Genetic toxicology assessments should not consist of a single test. The multiplicity of mechanisms that could potentially be involved in genetic toxicity necessitates use of battery of tests that will detect, at least, the primary genotoxic mechanisms. Virtually all regulatory strategies include tests for gene mutation and clastogenicity and require at least one in vivo assay. It is important at the outset of testing to carefully define the objectives desired in a testing program. Screening to prioritize agents for further testing may employ different types of tests than would be used in hazard identification. The general guidance developed by most international bodies considers the overall strengths and limitations of the tests recommended in an attempt to minimize missing genotoxicants with high intrinsic risk.

Compared to conducting the tests, data assessment and interpretation can often be a more complex task. There is minimal guidance regarding interpretation of heterogeneous outcomes from a test battery. The general recommendation for the interpretation of mixed results (either all positive or all negative) is to conduct additional testing until a weight-of-evidence (WOE) assessment of the intrinsic properties of the agent is clearly defined.

Most decisions made for regulatory purposes are based on the response profile from a battery of tests specified by regulations or guidelines.[86] A few computer-based approaches have been developed for evaluating the results of multitest data sets. The EPA GAP approach of Waters et al.[83] and a method published by the International Commission for

TABLE 23.7
Possible In Vivo Follow-Up Tests to Support Isolated In Vitro Positive Responses

In Vitro Test Giving Positive Response	UDS in Rat Liver	Transgenic Mutation Tests	DNA Adducts	Comet Assay	Micronucleus Assay	Chromosome Aberration Assay
Gene mutation	+++	+++	+++	++*	–	–
Structural chromosome Damage (breaks, deletions, rearrangements)	–	+	+	++*	+++	+++
Numerical chromosome damage (aneuploidy or polyploidy)	–	–	–	–	+++ (aneu) ++ (poly)	++ (aneu) +++ (poly)

+++ Efficiently detected, ++ detected depending on test design or * not enough data available, + not always detected, – not detected.

Protection against Environmental Mutagens and Carcinogens (ICPEM)[87] were designed to produce WOE classifications for chemicals characterized by large data sets including multiple trials of the same test. In 2006, the U.S. Food and Drug Administration (FDA) provided a guide for the integration of genetic toxicology results into the safety assessment of pharmaceutical products.[88]

The most problematic data evaluation situation is the unique, unexpected positive response found in a battery of otherwise negative results. The positive response may be an important piece of information defining potential hazard or it may be a false-positive result. Distinguishing between the two possibilities is not always a simple task. When the positive response is produced by an in vitro test that can be followed up by an in vivo analog, a decision can be derived from the results of the in vivo test. A well-conducted negative in vivo study often trumps the in vitro positive. This is especially true if the in vitro positive is associated with certain testing features linked to generation of false responses (e.g., excess toxicity, extreme osmolality). Important lessons have been learned that can be applied when testing in vitro that may avoid spurious results and unnecessary additional testing.[89]

Regulatory Guidance for Environmental Agents

Recommendations outlining methods for routine genetic toxicology assays have been published by the EPA,[90] Organisation for Economic Co-operation and Development (OECD),[91] Canadian Health and Welfare,[92] and the European Economic Community.[93] Over the past decade, substantial progress has been made in harmonizing genetic testing requirements as well as the protocols used to conduct the tests. Today, most regulatory test batteries include, at a minimum, (1) the Ames test, (2) a test for in vitro and/or in vivo cytogenetic analysis, and, in some batteries, (3) an in vitro test for gene mutation in mammalian cells. Other tiers and tests may be included to expand the profile on the agent if positive results were obtained in these tests (Table 23.7).[94] It is also possible to add special tests that may be particularly informative for special chemical classes. Table 23.8 summarizes a uniform strategy for genetic testing for environmental agents.

TABLE 23.8
Proposed Tier-Based Testing Strategy for Environmental Chemicals

Level 1	Three in vitro tests: Ames test In vitro gene mutation test in mammalian cells In vitro chromosome aberration test in mammalian cells
Level 2	One or more in vivo tests in mammalian somatic cells: Chromosome aberrations in somatic tissue Micronucleus Comet assay or other in vivo alternative tests (i.e., UDS, DNA adducts, transgenic mutation)
Level 3	In vivo tests in mammalian gonadal tissue (germ cell targets): Chromosome damage (aberrations, micronuclei, SCE) Dominant lethal Transgenic mutation models
Level 4	In vivo intergenerational tests in mammals: Visible or biochemical-specific locus mutation Heritable translocations

Regulatory Guidance for Pharmaceutical Products

A standard core battery of tests for evaluating pharmaceuticals was developed under the International Conference on Harmonization of the Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). The ICH process resulted in two guidelines: (1) ICH S2A that provides guidance and recommendations for the conduct of genetic tests and (2) ICH S2B that establishes a standard genotoxicity test battery. In 2008, the ICH revised the recommendations[95] to include two options for a standard test battery:

Option 1

- A test for gene mutation in bacteria
- A cytogenetic test for chromosomal damage (the in vitro metaphase chromosome aberration test or in vitro micronucleus test) or an in vitro mouse lymphoma *tk* gene mutation assay
- An in vivo test for genotoxicity, generally a test for chromosomal damage using rodent hematopoietic cells, either for micronuclei or for chromosomal aberrations in metaphase cells

Option 2

- A test for gene mutation in bacteria
- An in vivo assessment of genotoxicity with two tissues, usually an assay for micronuclei using rodent hematopoietic cells and a second in vivo assay

This new approach has been accepted for pharmaceutical registration in the United States, Europe, and Japan, and either option is considered appropriate.

In most situations, Option 1 tests include the Ames tests, in vitro cytogenetics using a cell line or cultured human lymphocytes (in vitro micronucleus is also accepted), and a test for micronuclei induction in mouse or rat bone marrow cells. The thymidine kinase heterozygous (TK+/–) mouse lymphoma assay was initially preferred because it can serve as an in vitro measure of both gene mutation and chromosome aberrations since data have demonstrated that induction of mutation at the target gene (TK+) can be produced by either base-pair substitution mutation in the normal allele or by deletions of the allele through chromosome breakage. The result is a tk–/– cell, which can grow in the selective media. Base substitution mutants result in large colony tk–/– mutants, and the deletion mechanism produces small mutant colonies; consequently, use of the mouse lymphoma assay for ICH purposes requires colony sizing.[96] Option 2 is a relatively new approach that includes the Ames test and either a combined micronucleus and comet assay or a comet assay evaluating two tissues (e.g., a presumed target tissue and one other). Other in vivo tests such as metaphase chromosome analysis in rodents, transgenic animals, or UDS may be used, especially for agents with unique testing issues. OECD protocols (as well as draft protocols) are readily available for tests commonly used in either option. The primary reasons for developing a second option was the knowledge that most of the mammalian in vitro tests were too sensitive to secondary effects from toxicity as well as the need to address the goal of reducing unnecessary animal use.

New guidance has also been proposed to detect and evaluate the presence of genotoxic impurities in drug substances (i.e., active ingredients).[97] The guidance recommends reliance upon a combination of structure–activity relationship (SAR) models and results from the Ames test for identification of genotoxic impurities. Limits of impurities permitted in the drug substances are based on the clinical use (duration of exposure) of the drug substance and are set as an allowable daily intake of the impurity.

Limitations of Current Testing Strategies

By 1980, a large number of test methods had been proposed for the identification of genotoxicity. Some involved unique methods or target organisms, but many were duplicative of other tests. In the following decade, extensive efforts were undertaken to validate and evaluate the best test or set of tests for the purposes of detecting genotoxicants. In the process, several valuable lessons were learned:

- Current testing strategies do not cover all genotoxic mechanisms associated with human disease or cancer. Prime examples would be the absence of test to specifically detect aneugens (agents producing aneuploidy) or tests for agents inducing epigenetic responses (acetylation of lysine or methylation of cytosine). It is possible to detect some aneugens with a properly designed micronucleus study.[98]
- Some test methods appear to be hypersensitive to chemicals, which are not directly genotoxic and pose no significant risk. SCE detection is an example of a method that has an extremely high level of sensitivity and can be produced by lifestyle activities such as exercise or stress. The in vivo comet assay that detects SSB and DSB is also susceptible to false-positive responses from excessive toxicity that generates apoptosis at the target tissue site.[99] When conducting in vivo comet tests, it is prudent to include supplemental evaluations for apoptosis and target tissue histopathology to preclude false-positive responses due to secondary toxicity.
- Test methods that worked extremely well in the laboratory of the developer have not always transferred to other testing laboratories. The Syrian hamster embryo (SHE) assay was an example of such a test. The problems surrounding successful transfer of the technology involved acquiring the skill to detect minor variations in scoring transformed colonies and coping with unique specifications for primary embryo cell culture conditions.
- Most mammalian cell in vitro tests are susceptible to false-positive responses generated by nonphysiological treatment conditions, excessive cytotoxicity, or the production of reactive oxidation species generated by S9 mix chemistry.[89]

Several actions were taken in an attempt to resolve these issues. Genetic toxicology testing schemes have been simplified, and most agencies now expect to see the results from a limited test battery consisting of tests for gene mutation and chromosome aberrations before asking for further tests. Further testing is then based on the profile from the limited battery. Treatment conditions and dose level limits for in vitro tests have been spelled out in more detail and modified to minimize false-positive responses.[95] Although data analysis and interpretation methods are not uniformly applied, more guidance is becoming available.

Supplemental Test Methods

Several supplemental technologies may be applicable to filling gaps identified in existing strategies or to provide confirmatory follow-up to equivocal or suspicious positive

responses in basic batteries. Generally, these methods are performed in vivo, which adds a dimension of relevance that is able to put in vitro findings into better perspective:

- The single-cell gel electrophoresis (comet) assay has eclipsed the in vivo UDS assay as the most common follow-up test for positive findings in the ICH core battery (Option 1) and as a primary in vivo test in Option 2. The comet assay measures both SSB and DSB in specific tissues and or cell types.[100,101] The method is extremely versatile and can be used in human monitoring.[102] The protocol is standardized, and the method permits analysis of tissue- or organ-specific genotoxicity not available in most other in vivo assays. By including supplemental analyses for cytotoxicity in the study design, the comet assay can be an extremely valuable test. The relevance of SSB and DSB to the prediction of genetic or cancer risk has not been determined making extrapolation of comet responses to risk uncertain.
- Transgenic animals for mutation detection were developed in 1990 using shuttle vector technology. A few models commercially available in the 1990s, such as the MutaMouse and BigBlue Mouse, measured *lac I* and *lac Z* gene activation.[103] These models include mice and rats, which contain multiple copies of chromosomally integrated shuttle vectors with reporter genes that can be recovered and evaluated for mutation and/or chromosomal damage in vitro. These tests have been proposed as in vivo confirmatory assays *for* in vitro gene mutation (e.g., Ames) responses. The OECD is presently developing standard protocols for transgenic gene mutation models.
- The SHE cell transformation assay has been used in special situations because of its high predictivity of rodent carcinogenesis.[104] The most common application of this assay has been following the discovery of a positive genetic toxicology response for a product, already in human use, that does not have an animal cancer bioassay completed. A negative result in the SHE assay provides some degree of comfort that the positive test result may not be relevant. Difficulties associated with establishing this assay in the laboratory have been discussed earlier.
- A new in vivo gene mutation assay, phosphatidylinositol glycan Class A (PIG-A), is currently under development as a possible confirmatory test for in vitro gene mutation positive responses.[105] The PIG-A gene is located on the X chromosome and codes for a catalytic subunit of the *N*-acetylglucosamine transferase complex involved in an early step of the glycosylphosphatidyl inositol (GPI) cell surface anchor that binds specific protein markers to the exterior cell membrane. Mutation in the gene renders cells deficient in GPI anchors and, as a consequence, deficient in GPI-anchored cell surface markers. Mutant cells (PIG-A) deficient in a GPI-anchor protein called CD59 can be detected using labeled anti-CD59 with flow cytometry.

PIG-A is the only gene involved in GPI-anchor synthesis located on the X chromosome. The preferred method for detecting *PIG-A* mutant cells is the staining of peripheral red blood cells (RBCs) with fluorescently labeled anti-C59 antibodies followed by flow analysis. Both white and red blood cells can be used for the assay; however, larger sampling volumes with RBCs favor the use of this cell type. Early studies indicate that base-pair substitutions, deletions, and possibly other end points can be detected. The assay has several advantages including (1) a low spontaneous background ($<5 \times 10^{-6}$), (2) a cycle of time of several hours using flow analysis methods, (3) minimal blood volumes required when performed on RBCs, and (4) the ability to detect gene mutations in humans as well as rats. The method appears promising; however, the location of the gene on the X chromosome may suggest gene regulation processes unlike those associated with autosomal genes. A substantial amount of research on the susceptibility of this gene to multiple mutation pathways is ongoing, and several reference chemical mutagens have been shown to produce *PIG-A* mutations of both base-pair substitutions and frameshift types.

ASSESSING GENETIC HAZARD AND RISK

Germ Cell Risk in Human Populations

Observations of new dominant mutations arising in human populations and extensive experimental data demonstrating chemically induced mutations in somatic cells as well as germ lines of mice document the presumption that all mammalian species, including humans, are susceptible to environmentally generated mutation.[11] The ability to demonstrate genetic toxicity to human populations through epidemiological methods has been limited by the following:

- The rarity of induced mutations in a population. The sample size required to detect even a large increase in mutation is prohibitive.
- The small number of dominant sentinel genes (i.e., express a visible phenotype) that are uniquely identified with specific genetic diseases.
- The difficulty in identifying reproductively active populations exposed to biologically significant levels of suspected mutagenic agents.
- Variable expression of newly induced recessive mutations in the F_1 postexposure.

In 1992, the United Nations Environment Program reviewed the status of and methods available for genetic risk assessment.[21] A more recent classification scheme was

TABLE 23.9
Qualitative Classification Scheme for Human Mutation Risk

Classification	Somatic Cells	Germ Cells
Human mutagen	Positive mutagenicity data from human somatic cells exposed in vivo. These compounds may also be human carcinogens	Positive data derived from human in vivo germ cell mutagenicity studies
Probable human mutagen	Unequivocal evidence for genotoxicity from in vivo mammalian tests with supporting in vitro evidence	Sufficient evidence of interaction with mammalian germ cells and genotoxicity. Includes positive results from studies of heritable mutation effects in vivo or positive germ cell chromosomal aberrations. Supporting evidence that the agent can reach human germ cells
Possible human mutagen	Some evidence for genotoxicity in vitro or in vivo	Evidence suggesting interaction with mammalian germ cells and some genotoxicity
Not mutagenic or equivocal classification	Negative and/or equivocal test results from valid in vitro and in vivo tests for genotoxicity	Absence of the ability for interaction with germ cells

Source: Dearfield, K.L. et al., *Mutat. Res.*, 521, 121, 2002.

proposed by the U.S. EPA.[12] The system provides a qualitative risk classification for an agent that is derived from a four-level testing scheme that starts with in vitro methods and progresses through in vivo somatic tests in level 2 and finally into germ cell assays in levels 3 and 4 (see Table 23.7). Based on the compilation of test results, chemicals will fall into one of the classes ranging from *not mutagenic* to *human mutagen* as shown in Table 23.9. Some regulatory agencies have modified the four-level strategy shown in Table 23.7 by combining levels (e.g., some combine levels 3 and 4); however, the scheme shown in Table 23.7 provides a suitable road map for most situations. A comprehensive list of OECD and EPA protocols is found in the review by Cimino.[86] The complete genetic risk assessment process involves several steps:

- Hazard identification—The qualitative assessment of the intrinsic toxicity of an agent. This is based on the existing database and addresses the question of whether there is potential for human genotoxicity.
- Dose–response assessment—The relationship between the dose of an agent and the induction of an adverse (genotoxic) effect is determined.
- Exposure assessment—A determination of the extent of human exposure to the agent.
- Risk characterization—A description of the nature and potential for genotoxicity risk to humans using the information from the exposure assessment and the dose–response data.

Although the risk classifications provided in Table 23.9 are a qualitative guide, quantitative risk analysis for genetic damage can be performed by extrapolating dose–response results from animal models such as the mouse-specific locus test or the mouse heritable translocation assay to humans (Table 23.10). From the mouse data, the incidence of mutation induction can be calculated for documented exposure levels and expressed as the probability of new disease occurrence in the exposed population. Additional scaling factors must then be included to extrapolate from mouse to human (e.g., DNA repair capacity differences, metabolic differences, dose rate differences). The same problems that confound cancer risk estimates derived from animal studies also affect the ability to generate accurate genetic risk estimates. These include the ability to quantify the nature and shape of the dose–response kinetics, define species differences in susceptibility, and determine factors that influence the phenotypic expression of new mutations. A small number of quantitative genetic risk assessments have been made using data from mouse models for mutation and clastogenesis.[19,20,106]

Somatic Cell Risk in Human Populations

Unlike germ cell risk, the evidence is clear that humans are susceptible to mutagenic effects in somatic tissues. Genotoxicity biomarkers have been used to assess environmental, occupational, medical, and lifestyle exposures on the genome of somatic cells.[107,108] The vast majority of the biomarker studies of genotoxic damage involve the evaluation of individuals for chromosomal alterations, micronuclei, and SCEs. Other methods used include DNA adduct formation,[41] comet assay,[102] mutagenic urine,[77] and Hprt mutation in mouse splenic T cells.[109] These tools work well where traditional epidemiologic studies are not suited and can accurately identify high-risk populations.

Au[108] summarized genotoxicity biomarkers according to their applicability for human assessment. Some methods such as DNA adductions and SCEs are ideal for measuring

TABLE 23.10
Road Map for Calculating the Frequency of New Mutations (n_n) Induced in a Human Population Using Animal Experimentation Data

Step 1	Induced mutation frequency per target gene per unit dose, determined in mice (n_i)	Exposure dose in humans (i)	Expected induced mutation, per gene, frequency following mutagen exposure (m_i)	$(n_i) \times (i) = (m_i)$
Step 2	Expected per gene mutation frequency due to mutagen exposure (m_i)	Number of disease-causing genes in the human genome (n_d)	Expected frequency of disease-causing mutations in the F_1 population following mutagen exposure (m_t)	$(m_i) \times (n_d) = (m_t)$
Step 3	Expected frequency of disease-causing mutations in the F_1 population following mutagen exposure (m_t)	F_1 population size (n_e)	Expected number of new mutations causing disease in the F_1 offspring resulting from exposure to the parental population (n_m)	$(m_t) \times (n_e) = (n_m)$
Step 4	Introduce scaling factors into the calculation			(n_m) = scaling factors $\times (m_t) \times (n_e)$

exposure but carry little or no information regarding hazard potential or risk (Table 23.11). The majority of biomarkers identify biological effects indicative of possible genetic hazard. Evidence supporting the reliability of chromosome aberrations was derived from a European collaborative study assessing the predictive value of chromosome aberrations and SCEs.[107] The results showed that aberrations, particularly chromosome rather than chromatid alterations, were predictive of cancer but that SCEs were not.

Peters et al.[110] were able to demonstrate that heterocyclic amine carcinogens formed during the cooking of red meat could be detected as mutagens in urine of individuals consuming the meat. The results of their case-controlled study demonstrated that urinary mutagenicity was a valid biomarker for exposure to the consumption of cooked meat and also for colorectal adenoma risk.

TABLE 23.11
Biomarkers Applicable to the Identification of Human Genotoxic Hazard and Cancer Risk

Biomarker Function	Methods
Identifies exposure to genotoxic agent	DNA adducts
	Protein adducts
	SCE
Identifies hazard potential	DNA breaks (e.g., comet assay)
	DNA repair by-products in urine
Identifies genotoxic hazard	Chromosome breaks
	Micronuclei
	Mutagens in urine
	Gene mutation (HPRT or PIG-A) in lymphocytes
Indicates cancer risk	Mutations in specific codons of cancer genes (e.g., *ras*, p53, breast/colon cancer genes)
	Chromosome aberrations

While most of the genes responsible for human disease are located in nuclear DNA, mutations in somatic cell mitochondrial DNA (mtDNA) are also linked to a wide array of diseases and to aging.[111] Mitochondria are maternally inherited, and there are several hundred mitochondria per cell. mtDNA codes for about 13 proteins primarily involved in oxidative metabolism. Both nuclear and mitochondrial genes are necessary for the normal function of mitochondria. DNA repair processes such as long- and short-patch BER and MMR are active in mitochondria.[112] Mutations found in mtDNA appear as base substation mutations or deletion/insertion mutations. Mutant mitochondria are randomly distributed to daughter cells during cell division and increase the number of cells carrying mutant (dysfunctional) mitochondria in a particular tissue. When energy output in that tissue eventually becomes insufficient, clinical symptoms appear.[112] The types of diseases associated with mitochondrial mutations include metabolic disorders such as diabetes and degenerative disorders including neurophysiological and cardiovascular dysfunction. Studies have also shown that mtDNA mutations accumulate in postmitotic tissues over time in animals and contribute to the aging process.[111]

NEW DIRECTIONS IN GENETIC TOXICOLOGY

In 2008, the International Life Sciences Institute (ILSI), Health and Environmental Sciences Institute (HESI) Project Committee on the Relevance and Follow-up of Positive Results in in vitro Genetic Toxicology (IVGT) sponsored a workshop to identify promising technologies that would improve future testing and hazard assessment. The workshop (summarized in *Environmental and Molecular Mutagenesis*, 2001; 52:205–223) reviewed 16 methods or technologies and identified their stage of development. Some of the tests reviewed have since replaced existing tests and/or moved into more routine use since 2008, but the summary

does give some view into the possible application of technologies that still remain on the horizon. Among the areas that are considered in the emerging category are the following:

1. PIG-A gene mutation—Reviewed in an earlier section. This method could fill an important testing gap in current strategies. A substantial amount of research activity has been focused on the refinement and validation of this assay and a special issue of *Environmental and Molecular Mutagenesis* (2001; 52(9)) was devoted to the technique.
2. Humanized in vitro systems—Human cells may offer more relevant metabolism and genetic background for assessing mutation than rodent cells. Differences in gene expression and DNA repair capacities may also contribute to inaccurate responses with nonhuman in vitro systems.
3. Transgenic in vitro techniques—In vitro models may be derived from cells isolated from transgenic mice such as Muta™ Mouse.[103] Cell lines or primary cells carrying the recoverable transgene can be used to facilitate mutation detection and sequence analysis.
4. Thin film biosensors with DNA/enzyme coatings—Biosensors consisting of thin films of DNA and purified metabolic enzymes can be structured to detect agents with genotoxic properties. The combination on a thin film biosensor provides close proximity between the DNA and potential metabolite(s) formed when a test material is added to the biosensor. Proposed methods for detection of reaction products include electrochemiluminescent sensors. Biosensors offer advantages of automated large-scale testing.
5. Toxicogenomics—Analysis of gene expression profiles is not a new technology. Its application to genetic toxicology continues to evolve with improved reliability.[113] Toxicogenomic technologies are being actively pursued, and an expanded discussion of this topic is provided in a later section.

With the exception of the PIG-A mutation assay and toxicogenomics, the level of technology development is too limited to know how these methods may function in general genetic toxicology testing or research.

A technology that has long been used for the prediction of genotoxicity is SAR assessment. The existing SAR methods rely upon a combination of mathematical algorithms and qualitative experience rules to define the biological relationships between molecular structure and genotoxicity.[114] Commonly used SAR models (e.g., MultiCASE, Derek for Windows) are primarily used as tools to suggest potential for genotoxic hazard and need for follow-up testing. The guideline developed for evaluating genotoxic impurities in pharmaceutical ingredients is an example of how agencies rely upon SAR for this purpose. At the present time, there is no system with sufficient accuracy to replace the existing battery of bioassays.

TOXICOGENOMICS AND EMERGING TECHNOLOGIES IN TOXICOLOGICAL RESEARCH

Toxicological testing and biomarker discovery as well as drug development and patient therapy have been influenced by advances in molecular biological techniques such as *-omics* technologies. These technologies utilize a broad range of molecular tools to support the study of various macromolecules or subcellular components in response to exposures (i.e., environmental, chemical) and therapeutic treatments. The Human Genome Project (which involved sequencing the entire human genome) fostered the expansion of toxicological testing to include a new field termed *toxicogenomics*. Toxicogenomics combines genomics and bioinformatics to characterize and identify mechanisms of toxicity induced by chemicals and various exposures (i.e., pharmacological, environmental, toxicity protocols). Within this scientific discipline, genomics, transcriptomics, proteomics, and metabolomics may be applied to assess the toxicological responses of chemicals using in vitro and in vivo models[115–129] (Figure 23.7).

Data from toxicogenomic studies can be analyzed by tools combining biology, computer software, and statistics to generate biological information that support efforts in predictive and mechanistic toxicology, biomarker discovery, risk assessment, identification of disease mechanisms, and drug development. U.S. governmental research agencies such as the National Institute of Environmental Health Sciences (NIEHS) are actively studying toxicogenomic applications to toxicology. The Toxicogenomics Research Consortium (TRC) of the National Center for Toxicogenomics (NCT), a division of the NIEHS, is comprised of the NCT microarray group and five institutions (University of North Carolina at Chapel Hill, Fred Hutchinson Cancer Research Center, Oregon Health and Science University, Massachusetts Institute of Technology, and Duke University). The goals of the TRC are to (1) evaluate

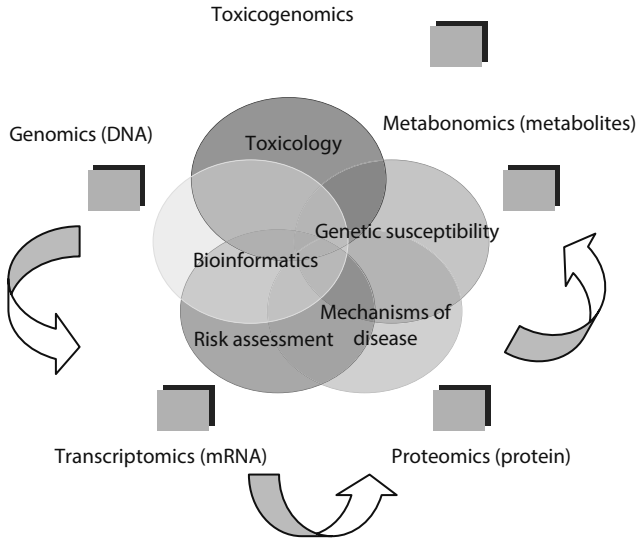

FIGURE 23.7 Interdisciplinary aspects of toxicological analyses.

toxicant-specific patterns of gene expression; (2) integrate gene expression profiling with proteomics, metabonomics, and phenotypic anchoring; (3) study the toxicological effects of chemical mixtures; and (4) contribute gene expression and proteomics data to the chemical effects in biological systems database (CEBS) (www.niehs.nih.gov).

In 2007, the National Research Council of the National Academy of Sciences issued a report, "Toxicity Testing in the 21st Century: A Vision and a Strategy." In this document, the authors suggest that the advances in fields such as molecular biology and biotechnology are offering enhanced methods for researchers to evaluate the health risks of potentially toxic chemicals in cellular systems of human origin. It is anticipated that knowledge from the initiatives of the governmental and academic consortiums will enhance the application of toxicogenomics to toxicological research and testing as detailed in the report.

This section summarizes the role of toxicogenomics in toxicology. Standard testing measures, challenges, and current advances including specific multiagency initiatives (toxicity forecaster [ToxCast] and Tox21) will be discussed.

OVERVIEW OF CURRENT TECHNOLOGIES

The four major -omics disciplines are defined as follows: (1) genomics (the study of gene sequences and genetic variability [humans possess ~30,000 genes]), (2) transcriptomics (the quantitative measurement of gene expression [messenger RNA, mRNA]), (3) proteomics (the measurement of protein production and levels in a cell, tissue, or biologic fluid), and (4) metabonomics (the multiparametric measurement of metabolites).

