select parameters evaluating the range and probability of plausible exposure levels. Instead of specifying input parameters as single values, this model allows for consideration of the probability distributions. The Monte Carlo statistical simulation is a statistical model in which the input parameters to an equation are varied simultaneously. The values are chosen from the parameter distributions, with the frequency of a particular value being equal to the relative frequency of the parameter in the distribution. The simulation involves the following three steps:

1. The probability distribution of each equation parameter (input parameter) is characterized, and the distribution is specified for the Monte Carlo simulation. If the data cannot be fit to a distribution, the data are "bootstrapped" into the simulation,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_426.html[2010/10/28 18:44:06]

meaning that the input values are randomly selected from the actual data set without a specified distribution.
2. For each iteration of the simulation, one value is randomly selected from each parameter distribution, and the equation is run. Many iterations are performed, such that the random selections for each parameter approximate the distribution of the parameter. Five thousand iterations are typically performed for each dose equation.
3. Each iteration of the equation is evaluated and saved; hence a probability distribution of the equation output (possible doses) is generated.
This technique generates distributions that describe the uncertainty associated with the risk estimate (resultant doses). The predicted dose for every 50th percentile to the 95th percentile of the exposed population and the true mean are calculated. Using these models, the assessor is not forced to rely solely on a single exposure parameter or the repeated use of conservative assumptions to identify the plausible dose and risk estimates. Instead, the full range of possible values and their likelihood of occurrence is incorporated into the analysis to produce the range and probability of expected exposure levels (15, 43, 49, 98, 120, 332).
The methodology is illustrated in the following examples. The first example characterizes the time needed to go shopping. Time spent shopping each month (minutes) is estimated by the product of two parameters: the number of trips per month and the total time spent in the store (minutes). Total time spent in the store is the sum of time spent shopping and time spent waiting in line. Using Monte Carlo techniques, a distribution of likely values is associated with each of these parameters. These distributions depend upon the detail of information available to characterize each parameter. For example, the distribution compares all of the information, such as those days when the line at the check-out counter is short, as well as those when the line is long. It is noteworthy that each parameter has a different distribution: lognormal, gaussian, and square. Total time spent shopping is then calculated repeatedly by combining parameter values that are randomly selected from these distributions. The result is a distribution of likely time spent shopping each month. Using this technique, information concerning each parameter is carried along to the final estimate.
The second example, which directly applies to toxicologists, is to build a distribution that describes the various soil ingestion rates for children. As shown in Figure 9.6, the three pertinent distributions are the basis for constructing the overall exposure distribution.
Most of the variables used in an exposure assessment actually exist as ranges, rather than single point values and this is captured in Monte Carlo analysis. For instance, the common assumption that adult body weight is 70 kg will be replaced by the appropriate distribution (i.e., normal) of body weights (including maximum, minimum, mean, and standard deviation). Using this approach, virtually every exposure variable, whether physiological, behavioral, environmental, or chronological, can be replaced with a probability distribution (15, 43, 45–47, 49, 119, 120, 133, 162, 226, 282, 306, 332, 351, 353, 354, 357). Since no population (or individual) is exposed to a single concentration; breathes, eats, or drinks at a single rate; or is exposed for the same length of time, it is not appropriate to assess them as such. To be protective, high values are employed, resulting in the problems of compounding conservatisms mentioned previously (5, 44, 81, 124, 209).
The probabilistic analysis addresses the main deficiencies of the point estimate approach because it imparts more information to risk managers and the public, and uses all of the available data (27, 221). The range of values (i.e., the distribution) for all the variables used in an exposure assessment is determined (e.g., normal, lognormal, uniform, triangular, etc.) and combined into a "distribution of distributions." Because of the extrapolations involved and the assumptions made, the area of single greatest uncertainty in risk assessment is associated with the dose-response evaluations.
It should also be clear that, in addition to exposure variables, data forming the basis of the toxicological criteria (carcinogenic potency factors [CPFs] and reference doses [RfDs]) are also amenable to Monte Carlo-style analysis where a robust database exists (21, 33, 76, 78, 79, 111, 112, 152, 319, 322–324, 398). As with exposure variables, the advantage to this approach is that it allows all data to be used (and weighted appropriately, where necessary), thus avoiding reliance on a single experiment or endpoint.
Probabilistic analyses have in recent years been recognized in regulatory guidance (376), and the U.S. EPA Risk Assessment Forum has published a document of principles for conducting Monte Carlo analyses (76) (Table 9.13). Recently, the U.S. EPA (392) published a comprehensive guidance document on how to conduct Monte Carlo assessments.
Like traditional exposure analysis, one challenge to performing a Monte Carlo analysis properly is having

appropriate distributions for use in the analysis. Numerous studies on individual variables have been published in the risk assessment literature (27, 41, 42, 73, 74, 117, 129, 315, 330, 337, 338, 387), and the impact on the distributions employed on the outcome has also been discussed (40, 72, 143, 146, 148, 154). It should be pointed out that these techniques can be combined with other advanced risk assessment methods (i.e., PBPK modeling) to further reduce uncertainty in risk estimates (77, 325). Recently,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_427.html[2010/10/28 18:44:06]