The development of technologies used in toxicology and toxicogenomics has evolved significantly over the last several decades. This review describes the current technologies used in toxicogenomics and provides examples where appropriate. Key technologies to be discussed include polymerase chain reaction (PCR) and quantitative reverse transcriptase/polymerase (qRT/PCR), microarrays (transcriptomics), methylation-specific PCR (MSP; DNA methylation), protein arrays (proteomics), and metabolic profiling (metabonomics) (Table 23.12). Extensions and applications of these technologies will be discussed as they relate to bioinformatics, transgenics, genomics, emerging technologies, and systems biology.

Polymerase Chain Reaction and Quantitative RT/PCR

PCR is a technique used to amplify specific DNA sequences with the aid of gene-specific primers (small sequences of DNA specifically designed for a gene target), heat-stable DNA polymerase enzymes, nucleotides, and other reagents. The process is often performed as a precursor to DNA isolation, forensic analysis, and disease diagnosis. It has been an integral part of in vitro toxicology and other scientific disciplines as applied to (1) gene expression analysis from in vitro and

TABLE 23.12
Technologies Used in Toxicogenomic Research

Technique	Application	Advantages	Limitations
Quantitative RT/PCR	Gene expression	Screen multiple samples; high-throughput screening	Limited gene targets per assay—even with multiplexing and gene cards; PCR array is improving this issue
SiRNA/RNAi	Gene silencing	In vitro assessment can be performed to test efficacy prior to in vivo assessments; drug discovery	Transfection efficiencies; toxicity in certain cases
Microarray (filter, chip)	Genomics/transcriptomics (transcripts, single-nucleotide polymorphisms [SNPS], DNA polymorphisms)	High-throughput screening of gene targets—thousands of genes	High-throughput analyses (i.e., many samples) are expensive; potentially large data set generation with limited understanding of biological impact
Next-generation sequencing	Genomics/transcriptomics (transcripts, SNPS, DNA polymorphisms)	High-throughput screening of gene targets—thousands of genes	High-throughput analyses (i.e., many samples) are expensive; potentially large data set generation with limited understanding of biological impact
Protein array (filter, chip, solution)	Proteomics	Profiling of multiple proteins	Some difficulties in correlating with mRNA changes; variations in time requirements for regulation of mRNA (transcription/stability) versus protein (translation, modifications)
Metabolic profiling (NMR, MS)	Metabonomics	Profiling of multiple metabolites; provides understanding of gene functions	Requires expensive/specialized equipment
MSP	Epigenetic DNA modification (i.e., methylation)	Provides gene-specific analysis	Multistep process leading to potential for sample lost; limited to gene-specific characterization—global methylation patterns must be assessed by other measures—advances are in progress

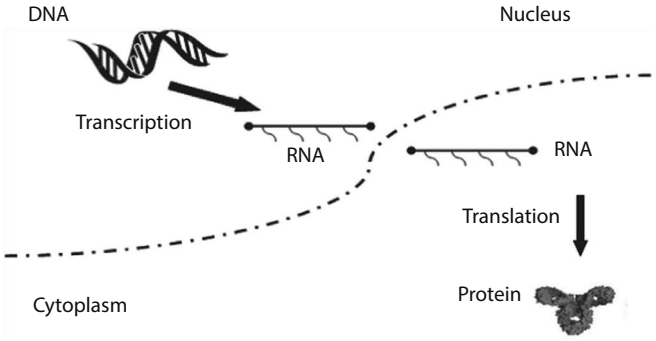

FIGURE 23.8 Cellular context of gene expression. RNA is synthesized in the nucleus through a process termed transcription in which the DNA code is transcribed to RNA. The RNA is subsequently transported to the cytoplasm where it is translated to protein, completing the chain for functional expression of the DNA (gene) following posttranslational processing.

in vivo samples, (2) in situ procedures of paraffin-embedded tissue, (3) gene cloning, and (4) genotyping since the 1990s.[130]

Gene expression is the process where the DNA code is expressed as RNA and ultimately protein, which serves as the functional product of the DNA code (Figure 23.8). Gene expression analysis requires the measurement of mRNA or protein. Since the late 1990s, qRT/PCR has dominated the field in assessing steady-state mRNA levels for individual/multiplex gene analyses. In this method, RNA is reverse transcribed to a complementary DNA copy, which is then amplified by PCR. Advances in chemical components developed to modify primers, probes, and reagents have resulted in significant improvements in quantitative and qualitative assessment of gene expression, thereby overcoming the prior limitations associated with detecting changes in mRNA levels[131,132] (Figure 23.9).

Advances in qRT–PCR facilitated the adoption of gene expression technology into toxicological testing and led to advanced methods of large-scale gene expression profiling via microarrays and gene chips.

Microarray Technology

Microarrays are grids of DNA fragments aligned on a chip to evaluate large amounts of biological information. Microarray technology has progressed from the use of nylon membranes formed to the size of an index card to gene chips designed as small as a letter-sized return address label. The arrays allow for the simultaneous assessment of genes/transcripts (i.e., 1000–30,000, entire genomes) involved in focused categories such as signal transduction (process that transfers the external cellular impact of chemical exposure to internal compartments and effects), stress response, cell cycle regulation, DNA synthesis/repair, inflammatory responses, and metabolism. Arrays are designed for different species (i.e., human, mouse, rat) and for disease and stress states (i.e., cancer, toxicology, inflammation). Array designs are aided by genome sequences from public databases and unique probe designs and are analyzed using bioinformatics techniques. Photolithographic techniques (adapted from the semiconductor industry) are used in the manufacturing process of microarray chips[133] (Figure 23.9). Aided by various data analysis

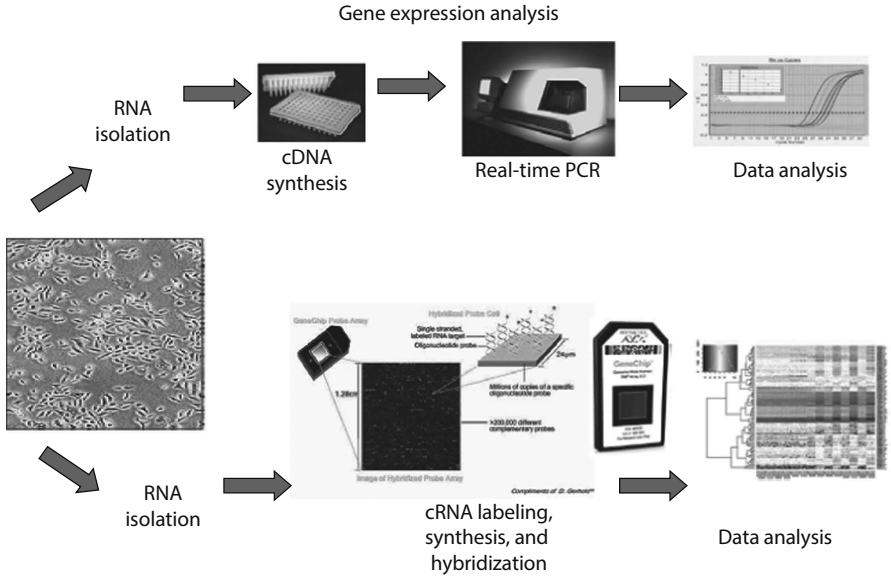

FIGURE 23.9 Advances in gene expression technologies. Upper panel. Real-time quantitative RT/PCR. RNA is reverse-transcribed to a complimentary DNA (cDNA) copy and subsequently amplified in the presence of buffers, enzymes, DNA bases, and fluorescent reagents via real time. Representative data analysis is depicted by the quantitation of mRNA facilitated by amplification of a relative standard curve prepared with positive control cDNA. Lower panel. Affymetrix gene chip expression analysis is conducted with RNA that is labeled, subjected to synthesis and hybridized to a specific gene chip. Various normalization, statistical and bioinformatic data analysis steps are conducted to simultaneously generate gene expression data from thousands of genes, which can be subsequently represented via hierarchical data comparisons (as depicted) for visual representation of differentially expressed genes.

methods including cluster and hierarchical analyses, researchers can obtain information on interactions in gene pathways.

Validation and standardization are important aspects of microarray research that are still under discussion. These issues addressed by Rockett and Hellmann[134] include measures for validation (quantitative RT/PCR, western or northern blots, in silico analyses), uniform formats for RNA amplification, normalization techniques, data analysis and representation, journal requirements for publication of array data and assay design, and standardizations for platform comparisons.[134,135] The minimum information about a microarray experiment (MIAME) checklist (www.mged.org) provides a good reference framework for microarray investigations.

DNA Methylation

Epigenetic modifications are changes in DNA that do not modify the gene sequence but may alter gene expression or phenotypes. DNA methylation is a process by which a methyl group is covalently added to the 5-carbon position of cytosine in a cytosine–guanine (CpG) sequence of base pairs. The methylation alters gene expression by preventing transcription of the gene. This process is referred to as gene silencing, is catalyzed by DNA methyltransferase,[136,137] and may be reversible. Since specific ratios of methylation in GC regions of DNA are required for normal maintenance of gene expression, global changes observed by hyper- and hypomethylation of genomic DNA can indicate epigenetic alterations induced by chemicals during disease progression.[138] Hyper- and hypomethylation patterns can lead to phenotypic changes that affect toxicological response to chemical exposure and may also define disease pathogenesis[138–142] (i.e., carcinogenesis, aging).

DNA methylation changes may be either global- or gene-specific (i.e., p16, GSTπ HOXA5). Global methylation—the overall level of methyl cytosines in a genome—may be determined via methyl-accepting capacity assays (SssI DNA methyltransferase) and chromatographic assays (high-performance liquid chromatography, thin-layer chromatography, or liquid chromatography/mass spectroscopy [LC/MS]). The latter assay requires digestion of the DNA into single nucleotides.

Numerous methods have been developed for analyzing gene-specific methylation including bisulfite-based methods. Bisulfite can selectively deaminate cytosine but not 5-methylcytosine to uracil. This leads to a sequence change in the DNA that discriminates cytosine from 5-methylcytosine. After the conversion has taken place, sequence differences between a methylated and unmethylated cytosine can be assessed by several methods including direct sequencing, restriction enzyme digestion, nucleotide extension assays, and MSP.

Cells can be exposed in vitro to chemicals causing demethylation and then analyzed for reversal patterns. Such investigations have led to the understanding of the efficacy of certain drug therapies and mechanisms of toxicity. Studies using in vivo models have shown methylation (either permanent or reversible) in genes controlling cell proliferation, cell cycling, and in disease states such as lung cancer and skin tumorigenesis.

Proteomics

Proteomics is the measurement of protein levels and states in a cell, tissue, or biological fluid. These measurements are important since proteins are the expressed characteristics of genes and function as effecter molecules in cells. A variety of protein alterations result from cellular responses to stimuli and stress. For example, cells may secrete cytokines or chemokines, proteins that play a role in immune response and inflammation. Alternatively, proteins may be modified by numerous posttranslational processes, which can be assessed by proteomic methods. For example, phosphorylation is a process that controls protein activity by the addition of phosphate molecules and supports the transfer of signaling through a cell; a change in the phosphorylation state of a protein can impact the function of the protein.

Tissue profiling by proteomic techniques has led to the detection of biomarkers as well as establishment of specific signal pathway profiling.[143,144] Early proteomic technologies consisted of 2D gel electrophoresis followed by LC/MS and subsequent biomarker validation with western blot (protein detection via antibodies on protein-binding membranes) or enzyme-linked immunosorbent assay (ELISA; protein detection in multiwelled plates coated with protein-binding matrix layered with antibodies). Recent technologies provide time-saving higher throughput and increased reproducibility (e.g., matrix-assisted laser desorption/ionization mass spectrometry [MALDI MS]- and surface-enhanced laser desorption/ionization [SELDI]-based protein chip technologies). These technologies allow for the identification of proteins in biological matrixes by analysis of proteins digested into smaller units (peptides), which can be distinguished on a mass (molecular weight) basis.

Protein arrays (filter, chip, and suspension) facilitate screening protein profiles of tissue samples and biological fluids on a smaller scale. Protein arrays are used to assess biomarkers of diseases and pathogenic states, including alterations in expression, cytokines/chemokines, and post-translational protein modifications (e.g., phosphorylation). They may be used to assess the effects of candidate drugs and environmental toxicants/irritants on the biology of cells, research animals, and human subjects and may be applied to functional genomics, validation requirements in drug discovery, and toxicology. Protein filter arrays are similar to microarrays with the screening process performed by antibody probes instead of labeled DNA probes. However, compared to microarrays, the number of targets is fewer due to difficulties related to protein chemistry of each antibody–protein interaction.

Proteomics has subdisciplines or categories as well. For example, *kinomics* combines genomics and proteomics for the study of kinases, proteins that function as enzymes to support phosphorylation of macromolecules. Kinases

promote the activation of proteins involved in transducing signals from external to internal cellular environments. This subdiscipline provides an important complement to genomic assessments since some gene products exhibit modified expression and activity past the mRNA state; hence, complete understanding of the cellular responses to treatments or chemical exposures requires a combination of technologies that measure gene and gene product changes across a continuum (e.g., exposure dose, time).

Proteomic and systems biology approaches have been used to assess and integrate toxicogenomic investigations on multiple chemical platforms such as benzene exposures, protein oxidation, drug toxicity, and MOA investigations as well as human risk assessments. The NTP issued a report in 2005, which described the advantages and challenges of using such data in cross-species data extrapolations. The report summarized the importance of properly designed experiments to achieve effective comparisons between species. It was recommended that proteomic profiles be established in vivo (i.e., rodent), reproduced in in vitro rodent cell cultures, and replicated in in vitro human cell cultures and subsequently link the correlation via computational modeling. In these cases, the most accurate assessment of the toxicological response would occur when common pathways are modified between organisms.

Metabonomics

The need to advance the understanding of the biological relevance of genomic data is ever present. Metabonomics is a seminal technology in functional genomics—a discipline that involves assessing gene function and its control mechanisms. As the genome represents all of the gene sequences of an organism, the metabolome represents all the low-molecular-weight molecules in a cell at a given time. Analysis of the metabolome was born from two similar yet distinct methods that have evolved from the need to assess animal and microbial/plant biochemistry. Metabonomics and metabolomics both involve characterization of metabolites through multiparametric measurements. Metabonomics deals with biological systems, including extracellular environments in an integrated and multicellular approach allowing for quantitative measurements of metabolic responses following a stimulus. Metabolomics predominately deals with concentrations of intracellular metabolites in simple cell systems. In recent years, the terms have been used interchangeably and most often referred to as metabonomics.

In concert with chemometric and bioinformatics tools, metabonomic data can generate biochemically based fingerprints (biomarkers) of drugs and toxicants and hence support linkages to biologically relevant end points from data obtained from various *-omics* technologies. Metabonomics offers the promise for obtaining drug effect and disease end points to support drug development, risk, and toxicological assessments in living systems[145,146] via analysis of biofluids, tissues, and cell lysates. This technology has been applied in ecotoxicological assessment of environmental contaminants,[147] physiological influences on biofluids,[148] systems biology in pharmaceutical research,[149] physiological monitoring, drug safety assessments and disease diagnosis,[150] toxicological assessments,[151–153] and cigarette smoke effects in cultured lung cells.[154]

APPLICATIONS AND EXTENSIONS OF TOXICOGENOMIC TECHNOLOGIES

Gene Expression and Genomics

Differential gene expression profiling and genomic evaluations via PCR, qRT/PCR, and microarrays have been conducted in in vitro, in vivo, and human samples to support chemical evaluations, risk assessment, drug discovery, genetic susceptibility, and analysis of tissue for disease pathogenesis (Table 23.13).

Complex mixtures of chemicals such as cigarette smoke condensate (CSC; also referred to as total particulate matter [TPM]) and diesel exhaust extracts can alter gene expression in lung cells as detected by qRT/PCR. For example, human bronchial epithelial cells exposed to CSC exhibited changes in interleukin (IL-8) mRNA and secreted cytokine levels, changes associated with inflammation.[155] Individual smoke constituents may also cause alterations. c-*myc* (a gene that promotes uncontrollable cellular growth) was evaluated in normal human bronchial epithelial (NHBE) cell cultures exposed to benzo[*a*]pyrene and benzo[*a*]pyrene diol epoxide (BPDE). Differential mRNA responses were observed between the chemicals and correlated with distinctions in DNA adduct accumulation and cell cycle regulation.[156]

Fukano et al. evaluated the effect of different cigarette filters on gene expression in in vitro lung cultures.[177] Cells exposed to smoke from cigarettes with a carbon filter exhibited reduced activation of heme oxygenase 1 (HO-1), a gene responsive to oxidative stress, compared to cells exposed to smoke from cigarettes with cellulose acetate filters.

Pathway-specific analyses have recently been enhanced by PCR array technologies and may be used in tobacco-related research. Typical platforms such as the PCR arrays from SA Biosciences offer 96- and 384-well formats to allow for quantitative and high-throughput screening for specific disease states, cellular conditions, signaling pathways, biological functions, gene regulation, and DNA methylation. The signal transduction pathway finder PCR array and inflammatory cytokine PCR array were used by Parsanejad et al. to determine the effect of tobacco smoke on selected molecular pathways.[172,173] Assessment of whole smoke in NHBE cells yielded responses in pathways associated with inflammation, apoptosis, and wound healing. The group subsequently evaluated a repetitive smoke exposure regimen to mimic a smoker's frequency of exposure[173] (Figure 23.10). The resulting cytokine responses exhibited adaptive, sustained, and chronic expression patterns over the time course of exposure.

Transcriptomic analyses with qRT/PCR and microarray have also facilitated numerous toxicological assessments

TABLE 23.13
Toxicological Assessments: Gene Expression and Methods of Detection

Agent/Disease	Model	Method	Reference
Acetaminophen/liver	Human and rat	Transcriptomics	Kerns and Bushel[157]
Multiple organs	In vivo (Balb/c mice)	Nanocapillary quantitative real-time PCR	Fabian et al.[158]
2,3,7,8-Tetrachlorodibenzo-*p*-dioxin	In vitro (HepG2)	Transcriptomics; metabonomics	Jennen et al.[153]
Peroxisome proliferator chemicals	In vivo (rat and mouse)	Transcriptomics	Ren et al.[159]
2,4-Diaminotoluene, benzo(*a*) pyrene, 2-acetylaminoflourene, or 3-methycholanthrene	In vitro (Balb/c 3T3 cells)	Transcriptomics	Rohrbeck et al.[160]
Endocrine-disrupting compound (bisphenol A)	In vivo (mouse)	Epigenetics	Bernal and Jirtle[161]
Diesel exhaust	In vitro (human airway cells; rat alveolar macrophages)	Semi-qRT/PCR	Baulig et al.,[162] and Koike et al.[163]
Bromobenzene	In vivo (rats)	Transcriptomics; proteomics	Heijne et al.[164]
Cytotoxic anti-inflammatory drugs; DNA-damaging agents	In vitro (HepG2)	cDNA microarray	Burczynski et al.[115]
Arsenic	In vivo (Tg.AC mice)	DNA methylation	Xie et al.[165]
Benzo[*a*]pyrene	In vitro	qRT/PCR	Fields et al.[156]
Cigarette smoke	In vivo	cDNA microarray; Gene Chip	Hackett et al.,[166] Shah et al.,[167] Gebel et al.,[168] and Beane et al.[169]
CSC/extracts; cigarette smoke	In vitro (human bronchial cells; SWISS 3T3 cells)	Real-time qRT/PCR; PCR array; cDNA microarray	Fields et al.,[170] Maunders et al.,[171] Parsanejad et al.,[172,173] and Bosio et al.[174]
Asbestos	In vitro	cDNA microarray, real-time PCR	Ramos-Nino et al.[175]
Oxidative stress	In vitro (Hep-G2)	cDNA microarray, real-time PCR	Morgan et al.[176]

associated with elucidating MOA, organ toxicity, reproductive toxicity, and chemical characterization.[157–160] Rohrbeck et al. applied toxicogenomic analysis to correlate in vitro carcinogenicity testing in Balb/c 3T3 cells to in vivo by identifying gene signatures predictive of select chemical carcinogens.[160] The testing strategy identified gene signatures and common regulated carcinogenic pathways that accurately predicted three previously classified carcinogens: 2,4-diaminotoluene, benzo(*a*)pyrene, and 3-methycholanthrene.

DNA Methylation

Recently, Liu et al. reported the effect of CSC on DNA methylation in normal small airway epithelial cells and immortalized bronchial epithelial cells following chronic exposure (9 months) to CSC.[178] Changes in expression profiles of genes associated with DNA methylation and altered hypo- and hyper-DNA methylation patterns along with growth of cells in soft agar (preneoplastic characteristic) were observed. The authors conclude that CSC induced cancer-related epigenetic changes along with the development of preneoplastic morphological transitions in the cells. The resulting model may support in vitro studies of lung cancer pathogenesis.

Development from the early stages in utero and throughout a life span is regulated through maintenance of the epigenome. Bisphenol A, an endocrine-disrupting compound used in the chemical industry in polycarbonate plastic production and in epoxy resin lining of metal beverage and food cans, can leach into the food supply from the container leading to exposures that impact development. Bernal and Jirtle evaluated the impact of bisphenol A on growth and development in a mouse model with biosensors helpful in determining the impact of in utero toxicant exposures on epigenetic programming in the offspring.[161] Bernal and Jirtle observed hypomethylation in the offspring, which led to distinguishing phenotypical differences.

Bioinformatics

Bioinformatics was developed out of a need to maintain, correlate, and evaluate large volumes of biological data generated from molecular and toxicogenomic studies. Bioinformatics is a multidisciplinary science that encompasses biology, computer programming, and statistics. The integration of data from toxicogenomic studies into databases supports investigations for risk assessment, mechanistic and predictive toxicology, and pattern recognitions in disease progression. Such efforts have been initiated by various agencies and research teams (Table 23.14) and provide valuable means for understanding toxicological responses at the molecular level. However, there are some challenges with database design and maintenance involving data integration (standardized data storage and exchange), uniform nomenclature, and standardized assay design.[179]

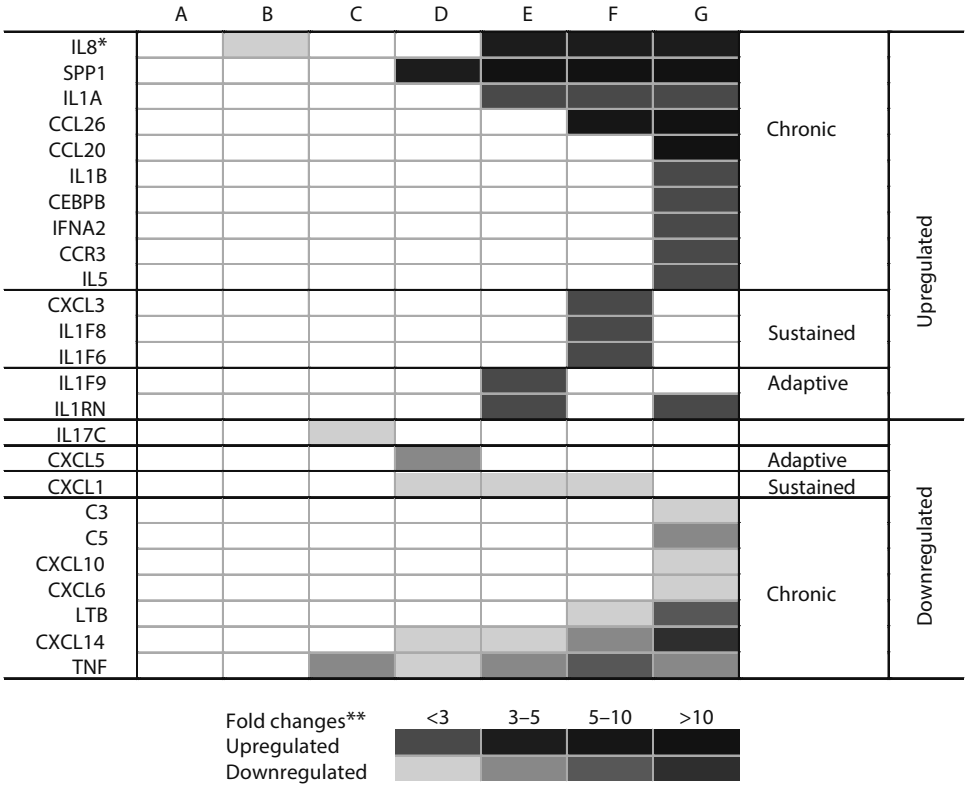

FIGURE 23.10 Inflammatory cytokine PCR array responses to CSC exposure in NHBE cells. Gene expression patterns in NHBE cells displaying adaptive, sustained, and chronic expression in response to 60 μg TPM/mL media. Groups A to G represent different treatment methodologies from 15 min to alternating repeated exposure and recovery times over a 24 h period. In this study, adaptive gene regulation refers to genes that adapted to the CSC exposure and short-term recovery (3 h) by returning to the baseline; sustained gene regulation refers to genes that remained up- or downregulated only during CSC exposure and short-term recovery; and chronic gene regulation refers to genes initiating or maintaining elevation or suppression patterns after a 12 h (long-term) recovery. *IL8 was the exception in expression pattern by exhibiting both up- and downregulation in the seven groups. **The fold changes are scaled by color intensity. Upregulation indicates gene expression is increased and is represented on the upper panel. Downregulation indicates that gene expression is deceased and is represented on the lower panel. The color scale shows enhanced color intensity as the fold change in expression as compared to the control samples gets larger either positively or negatively. The categories are <3, 3–5, 5–10, and >10. (From Parsanejad, R. et al., *J. Cytokine Interferon. Res.,* 28, 703, 2008.)

Additional web-based databases and software platforms are also useful resources. For example, the Biocarta system provides information on gene function and specific gene pathways as well as information on reagent/assay resources and links to pertinent scientific citations (PubMed). Software platforms such as Ingenuity, SpotFire, GeneSpring, GeneSifter, and Pathway Studio are also valuable tools for analyzing and supporting the interpretation of genomic data.

Transgenics

In vitro gene reporter assays serve as measures to detect toxicological effects of chemicals on promoters of genes involved in cellular regulation (i.e., transcription factors). Gene reporters consist of the promoter (controlling elements) for a gene of interest linked to DNA for luciferase or green fluorescence protein (e.g., proteins that liberate fluorescent light when induced or turned on). Gene reporter assays are facilitated by transfection (insertion) of gene reporter constructs into a variety of cell types, and subsequent quantitation of signal or protein generation in response to chemical treatment (Figure 23.11).