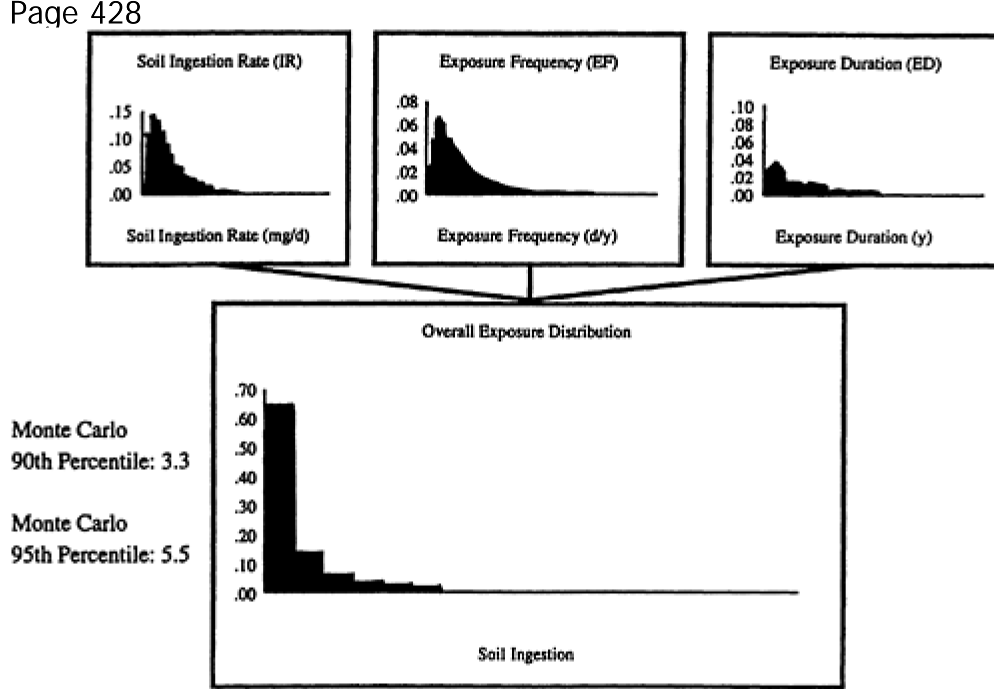

FIG. 9.6. Example of how probability density functions (distributions) for three different related exposure factors are combined to form a distribution for the amount of soil ingested by a population of children. The Monte Carlo technique allows the risk assessor to account for the variability in many exposure parameters within a population and then produce a distribution that characterizes the entire population.

two-dimensional Monte Carlo analyses have been developed that take into account both variability and uncertainty (82, 399). Information appropriate to probabilistic analyses can often be found in published papers in fields quite distant from the environmental sciences.

Case Study Using Monte Carlo Technique

An example might be useful (129). Assume that persons are likely to be exposed to contaminated drinking water at the maximum contaminant limit (MCL). Concern has been raised that these regulatory limits are not sufficiently protective, and that certain federal and state regulatory programs (i.e., Resource Conservation and Recovery Act) are justified in requiring groundwater remediation to levels below that of drinking water standards. To test this supposition, it is necessary to evaluate the possible incremental cancer risk of exposure via tap-water ingestion, dermal contact with water while showering, inhalation of indoor vapors, and ingestion of produce irrigated with groundwater, using a probabilistic approach. Probability density functions for each exposure variable (e.g., water ingestion, skin surface area, fraction of exposed skin, showering time, inhalation rate, air exchange and water use rates, exposure time, etc.) are then identified and used in the appropriate exposure equation to calculate dose and risk. A commercially available software package (i.e., @RISK) could be used to conduct the Monte Carlo analysis (357).

Some have suggested that the Latin hypercube (LHC) approach offers some advantages to traditional approaches for identifying the correct number of iterations. Often, one can reach convergence sooner with LHC than the Monte Carlo option in @RISK/Crystal Ball. In addition, LHC is more reproducible (to the hundredth decimal place). The Monte Carlo option needs more iterations to reach convergence.

The results of such an analysis are presented in Table 9.14 (129). The risk associated with exposure to water at the current maximum contaminant level (MCL) level for four different contaminants, as well as the 50th

Page 429

Table 9.13 U.S. EPA guiding principles for Monte Carlo analysis

1. Conduct preliminary sensitivity analyses to identify important contributors to the assessment endpoint and its variability and uncertainty.
2. Based on the results of the sensitivity analyses, include probabilistic assessments only for the important pathways and parameters.
3. Use the entire database of information when selecting input distributions.
4. When using surrogate data, identify sources of uncertainty, and whenever possible, validate the use of these data by collecting site/case specific data.
5. If empirical data are collected for use in the assessment, use collection methods that improve the representativeness and quality of these data (especially at the tails of the distribution.)
6. Identify when expert judgment, rather than hard data, is used in the assessment.
7. Separate uncertainty and variability during the analysis.
8. Use appropriate methods to address uncertainty and variability, e.g., two-dimensional Monte Carlo.
9. Discuss the numerical stability of estimates at the tails of the distribution.
10. Identify which sources of uncertainty are addressed by the assessment, and which are not.
11. Provide a detailed description of all models used.
12. Provide a detailed description of the input distributions, including a distinction between variability and uncertainty in these distributions, and a graphical representation of the probability density and cumulative distribution functions.
13. Provide a graphical representation of the probability density and cumulative distribution functions of each output distribution.
14. Consider the potential covariance between important parameters. If the covariance cannot be determined, evaluate the impact of a range of potential covariances on the output distributions.
15. Present point estimates and identify where they fall on the exposure distribution. If there are large differences between point estimates and Monte Carlo estimates, explain if the differences are due to changes in the data or models used.
16. Present results in a tiered approach.

Note. From Reference 161.

Table 9.14 Risks calculated for exposure to four halogenated solvents in water using probabilistic analysis at the MCL level and for the 50th and 95th percentile exposure

Chemical	50th Percentile risk	95th Percentile risk	MCL risk
Tetrachloroethylene	0	0.000005	0.000007
Chloroform	0.000009	0.00014	0.000017
Bromoform	0.000002	0.000016	0.000023
Vinyl chloride	0.000005	0.000029	0.000054

Note. Adapted from Reference 117.

and 95th percentile of exposure as determined by the probabilistic analysis, are shown. At the 50th percentile level ("the best estimate"), the risk ranges from 6×10^{-7} (tetrachloroethylene) to 9×10^{-6} (chloroform), while at the 95th percentile ("the upper-bound risk"), these risks range from 4×10^{-6} (tetrachloroethylene) to 1.5×10^{-4} (chloroform). These values can be compared to the point estimate risks calculated for the MCLs, which range from 7×10^{-6} (tetrachloroethylene) to 5.4×10^{-5} (vinyl chloride). For the 50th percentile (average) person, all calculated risks are within the range of "acceptable" risks adopted by regulatory authorities for Superfund sites (1×10^{-4} to 1×10^{-7}). For the 95th percentile person (upper bound), the risks are still mostly below the 1×10^{-4} benchmark risk level generally used to separate acceptable from unacceptable risks. For tetrachloroethylene,

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_429.html[2010/10/28 18:44:07]

these results are 30 (50th percentile) to 3 (risk at the MCL) times below the reasonable maximum exposure (RME) risk of 2×10^{-5} developed by combining the 95th percentile values for each exposure variable using standard U.S. EPA risk assessment methodologies. This point estimate is greater than the 99th percentile of risk and is consistent with statements regarding the conservatism of the RME approach. These results suggest that chemical residues in drinking water at the MCL levels will be health protective and that remedial goals based on de minimis requirements (1×10^{-6}) might be unnecessarily low (129).

In terms of estimates for the reasonably maximally exposed (RME) individual, which often serve as the basis for regulatory decisions, several observations on the utility of probabilistic assessment can be made. First, exposure assessments that incorporate two to three direct exposure pathways usually show that the 95th percentile probabilistic estimates are three to five times below the traditional RME estimates. Second, for multipathway assessments that contain several indirect exposure pathways, the 95th percentile probabilistic estimates can be as much as an order of magnitude below the RME estimates. Third, when the number of distributions used in the exposure assessment is 10 or more, the difference between the 50th and 95th percentile estimates may be between 5 and 10. Finally, in such assessments, the difference between the RME estimates and the 95th percentile probabilistic estimates can be as high as 100 (117). In the probabilistic approach to estimating exposure and risk, the complete range of potential risks can be illustrated along with the likelihood estimates and estimates of uncertainty associated with such risks. While the availability and confidence of distributions for exposure variables differ, risk assessors ought to take advantage of this and similar approaches in their risk assessments to advance and improve the process. Additionally, since the highest degree of uncertainty in risk assessment tends to be the CPFs, attention ought to be directed to applying probabilistic analysis to the development of toxicity criteria in a similar manner (111, 116, 398).

Sensitivity Analysis

In addition to establishing exposure and risk distributions, probabilistic analysis can also identify variables with the greatest impact on the estimates and illuminate uncertainties associated with exposure variables through sensitivity analysis (30, 160, 287, 299, 319). This provides some insight into the confidence that resides in exposure and risk estimates, and has two important results. First, it identifies the inputs that would benefit most from additional research to reduce uncertainty and improve risk estimates. Second, assuming that a thorough assessment has been conducted, it is possible to phrase the results in more accessible terms, such as "the risk assessment of PCBs in smallmouth bass is based on a large amount of high-quality reliable data, and we have high confidence in the risk estimates derived. The analysis has determined that 90 percent of the increased cancer risk could be eliminated through a ban on carp and catfish, but there is no appreciable reduction in risk from extending such a ban to bass and trout." Such a description provides all stakeholders with considerably more information than a simple point estimate of risk based on a traditional exposure and risk assessment (257).

If the most "sensitive" exposure variables are based on limited or uncertain data, confidence in these estimates will be poor. Robust data sets, on the other hand, lead to increased confidence in the resulting estimates. In the preceding example involving smallmouth bass, sensitivity is defined as the ratio of the relative change in risk produced by a unit relative to change in the exposure variables used. A Gaussian approximation (the product of the normalized sensitivity and the standard deviation of the distribution) of intake was used to allow both sensitivity and uncertainty to be gauged. In this case, the true mean of each distribution was chosen as the baseline point value, and the differential value for each variable was calculated by increasing this value by 10%. For each variable, the differential value was substituted, the risks recalculated, and the baseline value replaced (129). Sensitivity was calculated using the following formula:

$$\text{Sensitivity} = \frac{|\text{Risk}_{\text{baseline}} - \text{Risk}_{10\%}|}{|X_{\text{baseline}} - X_{10\%}|} \cdot [\sigma]$$

where Xbaseline and X10% are baseline and differential values for the variable *X*, and σ is the standard deviation for the distribution of variable *X*. The sensitivity of each variable relative to one another is assessed by summing the unitless sensitivity values and determining the relative percent that each variable contributes to the total.