Several laboratories are investigating the use of luciferase models to evaluate transcription factor regulation of cell signaling pathways, including the nucleus-related factor 2 (Nrf2), AP-1, and NFκB pathways. Nrf2, AP-1, and NFκB

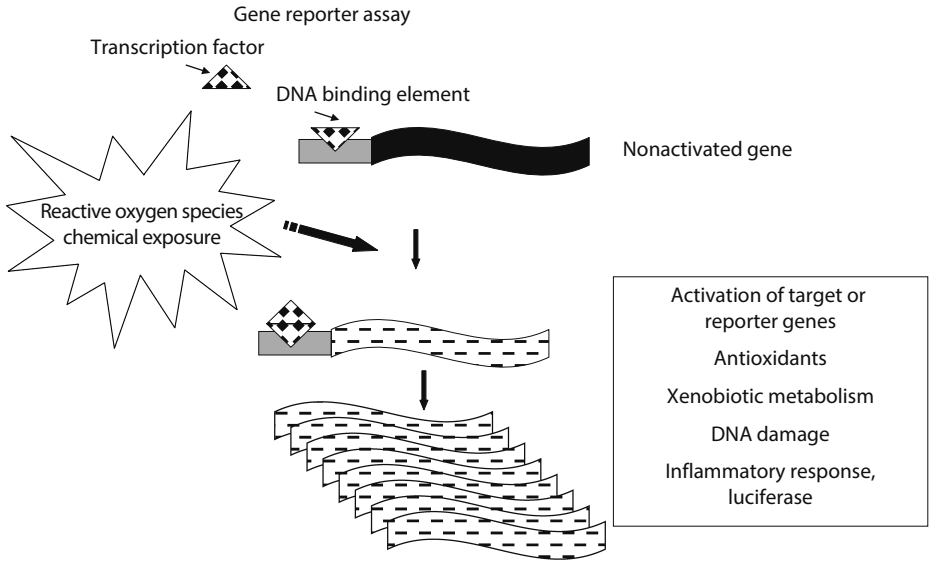

FIGURE 23.11 Gene reporter assay. Chemical exposures, processes that generate reactive oxygen species, DNA damage, or inflammatory mediators can direct transcription factors (such as Nrf2, AP-1, NFκB) to complimentary DNA-binding elements (bases) of a gene. After binding, the transcription factor can activate the expression of multiple target genes.

are transcription factors that play key roles in regulating the responses of genes involved in oxidative stress, cell proliferation/transformation, and inflammatory response via control of DNA transcription. BPDE has been observed to affect AP-1 and NFκB responsive genes, and the transcriptional regulation of these genes was confirmed via the dose-dependent activation of the luciferase gene through interactions with the AP-1 and NFκB promoters,[180] respectively (Figure 23.12). However, cotreatment with phenolic fraction of tobacco smoke condensate (TSC) (10 μg/mL or 30 μg/mL) resulted in a dose-dependent decrease in NFκB activation suggesting that fractions and mixtures of chemicals can differentially impact the response of individual chemical exposures.

Transgenic animals for mutation detection were developed in 1990 using shuttle vector technology.[181,182] A few models commercially available in the 1990s, such as the MutaMouse and BigBlue Mouse, measured *lac I* and *lac Z* gene activation.[183,184] These models laid the foundation for the development of genetically modified animals with altered gene expression patterns via either gene knockout or enhancement. Knockout (gene capability removed) and transgenically enhanced (gene capability increased) models are also being investigated to advance knowledge on the response of specific gene modifications on toxic responses and disease pathogenesis. Mouse models have been developed with enhanced tumorigenic potential due to genetic alterations. The Tg.AC mouse harbors increased ras gene activity and enhanced growth via transgene expression of oncogenic viral Harvey ras (v-Ha-ras) within the skin. UL53-3 X A/J mice harbor a dominant-negative p53 mutation, which inhibits cell cycle control. Such genetic alterations may support studies designed to evaluate tumorigenic potentials of chemical exposures in previously unresponsive

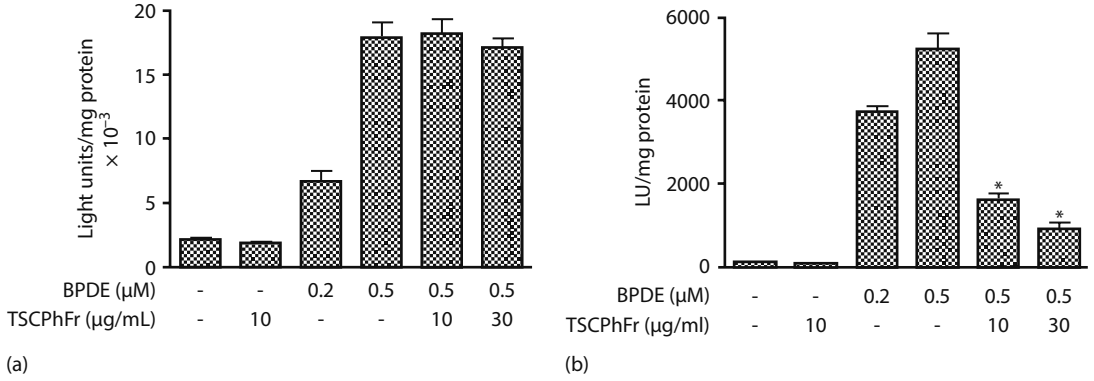

FIGURE 23.12 Effect of BPDE and TSC phenolic fraction on activation of AP-1 and NFκB. (Request for permission to reprint is in progress.) JB6 (P+) Cl 41 epidermal cells were transiently transfected with the AP1-luciferase and NFκB-luciferase reporter plasmids. Effect of TSC phenolic fraction on activation of AP-1 (a) and NFκB (b) was assessed following treatment with BPDE in the absence and presence of TSC phenolic fraction. Each bar indicates the mean ± SD of three parallel experiments. (*) indicates statistical analysis of significance with paired *t*-test ($p < 0.05$). (From Mukherjee, J.J. and Kumar, S., *Mutat. Res.*, 696, 89, 2010.)

models or models requiring long-term exposure regimens. These models have been used to assess the multistage aspects of tumorigenesis via exposure to 7,12-dimethylbenz(*a*)anthracene (DMBA), 12-*O*-tetradecanoylphorbol-13-acetate (TPA), or cigarette smoke.[185–187] Lung tumorigenicity has also been assessed to compare the A/J and *ras*H2 transgenic mouse models in response to mainstream tobacco smoke whole-body and nose-only exposure regimens.[188]

Transgenic animal research is used to facilitate understanding of disease progression and significance of DNA polymorphisms. For example, transgenic models for several research interests including apoptosis, cancer, diabetes and obesity, immunology and inflammation, cardiovascular diseases, and metabolism are commercially available. Additionally, efforts to assess the role of genotype variations in toxicology have been undertaken by the Environmental Genome Project (EGP). The EGP is a program initiated by the NIEHS, which has the mission to *improve understanding of human genetic susceptibility to environmental exposures*. To address this issue, EGP has undertaken several major research initiatives, including the Comparative Mouse Genomics Centers Consortium (CMGCC), Human DNA Polymorphisms Discovery and Characterization, and the GeneSNPs Database of Human and Mouse Environmental Responsive Genes. To improve understanding of the biological significance of human DNA polymorphisms, the CMGCC is charged with developing transgenic and knockout mouse models based on human DNA sequence variants in environmentally responsive genes. The candidate target genes include genes involved in DNA repair, cell cycle control, cell signaling, cell structure, gene expression, apoptosis, and metabolism. The models developed by the consortium are distributed by the Mutant Mouse Regional Repositories (http://www.mmrrc.org/) via arrangements with the National Center for Research Resources.

GENOMICS: PERSPECTIVES OF GOVERNMENTAL AGENCIES

Governmental research agencies such as the NIEHS are active in characterizing toxicogenomic applications in toxicological experiments. The TRC of the NCT, a division of the NIEHS, has goals to evaluate toxicant-specific patterns of gene expression as related to dose–response, molecular mechanisms, and biomarkers of human exposure. The consortium also plans to integrate gene expression profiling with proteomics, metabonomics, and phenotypic anchoring, study toxicological effects of chemical mixtures, and contribute gene expression and proteomics data to the CEBS (www.niehs.nih.gov). Due to these collective efforts, the genomic techniques in toxicological sciences are now more frequently employed and are anticipated to expand in the future.

Knowledge from these consortiums and agencies is anticipated to enhance the application of toxicogenomics to toxicological research as detailed in the report, "Toxicity Testing in the 21st Century: A Vision and a Strategy," prepared by the U.S. National Academy of Sciences (2007). The report provided a strategy by which in vitro testing using cell lines and human cells in concert with high-throughput screening of toxicity pathways can be a routine component of toxicity testing in the future.[189] The vision for toxicity testing for the twenty-first century consists of in vitro and short-term in vivo tests that are proposed to evaluate chemicals in a four-component framework: chemical characterization, toxicity pathways and target testing, dose–response and extrapolation modeling, and population-based and human exposure data. The toxicity testing tools consist of high-throughput screens, stem cell biology, functional genomics, bioinformatics, systems biology, computational systems biology, physiologically based pharmacokinetic models, SARs, and biomarkers. The goals of two specific multiagency initiatives, Tox21 and ToxCast, are in line with the vision.

Tox21

Tox21 is a collaboration between the U.S. EPA, National Institutes of Environmental Health Sciences (NTP), National Institutes of Health (National Human Genome Research Institute and NIH Chemical Genomics Center [NCGC]), and the FDA. The agencies are involved in a multidiscipline research initiative designed to develop and validate testing methods, which evaluate the impact of chemicals on toxicity pathways.[190] The charge of the consortium includes efforts to (1) research ways to use new tools to identify chemical-induced biological activity mechanisms, (2) prioritize which chemicals need more extensive toxicological evaluation, (3) develop models that can be used to more effectively predict how chemicals will affect biological responses, and (4) identify chemicals, assays, informatic analyses, and targeted testing needed for the innovative testing methods (www.epa.gov/ncct/tox21/; accessed March 22, 2012). Collectively, the work will support chemical prioritization, risk assessment, and hazard identification. The Tox21 chemical inventory consists of compounds with structural diversity and varying chemical characteristics such as industrial and food-use chemicals, pesticides, and drugs as well as chemicals and defined mixtures that have been tested by the NTP for genotoxicity, carcinogenicity, immunotoxicity, reproductive toxicity, and/or developmental toxicity. The complete Tox21 chemical inventory will undergo screening at the NCGC via multiple high-throughput screening assays. These data will be publically available via several databases ACToR (EPA), CEBS (NIEHS), and Tox21 Browser (NCGC) and PubChem.

ToxCast

ToxCast is a chemical screening tool that is part of the EPA's risk assessment program. ToxCast was initiated in 2007 in a phased manner to set priorities for chemicals requiring toxicity testing. The initiatives outlined to achieve this deliverable are detailed as follows:

- *ToxCast uses advanced science tools to help understand how human body processes are impacted by exposures to chemicals and helps determine which exposures are most likely to lead to adverse health effects.*

TABLE 23.15
Select ToxCast Publications

ToxCast Phase I data	In vitro screening of environmental chemicals for targeted testing prioritization—the ToxCast Project[191]	2010
Transcription regulators	Impact of environmental chemicals on key transcription regulators and correlation to toxicity end points within EPS's ToxCast program[192]	2010
BioMap cell systems	Profiling bioactivity of the ToxCast chemical library using BioMap primary human cell systems[193]	2009
Genotoxicity assays	Evaluation of high-throughput genotoxicity assays used in profiling the U.S. EPA ToxCast chemicals[194]	2009
ToxCast chemicals	Xenobiotic-metabolizing enzyme and transporter gene expression primary cultures of human hepatocytes modulated by ToxCast chemicals[195]	2010
Dosimetry and exposure	Integration of dosimetry, exposure and high-throughput screening data in chemical toxicity assessment[196]	2012
Chronic toxicity	Profiling chemicals based on chronic toxicity results from the U.S. EPA ToxRef database[197]	2009

- *ToxCast testing methods include over 650 state-of-the-art rapid tests (called high-throughput assays) that are screening 2000 environmental chemicals for potential toxicity.*
- *Phase I, proof of concept was completed in 2009, and it profiled over 300 well-studied chemicals (primarily pesticides).*
- *Phase I chemicals have over 30 years' worth of existing toxicity data since they have been tested already using traditional toxicology methods (primarily animal studies). Data from animal studies can be searched and queried using EPA's toxicity reference database (ToxRefDB) that stores nearly $2 billion worth of studies.*
- *Phase II was completed in 2013 and over 1800 chemicals were screened from a broad range of sources including industrial and consumer products, food additives, and drugs that never made it to the market to evaluate the predictive toxicity signatures developed in Phase I.*
- *Data from the high-throughput assays are available via the ToxCast database.*
- *Toxicity signatures from ToxCast are defined and evaluated by how well they predict outcomes from mammalian toxicity tests and identify toxicity pathways relevant to human health effects.*
- *ToxCast provides the Tox21 collaboration access to ToxCast's high-throughput screening data and chemical library to increase the data available on the nearly 10,000 chemicals being studied (www.epa.gov/ncct/toxcast/; accessed March 22, 2012 and March 6, 2013.)*

The tool combines several testing platforms including more than 500 high-throughput screening assays to assess the impact of chemical exposure in humans and the associated adverse health effects (e.g., chronic disease or reproductive problems). The initial *proof of concept* phase was completed in 2009 and included the evaluation of 300 chemicals consisting primarily of pesticides. These data were compared to prior animal testing of the chemicals in order to assess the concordance of the in vitro screens with the in vivo data. The second phase will incorporate the screening of 700 more chemicals including chemicals of consumer product, cosmetics, and drugs. The data from these studies are retained in the ToxCast database such that queries on the chemicals and assay used as well as affected end points, genes, and pathways can be conducted. Relevant publications from the program to date are listed in Table 23.15.

Collectively, the application of toxicogenomics in exposure assessment, hazard screening, risk assessment, human susceptibility, and mechanisms of action is showing promise and is becoming an integral part of toxicological research and in vitro testing. Current advances in drug discovery and personalized medicine and by the NCT support this assertion should provide key information to support the integration of toxicogenomics into toxicological test batteries.

QUESTIONS

23.1 Define epigenetic genotoxicity and identify the primary differences and similarities between epigenetic and nonepigenetic alterations to genes and gene expression processes.

23.2 What is the human *genetic burden* and what might be its origins?

23.3 While most testing strategies involve a battery of tests, what are the primary limitations associated with increasing the number of tests in a battery?

23.4 What were the reasons for expanding the testing options in the 2008 update to the original ICH genetic toxicology test battery for pharmaceutical products?

23.5 What factors make it difficult to perform quantitative risk estimates for heritable genetic effects in human populations?

23.6 What is transcription-coupled DNA repair and which of the various DNA repair processes is primarily involved?

24 Short-Term, Subchronic, and Chronic Toxicology Studies

Daniel T. Wilson, Jerry F. Hardisty, Johnnie R. Hayes, and Nelson H. Wilson

CONTENTS

INTRODUCTION

Repeated-dose toxicity studies are conducted to screen for potential adverse effects of compounds such as pharmaceuticals (small molecules as well as biological agents), pesticides, food additives, or other chemicals using laboratory animals as surrogates for the intended exposed population or target species, most often the human. Repeated-dose studies may be of varying duration, generally 1–4 weeks for short-term studies, 3 months for subchronic studies, and 6–12 months for chronic studies. Many parameters indicative of the health of the test species are monitored in short-term, subchronic, and chronic toxicity studies, resulting in the ability to detect a variety of adverse effects, identify alterations due to exaggerated pharmacology, and/or assess the reversibility of findings. Sometime during their career, most toxicologists are involved in designing, performing, monitoring, or reviewing data from these types of toxicity studies as a result of the central role of these studies in safety assessment.

It has been suggested that subchronic data alone may be sufficient to predict the hazard of long-term low-dose exposure to a compound.[1] While this may be true for compounds where adequate structure/activity relationships exist and there is no indication of genetic toxicity, it generally is not true when compounds have completely unknown toxicity or when structure/activity relationships predict a potential adverse effect. For certain chemicals or mixtures, results from a short-term or a subchronic toxicity study may represent the most sophisticated toxicology data available. With many chemicals, a subchronic study is critical to the design of longer-term hazard assessment studies.

It is essential that toxicologists become familiar with the scientific principles upon which repeated-dose toxicity studies are based and understand the methodology used to perform these studies. This chapter provides an introduction to these studies and many of the principles upon which they are based. It focuses mainly on hazard assessment for chemicals that are small molecules. Today, biotechnology is a rapidly developing field. Hazard assessments for biologics, for example, recombinant proteins and conjugated antibodies, are special cases that will not be discussed in detail in this chapter.

The hazard assessment for a biologic is tailored specifically to the compound and may be more or less comprehensive than a classical assessment with a small molecule. Throughout this chapter, important differences between small molecule and biological development will be noted, when appropriate. Guidelines for testing biological materials have been drafted and can be consulted for more detailed information regarding considerations involved in the development of a biologic.[2] Despite some differences in requirements for development, many of the principles and methods of individual studies with small molecules are applicable to testing with biotechnology products. The toxicologist responsible for investigating the safety of these materials should become familiar with the current guidelines and suggestions for their testing.

REPEATED-DOSE STUDIES AND HAZARD (SAFETY) ASSESSMENT

The major steps performed in a typical hazard assessment are illustrated in Figure 24.1. However, in practice, there is no such thing as a *typical* hazard assessment program. This is particularly true in the case of pharmaceutical development where advancements in medical science have led to such things as targeted therapies, the use of nanotechnology, development of biological products, and gene therapy. Oftentimes, each hazard assessment program is unique and is based upon the characteristics of the individual material being tested, its intended use, and the intended patient/target population. Furthermore, the temporal sequence of the studies presented in Figure 24.1 may be modified depending on organizational practices. For example, some pharmaceutical companies may conduct the in vitro genotoxicity and/or screening reproductive toxicity assessments earlier in the development program in order to truncate the development of compounds with positive genotoxicity results or potential for teratogenicity, thus minimizing time and costs associated with the development of these *bad* drugs.

It may seem obvious, but the first step in any hazard assessment is determination of the material to be studied and the purpose of the assessment. Both of these factors will influence the final design of the program. At the time of selection of the material to be tested, its intended use in the marketplace will have been defined. In most cases, this dictates factors such as exposure route, test species, and the types of studies required. For example, a chemical company may need to assess the risk of a compound they are developing to be used in packaging of foods and to which humans could be exposed through the diet while a pharmaceutical

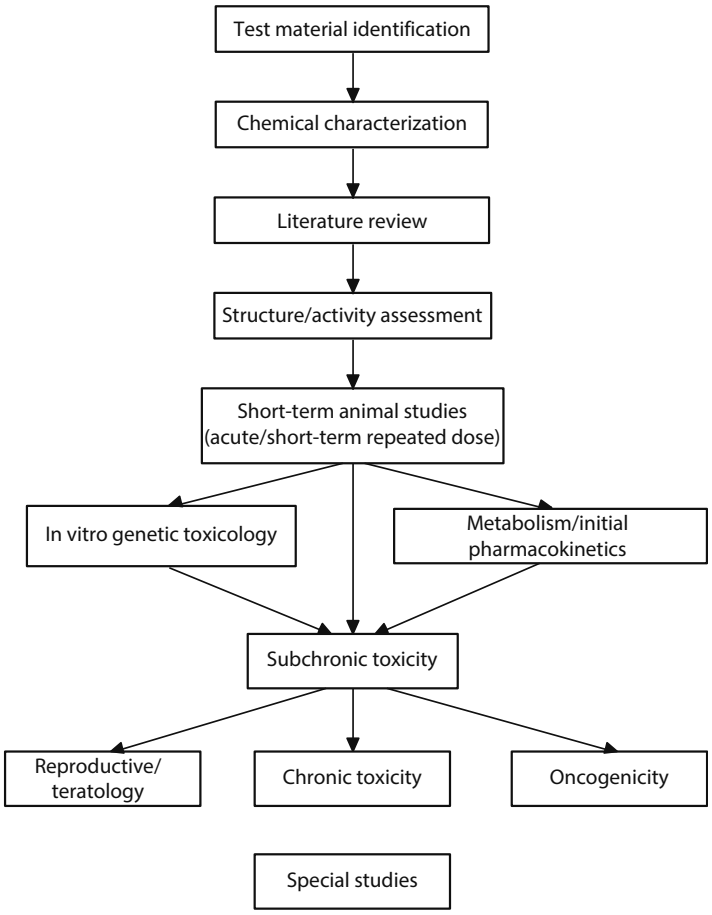

FIGURE 24.1 Schematic representation of a typical hazard assessment program illustrating a step-by-step, tiered approach and the interactions between the various elements. It should be noted that the approach presented here is not the only approach that could be used.

company may want to examine potential toxicity of a new drug administered intravenously that targets proteins in cell cycle pathways involved in cancer.

The next step is the chemical and physical characterization of the material or mixture to be investigated. Knowledge of the major component(s) and any associated contaminants is required for almost every phase of the hazard assessment program. The more detailed the chemical and physical characterization, the greater the likelihood that the entire program will be successful.

Once the toxicologist has information concerning the chemical nature of the test material, the scientific literature is searched to determine what is known, if anything, about its biological activity. If no information is available, the potential biological activity of chemicals with similar chemical structure should be ascertained. There are several computerized programs designed to search for structural alerts; two of the most commonly used databases are DEREK and MultiCASE.[3,4] Also, for targeted therapies, literature regarding effects of other compounds that target the same receptor as the novel compound should be reviewed to evaluate potential class effects. Based upon the chemical characterization and any toxicology information available in the scientific literature, the toxicologist can perform a structure/activity assessment. This will aid in developing the hazard assessment program and the specific designs for each of the toxicity studies.

Following test material characterization, literature evaluation, and structural analysis, in vivo testing is usually initiated. The first studies to be conducted are normally short-term toxicity studies. Historically, the initial short-term toxicity study was generally a single-dose acute toxicity study. Results from acute toxicity studies are used to estimate dosages to be used in short-term repeated-dose studies and to obtain initial data useful in assessing relative toxicity. A number of regulatory agencies have made recommendations concerning designs for acute studies as discussed in the acute toxicity chapter of this text. If warranted, additional endpoints may be added to these recommended designs based upon the structure/activity assessment and literature review. It should be noted, however, that in some cases, such as during pharmaceutical development, acute toxicity studies may not be required because it is currently believed that information from these studies can be garnered from dose escalation studies or other repeated-dose studies that establish a maximum tolerated dose.[5–7]

Data obtained from short-term repeated-dose toxicity studies are generally required for the successful design of subchronic toxicity studies. Similarly, data from subchronic studies are essential for the design of chronic studies. Table 24.1 lists objectives for short-term repeated-dose toxicity studies. Table 24.2 lists examples of data obtained from these studies that are useful in the design of subsequent studies. As will be discussed later, one of the difficult decisions for a toxicologist designing a toxicology study is the selection of the dose range to be used. Data on dose–response and the other toxicological endpoints evaluated in short-term toxicology studies are critical to the successful dose selection for subsequent toxicity studies.

TABLE 24.1
Objectives of Short-Term Repeated-Dose Studies

- Determine adverse effects of the test compound at doses low enough to allow survival of most animals, as opposed to acutely toxic doses.
- Determine adverse effects over a longer exposure (dosing) period than used in acute studies.
- Determine reversibility of adverse effects after discontinuation of treatment.
- Determine dose–response for adverse effects following repeated dosing and identify a no-observable-adverse-effect level (NOAEL).
- Identify organs affected by exposure to test material (target organs).
- Provide data concerning species differences, if any, in sensitivity to potential adverse effects.
- Provide initial data for comparative risk assessment.
- Determine the need for specialized endpoints to be assessed in longer-term studies.

TABLE 24.2
Data Obtained from Short-Term Repeated-Dose Studies That Are Useful in the Design of Subsequent Studies

- Palatability of test material/diet mixture, if dosing is by feed
- Body weight response patterns
- Physical observations
- Behavioral changes
- Clinical pathology
- Toxicokinetics
- Gross necropsy
- Histopathology
- Identification of target organs
- Dose–responses

Although not always available, data from genetic toxicity and metabolism studies are useful adjuncts to that from short-term repeated-dose studies. For instance, if the in vitro phase of the genetic toxicology program has indicated the test material has genotoxic potential, it may be dropped from consideration for further development and further testing may be unnecessary. It may also be possible to add in vivo genetic toxicity assessment to the design of subchronic or chronic toxicology studies. This can, in many cases, reduce the number of animals used in the overall safety assessment and conserve resources. Also, if information concerning the metabolism and pharmacokinetics of the test material is known, it should be used in the design of repeated-dose toxicity studies. For example, if pharmacokinetic or toxicokinetic studies indicate a potential for the accumulation of the test material after repeated dosing, this is an important consideration in deciding the most appropriate dose range. Furthermore, because different species may metabolize test materials differently, this information is important in the selection of appropriate animal species and strains for subsequent testing (i.e., a species that metabolizes the test material

TABLE 24.3
Objectives of Subchronic Toxicology Studies

- Identify adverse effects not detected in shorter-term acute or repeated-dose studies
- Provide additional information on adverse effects identified in short-term studies such as progression or reversibility of effects
- Identify observable effect level and the NOAEL
- Provide data for dose selection and other study design features for chronic toxicity and other longer-term studies
- Confirm and/or identify target organs or sites of action
- Provide data to determine if specialized endpoints are required
- Provide a basis for species selection for additional studies, if required, and for data extrapolation to humans
- Provide information for regulatory agencies in support of the safety of the test material
- Provide risk assessment data

in a manner similar to humans would be preferred over a species that metabolizes the test material by dissimilar metabolic pathways). The major objectives of subchronic toxicity studies are presented in Table 24.3.

In some cases, such as when environmental exposure will be limited/brief or during the development of cancer therapies intended to treat patients whose long-term survival is unlikely, subchronic toxicity testing may complete the data package required for a hazard assessment. In other cases, such as when drugs are being developed for non-life-threatening diseases or when the target species will be exposed to the test material for a significant portion of its life, data from subchronic studies are used to design additional studies, including chronic toxicity studies (as illustrated in Figure 24.1). Data from subchronic toxicity studies are useful in the design of oncogenicity and reproductive toxicity studies as well as any *special* studies that may be warranted based on the results of other studies and/or requested by a regulatory agency.

As noted earlier, data from a short-term repeated-dose study should be available before the initiation of subchronic toxicity testing and, generally, data should be available from a subchronic study before proceeding with chronic testing. The major utility in progression from shorter-term to longer-term studies is to ensure, to the extent possible, that proper dose ranges are selected. Requirements for a scientifically valid short-term repeated-dose study are similar to those of subchronic toxicity studies. Therefore, the general aspects of short-term studies will not be discussed separately. However, three aspects of short-term repeated-dose studies are especially important and need to be mentioned.

First, as implied by the description *short-term repeated-dose study*, these studies are of shorter duration than subchronic toxicity studies. Generally, the duration of these studies is either 14 or 28 days with the compound administered daily, although dosing frequency can vary and, in the case of pharmaceuticals, should be based on the intended dosing frequency/regimen to be used in the clinic, if known. A 28-day study can produce more robust information than a 14-day study, which, in turn, will provide more data than a 7-day study. The shorter-term studies may be valuable in identifying target organs due to exposure at high levels, while the longer studies provide more valuable information regarding adverse effects following prolonged exposure at lower dose levels.

Second, dose selection is somewhat dependent upon the purpose of the study. If the short-term study is designed to produce information to be used in the design of a subchronic study, dose levels should be selected to ensure any potential adverse effects are observed. Higher doses are generally used in short-term studies to determine target organs, and it may not be as critical to ascertain a no-observable-adverse-effect level (NOAEL). However, it is always useful to have a NOAEL in a toxicity study. If no further studies are anticipated with the compound, a dose range that includes a NOAEL becomes very important. Because little information other than acute toxicity data is generally available during early compound development, it may be necessary to run a more comprehensive range of dose levels in short-term repeated-dose studies. Four, five, or more dose groups are generally used in short-term studies. This increases the chances of characterizing the dose–response and should increase the confidence of dose range selection for subsequent studies.

A third aspect of short-term studies that is different from subchronic studies is the number of animals per group. Although fewer animals may be used, 5–10 animals of each gender in each dose group are recommended for short-term rodent studies, depending on which agency's recommendations are being followed. Additional animals may be required for nonroutine endpoints, such as a group added to ascertain the reversibility of an adverse effect upon cessation of dosing (often referred to as a recovery group). Also, additional animals may be placed in the high-dose group if potential compound-related mortality is expected.

To summarize, many factors influence the design of all repeated-dose toxicity studies. Before initiation of a study, it must be decided if the specific chemical or chemical mixture, that is, the test material, to be used in the study is appropriate. The appropriate animal model must be chosen, the correct route of exposure must be selected, and the study duration and dosing frequency must be decided. Control and treatment groups and their doses have to be selected. Parameters to be evaluated must be selected to maximize the probability of detecting potential adverse effects. By taking time to design a study carefully, the toxicologist can ensure the study will meet the regulatory requirements and provide adequate data to support the risk assessment.