Table 9.15 indicates which are the most important variables in a probabilistic analysis of tetrachloroethylene in household tap water. In this case, the most sensitive exposure variables in household exposure to tap water are exposure time in shower and exposure duration. Relatively small changes in these variables will result in relatively large changes in the risk estimates. Since these

estimates are based on actual time-use studies and census information, this suggests a high level of confidence can be placed on this estimate, particularly if site-specific data are being used. If the critical variables (in terms of sensitivity) were not based on robust data, this would suggest that the risk assessment could be improved by additional research on these exposure variables. It is interesting that the form of the distribution chosen for

Table 9.15 Results of sensitivity analysis for tetrachloroethylene exposure in household water

Exposure variable	Sensitivity (unitless)	Percentage rank
Shower exposure time	0.000004	55.0%
Exposure duration	0.000001	20.0%
Plant-soil partition factor	0	8.4%
Water ingestion rate	0	4.6%
Surface area of exposed skin	0	4.4%
Body weight	0	3.8%
Dermal permeability constant	0	1.8%
Skin fraction contacting water	0	1.5%

Note. Adapted from Reference 117.

the variables is less important than the validity of the data (118). When the empirical distribution of the tapwater ingestion rate from Ershow and Cantor (108) was substituted with a lognormal distribution developed by Roseberry and Burmaster (303), the resultant change in the risk estimates was less than 1% (357).

In this case, the value of the sensitivity analysis is that it allows input variables to be ranked in order of importance and confidence in the output to be established to a higher degree than previously possible. As pointed out by the U.S. EPA, where possible, exposure assessors should report variability in exposures as numerical distributions and should characterize uncertainty as probability distributions. They need to identify clearly where they are using point estimates for 'bounding' potential exposure variables or estimates; these point estimates should not be misconstrued to represent, for example, the upper 95th percentile when information on the actual distribution is lacking (324). As noted by the U.S. EPA, such explicit presentation of the data reduces the temptation to use the exposure assessment process for veiling policy judgments (141).

ISSUES IN EXPOSURE ASSESSMENT

The field of exposure assessment will continue to benefit from ongoing research efforts. The following are some fruitful areas of ongoing research.

Bioavailability

Applied research that will improve the practice of exposure assessment include bioavailability, speciation, chemical fate, and the role of biological monitoring. Bioavailability has become an increasingly important issue in the exposure assessment process (159, 202, 266, 305, 311). Alexander (3) has shown that a variety of organic chemicals in soil lose the ability to interact with biological

Table 9.16 Effect of matrix and aging on the bioavailability of lead from soil

Treatment			
Lead acetate (ppm diet)	Soil lead (ppm)	Tibial lead (standard deviation)	Relative lead absorption
—	—	0.3 (0.3)	—
—	11.3	0	—
50	—	247 (10)	100
50	11.3	130 (30)	53
—	706	40 (6)	16
—	995	108 (26)	44
—	1080	37 (7.3)	15
—	1260	53.6 (7)	22
—	10420	173 (22)	70

Note. Lead acetate in the diet results in an increase in tibial lead, while lead acetate mixed with soil is only 50% as well absorbed. Aged lead from garden soil must reach high levels before significant absorption occurs. Adapted from Reference 64.

receptors over time, despite the fact that the chemical concentration in soil remains largely the same. The alteration in bioavailability extends across the various routes of exposure as well (307, 321, 326, 358, 359, 420, 421). Inorganic compounds, even those posing a potentially significant degrees of hazard (i.e., cyanide) react similarly (85–87, 318). These losses in hazard potential are presumably due to irreversible chemical interactions with soil constituents. Table 9.16 indicates that the bioavailability of lead added to soil is immediately halved and that it is further reduced over time (64). This would suggest that an assumption of 100% bioavailability of this compound (and many others) from soil is erroneous. It is also clear that the environmental media in which the compound occurs will influence its uptake into the body (307). The U.S. EPA recognized this fact when it developed two reference doses (RfDs) for manganese depending on whether it occurred in solid matrices (e.g., food, soil, etc.) or water

(390). One simple method to improve bioavailability estimates is to conduct extractions under more biologically relevant conditions.

Bench-scale extraction experiments in simulated gastric fluids or sweat can be used to inexpensively and accurately measure how readily environmental residues can be released from the media in which they occur (157, 304, 305). As with inhalation or ingestion of vapors or solutions, both the release and absorption rates of agents from an environmental matrix (i.e., soil) across biological membranes need to be incorporated into the risk assessment when such data are available, and generated when absent. This need is particularly great when assessing dermal exposure. The problem for materials in aqueous solutions is less problematic than from solid

matrices (192). For liquids, permeability constants expressed in terms of agent weight per unit area per time (mg/cm2-min) have been developed for a number of agents, and in vivo and in vitro techniques or mathematical models exist to develop similar flux rates if needed (22, 26, 29, 31, 123, 142, 217, 316, 349, 419, 420). From soil, however, the typical approach in many risk assessments has been to assume a constant percent absorbed from soil adhered to skin as a default. For volatiles, an absorption rate of 25% has sometimes been used. For semivolatiles and inorganics, absorption rates of 10% and 1% have been used, respectively.

Some experimental data for absorption are available for a few agents (e.g., PCBs, DDT, dioxin, benzo[a]pyrene, etc.), suggesting that the simple assumption of a constant percentage absorbed may overestimate or underestimate the dose depending on the agent, cocontaminants, soil type, exposure duration, and similar considerations (321, 326, 420, 421). The impact of using this default approach results in an instantaneous dermal dose being assumed, regardless of whether the soil remains in contact with the skin for 1 min or 1 day. This assumption, together with the questionable route-to-route adjustment of toxicity criteria from oral to dermal, results in a predicted dermal absorption of agents from soil, which arguably should present a minor risk in most cases, being a major driver in the risk assessment of soilbound contaminants.

Chemical Fate

Risk assessors ought to incorporate information on the fate of chemicals in the environment in their exposure estimates, whenever possible (86). Many organic compounds tend to degrade over time, and may disappear from exposed surfaces relatively quickly or otherwise change (6, 255). As already suggested, inorganic compounds may also undergo changes in the environment over time that affect their fates (64, 318). Influencing factors include degradation by sunlight, soil and water microbes, evaporation, and chemical interactions. The resultant changes can dramatically alter the outcome of exposure assessments (87, 266). For instance, much of the criticism of incinerators has focused on the inhalation risk of dioxin emitted from the stacks. As it turns out, the environmental half-life of dioxin (as a vapor) is only 90 min because of photolytic degradation. In contrast, the half-life for dioxin in soil or fly-ash is 50 to 500 yr. The focus of concern is often not the main risk issue when environmental fate is considered because levels and availability change over time (269). Incorporation of half-life data into risk assessments can have substantial benefits for improving understanding of the potential exposures and risks associated with a specific situation (32).

In a similar manner, the risk from persistent contaminants (i.e., DDT) in fish has usually been assessed using results from the analysis of raw fish fillets in combination with assumptions about the size and number of fish meals. The effects of cleaning and cooking on these residues are not typically considered, but have been shown to be reduced substantially in many cases (i.e., 50% or greater) when cooked or processed (224, 427). Since many of these risk assessments form the basis of fish advisories or bans with potentially significant economic repercussions, there is obviously an important reason to make these exposure estimates as accurate as possible. Additionally, since there are known health benefits to fish consumption, making recommendations against eating fish based on theoretical risk deserves careful evaluation (352).

Biomarkers and Molecular Epidemiology

The past decade has witnessed a dramatic increase in the level of research activity, derivation of theoretical constructs, and development of practical applications for the direct measurement of biological events or responses that result from human exposure to xenobiotics (89, 147). These measurements, conveniently grouped under the descriptor "biological markers" or "biomarkers," reflect molecular and/or cellular alterations that occur along the temporal and mechanistic pathways connecting ambient exposure to a toxicant and eventual disease. As such, an almost limitless array of biomarkers is theoretically available for assessment, and only a minute fraction of these has been recognized and investigated to date (147, 155, 220). Some events that can technically be classified as biomarkers of chemical exposure (e.g., hematological changes following high levels of exposure to lead or benzene, acetylcholinesterase inhibition by organophosphates) have been measured for decades. However, the recent surge of interest in this field has been driven by technical advances in analytical chemistry and molecular genetic techniques and by the recognition that "classical" toxicology and epidemiology may not be able to alone resolve critical questions regarding causation of environmentally induced disease (89).

Biomarkers are an important component of the emerging discipline of molecular epidemiology, which seeks to expand the capabilities and overcome the limitations of classical epidemiology by incorporating biological measurements collected in exposed humans (89,429). Early efforts at utilizing biomarkers to

make quantitative estimates of exposure and to predict human cancer risk were made by Ehrenberg and Osterman-Golkar (105). Using ethylene oxide as a model xenobiotic, these investigators explored the use of macromolecular reaction products (i.e., hemoglobin

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_432.html[2010/10/28 18:44:09]

adducts) as internal dosimeters. By employing hemoglobin adduction data, they predicted the level of ambient ethylene oxide that would correspond to a tumorigenic dose of g-radiation, which they termed the "rad-equivalent dose." Seminal work in the area of biomarkers as applied to the molecular epidemiology of cancer was performed by Perera and Weinstein (271), who proposed the use of such techniques to identify environmental contributors to human cancer incidence. Important early applications of biomarkers to characterize environmental and occupational exposure have also been explored by several other groups in the United States and abroad.

As presented in the original NRC report, biomarkers of internal dose reflect the absorbed fraction of a xenobiotic, that is, the amount of material that has successfully crossed physiological barriers to enter the organism. Consequently, the magnitude of the biomarker accounts for bioavailability and is influenced by numerous parameters such as route of exposure, physiological characteristics of the receptor, and chemical characteristics of the xenobiotic. Generally, simple measurement of xenobiotic levels in biological media (blood, tissue, urine) can provide data on internal dose, and this is called biomonitoring (17, 18, 203). Biomarkers, on the other hand, reflect internal dose (in terms of proximity to downstream events in the sequence) and could include the measurement of a metabolite in selected biological media, particularly if such metabolite is active or critical to the toxic effects seen (89).