Regulatory Requirements

National and international regulatory bodies have issued guidelines for the design and conduct of repeated-dose toxicity studies. Even though study designs described in these various guidelines have similar characteristics, some differences between the requirements have existed historically within and between regulatory agencies. This has resulted, in

some cases, in the duplication of studies to ensure guidelines of different agencies are satisfied. The agencies themselves and the regulated community agreed that this duplication of the use of animals and other resources was undesirable. As a result, regulatory authorities worldwide have harmonized many of their guidelines to ensure toxicity studies conducted under a single set of regulations will be universally acceptable. In the United States, the Environmental Protection Agency (EPA) has issued a single set of harmonized toxicity testing guidelines[8] to blend the requirements of the separate guidelines previously promulgated through the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), the Toxic Substances Control Act (TSCA), and the Organisation for Economic Co-operation and Development (OECD). OECD, an international organization of 30 countries including the United States, has issued its own toxicity testing guidelines.[9] Each member country has agreed to accept studies conducted according to these guidelines. In 1991, regulatory authorities and trade organizations from the United States, Japan, and the European Union initiated a cooperative effort through the International Conference on Harmonization (ICH) to produce guidance documents concerning requirements for safety studies with pharmaceutical products. ICH guidance documents generally address specific issues related to toxicity testing, for example, the duration of chronic toxicity testing,[10] handling of impurities,[11] and specific requirements for the testing of oncology agents[12] or biological products,[2] and are not detailed guidelines for toxicity study design.

Each regulatory harmonization effort discussed earlier has been useful, allowing for any well-planned, scientifically valid, adequately conducted, repeated-dose study to satisfy the requirements of multiple regulatory agencies. The scientific foundation for toxicological hazard assessment is continually expanding, and to compromise this foundation by pursuing standard checklist protocols is irrational, wasteful, and unscientific. Today, regulations generally recognize the importance of scientific judgment and encourage discussions between the regulated community and the regulator about alternative study designs. Investigators and regulators share in the obligation to conduct a scientifically sound study.

The remainder of this chapter relates to the typical design and conduct of subchronic and chronic repeated-dose toxicity studies. The information presented should provide the toxicologist with enough information to design a study to satisfy most regulatory guidelines. Parameters evaluated in subchronic and chronic toxicity studies are essentially identical, the major difference being the schedule for data collection. Table 24.4 compares the minimum requirements for subchronic and chronic toxicity studies using rodents as described in the EPA,[8] U.S. Food and Drug Administration (FDA)[13] and OECD[9] testing guidelines. For repeated-dose study designs intended to satisfy guidelines of a particular regulatory authority, it is recommended that the reader (1) use the testing guidelines of that authority as a starting point during the design of a study, (2) refine the design based upon characteristics of the compound of interest, (3) document the design in a detailed, written protocol, and (4) discuss the protocol with a representative of the regulatory authority prior to initiating a study.

Good Laboratory Practice Regulations

In addition to regulations and guidelines concerning the design of repeated-dose studies, the United States and international regulatory authorities have issued good laboratory practice (GLP) regulations, which are principles concerning the manner in which all nonclinical hazard assessment studies (e.g., animals studies) are to be conducted, documented, and reported.[14–21] These GLPs are designed to assure the quality of the study data and report. Requirements from each of the regulatory agencies are similar. GLPs set standards for the test system, laboratory organization, personnel, facilities, equipment, operations, and record keeping. They require that studies be conducted according to written protocols (see Table 24.5) and validated written standard operating procedures (SOPs). Chemical analyses are required to characterize the test article and control article administered during the studies. Study procedures and data must be clearly and completely documented and reported. Automated data collection systems must be qualified and validated prior to use.

Regulatory agencies inspect testing laboratories periodically to assure GLP compliance. Safety studies not conducted according to GLPs will not be accepted by regulatory agencies as pivotal studies to support registration; however, during early pharmaceutical development or during early stages of a risk assessment, studies may be conducted under non-GLP conditions in order to provide preliminary information regarding potential toxicities and can be valuable in dose selection for subsequent GLP-compliant studies. In addition, some versions of GLPs, including those of the U.S. regulatory agencies, provide for disqualification of laboratories that are in major noncompliance with GLP requirements. For these reasons, laboratories conducting studies for regulatory submission generally take great care to comply with GLPs. GLP regulations are generally similar between regulatory bodies. A comparison chart illustrating the requirements of FDA, EPA, and OECD GLP regulations can be downloaded from the FDA website at the address listed in Table 24.17.

STUDY DESIGN

Chemical and Physical Characterization of the Test Material

It may seem that selection of the test material for repeated-dose toxicity testing should require little involvement by the toxicologist because the test material is usually provided by a chemist or product manager. However, several important factors must be considered by the toxicologist to ensure that a study will adequately assess the potential toxicity of the chemical and be accepted by regulatory agencies. Obviously, one of these considerations is that the batch or lot of test material is representative of the chemical intended to be tested

NA, not applicable; y, yes/required; n, no/not required; o, optional; AA, all animals; AS, all survivors.

[a] If a test at one dose level of at least 1000 mg/kg body weight/day produces no observed adverse effects and if toxicity would not be expected based upon data from structurally related compounds, then a full study using three dose levels may not be considered necessary.

[b] Contingent upon the route of exposure in the test article–treated groups.

[c] Extra animals must be added for interim sacrifices and special determinations, for example, toxicokinetics and reversibility of effects.

[d] Not required if similar data are available from other studies or if other clinical signs are noted to an extent that would interfere with evaluation.

[e] Animals in intermediate groups are to be evaluated if compound-related findings are noted in the high-dose group.

[f] If previous studies indicate potential to cause neurotoxic effects.

TABLE 24.5
Protocol Contents Required by FDA Good Laboratory Practices Regulations

- Title and study objective
- Identification of test and control articles
- Identification of sponsor and testing facility
- Justification of test system (animal model)
- Test system information (number, body weight, gender, source, species/strain, age, method of identification, etc.)
- Description of study design and methods for control of bias, such as random assignment of animals to treatment groups, processing of clinical pathology samples in replicates, etc.
- Animal husbandry information
- Dosing information, including dose form preparation and route of administration
- Methods by which degree of absorption of the test and control articles by the test system will be determined, if necessary
- Types and frequencies of assays, analyses, and measurements to be made
- Description of statistical methods
- Records to be maintained

and eventually marketed. Adequate chemical and physical characterization is essential for this determination. Several regulatory agencies and organizations have issued guidelines to describe the information needed and some of the methodology to be used to characterize a chemical.[22–25]

A safety assessment should include a partnership between the toxicologist and a chemist that understands the chemical characteristics of the test material. A thorough chemical characterization of the test material should be provided to the toxicologist. This characterization should include methods of synthesis, precursors used in the synthesis, and any solvents and manufacturing aids used in the manufacturing process. It should also include a quantitative assessment of the major components, with associated accuracy and precision information, and at least a qualitative analysis of minor components. Ideally, the toxicologist should be provided with a mass balance for the test material. Also, the methods of purification of the test material should be provided. This enables the toxicologist to determine the potential for the occurrence of residues and impurities that could produce adverse effects. It also provides the toxicologist with information needed to determine if any specific residues or impurities should be specifically targeted for additional analytical determinations. Prior to initiation of a repeated-dose study, the toxicologist should carefully review the chemical and physical characterization data and applicable regulatory guidelines such as those issued by ICH dealing with residual solvents[26] and impurities.[11]

The specific characterization information required by the toxicologist may vary with each test material. The required data may be different from that used to establish manufacturing and quality control specifications. However, it is essential that the manufacturing and quality control specifications and procedures meet the specific regulatory requirements for toxicity testing. For instance, good manufacturing practices (GMPs), which are somewhat similar to GLPs, are required for some chemicals.[27–32] The chemist should ensure that adequate GMP records exist, if required.

Before initiation of a repeated-dose toxicity study, chemical analyses should be conducted to assure that the bulk test material is stable and that the test material is stable over the range of anticipated concentrations in the vehicle to be used in the study for the maximum period of use. According to GLPs, this evaluation can be conducted concurrently with the study, but detection of instability could invalidate the study results. If the material is stable only under certain conditions, for example, frozen storage, special arrangements for its storage should be made to eliminate instability problems. Instability of the test material may result in lower than expected doses and exposure of the animals to degradation products. The products of degradation may either have their

own unique toxicity or alter the toxicity of the test material. This may make it impossible to correctly interpret data from the study. Stability of the test material in different matrices may also need to be established to support a toxicity study. For example, stability in serum or plasma may need to be demonstrated if toxicokinetic sampling and analysis will be performed.

The toxicologist will have assessed the chemical characterization of the test material at the initial stages of the hazard assessment. However, more complete information may become available before the initiation of repeated-dose toxicity studies. Sometimes, the chemical synthesis or other production methods may change between the initial assessment and the start of subchronic or chronic studies. Therefore, it may be necessary to reassess the chemical characterization before the initiation of these studies. Unanticipated changes in the chemistry of the test material or mixture may necessitate changes in the toxicity study design and/or require additional studies to be performed in order to qualify newly identified impurities. As part of the test material evaluation process, the toxicologist also needs to be aware of any potential genotoxic impurities (GTIs) that arise during the synthesis process. Guidelines for dealing with GTIs and other impurities have been drafted[33,34] and should be consulted when setting limits for these contaminants.

Natural products of plant origin, for example, some of the herbal remedies that are popular today, are often complex mixtures, which present challenges to the chemist and toxicologist. The quantitative chemical composition can be quite variable based upon the environmental growing conditions of the plant, such as soil composition, rainfall, and temperature, and the particular cultivar. This variability results in a range of quantitative values for the components of the mixture and must be considered by the toxicologist.

The test material should be as similar as possible to the chemical to which humans will be exposed. Every attempt should be made to ensure that the test material is either identical to the final commercial product or representative of the anticipated final product. This may not always be possible with commercial products because large-scale production facilities are usually not available during early phases of a safety assessment. When such facilities become available, it may be possible to bridge between the final commercial product and the test material by chemical analysis. *Bridge chemistry* should identify any differences between the chemical that was tested in toxicity studies and the commercial product. This will allow a determination of the toxicological bioequivalence of the test material and final commercial product.

If a impurity of unknown toxicity (i.e., an impurity that was not identified in the test article batches used for toxicity testing) is detected in a drug substance or drug product after animal studies have been completed, the ICH requires that an evaluation be performed taking into account identification and qualification thresholds as described in the ICH quality guidance documents.[24] Based on this evaluation, additional testing may be required including genotoxicity studies, general toxicity studies, and/or other toxicity studies to address specific endpoints. Impurity identification and qualification should be done on a case-by-case basis, and it is suggested that the toxicologist familiarize him/herself with the recommendations and decision trees presented in the appropriate guidelines.

The test material should not only have the same chemical characteristics as the commercial material but also have the same physical characteristics, when possible. If the test material is a solid intended to be used as a powder, it should be administered to the test animals in powder form. Particle size of the powder should be similar for the test material and the material to which humans will be exposed. If humans will be exposed to the material in solution, a solution of the material should be used in the repeated-dose study. During drug development, the final drug product physical form (e.g., tablet, capsule, gel) is generally not defined and/or is not available for preclinical toxicity testing. For this reason, the form of test material used in these studies is oftentimes the neat material that is dissolved or suspended in some type of vehicle. Analyses should be conducted to ensure that the composition of the test material falls within the limits of anticipated or known product specifications. Physical specifications will allow the toxicologist, oftentimes in consultation with the chemist, to determine the most appropriate method of adding the test material to the dosing matrix, such as the diet or drinking water (also see route of administration section provided later).

It is important for the toxicologist to ensure that an adequate supply of test material is available before initiating a toxicity study. A single lot of the test material should be used throughout the subchronic or chronic study, whenever possible. Furthermore, if the repeated-dose study is part of a series of studies in a safety assessment program, it is desirable to use a single lot of test material for the entire program. This reduces the probability of encountering inconsistent results in different studies with the same test material, resulting from inter-lot differences in chemical/physical characteristics. If a single lot of test material is not available in sufficient quantity to complete a study or studies, multiple lots may be used. Chemical characterization of each new lot is required to ensure that it meets all specifications and reasonably duplicates previous lots.

The U.S. FDA has issued guidelines addressing the chemistry data requirements for direct food additive petitions.[23] ICH has issued guidelines for chemistry requirements for drug candidates during preclinical hazard assessment.[24] Although the toxicologist may not have as complete a data package as described earlier before the initiation of a repeated-dose study, sufficient data must be available to meet GLP requirements. FDA GLPs state that "The identity, strength, purity, and composition or other characteristics which will appropriately define the test or control article shall be determined for each batch and shall be documented. Methods of synthesis, fabrication, or derivation of the test and control articles shall be documented…."[35] U.S. EPA GLP statements concerning the requirements for chemical characterization of the test

material are essentially identical to those of the FDA.[36] The OECD GLP guidelines for chemical characterization state, "For each study, the identity, including batch number, purity, composition, concentrations, or other characterizations to appropriately define each batch of the test or reference items should be known."[20] Further information on the chemical characterization of the test material is provided by the FDA in its guidelines for toxicity studies, "The composition of the test substance should be known including the name and quantities of all major components, known contaminants and impurities, and the percentage of unidentifiable materials." The guidance also states that "the test substance used in toxicity studies should be the same substance that the petitioner/notifier intends to market."[37]

Route of Exposure and Method of Test Material Administration

The anticipated human route of exposure to the test material dictates the route of exposure for most subchronic and chronic toxicity studies. Nonintended routes of human exposure should also be considered during the selection of exposure route. The most common routes of exposure in these studies are dietary, oral (gavage or capsule), dermal, intravenous (IV), subcutaneous, and inhalation. Parenteral administration by infusion using implanted or external pumps or IV, subcutaneous, intraperitoneal (IP), or other types of injection is becoming increasingly common, especially with the increasing number of biological agents being developed that need to be injected because they are not absorbed from or broken down in the gastrointestinal (GI) tract. Less frequently, test materials are administered in the drinking water or by intraocular, intravaginal, or some other route.

Although the route of administration/exposure to pharmaceutical agents is usually clearly defined, there are several potential routes of human exposure to a single compound when dealing with compounds such as pesticides and industrial chemicals. For example, consumer exposure to a pesticide may occur by dietary consumption of food crops containing residues of the chemical. Farmworker exposure to the same pesticide may occur by either inhalation or dermal routes during application and harvesting. In such cases, subchronic testing may be required to assess the effects of exposure by all three routes. Emphasis is generally placed upon the route by which the most widespread human exposure would occur; chronic testing is usually conducted only using this route of exposure. Several of the more common routes of exposure are discussed below.

Capsule Administration

If expected human exposure is by the oral route, a solid test material (e.g., a dry powder) can be administered by capsule. Unformulated bulk test material can be given to some large animals, such as dogs and cats, in gelatin capsules inserted into the esophagus manually or with the aid of a mechanical device designed to prevent the animal from biting the individual administering the capsule. Capsules are available in a wide range of sizes and can hold, depending on the density of the test material, as much as 1.5 g. The amount of test material that can be administered is limited by the capacity of each capsule and the practical number of capsules that can be administered at one time. For smaller species such as rodents, small capsules are available; however, capsule dosing of rodents is oftentimes impractical, and the test material is usually administered orally as a solution or suspension in an appropriate vehicle.

Oral Gavage

Another common route of oral administration is oral gavage by intubation. This technique may be used for rodent and nonrodent species. For oral gavage, a solution or suspension of the test material is deposited into the stomach via the esophagus using an intubation tube attached to a graduated syringe or other device. A test material is added to an appropriate vehicle, usually aqueous. If the material is not readily soluble, a suspension may be prepared. For suspensions, a material such as methylcellulose, carboxymethylcellulose, ethylcellulose, or gum tragacanth is added to water to increase the viscosity, and the test material is homogeneously suspended in the vehicle. A wetting agent such as Tween 80 can be used to increase the suspendability of the material. Although aqueous vehicles are preferred, it is possible to use an oil vehicle for lipid-soluble materials. Food oils, such as corn oil, may be used at appropriate volumes, but mineral oils must be avoided. Also, absorption of the test material may be quite different from an oil vehicle compared with an aqueous vehicle, and absorption may be highly volume dependent. When a dosing formulation is a suspension, it is important to document that the suspension is homogeneous and stable. This can be accomplished by taking samples from the top, middle, and bottom of the formulation and assessing the concentration at each level. If the formulation is homogeneous, the variability between the concentrations at each level will be minimal.

The volume of test solution or suspension administered can influence gastric emptying time.[38,39] Since gastric emptying time may affect GI uptake and bioavailability, it generally is preferred that the doses of the test substance be administered on a constant-volume (mL/kg), variable-concentration (mg/mL) basis. For dosing using a constant volume, 10 mL/kg body weight is commonly used as the upper limit although the upper limit may vary by species. At 10 mL/kg, a 260 g rat would receive a dose volume of 2.6 mL, a 35 g mouse would receive 0.35 mL, and a 10 kg dog would receive 100 mL. Dosing usually is conducted once daily but may be performed more frequently in order to mimic the intended human dosing regimen or if concentration and/or pharmacokinetic considerations limit the achievable single-dose exposure to less than the amount desired. When multiple doses are administered each day, it is important not to exceed a reasonable maximum daily dose volume. Publications regarding maximum recommended daily dose volumes are available from various sources[40] and should be consulted when considering dose volumes to be used in a study. Generally, the maximum oral

gavage dose volumes for rats and dogs are 40 and 15 mL/kg, respectively, and maximum dose volumes for a bolus IV dose are 5 and 2.5 mL/kg for rats and dogs, respectively. There may be occasions when the maximum recommended dose volumes may be exceeded; however, these exceptions should be scientifically justified and should be discussed with veterinary personnel at the test facility prior to study initiation.

Daily exposure by oral gavage results in a bolus dose. Administration via the diet or drinking water results in a more constant exposure throughout the duration of the study that is more dependent on feeding patterns. Because rodents are nocturnal, the peak periods for activity and feeding behavior are the end of the light and dark periods (i.e., just before lights on or just after lights off). If high volumes of dosing solution (i.e., 20–50 mL/kg) are to be administered to rodents and/or if the presence of feed may interfere with the absorption of the test substance, consideration should be given to dosing animals during late morning or in the afternoon. For nonrodents, timing of dosing relative to feeding (i.e., before or at a certain time after daily feeding) will also affect test substance absorption and should be considered when designing a study. The timing of gavage dose(s) in relation to feeding should be stated clearly in the study protocol and report.

Administration of a test article as an undiluted liquid, as a diluted liquid, as a dissolved solid, or as a solid in suspension by oral gavage generally results in accurate delivery of the intended dose to each animal in a repeated-dose study. To deliver an accurate dose of test article in solution or suspension, the compound must be mixed with solvent or suspending agent at the proper concentration. The appropriate concentration of test solution or suspension can be calculated using the intended dose level and the dose volume of the solution/suspension to be administered to the animals. This calculation is illustrated in Figure 24.2. Obviously, this same calculation applies to solutions or suspensions for other exposure routes, for example, administration by capsule, dermally or parenterally.

Use of a vehicle to carry the test material into the animal has been mentioned several times in the preceding discussion. Choice of vehicle is a critical decision for toxicology studies. Obviously, the vehicle should be nontoxic at the dose (volume) administered. It should not act in an additive or synergistic manner to enhance the toxicity of the test material, nor should it interfere with the expression of any potential toxicity. Because such interactions are not always predictable, it is imperative that vehicle controls be used in all oral gavage toxicity studies. However, even including a vehicle control group may not always compensate for the administration of vehicle in the groups receiving the test material. Interactions between vehicle and test materials can be encountered and must be considered during the design of studies. Vehicles may produce physiological/nutritional alterations that may affect the toxicity of the test material, especially in longer-term studies. For instance, an oil vehicle may result in poor

Formula

$$\text{Concentration (mg test material/mL solution or suspension)} = \frac{\text{Intended dose level (mg test material/kg body weight/interval)}}{\text{Dose volume (mL solution or suspension/kg body weight/interval)}}$$

Example

The concentration of a solution intended to deliver a daily 1500 mg/kg dose level of test material A to rats at a dose volume of 5 mL/kg body weight (BW) is calculated as follows:

$$\text{Concentration (mg A / mL)} = \frac{1500 \text{ mg A/kg BW/day}}{5 \text{ mL solution/kg BW/day}}$$

$$= 300 \text{ mg A/mL solution}$$

As indicated in the following, a 300 g rat would receive 1.5 mL of this solution each day and, therefore, would receive the intended daily dose level. First, calculating the volume of solution administered to the rat,

$$0.3 \text{ kg BW} \times 5 \text{ mL solution/kg BW/day} = 1.5 \text{ mL/day}$$

Then, calculating the amount of test material A in that volume,

$$1.5 \text{ mL of solution/day} \times 300 \text{ mg A/mL solution} = 450 \text{ mg A/day}$$

Finally, calculating the dose level resulting from the administration of that amount of test material,

$$\frac{450 \text{ mg A / day}}{0.3 \text{ kg BW}} = 1500 \text{ mg A/kg BW/day}$$

FIGURE 24.2 Calculation of test material concentration in a solution or suspension.

absorption of fat-soluble nutrients. Food oil vehicles add to the caloric intake of the animal and may produce effects in longer-term studies. Absorption of fat-soluble materials from oil vehicles can be slower than when the same material is administered in an aqueous matrix. The resulting change in the toxicokinetics of the test material can produce profound differences in toxicity. Since toxicity testing generally uses exaggerated doses compared to human dose/exposure, it is sometimes difficult to formulate test article solutions of sufficient concentration to provide the necessary doses. In such cases, suspensions are sometimes used. The use of a suspension rather than a solution can also affect toxicokinetics and influence toxicity. For these reasons, among others, great care must be utilized in selecting an appropriate vehicle and formulation procedures for the administration of test materials to animals. Literature exists comparing the different types of vehicles commonly used and may be helpful when selecting an appropriate vehicle for toxicity studies.[41]

Dermal Application

For a drug, cosmetic, industrial chemical, or pesticide with dermal exposure potential for humans, dermal application is the most appropriate route of administration for repeated-dose studies. The test material is applied to a defined area of skin from which the hair has been removed. Shaving and/or depilatories are common methods for hair removal; however, both procedures can alter skin permeability. Because the test animal can ingest some of a dermal dose during grooming, it is common practice to cover the test material application site by wrapping the trunk of the animal with a semiocclusive material (e.g., gauze strips) during the exposure period. Occasionally, if exaggerated dermal absorption is desired, the application site is covered with an occlusive material (e.g., rubber dam). Either method of wrapping, that is, occlusion or semiocclusion, maintains the test material in contact with the skin. Wrapping also increases the accuracy of the administered dose since, on unoccluded animals, dry test materials may fall off the application site and liquid materials may run off or evaporate from the site. Restraint and/or *Elizabethan* collars are also sometimes used to prevent the animal from tampering with the wrap or to prevent oral ingestion if the application site is unoccluded. However, use of restraint or collars may stress the animals and potentially alter the outcome of a study. To avoid unnecessary stress, the animals should be acclimated to restraint devices and/or collars before dosing is initiated.

Parenteral Administration

A pharmaceutical intended for administration to humans by injection should be administered to the test animals by the same parenteral route. A common type of parenteral exposure is subcutaneous injection. To avoid irritation and other potential effects, such as fibrotic reactions, the specific site of injection should be changed daily. It is recommended that the dosing vehicle be aqueous since oil vehicles may track back along the needle path and be deposited in the lipophilic skin and hair. As with oral gavage dosing, absorption from an oil vehicle may differ compared to an aqueous vehicle. For subcutaneous administration, care must be taken to ensure that the material is deposited subcutaneously rather than intradermally or intramuscularly. This can be accomplished by lifting the skin of the animal to form a pocket and injecting the dosage into the subcutaneous space.

Other common routes of parenteral administration include IV, intramuscular (IM), and IP injections. Special considerations are required for each of these routes. For IV administration, the test material must be soluble in an aqueous vehicle because physiologic saline is the usual vehicle. Air bubbles must be cleared from the delivery system, that is, needle, catheter, and/or syringe, before injecting the material intravenously. The dosing solution for IV administration must be at a physiologic pH and must not be extremely irritating or corrosive. Repeated use of the same injection site must be avoided. To prevent inadvertent delivery of the test material into the muscle or other surrounding tissue, care must be taken to ensure that the needle tip is in the lumen of the vein before injecting the test material. Proper placement of the needle can be assessed by drawing a small amount of blood back into the delivery device, for example, catheter or syringe. If no blood is observed, the needle is not located in the lumen of the vein. For IM and IP routes of exposure, proper placement of the needle tip also must be assessed before administering the dose. In contrast to IV, drawing back on the delivery device without obtaining blood is required prior to administering material by the IM route. Similarly, drawing back on the device without obtaining blood or intestinal contents prior to injecting test material is necessary for correct IP administration. Most other considerations for IM and IP exposure are similar to those for IV administration, for example, the material must not be corrosive or irritating and repeated injections at the same site should be avoided.

Continuous infusion may be used to simulate a constant human exposure or, for IV infusion of poorly soluble test substances, to deliver a sufficiently large daily dose for safety assessment. Infusions may be administered using either implanted or external pumps. Implanted pumps may be battery-operated mechanical pumps (nonrodents) or osmotic pumps (rodents and nonrodents). These pumps permit unrestricted movement of the animal. Practical considerations of volume and weight of implanted pumps restrict their use to very soluble and/or potent test articles that can be administered slowly over a long period. External pumps may be connected to rodents and nonrodents using tethers and swivels or affixed to nonrodents as *back-packs*. External pumps not only allow for infusion of larger volumes of test substance but also require more waste substance because of the larger *dead space* of the tether catheter. Use of external pumps may be problematic for subchronic or chronic studies because of the relatively long study duration. The patency of the catheter for implanted and external pumps must be confirmed frequently. Infusion pumps should be calibrated prior to use on study to ensure that they will deliver the expected amount of test solution over the infusion period. The dose received by each animal should be

confirmed based on measurements of the actual amount of test solution infused during the dosing period. This is determined by measuring the weight of the pump or syringe and the solution prior to initiation and following completion of infusion.

Implantation

Subcutaneous or IM implantation is often used for evaluating biopolymers for medical devices or prostheses. In addition, test materials have been embedded in special matrices that allow continuous, sustained release for weeks or months after subcutaneous implantation. Demonstration of the stability of the test material in the matrix, both during preparation of the pellet and after implantation, is required when using this technology. The determination of plasma concentrations of the test material and/or its metabolites can be used to confirm proper dosing. Because of size limitations, these pellets are only useful for delivery of very potent substances, such as hormones and biological proteins.

Dietary Administration

Dietary administration is appropriate for a food additive or a pesticide that has potential to become a residue in or on food crops. This type of administration, although frequently used in subchronic and chronic toxicity studies, yields less accurate/more variable doses than most other routes of dosing. This is primarily because of differences between body weight and feed consumption of individual animals, which results in variable compound consumption. A further complication in rodent studies is that these animals tend to add body fat and not lean body mass as they age. Therefore, lipophilic compounds have a larger mass of fat into which they can partition as an animal grows older, thereby decreasing the effective dose. In addition, fat does not have significant detoxification enzymes. Therefore, as dose is increased to account for increased body weight in older rodents, detoxification capacity may be stressed, resulting in unanticipated toxicity. This complication is not unique to dietary exposure studies and will also affect the effective dose of a test material in rodents exposed by most other routes. While potential variability in effective dose is important to the interpretation of the results, no attempt is generally made to compensate for this variability during preparation of the test diet or calculation of the administered dose in repeated-dose dietary toxicity studies. Spillage or soiling of feed, which occurs fairly frequently with some test animals, is a factor that contributes variability to the calculation of dietary dose. Significant spillage or soiling must be considered when collecting feed consumption data to be used in the calculation of dietary concentration or compound consumption. Dietary concentrations used in repeated-dose studies can be determined by either of two methods: (1) attempting to keep a constant mg/kg dose level by adjusting the dietary concentration of the test material to account for changing body weight and feed consumption or (2) feeding a constant concentration in the diet (and therefore, the mg/kg dose level will decrease as animals gain weight).