Very useful exposure biomarkers for reactive xenobiotics or their activated (i.e., electrophilic) metabolites are macromolecular reaction products. Substantial research effort has been devoted to the use of protein and DNA adducts as molecular dosimeters. Ehrenberg and co-workers first proposed using hemoglobin (Hb) adducts to monitor the internal dose of alkenes and epoxides such as ethylene oxide over two decades ago (105). This methodology has since evolved into a widely-used and highly sensitive technique for quantitating N-terminal Hb adducts of a variety of xenobiotic metabolites in human blood. Hb adducts have been employed as internal exposure biomarkers for aromatic amines, nitrosamines, polycyclic aromatic hydrocarbons (PAHs), and other compounds (89).

Protein and DNA adducts can be considered as biomarkers of either internal or biologically effective dose (BED), depending upon how close their relationship is to actual disease occurrence. The NRC report defined BED as dose at the site of action, dose at the receptor site, or dose to target macromolecules (233). This definition is troublesome since, strictly speaking, complete characterization of molecular site and mechanism of action for a given xenobiotic would be necessary in order to assign a particular measured end point as a marker of biologically effective dose. For example, protein adducts cannot be considered as effective dose biomarkers for carcinogens, since they do not satisfy these criteria. Ambiguity exists even for DNA adducts, since in no reported instance has xenobiotic-induced adduction of a specific base within a particular DNA sequence in a target cell type been unequivocally linked to a specific clinical outcome in people (89). Despite these uncertainties, adducts in total lymphocyte DNA are considered as appropriate BED biomarkers for carcinogens, based upon the postulated mechanism of chemical carcinogenesis and limited experimental data indicating correlations between DNA adducts in lymphocytes and target tissues (89).

Ideally, a biomarker should be biologically relevant, sensitive, and specific (i.e., valid). In addition, it should be readily accessible, inexpensive, and technically feasible. This combination of requirements is rarely achieved, and some trade-off is inevitable in order to obtain useful biomarker data in a timely manner. A few promising examples are presented in Table 9.17. The validation process for a biomarker involves determining the relationship between the biological parameter measured and both upstream and downstream events in the continuum, that is, the dose-response curve must be characterized (89). For example, an Hb adduct considered for use as an exposure biomarker for a xenobiotic should exhibit a predictable relationship to ambient exposure level. In addition, if used as a surrogate for DNA adduction, then a reproducible correlation between Hb and DNA adducts must be demonstrated. Biological relevance refers to the nature of the phenomenon being measured and its mechanistic involvement in the pathway from exposure to disease. For biomarkers of exposure, disease relevance is not as critical a requirement as is a predictable exposure-response relationship; the opposite is true for biomarkers of effect (89).

There are a few terms that are used when discussing biomarkers that help define their usefulness. *Sensitivity*, for example, reflects the ambient exposure level that can be detected by means of the biomarker. Highly sensitive markers are necessary to quantitate the low ambient levels typical of environmental exposures in industrialized Western nations. *Specificity* is the probability that the biomarker is indicative of actual exposure to the specific xenobiotic that it is designed to detect. For example, certain macromolecular adducts can be derived from exposure to a number of chemical species and are thus less specific than one unique to a single compound. Biomarkers must also be reasonably

accessible. Thus, with the exception of occasional tissue biopsies, samples for use in exposure biomarker studies generally consist of blood, urine, milk, or other readily obtainable biological media. Since these are rarely target tissues for toxicological or carcinogenic effects, how the concen

aBiomarkers for which cumulative data indicate best correlation with ambient exposure.

tration relates to the incidence of disease must be inferred. Finally, cost and technical feasibility are important considerations in selection of appropriate biomarkers for applied studies (89).

Statistical and Analytical Issues

Despite the use of precise and reproducible analytical methods, we often do not have enough data of chemical concentrations to estimate exposure with great certainty. Due to resource availability, over the past 15–20 yr it has often been the case that a single round of analytical results or samples collected for other purposes (140) serves as input and the surrogate for long-term or lifetime exposure. As noted previously, chemical concentrations vary over both time and space, which makes the task of dose estimation all the more difficult (224). For instance, to use the (estimated) average dose to predict the typical lifetime dose may seriously overestimate or underestimate the actual dose. Additionally, the average dose may be less important in the biological scheme of things than peak exposures or exposures at specific times (i.e., developmental effects), and ought to be considered as such in the evaluation of exposure (11). Techniques do exist for estimating long-term exposure from short-term data (37, 38, 328), but the reliability of these estimates is uncertain. Similarly, various mathematical or bench-scale models exist that have been used to estimate exposure in the absence of measurements or long-term monitoring data (342). As has been noted on several occasions, "all models are wrong, but some are useful," and risk assessors should carefully evaluate mesoscale and microscale models, as well as model outputs, for relevance and accuracy. Often, field measurements can serve as useful and relatively inexpensive "reality checks" on model results.

Equally important in exposure assessment are the statistics used to analyze field data. Environmental data are most often lognormally distributed. Under such conditions, a geometric average is generally assumed to be a better measure of the central tendency of data than the arithmetic mean (80). Despite this, the arithmetic mean (and the 95% upper confidence limit of the arithmetic mean) is typically used to identify environmental concentrations for use in exposure assessment. Since the advances in analytical chemistry have improved our ability to measure trace amounts of chemicals in different media and identify potential sources in some situations, less reliance should be placed on the use of mathematical models to predict the distribution of chemical and physical agents in the environment, and actual field data should be collected.

Another important issue in exposure assessment is how the analytical limit of detection (LOD) is handled in calculations. An agent reported as a nondetect may be treated as a numerical zero, or occurring at the LOD or some fraction of the LOD, typically one-half, for purposes of calculating statistics. The manner in which

censured data are assessed may affect the outcome of the risk assessment process (132, 144, 150, 158, 251, 272, 290, 356). For instance, analysis of highly contaminated samples or samples containing interfering substances may result in high LODs. Under such conditions and in the absence of additional analysis, assuming that nondetects are present at one-half the LOD could result in the exposure assessment and subsequent risk assessment being driven by compounds that are not truly present in the environmental media. When such an approach is used on a site that may be only 2 to 10% contaminated (based on surface area), the predicted severity of the level of contamination will be much higher than what actually occurs (80).

The practical result of these decisions can be illustrated by considering the following 11 data points resulting from analysis of field samples: Nondetect (ND), ND, ND, ND, ND, 5, 6, 6, 8, 55, and 500 ppm. The results are lognormally distributed as expected. The detection limit is 0.05 ppm, and nondetects are assumed to be present at one-half the detection limit (0.025 ppm). Using these assumptions, the arithmetic mean of the data set is 52.7 ppm, while the geometric mean is 1.3 ppm. The practical consequence of choosing one descriptor over the other may be to mischaracterize the dose and ultimately the risk, and this could influence regulatory decisions involving remediation or regulation.

CLOSING THOUGHTS

The field of exposure assessment has evolved significantly over the past 20 yr. We have learned a great deal about where people are exposed to xenobiotics and the relative degree of exposure. Not that long ago, most of our concerns were about industrial chemicals in our water, ambient air, and the soil. Today, we know that indoor exposure to particles, vapors, and gases (influenced by smoking) often represents the predominant source of exposure for most persons. A greater portion of our work in the future will undoubtedly focus on better understanding of both occupational and indoor exposure, rather than environmental exposures.

It is my personal view that of the four portions of a risk assessment, exposure assessment has made the biggest improvement in quality over the 20-yr history of health risk assessment. Usually, exposure assessments will contain less uncertainty than other steps in a risk assessment, especially the dose-response portion. Admittedly, there are a large number of factors to consider when estimating exposure, and it is a complicated procedure to understand the transport and distribution of a chemical that has been released into the environment. Nonetheless, the available data indicate that scientists can do an adequate job of quantifying the concentration of the chemicals in the various media and the resulting uptake by exposed persons if they account for all the factors that should be considered.

There are at least 11 significant lessons we have learned about conducting exposure assessments in recent years. Had we not had to learn through experience, avoiding these lessons could potentially have saved the United States hundreds of millions of dollars and thousands of person-years of work. First, experience has shown that in our attempts to be prudent, we placed too much emphasis on the "so-called" maximally exposed individual (MEI) (117, 242). Often, the results of those analyses were misinterpreted by the public and/or misrepresented by some scientists or lawyers. Often, as a result, poor decisions were made by risk decision makers.

Second, as we have learned how to accurately characterize the risks of exposure for about 95% of the population, more emphasis has been placed on evaluating the various special groups (e.g., Eskimos, subsistence fishermen, dairy farmers). Although the risk for these populations, who can be exposed to particularly high doses (the 95–99.99% group) needs to be understood, the typical levels of exposure for the majority of the population should be the initial focus of the assessment. Perhaps the most significant change in exposure asessment of the past three years has been the national interest in characterizing the risks to children.

The third lesson is a variation of the second: Do not allow the repeated use of conservative assumptions to dictate the results of the assessment. In recent years, many investigators have addressed this issue and have demonstrated its importance. Monte Carlo techniques can generally be successful in addressing this problem.

Fourth, we have learned that risk managers and the public want to understand the statistical confidence in our estimates of risk. Sensitivity analyses can yield important information about the critical exposure variables (132, 144, 290, 356). Further, most risk assessments can benefit from analyses of both variability and uncertainty. Without these, risk managers are not fully informed.

Fifth, we have improved our techniques for statistically handling data; and particularly for samples that have no detectable amount of a contaminant. In the past, regulatory agencies have used the limit of detection (LOD) of the analysis or one-half the LOD in the exposure calculations relying on the premise that the contaminant might be present at that level. We learned that when such an approach is used

(without reflection) on a site that may only be 2–10% contaminated (based on surface area), the impact of a few samples on the results could lead us to improper conclusions about the actual level of risk to persons who live there or nearby.

Sixth, we have gained a significant degree of confidence in our ability to estimate historical exposures; so-called

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_435.html[2010/10/28 18:44:11]

dose-reconstruction or retrospective risk assessments, a term that this author coined in 1983. Over the past ten years, for use in epidemiology studies, the likely exposure of workers and/or those in the community nearly forty to fifty years ago have been estimated using chemical usage and emission data, measured data, and models (145, 265, 294, 333, 345, 424).