Routinely adjusting the dietary concentration of a test material based upon the changing body weight and feed consumption of the animal provides reasonably good control over the delivered dose during a repeated-dose study. Dietary concentration is usually adjusted weekly during a subchronic study. In a chronic study, diet concentration is usually adjusted weekly during the first 13–14 weeks (especially for rodents because of the rapid growth of the animals during this period) and biweekly or sometimes monthly thereafter. Using this method, the mean feed consumption and body weight of a dose group during a given study interval are used to calculate the dietary concentration to be fed to that group during the following interval. There are several ways to calculate the concentration. One formula for this calculation and an example of its use are presented in Figure 24.3.

Feeding a constant concentration of the test material in the diet throughout the study is the second form of dietary administration. This method provides less control over the administered dose because it is a function of the amount of feed (and, therefore, test material) consumed and body weight gained by each animal. The consumed dose, or compound consumption, of each individual animal can be calculated using its feed consumption and body weight. The mean of the individual animal compound consumptions represents the compound consumption for each dose group. A commonly used formula for the calculation of individual compound consumption is illustrated in Figure 24.4.

When feeding a constant concentration in a rodent study, the toxicologist must be aware that the compound consumption may vary significantly for an individual animal or group of animals during the course of the study. For example, compound consumption during the first week of a 13-week rat study in which the test compound is fed at a constant dietary concentration is frequently more than twice the compound consumption during the last week of the study. This variation results from the rapid decrease in feed consumption relative to body weight (g feed/kg body weight/day) during the first several months of life. This variability in compound consumption is illustrated in the example given in Figure 24.4.

Drinking Water

Water-soluble test materials can be offered as a solution in the drinking water, providing adequate dosage can be achieved. This route may be preferred when it mimics human exposure conditions, compared with event-oriented exposure such as pill taking. Spillage can be a significant problem when administering material in drinking water, and recovery of spilled water is usually not feasible. Another complication with drinking water administration is that evaporation of water and/or volatilization of the test material can occur from the tip of the drinking (sipper) tube, resulting in the alteration of the concentration of the test material in the water. The use of a sipper tube containing a ball-bearing tip minimizes this problem. Finally, consideration should be given to the type/composition of water bottles, stoppers, and sipper tubes used in a toxicity study. The bottles, stoppers, and tubes should be made of material that will not degrade when exposed to water containing the test material.

Formula

$$\text{Concentration (mg test material / kg diet)} = \frac{\text{Intended dose level (mg test material/kg body weight/day)}}{\text{Projected feed consumption (kg feed/kg body weight/day)}}$$

where projected feed consumption (PFC) for a study week is based on body weight (BW) and absolute feed consumption (AFC) data from the previous week and is calculated as follows:

$$\text{PFC (kg/kg/day) for week}_n = \frac{\text{AFC week}_{n-1}\text{ (kg)}}{\text{7 days}} \div \left[\text{BW end of week}_{n-1}\text{ (kg)} + \frac{\text{BW gain during week}_{n-1}\text{ (kg)}}{2}\right]$$

Example

In a subchronic rat study, the mean body weight of the males in the 15 mg/kg/day dose group at the beginning of week 11 is 520 g. At the end of week 11, the mean weight for these males is 540 g. Mean feed consumption of these animals is 154 g during the 7 days of week 11. The dietary concentration intended to deliver a 15 mg/kg/day dose level of compound A to this group of rats during week 12 of the study is calculated as follows:

$$\text{PFC (week 12)} = \frac{0.154\text{ kg feed}}{\text{7 days}} \div \left[0.540\text{ kg BW} + \frac{0.020\text{ kg BW gain}}{2}\right]$$

$$= 0.04\text{ kg feed/kg BW/day}$$

and, therefore,

$$\text{Concentration (week 12)} = \frac{15\text{ mg A/kg BW/day}}{0.04\text{ kg feed/kg BW/day}}$$

$$= 375\text{ mg A/kg feed}$$

Note that, because their body weight and feed consumption differ, the diet concentrations for males and females in the same dose group will generally differ throughout the study.

FIGURE 24.3 Calculation of adjusted diet concentration to yield constant dose level.

Assessment of the Adequacy of Test Material Preparations

Whatever the route of administration, it is critical to confirm that the test material is delivered to the animals at the intended doses. For dietary studies, test diets should be prepared before the initiation of a repeated-dose study using the intended diet preparation method. It must be shown that this preparation method yields diets containing the appropriate amounts of homogeneously mixed test material. Chemical analysis of samples taken from several locations in each test diet preparation should be conducted to determine if the proper concentrations of test material have been achieved and to assess the homogeneity of the dietary admixtures. If the results of these analyses indicate that the anticipated concentrations were not achieved or the distribution of test material in the diet was not homogeneous, the diet preparation method should be revised and retested. Diet preparation must be validated before the study can be initiated.

During the prestudy homogeneity determinations, additional diet samples should be collected and analyzed to show that, within the range of concentrations to be used in the study, the test material is stable in the diet. These samples should be stored under animal room conditions and under frozen conditions for the maximum period of time during which the diet will be used or stored. For a study in which dietary admixtures will be prepared and fed once per week, stability of the test material in the diet would commonly be assessed for samples stored under animal room conditions for at least 7 and 14 days. This allows the estimation of the degradation rate at room temperature. Analysis of frozen diet samples stored for several intervals is also advisable. Demonstration of stability under frozen storage conditions makes chemical analysis of diet samples immediately after collection during the toxicity study unnecessary. It also validates the possibility of confirming analytical results by reanalysis of stored frozen samples, if needed.

Even though the adequacy of the diet preparation method and stability of the test material in the diet have been demonstrated, it is important to monitor diet concentrations during the study. For each diet preparation during the first several weeks of the study, concentrations of the test material in the diets should be assessed. Subsequent analysis of diet preparations every 2–4 weeks will add assurance that diets were prepared properly. More frequent analysis, for example, weekly throughout the study, is even more desirable.

For routes of administration other than dietary, the principles cited earlier also apply. Concentration, homogeneity, and stability of the test material in solvents or suspending agents must be determined for studies using oral, dermal, inhalation,

Formula

Compound consumption (mg test material/kg body weight/day) = Concentration (mg test material/kg feed) × Relative feed consumption (kg feed/kg body weight/day)

where relative feed consumption (RFC) for a study week is based on body weight (BW) and absolute feed consumption (AFC) during that week and is calculated as follows:

$$\text{RFC (kg/kg/day)} = \frac{\text{AFC (kg)}}{\text{7 days}} \div \text{BW start of week (kg)} + \frac{\text{BW gain during week (kg)}}{2}$$

Example

In a subchronic rat study, a group of males is fed test material A at a constant dietary concentration of 2% (w/w). The body weight of one animal in this group is 175 g at the start of week 1 and 225 g at the end of week 1. Its feed consumption during the 7 days of week 1 is 168 g. Subsequently, this rat weighs 490 g at the start and 510 g at the end of week 13 and its feed consumption during that week is 196 g. The compound consumption of this rat for each week is calculated as follows:

$$\text{RFC (week 1)} = \frac{0.168\,\text{kg feed}}{\text{7 days}} \div \left[0.175\,\text{kg BW} + \frac{0.050\,\text{kg BW gain}}{2}\right]$$

$$= 0.120\,\text{kg feed/kg BW/day}$$

$$\text{RFC (week 13)} = \frac{0.196\ \text{kg feed}}{\text{7 days}} \div \left[0.490\,\text{kg BW} + \frac{0.020\,\text{kg BW gain}}{2}\right]$$

$$= 0.056\,\text{kg feed/kg BW/day}$$

and, therefore,

$$\begin{aligned}
\text{Compound consumption (week 1)} &= \text{2\% test material A} \times \text{RFC (week 1)} \\
&= \text{2 g A/100 g feed} \times \text{0.120 kg feed/kg BW/day} \\
&= \text{20,000 mg A/kg feed} \times \text{0.120 kg feed/kg BW/day} \\
&= \text{2400 mg A/kg BW/day} \\
\text{Compound consumption (week 13)} &= \text{2\% test material A} \times \text{RFC (week 13)} \\
&= \text{20,000 mg A/kg feed} \times \text{0.056 kg feed/kg BW/day} \\
&= \text{1120 mg A/kg BW/day}
\end{aligned}$$

FIGURE 24.4 Calculation of compound consumption resulting from constant diet concentration.

or other routes of administration when the test material is to be administered in solution, in suspension, or as an aerosol. Suspensions represent a special case because care must be taken to assure that the suspensions do not settle and become nonhomogeneous during administration to the test species. For inhalation studies, the concentration of gas, aerosol, or particulates to which the animals are exposed and the homogeneity of the atmospheres within the exposure chambers should also be assessed using appropriate analytical methods.

Duration of Exposure

As stated previously, subchronic toxicity studies involve the administration of the test material to the test species during a significant portion of its lifetime. Classically, these studies are conducted for 90 consecutive days or approximately 13 weeks. Chronic toxicity studies in rodents most commonly involve dose administration for a major portion of their life span, generally 12 months, although studies of shorter duration (i.e., 6–9 months) are considered acceptable by some groups.[10] Rodent chronic toxicity studies are sometimes combined with lifetime oncogenicity studies in order to achieve efficiencies during some of the study procedures, for example, diet preparation. During these combination studies, the animals in the chronic toxicity segment are generally studied during the first 6–12 months and then are euthanized and evaluated. Those in the oncogenicity segment continue on study generally for at least 24 months. In nonrodents, for example, dogs and nonhuman primates, which are longer lived than rodents, 6–12 months represents a significantly smaller portion of their life span but is currently considered an adequate duration of exposure to detect chronic effects.

Test material administration during a repeated-dose toxicity study can be continuous, intermittent, or repeated. In most dietary and drinking water studies, the animals have free access to diets or water containing the test material throughout the study and exposure is essentially continuous, although influenced by diurnal patterns of consumption. In dermal or inhalation studies, exposure to the test material is intermittent, generally 4–6 h/day. When the route of administration is IV infusion, exposure may be either continuous or intermittent. With bolus dose parenteral administration or oral gavage, test material administration is generally once or, at most, a few times each day. In some cases, such as with some biological agents, dose administration will only be performed once each week or even once monthly due to the prolonged pharmacologic response of these compounds. In the past, labor-intensive methods of administration, such as oral gavage, were sometimes done only during the standard work week, that is, 5 days/week. This is not recommended because 2 days of nonexposure each week during the study may be sufficient to allow modification or reversal of toxic responses.

Dose Groups

The minimum number of groups receiving test material in a repeated-dose toxicity study is generally three (low, mid, and high dose). According to OECD guidelines, "the highest dose level should be chosen with the aim of inducing toxic effects but not death or severe suffering" while FDA guidelines simply state "the high dose should be sufficiently high to induce toxic responses in test animals." Wording in the guidelines differs slightly regarding mid- and low-dose levels. Essentially, the mid-dose level should produce no more than slight toxicity and the low-dose level should produce no toxicity yielding a NOAEL. As previously stated, a short-term (2–4 weeks) repeated-dose study should be conducted to aid in the selection of doses for subchronic testing. For test materials where a dose–response has not been well defined during a short-term repeated-dose study, additional dose groups may be required in the subchronic study to ensure that the range of desired responses, that is, no toxicity to significant toxicity, is achieved. However, it is sometimes difficult to completely satisfy these criteria. Before selecting doses for a chronic toxicity study, a subchronic study that defines no-effect and effect levels should be completed.

Limit Studies

For test materials that possess very low potential for toxicity, the inclusion of only one test material dose group in a repeated-dose study is sometimes acceptable. A study with this design is termed a limit study. Limit testing is inappropriate for materials with anticipated high human exposure. The dose level for the test material group in dietary and dermal limit studies is normally at least 1000 mg/kg/day. Another type of limit study involves utilization of the maximal exposure level under the conditions of the study. For example, suppose the majority of toxicology data concerning a lipophilic drinking water contaminant has been collected using oral administration in a corn oil vehicle and additional data are desired using a water vehicle. The limited water solubility of the test material may result in the maximal dose being significantly lower than the dose used in the corn oil gavage studies. However, the test material can be tested as a saturated water solution. Such a study may reveal the test material to be either more or less toxic in water than in the oil vehicle. The data are relevant to the assessment of hazard associated with exposure in the drinking water because the maximal possible exposure by this route of administration was tested. Thus, while a limit study may not define the *complete* toxicology of a test material, it can define the *practical* toxicology of the material.

Control Groups

Adequate controls are essential to successful toxicity studies of all types, including repeated-dose studies. Studies should contain at least one control group for comparison with the groups receiving the test material. The control group should be treated identically to the treated groups except the control group should receive no test material. Control groups can be either negative or positive controls.

Negative control groups are intended to demonstrate the normal state of the animal for comparison to data from the groups treated with the test material. They also provide an opportunity to compare baseline data for the current study to baseline data from previous studies. There are several types of negative controls. If the test material is dissolved or suspended in a vehicle for administration, a vehicle control group should receive, by the same route of exposure, the maximum amount of solvent or suspending agent administered to any of the test material groups. If the test material is administered in the diet, an untreated control group should receive the same diet without test material. For test materials administered undiluted, a sham control group should receive the same physical treatment as the treated groups, for example, insertion of an intubation tube with or without the delivery of an innocuous substance like water, administration of empty capsules, and injection of physiological saline.

Positive control groups are intended either to demonstrate susceptibility of the animal to a specific toxicity or to compare the response of test material–treated animals with that of animals treated with a chemical that produces a known toxicity similar to the test material. If a positive control group is included in a study design, at least one negative control group should also be included. Positive control groups are infrequently used in repeated-dose toxicity testing. However, if the chemical structure of a test material suggests that it may possess a specific toxicity, for example, neurotoxicity, it may be important to demonstrate that the species and the strain selected for testing are susceptible to that toxicity.

A positive control that is sometimes useful in repeated-dose studies is the reference control. This control consists of a material that is chemically or physically similar to the test material but has either a comprehensive toxicology database associated with it or a history of use without adverse effects.

Inclusion of a reference control group allows a comparison between reference and test material within the same study. This can assist in identifying any effects related to the general characteristics of the reference material. For instance, oral administration of a poorly absorbed oil can decrease the absorption of fat-soluble vitamins. If the test material is known or suspected to produce this effect, use of a reference material, such as mineral oil, can be useful. This would distinguish effects related to vitamin depletion from effects produced directly by the test material. Additionally, if the test material were to add substantially to the caloric intake, a reference control diet isocaloric to the test diet would be useful, especially in longer-term studies. A reference control group also may be useful to compare the degree of anticipated toxicity of the test material to a reference material of known toxicity. For example, it could be important to demonstrate that the hepatotoxicity of a test material intended for use as an anesthetic is significantly less severe than that produced by an anesthetic already in use.

Animal Models

To increase the probability of testing in a species that may respond to the test material in a manner similar to humans, two species are generally used for repeated-dose toxicity studies. Routinely, one rodent species and one nonrodent species are utilized. Rats and dogs are the generally preferred species for most routes of administration. The rabbit is the preferred nonrodent for dermal administration. Mice, hamsters, miniature swine, guinea pigs, nonhuman primates, and a few other species are used on occasion in these studies. Many factors should be carefully considered during the selection of the most appropriate species and strain for testing with a specific chemical. Some of these factors are summarized in Table 24.6.

Toxicokinetics

Ideally, the selection of an animal model for repeated-dose toxicity studies should be based upon the similarity between toxicokinetics/metabolism of the test chemical in that species and strain to its toxicokinetics/metabolism in humans. This selection criterion assumes that these factors are known in potential test animals and in humans. Often, these data are unavailable during the initial phase of a hazard assessment.

TABLE 24.6
Selection Criteria for Species and Strain in Repeated-Dose Studies

- Requirements by regulatory agencies
- Metabolism of test material in a manner similar to humans
- Availability of historical control data
- Most sensitive species and strain
- Responsiveness of particular organs and tissues to specific toxicities
- Availability of the species and strain
- Availability of appropriate animal housing and husbandry
- Experience of the laboratory in the use of the species and strain

Although the metabolism of a chemical may be understood in one strain of one species of laboratory animal before the initiation of repeated-dose testing, it is seldom known in several species and strains. With the exception of pharmaceuticals, the metabolism of a chemical in humans is almost never known before the initiation of a subchronic or chronic study. Consequently, similarity in metabolism between humans and animal models is seldom the initial basis for the selection of test species and strain. This may change, however. Currently, human microsomes and systems that express specific human detoxification enzymes are commercially available. Therefore, in vitro metabolism in human hepatocytes and hepatocytes isolated from various test species can be compared before initiating a hazard assessment.[42]

Sensitivity to Test Material

Another commonly used criterion for the selection of the animal species and strain for repeated-dose testing is sensitivity to the test material. As a conservative approach to the extrapolation of toxic effects seen in animals to humans, the animal model selected should be the most sensitive to the effects of the chemical. Data required for this decision are often not available until a significant portion of the total hazard assessment program for the chemical has been completed. Acute and short-term repeated-dose studies may reveal information concerning species sensitivity. However, relative sensitivity of different species and strains frequently only can be determined following the completion of longer-term studies with their more comprehensive endpoints.

In any event, sensitivity to the chemical should be considered during the selection of the test animal. For example, differences in sensitivity of particular organs and tissues to toxic compounds among different species should be considered. Strains that have aberrant metabolic pathways, especially those associated with detoxification, should not be used except in special cases. For instance, the Gunn rat does not produce certain glucuronides[43] and would not be an appropriate animal model for a hazard assessment. Cats are deficient in their ability to produce glucuronides but can produce sulfate conjugates.

After the determination of which species in repeated-dose toxicity studies is the more sensitive species, it is appropriate to use the data gathered for that species (e.g., NOAEL values) in the hazard assessment, whether it will be used for setting exposure limits for environmental contaminants or setting human doses in pharmaceutical trials. It is also important to base the evaluation of the most sensitive species on internal exposure rather than simply using dose level to compare sensitivity. It may also be appropriate, in some cases (e.g., oncology compounds), to convert doses from dose based on body weight (mg/kg) to dose based on surface area (mg/m^2) when evaluating sensitivity to test articles.

Historical Control Information

Availability of historical control data for the parameters evaluated during repeated-dose toxicity testing is an important consideration in selecting the test species and strain.

These data are frequently useful in determining the toxicological relevance of a finding when comparison of data from treated and concurrent control groups suggests a potential compound-related effect. Historical data concerning growth, feed consumption, clinical pathology, and other parameters are often useful in interpreting findings from a subchronic or chronic study. Historical histopathology data are of particular importance due to the subjective nature of these data. Although published data can be useful, historical data from the laboratory at which the study is being conducted are most relevant. Most laboratories have historical databases for commonly used species and strains. If less common species are being considered, the availability of historical data should be assessed before final selection.

Other Animal Model Considerations Involved in Study Design

After consideration of the earlier criteria, pragmatic considerations are necessary during the selection of a species and strain. The animals should be obtained from a reputable, reliable supplier who will guarantee the health of the animals and will arrange expeditious and controlled shipment of the animals to the laboratory. It should be ensured that the supplier maintains careful records concerning the animal colony and maintains a healthy colony. The supplier should provide disease-free animals because it is often not desirable/possible to treat for disease once a study has initiated. Furthermore, the use of diseased animals will ultimately affect the outcome of the study and could cause results of the study to be inaccurate and misleading. Animal health issues can be minimized, in part, by receiving animals from suppliers that are accredited by the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC) and that follow animal care procedures as described in the Institute of Laboratory Animal Resources (ILAR) *Guide for the Care and Use of Laboratory Animals* (aka "The Guide").[44]

The quantity of available test material may influence the selection of the animal model. For example, it may be necessary to select a rodent species if the amount of test material available is insufficient for long-term administration to a larger species such as the dog.

Capabilities of the testing laboratory should be considered during test animal selection. The laboratory must have appropriate caging and other equipment and must be able to maintain the proper environmental conditions in the animal room. In addition, the laboratory conducting the study should have experience with the use of the chosen species in toxicology studies to avoid problems associated with species-specific physiology and anatomy.

Age of Animals

The age of animals used in subchronic and chronic toxicity studies is relatively standard. For rodents, initiation of test material administration at 6 weeks of age will satisfy virtually all guidelines for testing. Dogs approximately 4–6 months of age at initiation of exposure to the chemical are usually acceptable, but if the test material is expected to produce toxicity in reproductive organs, older dogs should be used in order to avoid confusing results due to the variability in the degree of sexual maturity noted in 4- to 6-month-old dogs. Precise age of nonhuman primates is frequently not known; however, age can be approximated by experienced suppliers. For nonhuman primates and other less commonly used species, young animals should be used, keeping in mind that sexually mature primates must be used for reproductive and developmental toxicity studies and/or when effects on the reproductive organs are suspected.

Prestudy Health Assessment

To the extent possible, it should be assured that each animal included in a repeated-dose study is in good health. The animals must not have been previously used for any other type of experimental procedures. An exception is sometimes made for nonhuman primates, which may occasionally be used for more than one study, with a reasonable period between studies to ensure that any residual test material is absent. These animals should undergo extensive health screening, including clinical pathology evaluations, between studies.

For rodent studies, enough animals of each gender should be obtained to allow exclusion of those with conditions that could interfere with completing the study or be interpreted as compound related at completion of the study. It is good practice to obtain 5%–10% more animals than will be required to fill the study groups. Minimally, pretest physical examination and body weight measurement should be conducted to assess the health of each animal before study initiation. Pretest ophthalmologic examination and clinical pathology evaluations are advisable. Animals in poor health or exhibiting ocular or other defects should be eliminated from consideration for the study.

To ensure that the toxicologist is aware of any infection that the animals may be exposed to during the study, a sentinel group is often maintained in the room with the study animals. For rodents, this group normally contains 5–10 animals of each gender. Serum antibody titers are assessed in these sentinels at the initiation of the study and at the termination of the in-life phase of the study. If necessary, antibody titers and/or other evidence of infection can also be obtained from these animals during the study without disturbing the test animals. A relatively complete list of antibody analyses used in rodent species is presented in Table 24.7. In addition to serology testing, samples (tissue, feces, bronchial lavage) can also be collected for the evaluation of the presence of microorganisms and/or parasites that may be present in test animals.

Health assessment of nonrodent species by the supplier is generally more comprehensive than rodents. This reduces the need to obtain many extra nonrodents. However, it is good practice to conduct procedures after receipt of nonrodents to assure that their health status has not changed before use in a subchronic or chronic toxicity study.

TABLE 24.7
Serum Antibody Analyses in Rodents

Rat	Mouse
Sendai virus	Sendai virus
Pneumonia virus of mice	Pneumonia virus of mice
Reovirus type III	Reovirus type III
Mycoplasma pulmonis	*Mycoplasma pulmonis*
Lymphocytic choriomeningitis virus	Lymphocytic choriomeningitis virus
Mouse adenovirus FL/K87	Mouse adenovirus FL/K87
Mouse polio virus	Mouse polio virus
Hantaan virus	Hantaan virus
Encephalitozoon cuniculi	*Encephalitozoon cuniculi*
Cilia-associated respiratory bacillus	Cilia-associated respiratory bacillus
Rat parvovirus—IFA	Mouse parvovirus—IFA
Rat coronavirus/sialodacryoadenitis virus	Murine hepatitis virus
Kilham rat virus	Minute virus of mice
Toolan H-1 virus	Ectromelia virus
Rat minute virus	Mouse pneumonitis virus
Rat theilovirus	Polyomavirus
Pneumocystis carinii	Mouse thymic virus
Infectious diarrhea of infant rats	Epizootic diarrhea of infant mice virus
	Mouse cytomegalovirus
	Mouse norovirus
	Mouse rotavirus

Number of Animals

Regardless of the study type/design, the minimum number of animals necessary to achieve the study objectives should be used. The *3Rs* principles (replacement, reduction, and refinement), first described by Russell and Burch,[45] should be employed when determining ways to minimize animal usage in toxicity studies. To satisfy most regulatory guidelines, a minimum of 5–20 rodents of each gender should be included in each control and test material dosed group, depending on the duration and specific study design in a repeated-dose study. For nonrodents, the minimum number of animals of each gender in each group is four. However, the minimum number of animals is frequently exceeded in an attempt to compensate for unexpected mortality or to increase the sensitivity of the study. Twenty rodents or five to six nonrodents of each gender per group are often used as the base number of animals for the study. Some study designs include an interim necropsy at one or more intervals for the detection and evaluation of the progression of potential effects during the study. Other designs may contain treated animals that will be maintained without exposure after the termination of the main study groups to determine the reversibility of any adverse effects. Still other designs include satellite groups for special purposes, for example, toxicokinetic determinations or untreated sentinel animals used to monitor the health of the study animals. The base number of animals placed on study at its initiation should be increased by the number of animals to be used for these enhanced study designs.

Individual Animal Identification

Before assignment to study, each animal must be assigned a unique identification number. This number will be associated with the animal throughout the study and will be used to identify specimens, tissues, and data from the animal after the in-life portion of the study is completed. Therefore, this number must stay with the animal continuously during the study so that there is no chance of misidentification. It is not adequate to simply attach the animal identification to the animal's cage. Animals may escape from their cage or may be placed in the wrong cage during cage-changing operations. Unique identification numbers can be placed on the animals by a number of methods. Whatever the identification method, it should remain permanent and readable for the duration of the study. Older identification methods used for rodents included toe clipping, where a small portion of the toe was removed in a specified coded manner, and ear punching, where holes were punched through the ears in a specified coded manner. These methods are not acceptable today as more precise and humane methods have become available. Currently, the use of a numbered tag attached to an ear or tattoos placed on the tail or ear are commonly used methods for large and small animal identification. Another commonly used method involves subcutaneous implantation of a microchip that can be read by a hand-held scanner. In many cases, these *chip readers* can be interfaced with computerized on-line data collection systems that can help ensure the proper data are collected and procedures are performed on the animals.

Randomization of Animals

After excluding all animals that do not meet the study acceptance criteria (e.g., animals that do not pass physical examination or are not within specified body weight boundaries) and assigning unique identification numbers to the remaining animals, the next step is to randomly place them into study groups. This is a critical step in the study to ensure the greatest ability to detect statistical differences between the groups in the study without bias. A number of randomization methods have been devised, some more appropriate than others. Historically, one of the most popular methods was the use of manual random number tables. However, as technology has advanced, the use of computerized randomization procedures has become the norm. After randomization into the various study groups, some method should be employed to determine if the animals are truly randomized based upon a parameter critical to the study. The most commonly used parameter is body weight. Statistical analysis of mean body weight data is conducted to show that there are no statistically significant intergroup differences in mean body weight at the initiation of the study. It is not uncommon to find that the mean body weight

in one of the study groups is significantly different from one or more of the other groups. In cases where there is a significant difference between the mean body weights of any of the study groups, the randomization process is repeated until no statistically significant differences exist. Randomization must be conducted independently for each gender because of body weight differences between males and females.

Animal Husbandry

Proper care and maintenance of animals in a repeated-dose toxicity study is essential not only for ethical reasons but also to minimize mistakenly attributing adverse findings due to poor husbandry to the test material. The Animal Welfare Act (AWA), enforced by the Animal and Plant and Health Inspection Service of the U.S. Department of Agriculture (USDA), mandates standards for acceptable handling, care, treatment, and transportation of many species, including most laboratory species except rodents.[46] In its *Guide for the Care and Use of Laboratory Animals*, the Institute of Laboratory Resources (ILAR) of the National Research Council has published guidelines that are widely accepted as standards for laboratory animal husbandry.[44] From their arrival at the laboratory, animals must be maintained in an appropriately controlled environment. They must be provided an adequate quantity and quality of feed and water and be housed in clean cages of appropriate design. Although there may be occasional exceptions based on specific study requirements, animals should be acclimated to the study room conditions for at least 1 week before study initiation.

Environmental Factors

Temperature and humidity should be controlled within limits specified in the documents referenced earlier. Table 24.8 is taken from the ILAR document and contains the recommended temperature ranges for various laboratory animal species.[44] Low humidity can result in drying of the mucous membranes and eyes of laboratory animals. High humidity can result in the growth of bacterial and fungal populations that result in respiratory distress and dermal involvement such as ringworm. In addition, urine and excreta may not dry as readily, thereby increasing room odor. Relative humidity of 30%–70% is considered acceptable by ILAR for most laboratory species.[44]

TABLE 24.8
ILAR-Recommended Dry-Bulb Temperatures for Common Laboratory Species

	Dry-Bulb Temperature	
	°C	°F
Mouse, rat, hamster, gerbil, guinea pig	20–26	68–79
Rabbit	16–22	61–72
Cat, dog, nonhuman primate	18–29	64–84
Farm animals and poultry	16–27	61–81

Adequate ventilation is a key factor in maintaining good animal health during a toxicity study. Establishing a positive room air pressure reduces possible exposure of animals to test materials being used in other animal rooms. When more air is forced into a room than can be completely cleared by exhaust systems, air flows through the cracks, around the door, and the partial pressure of air in the room becomes positive with respect to the hallway or area outside the room. Ventilation should be homogeneous throughout the room; this generally is controlled by adjustable diffusers, and the ventilation of all rooms in a facility must be *balanced* periodically to provide the same relative air flow and positive pressure with regard to hallways. In general, 10–15 fresh air changes per hour is considered acceptable but this range is highly dependent on a number of factors, for example, the number of animals/cages in the room.

Common lighting schedules used are 12 h of continuous light and 12 h of darkness for rats, mice, dogs, and monkeys and 14 h of light and 10 h of dark for hamsters. This schedule allows the animals to become acclimated to a consistent light cycle. This stimulates a constant pattern of secretion of thyroid hormones, ACTH, and growth hormone. Regulated lighting cycles are necessary in reproduction studies because rodents enter continuous estrus under conditions of constant light phases without darkness.[47] Because high-intensity fluorescent light can cause blindness in albino rodents, current practice is to limit their exposure to high-intensity light to times when observations are collected by providing dual-intensity (high-low) lighting systems.

Animal Caging

Historically, in the United States, rodents were commonly housed one per cage during subchronic and chronic toxicity studies. In other countries, rodents are frequently housed in groups during these studies because it is believed that multiple housing increases survival and decreases background pathology. Although single housing of rodents is still preferred in some situations, many companies in the United States have adopted group housing procedures similar to other countries based on animal welfare considerations and recommendations in "The Guide." There are benefits and drawbacks to each housing option, which should be kept in mind when designing a study. On the positive side, multiple housing of rodents allows for greater social interaction. Animals that are group housed tend to gain less weight and may live longer than their individually housed counterparts. The negative aspects of multiple caging include problems associated with unique identification and trauma to the animals from fighting. Multiply housed rodents are more susceptible to transmitted disease and other health concerns. Furthermore, a multiply caged rodent that dies on study may sustain tissue destruction from cannibalism. It is also not possible to determine individual feed consumption when multiple animals are housed in a single cage, resulting in the inability to correlate body weight with individual feed intake. Additionally, if the test material is fed as part of the diet, it is not possible to calculate actual doses for individual

rodents in the absence of individual feed consumption data. Although some of the same problems exist for nonrodents, multiple housing of some species (e.g., nonhuman primates and dogs) on a regular or continuous basis during the study is a globally accepted practice to permit the social interaction and exercise considered necessary for these species.

Rodents generally are housed in metal (stainless or galvanized steel) or plastic (polyethylene, polypropylene, or polycarbonate) cages. Metal caging or floor pens are used for dogs. Minimum cage sizes for all species are stipulated in the ILAR publication[44] and, for nonrodents, in the AWA.[46] Compliance is monitored by federal and state health agencies. Since minimum sizes for cages are stipulated, only caging type remains to be decided. The two major types of caging are solid floor cages or pens and suspended-floor cages; both have advantages and disadvantages.

Solid floor caging requires bedding to be added to the cage to absorb and contain waste materials and may introduce dust. Sawdust and chips of some conifers induce hepatic cytochrome P450 monooxygenase activity, which may affect the outcome of the study and are, therefore, not recommended. In addition, solid floor caging allows animals to have access to their waste. Solid bottom shoebox-style cages used for rodents may restrict airflow and clear the atmosphere of potentially harmful gasses at a slower rate than suspended wire cages. Finally, special consideration should be given to the design of shoebox cages equipped with automatic watering systems. If designed improperly (and sometimes regardless of the design of the cages), all animals housed in a cage may be lost if the watering system malfunctions and fills the cage with water.

Cages with suspended wire floors also have disadvantages. Traumatic foot and leg injuries can occur, particularly with smaller animals. Plantar foot pad lesions are common in long-term studies of rats housed in wire-bottom cages. As a result, "The Guide" now recommends "Flooring should be solid, perforated, or slatted with a slip-resistant surface. In the case of perforated or slatted floors, the holes and slats should have smooth edges. Their size and spacing need to be commensurate with the size of the housed animal to minimize injury and the development of foot lesions. If wire-mesh flooring is used, a solid resting area may be beneficial…" Finally, wire-mesh cages also expose the animals to room drafts.

Most gradients in light, temperature, or airborne products in an animal room will occur vertically. Animals within groups should be distributed in cage racks so that members of each study group are present equally at all vertical caging levels. This practice, and the practice of periodically changing the relative position of each cage rack within the room, avoids confounding treatment group with cage position. Documentation of environmental conditions and of cage/rack rotation is essential.

Cleaning of cages at frequent intervals is also essential. Generally, sanitization of cages every 1–2 weeks depending on cage type and husbandry procedures is sufficient. Poor husbandry practices may result in skin lesions, alopecia, or the appearance of signs and behavior that may be interpreted as possible effects of the test article.

Diets

The influence of diet and nutrition on the toxicity of test materials is another important aspect of the design of toxicity studies. The diet fed to the animals during toxicology studies can influence the results. Therefore, the decision made by the toxicologist and/or animal husbandry/veterinary staff at a test facility concerning what diet to feed the animals may have a profound impact upon the outcome of the studies. The diet fed during a study should be designed to meet the nutritional needs of the test species. Although diets can be custom-made, they are generally obtained from commercial suppliers. The supplier should be reputable and capable of supplying information concerning basic diet composition and nutritional information. Although not feasible for a long-term study (e.g., 12 months), the same lot of diet should be used for the entire study whenever possible. Diets should be used before their expiration dates and should be stored under appropriate conditions to maintain their nutritional value, prevent insect and rodent infestations, and ensure they are not contaminated by environmental chemicals.

Commercial diets are available in either ground *powder* or pelleted form. When the test material is to be incorporated into the feed, a powdered diet is generally used. Use of powdered diet also facilitates the determination of feed consumption. Pelleted diets are most frequently used when test material administration is by routes other than dietary. A powdered diet can be pelleted after a test material has been added, which reduces the dust from the diets. Pelleted diets also decrease the potential exposure of animal room personnel to the test material. However, the heat and pressure involved during the pelleting process may cause degradation of test materials sensitive to these conditions.

Diets used in toxicity studies are of two basic compositions. Currently, diets made from natural ingredients are most commonly used. However, semipurified diets made from refined macronutrients, such as protein and carbohydrate, and micronutrients, such as vitamin and mineral mixes, are sometimes used. Each of these diets has advantages and disadvantages that must be carefully considered by the toxicologist.

Natural diets are formulated from unrefined plant and animal products to meet the nutritional requirements of a particular species. In closed-formula diets, the manufacturer does not provide the exact proportions of the constituents. The diets are formulated based upon nutritional specifications without emphasis on the consistency of specific ingredients between lots. Plant materials contain a number of *nonnutritive* components that can affect various physiological and biochemical functions, including detoxification and metabolic activation, in the test animal. These components may vary with plant species, strain, growing conditions, and site. Therefore, individual lots of closed-formula diets may differ in these constituents. Open-formula diets are formulated with constant quantities of specified ingredients. An example of an open-formula diet is the NIH-07 rodent diet, which has been relatively well characterized.[48] Open-formula diets have advantages for long-term studies because of their consistent

formulation and may be preferred by research institutions over closed-formula diets.[49] An additional consideration concerning both open- and closed-formula natural diets is their potential to contain contaminants, such as pesticides, heavy metals, and mycotoxins. To overcome this problem, some manufacturers provide diets that have been assayed for certain potential contaminants to ensure that they are below stated specifications. It is highly recommended that these *certified* diets be used in toxicity studies. A disadvantage of natural commercial diets is that their nutritional composition cannot be readily altered. It is possible to supplement these diets but not possible to remove constituents. An important advantage of natural diets is their long history of use and the resulting large quantities of historical control data.

As noted earlier, semipurified diets are made from refined macroconstituents, such as protein, carbohydrate, and fiber, and micronutrient mixes containing individual minerals and vitamins and a defined fat source, such as corn oil. Their constituents can be varied to design diets for specific nutritional purposes and allow for the inclusion of test materials that may provide nutrient activity or result in nutritional deficits. Nutrient composition can be reproduced exactly from lot to lot of semipurified diet. As opposed to natural ingredient diets, semipurified diets do not contain pesticides, mycotoxins, and other constituents that may alter the animal's response to the test material. However, a major problem with semipurified diets is a lack of historical data from their use in long-term studies. A large number of different dietary compositions are currently in use and data obtained from one semipurified diet may not extrapolate to another semipurified diet. Even with commonly used semipurified diets, such as the AIN-76A[50] and the AIN-93[51] diets, there are insufficient data to determine its impact on long-term toxicity studies, especially carcinogenicity studies.[52] Although these diets can be utilized in subchronic toxicity studies, the data obtained may not be as useful as that from studies with natural diets, especially when these data are used to design longer-term studies with natural diets. While it may be necessary to use semipurified diets with specific test materials, care must be taken if these studies are to be used in a safety assessment.

Drinking Water

Drinking water free of contaminants that could interfere with the objectives of the study should be available to the animals during repeated-dose toxicity studies. Water is frequently provided to the rodent and nonrodent animals through automatic watering systems. In these systems, a common water supply is piped to the animal cages and each cage contains a valve that allows the animal ad libitum access to water. Water bottles are another more labor-intensive method of providing water to rodents and some nonrodents. Each bottle is fitted with a stopper containing a sipper tube through which the animal can drink and the bottle is attached to the cage. A third method of water delivery, generally only used with nonrodents, is to provide the animals with water in a drinking bowl. Any of these methods is acceptable as long as procedures are in place to ensure that the animals are provided an adequate supply of potable water.

In-Life Evaluations

Physical Examination

Several parameters are routinely evaluated during the treatment and recovery phases of subchronic toxicity studies. Each animal should be observed twice daily at least 4 h apart (a.m. and p.m.) for overt signs of toxicity, moribundity, and mortality. During these a.m. and p.m. observations, the cage of each animal should be opened to permit unobstructed observation. In addition, each animal should be removed from its cage for a complete physical examination at least once per week. These examinations should include detailed observations to allow for the approximation of the time of onset of any changes as well as the severity and persistence of changes involving the skin, fur, eyes, mucous membranes, respiratory function, circulatory system, autonomic and central nervous system, somatomotor function, and general behavior. A study-specific or SOP-specific glossary of clinical terms and descriptive criteria for each finding is recommended. The terms should be simple and descriptive, using a minimum of medical or diagnostic terminology.

Body Weight Measurement

It is recommended that body weight be determined at least once per week, even though biweekly or monthly measurement after the first 3 months of a chronic toxicity study is acceptable to most regulatory agencies. Weekly measurement is recommended because body weight is one of the most sensitive indicators of the condition of an animal if it is monitored frequently and carefully. Rapid and/or marked body weight loss is usually a harbinger of ill health or death. Rapid body weight loss can be due to decreased feed and/or water consumption, disease, and/or specific toxic effects.

Feed Consumption

In rodents, feed consumption generally is measured once per week during subchronic studies and weekly the first 3 months of chronic studies. After the third month of a rodent chronic study, feed consumption may be measured less frequently, that is, biweekly or monthly. For nonrodents, in which the quantity of feed required usually does not allow weekly feeding, feed consumption is evaluated for shorter intervals, often once or twice per day. Accurate measurement of feed consumption is essential for studies in which the test material is administered in the diet. As discussed earlier in this chapter, feed consumption and the dietary concentration of the test material are used to calculate the dose of test material consumed by the animals in such studies. Some species, especially the mouse and the nonhuman primate, frequently soil or waste feed. This makes accurate measurement of consumption difficult. In these species, feed consumption measurement can be attempted using either a feed container designed to minimize wastage or by attempting to estimate feed wastage. Limitations of such data should be considered in evaluating test material consumption and the significance of any apparent differences between feed consumption in

test material–treated and control animals. Feed consumption measurement is another means of monitoring animal well-being. Animals that are ill or suffering adverse effects from exposure to the test material frequently may exhibit significantly decreased feed intake.

Ophthalmologic Examination

Ophthalmologic examination of all test animals should be conducted before the initiation of dose administration and at the completion of the dose administration period. Examination may also be performed at the end of a treatment-free recovery period (if included in the study design) based on findings at the end of dosing. Slit lamp examination and use of an indirect ophthalmoscope are two common methods of ophthalmologic examination during toxicity testing. These evaluations should be conducted by a veterinary ophthalmologist or other personnel experienced in the observation of the species used for the study.

Clinical Pathology

Clinical pathology parameters such as hematology, clinical chemistry, and urinalysis are important indicators of general health and toxicity and are assessed at the termination of a subchronic or chronic study. In addition, pretest and interim (typically at 4 weeks in subchronic studies and at 13 weeks in chronic studies) clinical pathology may be conducted to allow the evaluation of progression of any effects noted during the study. In rodents, clinical pathology determinations are usually conducted for 10 animals of each gender in each group. For nonrodents, clinical pathology should be done for all animals.

Sample Collection

Proper sample collection and handling are critical to completion of a meaningful clinical pathology evaluation. Whenever possible, the method of sample collection should be the same throughout the study and should be one that distributes variance, such as run-to-run variation in an enzyme assay, equally across groups. Samples generally are collected according to either a totally random design or a stratified random design. A stratified random design ensures that approximately the same numbers of animals of each gender and from each group are sampled within any block of time or during any set of assays.

Repeated blood sampling of rodents can be accomplished by serial collection from the same animals by nonterminal procedures (such as puncture of the jugular vein) or by collection from the abdominal aorta or vena cava at the termination of subgroups of animals. Because of practical restraints on the frequency and volume of blood collection in rodents, pretest studies often are not performed. Repeated collection of adequate volumes of blood is usually not a problem for nonrodents, and pretest clinical pathology is often included in studies using these animals.

The effect of repeated blood sampling on the animals and on the sample volume that can be reliably obtained at each sampling interval should be considered. Sample volumes should be sufficient both to conduct the assays indicated in the protocol and, if possible, to provide a reserve sample for any necessary repeat test. However, significant reduction of total blood volume (more than 10%) by blood collection should be avoided and a sufficient amount of *recovery* time should be allowed between sampling intervals. Publications regarding maximum blood sampling volumes and recovery periods are available and should be consulted when designing a toxicity study.[40]

Plasma or serum to be used for clinical evaluation should be clear and straw-colored. Red or pink plasma suggests that some hemolysis has occurred either as a result of pathology or, more commonly, as an artifact of the sample collection/preparation procedures. Severe artifactual hemolysis may alter the results for some of the clinical parameters to be evaluated. Slight hemolysis, commonly observed in serum and plasma collected from rodents by jugular venipuncture, generally is acceptable for clinical pathology studies as long as historical laboratory ranges have been established for blood collected by this method. If unusual or unexpected results are obtained, aliquots of serum or plasma can be *spiked* with ascending amounts of test material to determine if it interferes with the assay.

Clinical Chemistry, Hematology, and Urinalysis

Clinical pathology should include the determination of a number of serum or plasma chemistry and hematology parameters. The parameters included in the clinical chemistry evaluation should assess electrolyte balance, protein and carbohydrate metabolism, and organ function. An acceptable list of clinical chemistry parameters is shown in Table 24.9. Additional parameters should be assessed, as appropriate, to address other anticipated effects of the test material, for example, serum cholinesterase levels in the case of carbamate or organophosphate insecticides. It goes without saying that assays designed for the assessment of clinical chemistry

TABLE 24.9
Clinical Chemistry Parameters Normally Obtained in Repeated-Dose Studies[a,b]

- Glucose*
- Urea nitrogen*
- Creatinine*
- Total protein*
- Albumin
- Globulin
- Albumin/globulin ratio
- Inorganic phosphorus
- Calcium
- Sodium*
- Potassium*
- Chloride*
- Bilirubin (total)
- Cholesterol
- Triglycerides
- Alkaline phosphatase*
- Aspartate aminotransferase
- Alanine aminotransferase*
- Gamma glutamyl transferase*
- Ornithine carbamyl transferase*

[a] Based, in part, upon the recommendations of the U.S. FDA [23].

[b] This list does not include all clinical chemistry parameters that could be obtained. Additional parameters could be added depending upon the test material. When the blood volume obtained for analysis is small, the FDA recommends priority be given to those assays marked with an asterisk (*).

TABLE 24.10
Hematology and Urinalysis Parameters Generally Determined in a Repeated-Dose Study

Hematology	Urinalysis
Hematocrit	Appearance
Hemoglobin	Urine volume
Erythrocyte count	Specific gravity
Mean corpuscular volume	pH
Mean corpuscular hemoglobin	Glucose
Mean corpuscular hemoglobin concentration	Protein
Total leukocyte count	Microscopic evaluation of urinary sediment
Differential leukocyte count	
Reticulocyte count	
Platelet count	
Prothrombin time	

in humans must be validated for use with the species used in the toxicology studies. Typical hematologic parameters assessed during repeated-dose testing are shown in Table 24.10. The reader is referred to the chapter concerning clinical pathology in this text for a more detailed discussion of these clinical chemistry and hematology determinations. In addition, two excellent veterinary texts are available for further reference.[53,54]

Urinalysis is often included in the clinical pathology evaluation and may be important, especially for test materials that are nephrotoxins. Urinalysis parameters typically evaluated are listed in Table 24.10. However, urinalysis is frequently of limited value because collection of satisfactory urine samples is fraught with technical difficulties. Urine generally is collected in containers or tubes from troughs or trays placed below the cages in which the animals are housed and, therefore, steps must be taken to minimize fecal contamination. Because urine is frequently collected during an extended period, for example, overnight, bacterial growth in the sample is a concern. Collection of the sample on ice can reduce bacterial growth but presents technical challenges as well. Care should be taken that water be either freely available to the animals throughout the urine collection period or withdrawn at the appropriate time before collection. Care also must be taken to ensure that the sample is not inadvertently contaminated by feed or drinking water spilled by the animal. Because of these difficulties, the utility of urinalysis should be discussed with an experienced veterinary clinical pathologist prior to its inclusion in the design of a repeated-dose toxicity study. If urinalysis is conducted, its limitations must be kept in mind when the data are reviewed.

Postmortem Evaluations

One of the more definitive assessments of toxicological effects conducted during a repeated-dose study is the macroscopic and microscopic examination of tissues and organs from treated and control animals. In typical subchronic and chronic studies, samples of approximately 50 tissues and organs are collected during the necropsy of each animal. Table 24.11 presents a list of tissues that are commonly collected for potential histopathologic examination.

TABLE 24.11
Tissues Collected for Histopathology in Repeated-Dose Studies

Adrenals	Mammary gland (females)
Aorta	
Bone marrow smear	Nose
Brain	Ovaries
Cecum	Pancreas
Colon	Pharynx
Duodenum	Pituitary
Epididymides	Prostate
Esophagus	Rectum
Eyes	Salivary gland (submandibular)
Femur and bone marrow	Sciatic nerve
Gall bladder (when present)	Seminal vesicles
Heart	Skin
Ileum	Spinal cord (cervical, thoracic, lumbar)
Jejunum	Spleen
Kidneys	Sternum and bone marrow
Lacrimal gland	Stomach
Larynx	Testes
Lesions	Thymus
Liver	Thyroid with parathyroid
Lungs	Trachea
Lymph nodes (mandibular and mesenteric)	Urinary bladder
	Uterus

Necropsy

Necropsy of an animal is conducted when it dies during the study, when it is euthanized during the study for humane reasons (e.g., in cases of moribundity), or when it is euthanized at a scheduled interval (interim sacrifice or termination of the study). For animals that are euthanized, exsanguination should be included in the termination procedure to facilitate the subsequent fixation of the tissues. Necropsy should be completed as quickly as possible after the death of an animal to avoid autolysis that can interfere with the subsequent microscopic examination of tissues. Autolysis is an especially important consideration for animals that die during the study because their death may not be discovered for a significant period of time. Animals found to be moribund (i.e., about to die) during the study should be euthanized for humane reasons and to avoid tissue autolysis.

During necropsy, tissues and organs are systematically removed and macroscopically visible abnormalities are noted. These abnormalities include changes in color, shape, size, or consistency of a tissue. The documentation of an abnormality in the necropsy records should include its location and a clear description of the change, using nondiagnostic terminology. Completeness of the examination during

necropsy and the quality of the description of abnormalities are critical to the determination of pathologic effects. An abnormality in a tissue can only be prepared for microscopic examination if it was collected and accurately described during necropsy. Because of the central role that the necropsy plays in detecting effects in a repeated-dose toxicity study, it is extremely important that necropsy technicians are highly trained and experienced in the necessary techniques.

After collection, tissue samples are usually preserved by immersion in an appropriate fixative, commonly 10% neutral buffered formalin. In some cases, particularly for organs such as testes or eyes, special fixatives should be used.[55] In order to ensure adequate fixation, the volume of fixative should be at least 10 times the volume of tissues. Certain organs, for example, the lung and urinary bladder, are frequently perfused with fixative prior to immersion to improve fixation and the microscopic appearance of the tissue when sectioned. During the collection of large numbers of tissues from many animals, it is possible to inadvertently miss a tissue. Therefore, it is highly advisable to inventory and document the samples as they are placed into the fixative containers. This inventory will be invaluable during subsequent preparation of the tissues for microscopic examination and in reconstructing the study during poststudy auditing of the data. In addition, it must be ensured that the identity of each tissue is clearly maintained while in fixative. This is not a problem for tissues that are large or have distinctive morphology. In order to ensure subsequent identification of extremely small tissues and those with indistinct morphology, they are frequently placed in labeled plastic cassettes or cloth bags prior to being placed in the fixative container.

Organ Weights

Collection of terminal body weight and organ weights for all animals during necropsy is normal practice in repeated-dose toxicity studies. Minimally, weights should be recorded for the brain, liver, kidneys, testes, and adrenal glands. Frequently, other organs such as the thyroid/parathyroid, ovaries, spleen, thymus, uterus, epididymis, heart, or lungs are also weighed. Consideration should be given to the residual blood that remains in organs such as the spleen, heart, and lungs. Residual blood may be variable between animals due to the method of euthanasia and blood collection. Organs should be weighed as soon as possible after removal from the animal. They should be trimmed free of fat and connective tissue prior to weighing and placed into fixative immediately thereafter.

It is common practice to normalize organ weights by expressing them relative to body weight and brain weight. Relative organ weights are used to eliminate the influence of normal variation in animal growth on the interpretation of organ weight data. However, normalized organ weight data should be reviewed with the knowledge that they have limitations. Expressing organ weights relative to body weight can yield apparent, but artificial, compound-related effects on organ weights in studies where the test material affects body weight gain. Organ weights normalized to brain weight help overcome this problem because test materials that alter body weight generally do not alter brain weight. The best practice is to consider all three types of data, that is, actual organ weight and organ weight relative to body and brain weight. Histopathologic data are often used to help assess the significance of apparent differences between organ weights of test material–treated and control animals. Organ weight changes without correlative microscopic findings are given less credence than organ weight changes in tissues that also have microscopic abnormalities.

Microscopic Pathology

Microscopic examination of the tissues and organs of treated and control animals is one of the most time-consuming laboratory functions in toxicity studies. In nonrodent studies, sections of all protocol-specified tissues and organs from all animals should be prepared for microscopic examination. Generally, in rodent studies, only tissues and organs from the control and high-dose group animals and animals that were euthanized or died during the study are examined microscopically. For the other treatment groups, only a few major organs (e.g., liver and kidney, and any other organs in which macroscopic abnormalities were noted at necropsy or in which test material–related effects are detected in high-dose animals) are examined. Although initial histopathologic examination of control and high-dose tissues followed by examination of other doses is typical in rodent studies, simultaneous histopathologic examination of all tissues from all animals is not uncommon. This practice yields the most expeditious completion of the histopathologic evaluation phase of a study because sequential examinations are not required. Simultaneous examination also reduces the intergroup variability in diagnoses that might occur when tissues from intermediate groups are examined considerably after completion of the evaluation of the control and high-dose groups. Such variability can lead to incorrect conclusions concerning compound relationship of lesions noted in the intermediate-dose groups. The U.S. FDA has proposed that tissues from the high-dose and control animals initially be subjected to histopathologic examination with subsequent evaluation of lower-dose-group tissues based on findings in the high-dose animals.[56]

Routinely, tissues are prepared for light microscopic examination by embedding in paraffin, sectioning at 5–7 μm, and staining with hematoxylin and eosin (H&E). Special stains, such as stains for the presence of fat (e.g., Oil Red O) or connective tissue (trichrome stain) may be used for some tissues. The use of a protein-specific stain (Mallory–Heidenhain) to confirm suspected alpha-2-microglobulin nephropathy in male rats is illustrated in Figure 24.6. If desired, representative samples of selected tissues may be frozen at necropsy and stored for biochemical or immunohistochemical analyses. Tissues may be specially prepared for electron microscopy by fixation in paraformaldehyde or Karnovsky's fixative.[57] In the histology laboratory, it is important that tissues be prepared according to standardized procedures especially with respect to the type of section (i.e., cross, longitudinal), location, and orientation on the microscope slide. The histology technician must review the observations recorded during

necropsy of the animals to ensure that all grossly observed lesions are properly sectioned and mounted on the slide for subsequent microscopic examination. Whenever possible, samples of lesions prepared for examination should include the lesion and portions of surrounding *normal* tissue.

Histopathologic examination of the tissues requires specialized training and is performed by a pathologist trained and experienced in toxicological pathology. This training and experience provides the pathologist with the knowledge of the normal features and naturally occurring lesions that can be observed microscopically in tissues from laboratory animals. However, the pathologist's responsibility is more than evaluation of the tissues and accounting for all the lesions reported at necropsy. The pathologist should be an integral part of the protocol design team, providing input into many factors, for example, selection of the species/strain to be used and clinical pathology parameters to be evaluated. The pathologist should also provide guidance concerning the list of tissues to be collected in order to ensure that they are processed, stained, and evaluated in a manner that satisfies the study objective.

It is critical that the pathologist review the data generated during the in-life and necropsy phases of the study before proceeding with the histopathologic evaluation. Results of clinical observations, clinical chemistry and hematology determinations, organ weights, and necropsy examinations can lead the pathologist to focus on particular organs as potential targets for toxicity during the microscopic examination. For example, increased liver weight should lead to a more careful examination for hepatocellular hyperplasia or hypertrophy, while elevated serum creatinine along with a necropsy description of the surface of the kidneys as *rough* should result in a more thorough examination for nephropathy.