Seventh, we now understand the need to quantitatively account for indirect pathways of exposure. For example, the uptake of a contaminant in water by humans due to ingestion is obvious (and direct), but the uptake of the same contaminant by garden vegetables due to watering and the uptake via the inhalation of volatile contaminants from the water while showering are indirect pathways that had not always been evaluated in assessments. Perhaps the most important indirect route of exposure, which had not been considered before 1986 when regulating airborne nonvolatile chemicals, was the ingestion of particulate emissions that have deposited onto soil and plants and were subsequently eaten by grazing animals (125, 388). Much additional research in this area will be conducted, and the results will probably change our views about the hazards posed by numerous chemicals.

Eighth, we have learned that children and their exposure patterns are unlike those of adults. As some have said, in more ways than one, children are not miniature adults! Their intake of certain foods, percentage of time spent outdoors, proximity to carpets, and inhalation rates per body weight are all different than adults.

The ninth lesson learned is to use biological monitoring to validate or confirm the predicted degree of human exposure. Over the past 5 to 10 yr, analytical chemists have increased their ability to detect very small quantities of dozens of chemicals in blood, urine, hair, feces, breath, and fat. For many chemicals, these data represent a direct indicator of recent exposure, and in some cases (like PCBs and dioxins), chronic exposure. Validation of our exposure assessments should be one of the major areas of study during the next decade (through both biomonitoring and molecular epidemiology).

Tenth, it has become clear that in most cases, the most significant risks due to exposure to chemicals occur in the workplace. Even though great strides have been made in industrial hygiene over the past 50 yr, the doses to which persons can legally be exposed are much greater (often by a factor of 100) than those to which most persons not in the community will ever be exposed.

Eleventh, and perhaps most important, we have learned that (for most persons) exposures to chemicals and bacteria in the home pose a greater risk than to those in the ambient air or through the ingestion of water. Many fine studies conducted in the 1970s through the current day continue to show that in-home exposures to most chemicals are often about 2–20 times greater than that present in the ambient environment (83, 131, 167, 183, 195, 196, 247, 407). Recently, more than 200 scientists in the fields of epidemiology, exposure assessment, and medicine signed a document called a "consensus statement," which states that future research should focus on personal monitoring; especially of the indoor environment (104).

We have come a long way in a short time. Several professional societies, including the International Society of Exposure Analysis (ISEA), Society for Risk Analysis (SRA), American Industrial Hygiene Association (AIHA), Air and Waste Management Association (AWMA), American Chemical Society (ACS), Society of Toxicology (SOT), International Society for Regulatory Toxicology and Pharmacology (ISRTP), and others, have placed an emphasis on improving the practice of exposure assessment. All indications are that the information we have gained has significantly improved the quality of recent risk assessments, and it can be expected that due to better exposure assessments, future decisions by risk managers will be much better informed.

QUESTIONS

1. What are the routes of exposure normally considered in an exposure assessment?
Answer: Dermal, inhalation, and ingestion
2. What is the definition of exposure assessment?
Answer: Exposure assessment is the step in the risk assessment that quantifies the uptake of an agent resulting from contact with various media (e.g., air, water, soil and food). These assessments can address past, current or future anticipated exposures.
3. When estimating uptake through the skin, what are the factors to be considered?
Answer. Percutaneous absorption rate, surface area of exposed skin, the chemical concentration, exposure duration, and interspecies scaling factor (if data were not collected using human skin).
4. What is a PB-PK model and why are they considered an important improvement over traditional toxicological methods?
Answer. A physiologically-based pharmacokinetic (PB-PK) model is a quantitative description of the absorption, distribution, metabolism and excretion (ADME) of a chemical in living organism (fish,

laboratory animal or human). These models are usually capable of scaling-up animal data to predict the behavior of the toxicologically important substance (parent or metabolite) in humans, thus representing a major improvement over traditional qualitative or semi-quantitative approaches.

file:///E|/0203362837__gigle.ws/0203362837__gigle.ws/0203362837/0203362837/files/page_436.html[2010/10/28 18:44:12]

5. Uncertainty analyses are an important component of exposure assessments. In these analyses, uncertainty is contrasted with variability. What is the difference between these two terms and give an example?

Answer. Uncertainty represents a lack of knowledge about factors affecting exposure. For example, if one can precisely measure a particular value, such as the amount of chicken eaten by a specific person on a particular day, then there would be no uncertainty in the measurement. On the other hand, if one wanted to understand the ingestion of chicken during adulthood, this would vary from day to day and week to week; thus this would represent variability. To understand the degree of variability, which could be measured, then a large number of measurements would be necessary. The three most common forms of variability are the variability across locations, variability over time, and variability among individuals.

6. Over the past ten years, monte carlo or probabilistic techniques have become an important and useful component of exposure assessment. Describe the technique and discuss what is learned from their application.

Answer. Monte carlo techniques attempt to describe the uncertainty in select exposure parameters without having to make a particular measurement during every event over a lifetime. For example, these techniques allow one to estimate with confidence the daily ingestion of water by a typical adult male without having to collect every glass of water drunk by a person (or group of persons) over their lifetimes. The technique generates distributions that describe the uncertainty associated with the risk estimate. By using this approach, the assessor is not forced to rely solely on a single exposure parameter or the repeated use of conservative assumptions to identify the possible dose and risk estimates for a population of persons.