Some have suggested that knowledge of in-life and necropsy findings will bias the pathologist, causing a more stringent examination of the potentially affected tissue. Similarly, some are concerned that knowledge of the dose level administered to the animal during the study will bias the pathologist, resulting in a more thorough examination of the tissues from animals that received the test material. The second situation in particular could result in a higher incidence and/or severity of microscopic findings in treated animals compared with controls, a higher incidence that is simply an artifact of the thoroughness of the microscopic examination. One way to prevent potential bias is to keep the pathologist uninformed of other study findings and of the identity of the animal until histopathologic examination of the tissues has been completed. This so-called blinded reading does prevent bias but may also prevent the pathologist from identifying certain subtle, dose-related changes. Therefore, *blinded reading* is not recommended for routine histopathologic evaluations and should only be conducted in special situations.

Pathologic changes in cellular or subcellular structure can occur either spontaneously, such as with aging, or as a result of exposure to a chemical. Deciding which changes are toxicologically relevant and what severity should be assigned to a change during histopathologic examination is quite subjective. Because of this, it is possible that different pathologists looking at the same tissues will produce different diagnoses. It is even possible that, during histopathologic evaluation of a large number of tissues that extends over a number of months, the criteria for diagnosis of the same finding by a single pathologist will change somewhat. The variability that results from the subjective nature of histopathologic evaluation is unavoidable. In order to minimize its effect on the results of toxicity studies, several procedures can be useful. First, during each *reading period*, the pathologist should examine tissues from a small subset of the study animals. Each subset should contain approximately equal numbers from each control and treated group to be examined. Second, if a potential target organ is identified over an extended period of time, the pathologist should reexamine that organ from all animals during a compressed *reading period* of a few days or less in order to assess to what extent, if any, *diagnostic drift* occurred over time. Third, informal peer consultation concerning unusual or subtle tissue changes observed during the examination of the tissues can be conducted to arrive at a consensus diagnosis. Additionally, a formal peer review process involving (1) reexamination of target organs, (2) reexamination of a representative percentage of other tissues from the study, and (3) review of interpretation of the pathology findings can be conducted by a second pathologist in order to ensure consistency in diagnosis and grading of tissue changes and accuracy of the pathology conclusions.[58]

The objective of the histopathologic evaluation is the same as the objective of all other determinations during a repeated-dose toxicity study, that is, to detect adverse effects that could be relevant to humans or any other target species exposed to the test compound. Because of certain idiosyncrasies, some animals and strains are not useful for this purpose. In some cases, the animal exhibits a high spontaneous rate of pathology in a particular organ that prevents detection of any compound-induced increase in the background rate. For example, severe testicular pathology occurs spontaneously in a very high percentage of old male Fischer 344 rats (see Figure 24.5). Therefore, this strain of rat is generally not useful for the detection of testicular effects. In other cases, a pathologic change may occur in the laboratory animal in response to compound exposure, but that pathology would not be expected to occur in the target species. An example of this is light hydrocarbon nephropathy that occurs only in male rats. Many hydrocarbons produce this nephropathy, for example, D-limonene and unleaded gasoline. The pathology is caused by accumulation of a male rat specific protein, alpha-2-microglobulin, in the renal tubule following exposure to these chemicals. This nephropathy is characterized by hyaline droplets in the cytoplasm (Figure 24.6), granular casts in the lumen (Figure 24.7), and cellular regeneration in the tubules. Because humans do not produce alpha-2-microglobulin, this gender- and species-specific pathologic finding has no relevance to human hazard assessment, and the male rat is not a suitable model for human renal effects related to light hydrocarbon exposure. It should be noted, however, that for both examples cited, the test animal is perfectly acceptable for use as a human surrogate in toxicity testing as long as the limitations imposed by their idiosyncrasies are taken into account.

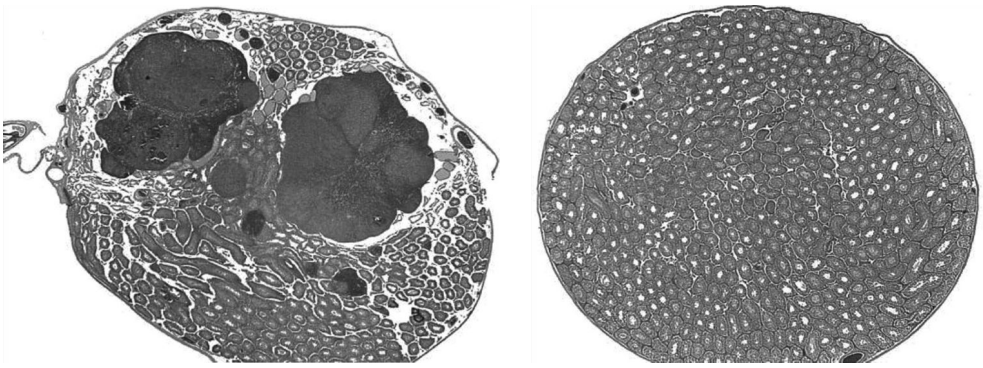

FIGURE 24.5 Photomicrographs of hematoxylin-and-eosin-stained testes from Fischer 344 rats (2.5× magnification). The testis on the left exhibits an interstitial cell tumor. The testis on the right is without pathologic changes.

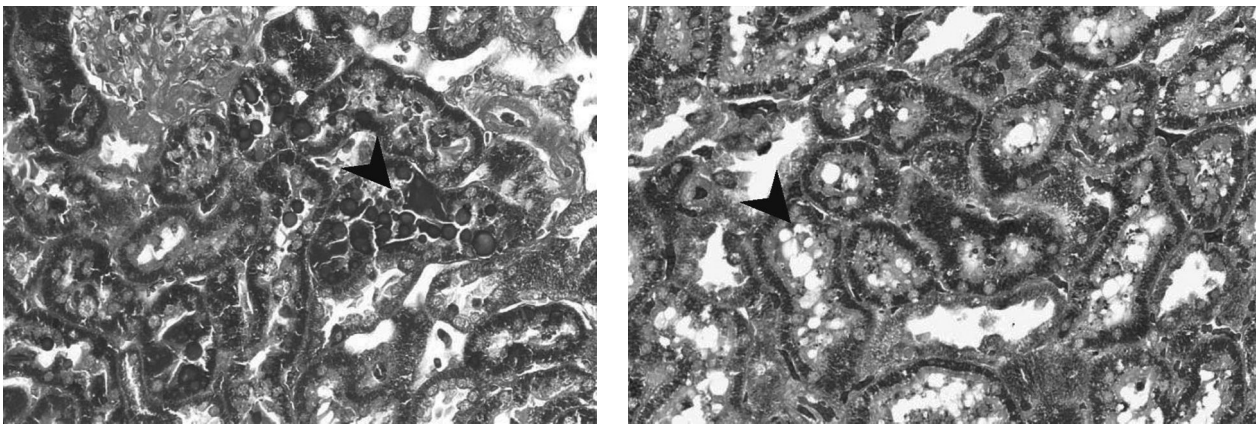

FIGURE 24.6 Photomicrographs of kidneys from Fischer 344 male rats stained for protein using Mallory–Heidenhain stain (100× magnification). The kidney tubules on the left are stained heavily and contain many hyaline droplets (arrow). The kidney tubules on the right exhibit normal levels of protein staining (arrow).

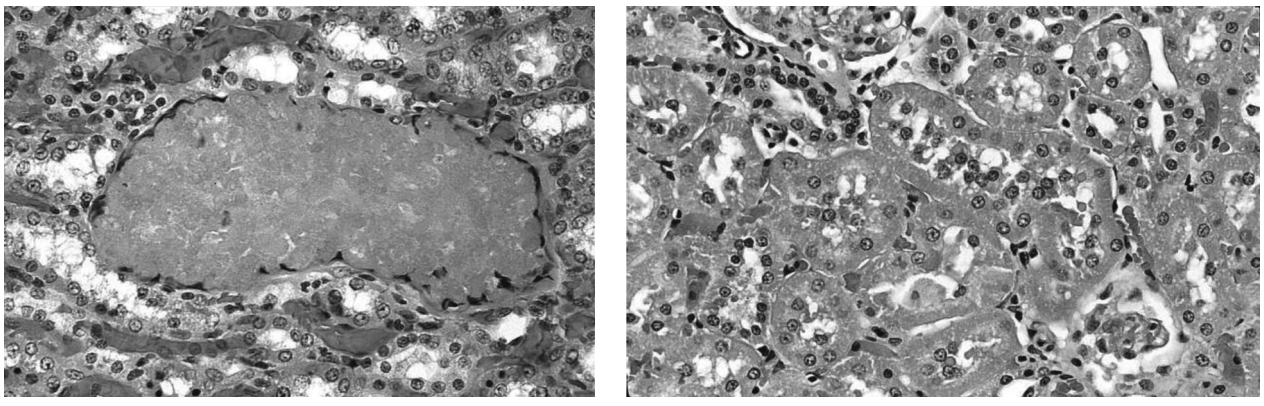

FIGURE 24.7 Photomicrographs of hematoxylin-and-eosin-stained kidneys from Fischer 344 male rats (100× magnification). The lumen of one tubule in the kidney on the left is obstructed by a large accumulation of granular casts. The kidney on the right is without pathologic changes.

Even though the idiosyncratic situations discussed earlier do occur occasionally, the pathology that occurs in most laboratory animals and most tissues is considered relevant to the assessment of hazard in humans. The histopathologic examination of tissues in a subchronic or chronic toxicity study can yield a vast array of diagnoses. A detailed discussion of possible chemical-related pathologic findings is beyond the scope of this chapter. For detailed descriptions of methods for and diagnosis of veterinary toxicological pathology, the reader is referred to a review by Hardisty[58] and two comprehensive texts on the subject.[59,60]

Additional Endpoints for Repeated-Dose Toxicology Studies

Evaluation of special endpoints can be added to repeated-dose toxicology studies to maximize the utilization of animal resources, minimize the time and cost of a hazard assessment, and obtain additional data. Care should be used in selecting these endpoints to ensure that valid methodology is used and that the data will be accepted by regulatory agencies. Guidelines for safety assessment of food ingredients suggest data concerning the immunotoxic and neurotoxic potential of the test material be generated during subchronic toxicity studies.[56] To ensure the methodology and data presentation is acceptable to the regulatory agencies, meetings should be held with the appropriate agency during design of the study.

It is possible, through the addition of special endpoints, to make a subchronic or chronic toxicity study so complicated that the main objectives are jeopardized. All the ramifications of addition of special endpoints to a study design, including practical considerations such as daily workload, should be considered to ensure that basic study endpoints are not compromised. Rather than overwhelming the capabilities of the testing laboratory, conducting a separate study designed to evaluate the special endpoints may be preferable. This is not to say that special evaluations should never be added to subchronic or chronic studies. With appropriate consideration of the possible complications, they can be and often are successfully added to standard study designs.

If a question still remains whether additional endpoints should be added to short-term repeated-dose studies or to longer-term studies, the following should be considered. If these endpoints were added to short-term studies, the data would be available to aid in the design of longer-term studies. However, if the potential change in the parameter to be evaluated occurs only after longer exposure periods, a change might not be observed in short-term studies. The most conservative approach is to add the endpoints to each study type. The following paragraphs provide examples of nonstandard toxicological endpoints that may be added to classical repeated-dose toxicity study designs.

Genetic Toxicology

Certain in vivo and in vivo/in vitro genetic toxicology data may be obtained during or at the termination of a repeated-dose toxicity study. Addition of these endpoints to a study could decrease the number of animals used in a hazard assessment and shorten its duration. In vivo genetic toxicology studies increase the value of a hazard assessment. They use the route of administration by which humans are/will be exposed to the test material and all processes of absorption, distribution, metabolism, excretion, and DNA repair are intact. Therefore, these in vivo studies provide important information that cannot be obtained from in vitro studies using cellular systems.

A number of in vivo genetic toxicology assays are currently in use, some of which are suitable for incorporation into repeated-dose toxicity assays. For example, the authors have incorporated the bone marrow micronucleus assay into a classic subchronic study design. During many repeated-dose toxicity studies, bone marrow smears are made (see Table 24.11). These bone marrow smears are made essentially in the same manner as those used for the in vivo micronucleus assay.[61] The slides are stained with acridine orange and the polychromatic erythrocytes analyzed for micronuclei. The use of bone marrow slides from the repeated-dose study has several advantages: (1) it incurs no additional time and cost for collecting the samples, (2) allows the assay to be conducted on animals exposed to the test material for long periods of time, (3) eliminates the need for resources to conduct an independent study, and (4) does not interfere with the histopathologic assessment of the tissues.

It may be possible to use bone marrow slides from repeated-dose toxicity studies for the bone marrow chromosomal aberration assay.[62] This is another in vivo genetic toxicology assay that could provide additional data without conducting an independent study. Another such genetic toxicology assay is the in vivo/in vitro unscheduled DNA synthesis assay.[63] In this assay, freshly isolated hepatocytes are used to determine unscheduled DNA synthesis. Although this assay is not compatible with histopathologic use of the liver, as few as 2–3 extra animals per group are all that is required. One problem associated with incorporation of additional endpoints, such as genetic toxicology, into a repeated-dose study design is that the laboratory conducting the study must have valid assay methodology. This is not always the case.

Recently, regulatory agencies have approved the evaluation of micronuclei in rat and mouse blood samples.[64] Although not common practice at this point, the ability to assess genotoxic potential in vivo using blood samples may become more prevalent as the pressure to reduce animal use and refine experimental techniques intensifies.

Not all in vivo genetic toxicology assays are completely suitable for incorporation into repeated-dose studies. For instance, the in vivo sister chromatid exchange assay requires the administration of deoxybromouridine to the animals. This compound can compromise the classical endpoints used in toxicity studies, including histopathology. However, it is possible to incorporate extra animals to assess specific endpoints while not compromising the main study animals.

Neurotoxicity

It is possible to incorporate neurotoxicity screening into repeated-dose toxicity study designs. In fact, the FDA states that neurotoxicity screening should be incorporated into these study designs.[56] EPA has similar recommendations.[65,66]

Neurotoxicity screening is designed to determine if the test material has the potential to produce adverse effects on the nervous system. Screening is conducted to determine if additional, more sophisticated, neurotoxicity testing is required. The first indication of a requirement for neurotoxicity testing may come from the structure/activity assessments. However, the neurotoxicity database is not as extensive as those for certain other types of toxicity and may not provide useful insight into the need for neurotoxicity testing. Drugs

and pesticides that target the nervous system are a well-known exception. For instance, there is no question that a new organophosphate insecticide will require neurotoxicity testing. For most compounds, it will be necessary to develop data through empirical testing.

Most classical repeated-dose study designs contain elements that may provide some information on neurotoxicity potential. These include cage-side observations of the animals, physical examinations, and measurement of parameters, such as food consumption, that may relate to behavior modifications during the study. Additional information is obtained during histopathologic examination of the nervous system tissues collected at necropsy, such as the brain and spinal cord. The FDA believes that these procedures, as well as others, should be specifically included into the design of repeated-dose toxicity protocols.[56] Table 24.12 lists the design elements recommended by the FDA for a neurotoxicity screen. Specific behavioral and neurotoxicity tests exist to provide most of the requested data. The particular test designs should be chosen based upon their validity, history of use, lack of undue stress to the animal, and the experience of the laboratory with the specific test. Care should be taken to perform these procedures on all the test article groups and controls in the study. A concern is that some of these tests may stress the animals and produce changes in the traditional parameters measured during a toxicity study. If this were to happen, it is assumed that the control group would also demonstrate these changes. This may or may not be true. Therefore, a conservative approach would be the addition of extra animals to the study that would be subjected to the manipulative procedures for neurotoxicity screening and not be used in the traditional phases of the study. For a more complete discussion of the FDA recommendations, the reader is referred to the guidelines for Toxicological Principles for the Safety Assessment of Food Ingredients.[56]

TABLE 24.12
FDA Criteria for a Neurotoxicity Screen as a Component of Short-Term and Subchronic Studies

- Histopathologic examination of tissues representative of the nervous system, including the brain, spinal cord, and peripheral nervous system
- Quantitative observations and manipulative tests to detect neurological, behavioral, and physiological dysfunctions. These may include
  - Physical appearance
  - Body weight
  - Body posture
  - Incidence and severity of seizure, tremor, paralysis, or other signs of neurological disorder
  - Level of motor activity and alertness
  - Level of reactivity to handling or other stimuli
  - Motor coordination and strength
  - Gait
  - Sensorimotor response to primary sensory stimuli
  - Excessive lacrimation or salivation
  - Piloerection
  - Diarrhea
  - Polyuria
  - Ptosis
  - Abnormal consummatory behavior
  - Any other signs of abnormal behavior or nervous system toxicity

Immunotoxicity

Rapid advances have been made during the last 20–30 years with respect to the detection of immunotoxicity. The two major forms of immunotoxicity are immunosuppression and hyperactivity of the immune system. Immunosuppression results in a reduction in the animal's resistance to infection and potential increase in susceptibility to tumorigenesis by a suppression of critical immunological responses. Hyperactivity of the immune system can result in autoimmune diseases and increased sensitivity to allergic disorders. Determination of the mechanisms associated with these disorders can be extremely complex because of the large number of biochemical, cellular, and physiological factors that can be affected as well as the cellular interactions required to mount an immunological defense. The detection of potential immunological changes is less complex, and a number of tests exist that can provide warning of a potentially immunotoxic compound.

The FDA has published recommendations for the inclusion of immunotoxicity evaluations in repeated-dose toxicity studies.[56] The agency suggests that such evaluations be conducted in rodents. Immunotoxicology testing procedures are divided into two broad categories. Type I tests are those assays that do not require study animals to be treated with an agent that presents an immunological challenge. Type II tests are assays that require study animals to be challenged with an agent that elicits an immune response, such as antigens, vaccines, infectious agents, or tumor cells. Because type I tests do not require manipulation of animals, they can be included in the routine assays done during a repeated-dose toxicity study. Because type II tests require treatment of the animals with an immunological challenge, these animals are not suitable for evaluations conducted during toxicity studies. Therefore, additional animals must be included in the study design if type II assessments are to be included.

Table 24.13 lists the immunotoxicology evaluations the FDA suggests be included in type I tests. Generally, these evaluations are those currently recommended for repeated-dose toxicity studies with the exception of more comprehensive histopathology of lymphoid tissues. Inclusion of these evaluations into standard study designs should have no impact on the validity of the study. Inclusion of the expanded type I tests listed in Table 24.14 would require more planning during the study design phase and assurance that the laboratory performing the study would be capable of performing the assays. Generally, the expanded type I test would only be conducted after consultation with the FDA.

Type II immunotoxicity tests recommended by FDA could be done as a component of a repeated-dose toxicity study but appear to be more appropriately conducted as independent studies and are beyond the scope of this chapter.

TABLE 24.13
FDA Draft Recommendation for Type I Immunotoxicity Test That Can Be Included in Repeated-Dose Toxicity Studies

Type I Test

- Hematology
  - White blood cell counts
  - Differential white blood cell counts
  - Lymphocytosis
  - Lymphopenia
  - Eosinophilia
- Histopathology
  - Lymphoid tissues
    - Spleen
    - Lymph nodes
    - Thymus
    - Peyer's patches in gut
    - Bone marrow
  - Cytology (if needed)[a]
    - Prevalence of activated macrophages
    - Tissue prevalence and location of lymphocytes
    - Evidence of B-cell germinal centers
    - Evidence of T-cell germinal centers
  - Necrotic or proliferative changes in lymphoid tissues
- Clinical chemistry
  - Total serum protein
  - Albumin
  - Albumin-to-globulin ratio
  - Serum transaminases

[a] More comprehensive cytological evaluation of the tissues would not be done unless there is evidence of potential immunotoxicity from the preceding evaluations.

TABLE 24.14
FDA Draft Recommendation for Expanded Type I Immunotoxicity Test That Can Be Included in Repeated-Dose Toxicity Studies

- Hematology
  - Flow cytometric analysis
    - B-lymphocytes
    - T-lymphocytes
    - T-lymphocyte subsets
      - TH and TS
    - Immunostaining of blood or spleen
      - B-lymphocytes
      - T-lymphocytes
- Serum chemistry
  - Serum protein electrophoresis
    - Albumin
    - α-Globulin
    - β-Globulin
    - γ-Globulin
  - Quantification of γ-globulin fraction
    - IgG, IgM, IgA, IgE
  - Complement
  - Cytokines
    - IL-2, IL-1, γ-interferon
  - Autoantibodies
  - Antiparietal cell antibodies
- Histopathology
  - Immunostaining of B-lymphocytes in spleen and lymph nodes with polyclonal antibodies to IgG
  - Immunostaining of T-lymphocytes and subsets with monoclonal or polyclonal antibodies
  - Micrometric measurements of germinal centers and periarteriolar lymphocyte sheath of the spleen and follicles and germinal centers of lymph nodes
- In vitro analysis of functional capacity of specific immune cells
  - Activity of natural killer cells
  - Mitogenic stimulation of B- and T-lymphocytes
  - Macrophage phagocytic index
  - Stem cell assays

Safety Pharmacology

The core battery of safety pharmacology studies includes studies to evaluate effects of test materials on the central nervous system, the cardiovascular system, and the respiratory system. In some cases, evaluations can be added to standard repeated-dose study designs to provide information regarding adverse effects on these systems.[67] In other cases, such as the development of oncology drugs intended to treat late-stage cancers, stand-alone safety pharmacology studies may not be required and data obtained in toxicity studies are considered sufficient.[12] A functional observational battery or Irwin screen may be added to a repeated-dose toxicity study in order to evaluate effects on CNS function. The addition of CNS evaluation is relatively noninvasive, while adding endpoints to evaluate respiratory and/or cardiovascular function can be more challenging. With the advent of telemetry and/or jacketed data collection systems, many of the complications involving respiratory and cardiovascular parameter assessment can be overcome. It is always important to keep in mind that adding too many additional endpoints to a study can compromise the overall objective of the study, which is to identify potential toxicity and target organs. Several publications regarding the integration of safety pharmacology parameters into toxicity studies and the potential challenges in doing so are available.[68]

Toxicokinetics

Advances in modern analytical chemistry, especially high-performance/mass spectroscopy, have provided the toxicologist with the capability of obtaining toxicokinetic data in the early stages of a hazard assessment. These data can be important in the interpretation of data from a current study as well as in the design of subsequent studies. Demonstration of systemic exposure is also important and may provide insight into factors that may influence the toxicity of the test material (see the toxicokinetic chapter in this volume). For these reasons, toxicokinetic assessments are increasingly being incorporated in more protocols for short-term and long-term repeated dosing studies. According to ICH guidelines, toxicokinetic evaluation should be performed in studies of pharmaceutical products because "Toxicokinetics is thus an integral part of the nonclinical testing programme; it should enhance the value of the toxicological data generated, both in terms of understanding the toxicity tests and in comparison with clinical data as part of the assessment of risk and safety in humans."[69]

It is currently possible to obtain in vitro metabolism and preliminary in vivo metabolism data before the initiation of short-term repeated-dose studies. These data can be useful in the design of 14-day repeated-dose studies and aid in the integration of toxicokinetic procedures into short-term protocols. Because of the small quantities of blood required with the current analytical procedures, blood collection from studies with larger animals can be done using the main study animals and eliminates the need for animals devoted to toxicokinetics alone. However, with rodent species, it still may be necessary to have an extra set of animals in the study for the assessment of toxicokinetics. Using a separate set of animals in rodent studies to obtain toxicokinetic data still has advantages over doing an independent toxicokinetic study. It ensures that the animals are similar to those in the toxicology study with respect to age, environmental factors, and dosing parameters. Recent advances in analytical and sampling procedures such as dried blood spot technology have reduced the number of separate toxicokinetic animals needed in rodent studies and may, depending on the number of sampling time points and other considerations, enable blood collection from main study rodents.

Whereas the initial in vivo studies may be single-dose studies, repeated dosing studies provide the opportunity to obtain data following multiple doses. They can, therefore, provide information concerning induction and inhibition of the test material's metabolism associated with the previous exposures. Toxicokinetic data obtained during different time periods in a subchronic study provide information concerning the effects of prolonged dosing on the absorption, distribution, metabolism, and excretion of the test article and also information concerning the disposition of metabolites and may provide explanations for unexpected results in the toxicology study. Data obtained at the initiation, midpoint, and near study termination may indicate important changes in toxicokinetics based upon biochemical or toxicological alterations of biodisposition of the test article and its metabolites. For instance, hepatotoxicity that is manifested after several weeks of dosing may significantly alter the metabolism of the test article. Toxicokinetic data can also provide information useful in the design of longer-term studies. For instance, gender differences in toxicokinetics may indicate a need for differential dosing of males and females. Species differences in the toxicokinetics may indicate the most suitable animal model for longer-term studies and aid in the extrapolation of the animal data to humans.

Miscellaneous Other Endpoints

There are a wide variety of additional endpoints that could be evaluated in repeated-dose studies to address specific issues. In part, any additional endpoints would depend upon the questions to be addressed and the creativity of the toxicologist designing the studies. For instance, the increased availability of electron microscopy makes this endpoint a more viable option today than in previous decades. The development of an increased number of histochemical assays, especially those employing specific antibodies, makes the preserved wet tissues, embedded tissues, and the histopathology slides obtained from these studies valuable for future use. In many cases, the need for additional endpoints is unknown until the initial results of the study are available. The preserved tissues then become a valuable resource. For instance, if it is found that the liver from a study contains vacuoles and the toxicologist suspects these to be fat vacuoles, it is possible to use special lipid stains to determine if the vacuoles are lipid. Other special stains exist for a variety of purposes. An example of a protein-specific stain, Mallory–Heidenhain, is illustrated in Figure 24.6. If the toxicologist believes that the histopathologic data indicate a particular compound is producing cellular proliferation, there are a number of approaches to investigate this hypothesis. A standard method to determine cellular proliferation is by injecting the animal with ^{3}H-thymidine and measuring the incorporation of the radiolabel into cellular DNA by methods such as autoradiography. However, if the study has been terminated, this is not possible. Also, the toxicologist may not want to administer radiolabel to the animals for a number of reasons, especially if the in-life portion of the study has not been terminated. If the evidence of increased cellular proliferation occurs in tissues with a relatively high rate of normal proliferation, such as the gut mucosa, it is possible to determine the mitotic index by counting mitotic figures in cells from slides previously prepared for histopathologic analysis. Alternatively, it is now possible to immunostain for specific proteins associated with cellular proliferation in preserved tissues.

In cases where potential effects and/or target organs are suspected prior to study conduct, the use of bioimaging techniques such as ultrasound, magnetic resonance imaging (MRI), and computed tomography (CT) scanning is becoming increasingly common. These imaging techniques can be useful because they allow longitudinal assessments of internal structures/organs. For example, imaging techniques can be used to evaluate tumor onset and progression in long-term studies and the ability of cancer treatments to shrink tumors, to evaluate hypertrophy of tissues in response to test article treatment, to examine bone density, or, in the case of medical devices, to verify the placement of the device. There is a growing amount of information regarding bioimaging techniques and their application in toxicity testing, and the reader is encouraged to review this information when evaluating potential inclusion of imaging methodology in their studies.[70,71]

Lastly, in certain situations, valuable information can be obtained by adding evaluation of specific biomarkers to a repeated-dose toxicity study in addition to the routine assessments that are normally performed. For example, if a test article is suspected to be cardiotoxic, evaluation of serum troponin T levels may be useful. Release of this protein from cardiomyocytes (resulting in elevated serum troponin T levels) can occur at dose levels that may not produce histological alterations. There has been an increase in interest in identifying biomarkers that would serve as early indicators of potential toxicity, and efforts have been initiated to identify sensitive biomarkers to predict liver, kidney, and testicular toxicity, to name a few.

DATA ANALYSIS AND INTERPRETATION

Compilation and Summarization of Study Data

Once the data have been collected from a repeated-dose toxicity study, the next steps involve data analysis, interpretation, and reporting. These data are derived either from the measurement of a parameter associated with the test animal, for example, body weight, feed consumption, and serum enzyme activity, or from the observation of the animal, for example, physical examination findings and macroscopic and microscopic pathology. The frequency, number, and variety of these measurements and observations in repeated-dose toxicity studies yield an extremely large volume of data that must be organized and summarized prior to analysis. Historically, individual animal data were recorded manually and then were compiled either manually or following entry into a computer. Some specialized data are still handled manually today; however, most routine data are collected, compiled, and statistically analyzed electronically using custom or commercially available computer programs.

For quantitative data such as body weights and feed consumption, individual animal data are used to calculate the mean values with a measure of statistical variation for each treated or control group. For other types of quantitative data such as the number of animals exhibiting a behavioral effect or the number of animals in which a particular finding is determined histopathologically, the incidence of the observation in each treated and control group, that is, the number of animals affected as a fraction of the total number of animals observed, is presented. Some data, like results of microscopic examination of urinary sediment, cannot be effectively summarized using a group mean or incidence value. Summarization of these types of data involves listing the individual animal data in their appropriate groups.

Despite advancements in technology such as on-line data collection systems and computerized table and report generation systems, the final evaluation of the vast amount of data gathered from even short-term repeated-dose toxicity studies and writing the study report still rely on the knowledge and judgment of the toxicologist. Data interpretation and report writing styles differ between toxicologists and evolve with experience. One approach to data evaluation is to first look at summary tables for each type of data and note mean values, sample size, variability, trends in the data over time, and any statistically significant findings. Differences from the control group values should be evaluated for dose responsiveness, and persistent and interrelated data should be evaluated for consistency (e.g., are there decreases in body weight gain that correlate with decreased feed consumption, and are there elevations in liver enzymes that correlate with microscopic findings?). After reviewing summary tables and identifying potential effects, it is helpful to evaluate the individual data in order to identify outliers that may be contributing to excessive variability in the data (if observed). After evaluating the individual and summary data, the toxicologist can then identify test article–related effects versus spurious findings. The use of scientific judgment coupled with the results of statistical evaluations and comparisons to historical control data will then allow the toxicologist to make a final decision regarding the relationship of changes in the data to the test material as well as the toxicological significance of the findings.

Determination of Compound-Related Effects and Adversity of Effects

Data from the test article groups are compared with data from the control group to determine if any compound-related effects have occurred. In virtually all cases, the data from one group of animals will differ somewhat from the data for any other group. Therefore, differences between the sets of data that are potentially related to the compound must be differentiated from spurious occurrences and from normal biological variation. This is accomplished by two methods. The first is simple examination of the data and detection of differences worthy of further consideration based upon the experience of the toxicologist and comparison with historical data. The second method uses statistical tests to detect differences for which the probability that the difference occurred by chance is low. These methods should always be used in combination. Although it is an extremely powerful and useful tool, statistical analysis alone should not be used to detect compound-related effects since, as stated by the FDA, "… statistical outliers are not always biological outliers, and a significant statistical test ($p < 0.05$) does not always indicate biological significance."[56]

Differences between the data from the control and treated animals that are detected using the methods cited earlier may indicate either an adverse effect associated with the test material, physiological adaptation to the test material, or normal biological variation unrelated to the test material. Determination of the relationship of test article treatment to differences observed during a study as well as the toxicological relevance of differences between treated and control groups is based on a number of factors that are frequently considered in combination with each other. These factors are listed in Table 24.15 and discussed in the following paragraphs.

TABLE 24.15
Factors Evaluated to Determine the Test Article Relatedness and Toxicological Relevance of Differences between Treated and Control Groups

- Dose-related trends
- Reproducibility
- Related findings
- Magnitude and type of difference
- Occurrence in both sexes

Dose-Related Trend

One of the best indicators of whether an effect is related to a test article is the presence of a dose-related trend in the data, that is, the magnitude of the effect varies directly with the dose level. Such an effect is reflective of the basic principle of toxicology stated by Paracelsus in the sixteenth century and often paraphrased as, "The dose makes the poison." If a difference from controls is noted in two or more dose groups and the severity or incidence of the difference increases as the dose level of the test material increases, it is probably a compound-related effect. When a difference from controls is noted only in animals receiving the highest dose level of the test material, it may or may not be compound related and other factors must be considered in determining its significance. Differences from control data in test material–treated animals are probably not associated with the compound if a dose-related trend is not observed. Because of this, as stated previously, selection of an appropriate range of dose levels is extremely important and facilitates data interpretation. One important consideration when evaluating dose–response relationships is the internal exposures (plasma concentrations) of the test material at each dose level. In some cases, absorption may be saturated at, for example, the mid and high doses. If saturation occurs, the internal exposure of the mid- and high-dose groups would not differ. In this case, effects on parameters in the study would be expected to be similar between the two groups and no dose–response would be evident. For this reason, it is important to examine the toxicokinetic data for dose proportionality in conjunction with the dose responsiveness of other findings.

Reproducibility of Effect

Another reliable indicator of a compound-related effect is its reproducibility. If a difference from controls is noted in the test article–treated animals at multiple intervals during a study, the difference is likely related to the compound. Further weight is given to the determination of the compound relationship if the same difference is noted in other independent studies in which the test material was administered to the same species and, even more weight is given, if the difference is observed in a second species. The absence of reproducibility, especially in the same species, is an indication that the difference may have occurred by chance.

Correlated Findings

Another consideration in the assessment of test article relatedness of an intergroup difference is the presence of related findings. For example, an elevation in the activity of serum alanine aminotransferase in treated animals when compared with the control group is probably related to the compound if there is an elevation in serum aspartate aminotransferase with concomitant hepatic necrosis. If no correlation with other findings is observed, the elevation may be unrelated to the test article or, at least, its relationship to test article exposure must be determined considering other factors. Furthermore, test article–related effects may be considered adverse or nonadverse based on correlative findings. For example, an increase in liver weight (or other organ weight changes) may not be considered adverse in the absence of microscopic findings in the tissue.

Magnitude and Type of Intergroup Difference

The magnitude and type of difference observed between treated and control data may also give an indication of its potential association with test material administration and also impact the assessment of whether or not findings in a study are considered adverse. For example, a doubling of an organ weight in treated animals compared to controls should be considered more likely to be compound related than a 10% increase, even if the smaller increase is statistically significant. Furthermore, a fairly large decrease in the activity of serum alanine aminotransferase in test article–treated animals is generally assigned limited clinical significance whereas an increase in the same magnitude in the activity of this enzyme may be considered indicative of a toxic effect. It is obvious that the assessment of the significance of a change on the basis of its magnitude or type requires knowledge of normal trends and ranges for the data.

Gender Differences

The determination if an effect is compound related is also influenced by whether or not the difference occurs in animals of both genders. Since compound-related effects often occur in both genders, a difference from controls that is noted only in treated animals of one gender may not be associated with the test material. It must be remembered, however, that there are cases where one gender is more sensitive to the toxicity of a chemical and, therefore, only the sensitive gender will exhibit the effect at a given dose. For this reason, a difference should not be considered insignificant solely on the basis of its absence in one gender. Male rats are well known for their greater capacity to detoxify certain compounds because of their higher activity of P450-dependent monooxygenases. Therefore, they may demonstrate less toxicity to these compounds than females. However, if the metabolic product is more toxic than the parent compound, they may demonstrate higher sensitivity than females. This gender difference is not seen in a number of other species, including humans.[72]

STUDY REPORT

After data from a study have been analyzed, a report is prepared. Depending upon the intended use of the report, it may contain various levels of detail. For example, a report prepared for submission to a regulatory agency in support of the safety of a chemical will generally contain much more detail (including all individual animal data) than a research report intended to be used by an organization or individual only to give guidance for future testing or a manuscript prepared for publication in the scientific literature. Whatever the purpose of the report, it should be written in sufficient detail to permit peer review of the conduct and conclusions of the study and to allow the study to be reproduced exactly, if required.

Report Content

All reports, regardless of their purpose, should contain certain common elements that are essential to adequately describe the conduct and results of a study. The report should clearly state the objective(s) of the study. It should precisely define the test material, indicate the test species used, and describe the methods and equipment employed to collect and analyze the data. Protocol deviations and an assessment of their impact upon the study should be presented. The report should present the data pertinent to the study objective(s) in a form that facilitates its review and should discuss these data in the depth required to support the conclusion(s) of the study. The discussion should describe any compound-related effects observed and should explain how the various factors described earlier were used to determine the toxicological relevance of any differences between treated and control animals in the study. Finally, the conclusion(s) drawn from the results of the study should be clearly and concisely stated.

Retrospective Report Audits

After the study has been completed and reported, retrospective audits of the study are frequently conducted. The manufacturer of the test material may audit the study prior to submitting it to a regulatory agency in support of registration or approval of the test material for its intended use. The regulatory agency to which the study report was submitted may also conduct an audit. Regulators also audit study reports to assess the compliance of the testing laboratory with GLP regulations. Whatever the reason for retrospective auditing of the study, the process is essentially the same. The raw data are inventoried to ensure that they have been properly maintained. The data are reviewed and compared with the study report to ensure the report accurately and completely presents the methods used and the data collected. Any deviations from laboratory SOPs, the study protocol, or GLP regulations that occurred during conduct and documentation of the study should have been clearly explained in the report. Individual animal data should support summary tables and discussion of the results should be consistent with the data. Retrospective auditing is of great value to all parties involved. The manufacturer of the test material can feel comfortable that they will receive no surprises during a subsequent audit by the regulatory agency. The regulator will be more confident about the quality of the study if the data have been audited. If the regulator is confident about the data, regulatory review will proceed more smoothly and, therefore, regulatory decisions will be expedited.

Data and Specimen Collection and Retention

The preceding sections of this chapter describe the design of repeated-dose studies and the main parameters to be evaluated during those studies. Knowledge of this information is critical to study conduct. Just as important to registration or acceptance of the data from these studies is proper documentation of the procedures and results. All GLP regulations require complete and accurate documentation of the study, documentation that would allow an appropriately trained and experienced individual to repeat the study with little variation from the original design.

GLPs require that documentation of study procedures and the resulting data be recorded in indelible ink that is suitable for photocopying. The individual responsible for creating the records must be documented along with the date the record was created. Any change or correction to the documentation must be made as soon as possible after the original entry and must clearly explain the reason for the change, identify the individual making the change, and indicate the date the change was made. If portions of the data are to be recorded electronically, the accuracy and reliability of any system used to collect and manipulate the data must be validated prior to its use. Electronic data collection systems are subject to the same basic requirements as hand-recorded data. That is, the individual responsible for entry or revision of the data must be identified, the date of these entries must be detailed, and an explanation of the reason for any changes to the original entry must be documented.

While the study is in progress, records and specimens must be stored in an orderly and secure manner that will facilitate report preparation once the study has been completed. At completion of the study, GLP regulations require that study documentation and specimens be placed into an archive facility that will ensure their integrity and security. The study protocol, all study records, test article samples, fixed tissues, paraffin blocks, microscopic slides, and the study report(s) must be archived following completion of data collection. Specimens with a limited useful life span such as blood samples for clinical pathology determinations and samples from mutagenicity assays do not need to be retained.

Access to the archive facility should be controlled by a designated archivist and limited to authorized individuals. The conditions of storage must prevent deterioration of the data and specimens. Archives must be temperature and humidity controlled and should have provisions for fire suppression and vermin control. The removal of any data or specimens from the archives should require documentation of the transfer, and procedures should be in place for retrieval of the items if they have not been returned to the archives in a timely manner.

The duration of retention for archived materials is dependent upon the regulatory agency to which the data will be submitted and the reason for the submission. Archival requirements for several regulatory agencies and types of submissions are shown in Table 24.16. After the materials have been archived for the required period, the data and specimens may be discarded without compromising the regulatory status of the study. However, many companies effectively archive data from pivotal studies indefinitely even though there is no regulatory requirement to do so. This extra precaution may prove useful in addressing future

TABLE 24.16
GLP Requirements for Duration of Data and Specimen Archiving

Regulatory Agency	Retention Requirement
FDA	The shorter of At least 2 years following date of approval of application for research or marketing permit At least 5 years following date of nonclinical laboratory study submission supporting application for research or marketing permit At least 2 years following date of study submission supporting application for research or marketing permit if submission is not approved or in other similar situations
EPA FIFRA	The longer of For the life of the approval for any study submitted in support of an approved research or marketing permit At least 5 years following date study submitted in support of a research or marketing permit At least 2 years following date of study submission if application for research or marketing permit is not approved or after the decision has been reached not to seek a research or marketing permit
EPA TSCA	At least 10 years following effective date of final test rule or publication of the acceptance of a negotiated test agreement
OECD	For the period specified by the appropriate authorities

liability issues related to the test material or in designing additional studies if new safety questions for the test material arise at some time in the future.

REGULATIONS CONCERNING GENERATION AND USE OF DATA FROM REPEATED-DOSE TOXICITY STUDIES

Almost every industrialized country in the world has regulations governing the introduction, transportation and use of new pesticides, food additives, human and animal drugs, and other chemicals. Many of these countries also have regulations governing medical devices, workplace exposure to chemicals, the introduction of industrial chemicals into commerce, and the disposition of chemical waste.

There is general uniformity in the objectives of these laws, that is, not to impede the beneficial use of chemicals, but at the same time to ensure their safety in use. Even though the regulatory agencies can agree, in broad terms, on one framework of toxicity testing guidelines, the toxicologist must become familiar with the details of particular guidelines to fulfill the role as a bridge between scientific and regulatory concerns. Several regulations governing repeated-dose toxicity and other types of toxicity testing are briefly described in the following text.

U.S. Laws and Regulatory Guidelines

Federal Food, Drug, and Cosmetic Act

Federal Food, Drug, and Cosmetic Act (FFDCA)[73] as amended by the FDA Modernization Act of 1997[74] controls the introduction of human and animal drugs, direct food additives, indirect food additives (such as packaging materials), and components of cosmetics. In the case of new human or animal drugs, safety and efficacy must be established for a particular therapeutic application before the FDA grants approval for marketing. The approval process is comprehensive and involves two sequential phases. For the investigational new drug (IND) phase, the industry is required to file preclinical toxicity data with the FDA before investigation of the safety and potential therapeutic value of a drug in limited numbers of humans. When the efficacy and safety of the drug in the treatment of a particular disease is established through extensive clinical trials, these data together with additional animal toxicity data are provided to the agency as part of a new drug application (NDA) or new animal drug application (NADA). The NDA is reviewed by the FDA with respect to safety and efficacy of the drug. As a consequence of the FDA review, the NDA is either approved or disapproved or has deficiencies in the data cited.

The summary of an NDA must address benefit/risk relationships, clinical data, nonclinical pharmacology and toxicology, human pharmacokinetics, bioavailability, and microbiology. It must also contain information on pharmacologic class, scientific rationale and clinical benefits, as well as chemistry and manufacturing.[75]

With respect to food additives, industry must show that a material either intended for direct addition to food, such as a preservative or flavoring agent, or having indirect contact with food, such as a packaging or can-coating material, is safe for its intended use. Results from a hazard assessment are submitted to the FDA for review as part of a Food Additive Petition. If the data demonstrate the safety of the chemical, a regulation is published allowing the chemical to be used for a particular purpose in food or in contact with food. In 1982, the FDA published *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food*.[13] This so-called Redbook delineated the nature of evaluations necessary to determine food additive safety. It provided a basic scheme for scientifically sound decisions for the development of the safety assessment. In 2007, the Redbook was replaced by a revised version, *Toxicological Principles for the Safety Assessment of Food Ingredients "Redbook 2000."*[56] These guidelines include a priority setting system that increases the efficiency of the food additive safety assessment.

FFDCA also provides an alternative method by which materials can be approved for use in or on food, that is, the Generally Recognized as Safe (GRAS) process.[76] For a material to be considered GRAS, its safety evaluation must satisfy three basic requirements. First, a group of experts qualified by scientific training and experience must conclude that the material, when used as intended, is safe for human

consumption. The sponsor of the potential additive convenes this expert group, and the group operates without regulatory oversight. Second, the information considered by the expert group during the GRAS review must be common knowledge, that is, available in the scientific literature. Third, there must be general agreement within the scientific community with the conclusion of the expert group. Final GRAS approval does not require regulatory review; however, many producers of such materials petition FDA to affirm their GRAS status prior to marketing them.

At the present time, there are no requirements for the FDA to review cosmetic formulations for safety prior to marketing. While the FFDCA only requires that the cosmetics be free of any *poisonous and deleterious* substances, responsible suppliers of ingredients for use in cosmetics and manufacturers of final products conduct toxicity studies relevant to the specific cosmetic.

The FFDCA also addresses the concentrations of pesticides permitted in foods in the United States. Under FFDCA Section 408, the EPA establishes maximum allowable concentrations for pesticide residues in raw agricultural commodities, that is, food crops, eggs, raw milk, and meat. Under FFDCA Section 409, EPA also establishes a maximum allowable concentration for a pesticide in processed food, if processing concentrates the residue of the pesticide in the raw agricultural commodity. These maximum concentrations are referred to as tolerance levels or tolerances. Human exposure resulting from consumption of foods containing tolerance levels of a pesticide must not exceed the maximum permissible intake of the pesticide established by EPA under the FIFRA. Tolerances for most foods are enforced by FDA, while those for meat, poultry, and some egg products are enforced by the Food Safety and Inspection Service within the USDA.

Federal Insecticide, Fungicide, and Rodenticide Act

The FIFRA was administered initially by the USDA and is now administered by the EPA.[77] Under FIFRA, EPA is responsible for the registration of pesticides for use in the United States. This act requires extensive toxicity testing to be conducted in mammalian, avian, and aquatic species to support the safety of a pesticide. Detailed guidelines for toxicity study design and reporting have been issued by the EPA.[8] Toxicity data submitted in an application for registration of a pesticide are reviewed by toxicologists in the Office of Pesticide Programs at EPA. Other data specifically required by FIFRA as a condition of pesticide registration include product chemistry, residue chemistry, environmental fate, reentry protection, spray drift, plant protection, nontarget insects, and product performance.

Food Quality Protection Act

The Food Quality Protection Act (FQPA) was signed into law in 1996 and amends sections of both FFDCA and FIFRA.[78] It is intended to establish more consistent regulation of pesticides and to protect human health using an approach that places increased emphasis on the scientific evaluation of pesticide safety data. Among other provisions affecting pesticide registration and tolerance setting, it (1) mandates special considerations for protection of infants and children, (2) requires determination of aggregate pesticide exposure from all sources (e.g., food, home use, and drinking water), (3) requires summation of exposures from multiple chemicals that exhibit a common mechanism of toxicity, (4) expedites approval of pesticides considered to be most safe, and (5) requires periodic reevaluation of tolerances for registered pesticides to be certain that the data supporting registration remain acceptable and complete by current standards.

Toxic Substances Control Act

TSCA is administered by the Office of Pollution Prevention and Toxics within EPA and is a complex and far-reaching law that affects industrial chemicals existing in commerce as well as new chemicals in the United States.[79] One of the first requirements of TSCA was the compilation of an inventory of chemicals that were active in commerce in the years 1977–1979 and the determination of the need for toxicity testing of these existing chemicals.

Manufacturers or importers of industrial chemicals that are considered new under the TSCA definition are required to notify the EPA at least 90 days before the manufacture or import of a new chemical. The act requires that certain information regarding the new chemical be submitted to the EPA for review in a premanufacture notification (PMN). While the act does not require toxicity testing to be conducted on a new chemical prior to manufacture, it does require submission of all existing health and safety data for the new chemical so that its risk to health or the environment can be assessed. If the EPA determines in its review that the new chemical does present an unreasonable risk, one of several actions it may take is to require that the chemical be tested for specific toxic effects. The EPA may also issue a testing rule requiring that a specified chemical or chemical mixture be tested for certain toxic effects. The EPA has issued test standards for the conduct of toxicity studies on chemicals or chemical mixtures for which testing will be required under TSCA. These standards are the same guidelines used for pesticide testing under FIFRA.[8]

Transportation Act

Regulations promulgated by the Department of Transportation (DOT) require that materials shipped in interstate commerce be labeled and contained in a manner consistent with the degree of hazard they present.[80] The DOT requires that acute toxicity data for chemicals be used to place them into *packing groups*. Labeling requirements for chemicals are based upon this packing group.

Coast Guard

Prior to importing a chemical into the United States, the Coast Guard requires a set of acute mammalian toxicity data for the chemical.[81] This acute toxicity profile should minimally include the following: acute oral toxicity, acute dermal toxicity, and skin and eye irritation studies.

Consumer Product Safety Act

Prior to passage of the Consumer Product Safety Act, the classification and testing for acute toxicity of household products was conducted under regulations promulgated by the FDA, which administered the Federal Hazardous Substances Act (FHSA). The function of administering FHSA now resides with the Consumer Product Safety Commission. If results obtained in acute oral or dermal toxicity tests conducted using methods outlined in the Code of Federal Regulations (CFR) for hazardous substances meet prescribed criteria of toxicity, labeling and packaging as prescribed in the regulation must be used.[82]

Occupational Safety and Health Act

This law, administered by the Occupational Safety and Health Administration (OSHA) of the Department of Labor, is designed to ensure safety in the workplace.[83] No requirements exist in this law for manufacturers to test substances for toxicity prior to their use in the workplace. The impact of the TSCA has an overlapping effect in that occupational exposure to new chemicals is considered in premanufacture notices. As indicated previously, specific test requirements under TSCA affect new or existing chemicals that are manufactured or processed in the United States.

Resource Conservation and Recovery Act

Resource Conservation and Recovery Act (RCRA) authorizes the EPA to institute a national program to control hazardous waste defined as "solid, liquid, semi-solid or gaseous waste that may cause increased mortality or serious illness, or may cause substantial hazard to the health or the environment when improperly managed."[84] The main purpose of these regulations is to control the generation, storage, treatment, transportation, disposal, record keeping, and reporting of hazardous waste. RCRA places the primary responsibility of identifying and managing hazardous waste on the waste generators. Other persons or institutions involved in waste disposal and management also have an obligation to know if the waste is hazardous. The degree of toxicity, concentration, migration to the environment, persistence or degradation in the environment, bioaccumulation in the ecosystem, types of improper management, quantities of waste, past human and environmental damage records, and other factors are all considered.

International Laws and Regulations Concerning Hazard Assessment and Toxicity Testing Guidelines

The United States has not been alone in developing laws to protect humans and their environment from possibly dangerous effects of new industrial chemicals in the marketplace. In the European Union, the Council of Ministers of the European Economic Community (EEC) has issued a directive concerning laws, regulations, and administrative procedures that relate to the classification, packaging, and labeling of dangerous substances.[85] An amendment to this directive was adopted later to protect humans and their environment from potential risks that might arise through the marketing of new chemicals.[86] It requires that a new chemical be subjected to a base set of tests to define its physical and chemical properties, mammalian toxicity, and ecotoxicologic effects. The base set of mammalian studies consists of the following: acute oral LD_{50}, acute dermal LD_{50}, acute inhalation LC_{50} (if applicable), skin and eye irritation, and dermal sensitization. A manufacturer or importer is required to furnish the appropriate authorities in his EEC member state with a notification containing, in part, the results of these tests with the new chemical. Such notification must be filed 45 days before marketing in the member state in which it is to occur.

The amendment to the EEC directive is the counterpart of the U.S. TSCA. There are, however, some differences, not the least of which is in the approach to toxicity testing. The EEC requires only notification of a new chemical prior to marketing whereas TSCA demands that the notification, in the case of a domestic manufacturer, be given to the EPA at least 90 days before manufacture.

The EEC has also provided guidance on the evaluation of safety and efficacy of drugs. The EEC has now adopted guidance notes for efficacy, testing of pharmacokinetics in humans and bioavailability of drugs for long-term use, as well as a number of more specific activity groups including cardiac glycosides, oral contraceptives, topical corticosteroids, nonsteroidal anti-inflammatories, antimicrobials, anticonvulsants, antianginals, and chronic peripheral arterial disease agents. Safety guidance notes also were adopted for single-dose and repeated-dose toxicities, pharmacokinetic metabolism, mutagenic potential, carcinogenic potential, and reproduction studies.[87]

As discussed earlier in this chapter, with many countries establishing their own regulations for safety assessment, it became more likely that manufacturers would have to perform several different versions of the same tests to satisfy the requirements of different countries. In an attempt to avoid unnecessary and wasteful duplication of work, the OECD, a group comprised of experts from a number of nations throughout the world, produced a set of toxicity testing guidelines that enable tests to be carried out in a similar manner in different countries.[9] The OECD package, which has been revised 10 times to implement improvements to individual study designs, includes guidelines on acute oral, dermal, and inhalation studies; eye and skin irritation and skin sensitization studies; subchronic oral, dermal, and inhalation studies; and teratogenicity, carcinogenicity, and chronic and combined chronic/carcinogenicity studies. Results from studies conducted according to OECD guidelines are generally fully acceptable to the various regulatory bodies throughout the world.

In order to facilitate more universal acceptance of data generated to support approval and use of pharmaceutical products, the ICH has developed guidance documents concerning the efficacy, quality, and safety of these drugs. ICH is made up of regulatory authorities and trade organizations from the United States, Japan, and the European Union. Instead of providing detailed instructions for study design or conduct, the ICH guidance addresses specific issues related to testing, for example,

the duration of chronic toxicity testing, definition of an acceptable battery of genotoxicity studies, and required elements of chemical stability testing of new drug products.[88] Because of ICH efforts, many hindrances to the approval and use of valuable pharmaceuticals around the world have been removed.

Regulatory Internet Sites

Many of the regulatory agencies and organizations worldwide that have responsibility for protection of humans from the hazardous effects of chemicals maintain Internet websites. These websites usually include information concerning the history, structure, and specific responsibilities of these organizations. The sites also generally contain or reference the statutes and guidelines under which the organizations operate. Internet addresses for a number of informative regulatory sites are listed in Table 24.17.

QUESTIONS

24.1 Five related compounds are under consideration for development by a pharmaceutical company named Nomohats Ltd. The compounds are hair regrowth agents. The intended treatment population includes males and females from 24 to 90+ years of age. All of the compounds have been thoroughly characterized chemically, and each has shown adequate efficacy following oral exposure during preliminary testing in animals. The effects of oral exposure in single-dose acute studies were similar for each of the compounds and none of the compounds were genotoxic in preliminary screens. Nomohats has budgeted funding to allow the development of one of the compounds. You are the toxicologist responsible for generating additional toxicity data to assist in selecting the compound to be carried forward in the development program. You have 2 months because a meeting with FDA has been scheduled by Nomohats 10 weeks from today. The purpose of the meeting is to review the chemical characterization and preliminary toxicity data for the compound and to suggest a toxicology program to demonstrate that there is no unreasonable risk-associated human exposure to the compound. Describe the study(ies) that you would conduct to aid in the selection of the compound for further development, remembering that these studies will also generate most of the new toxicity data to be reviewed during the meeting with FDA.

TABLE 24.18
Selected Results from the Subchronic Toxicity Study of *Fuzzypate* in Minipigs

	Compound Group: Males				Compound Group: Females			
Variable/Finding/Interval	**Control**	**Low**	**Mid**	**High**	**Control**	**Low**	**Mid**	**High**
Body weight (kg)	9.3 ± 0.7	8.6 ± 1.5	10.2 ± 0.6	7.2 ± 1.1[a]	9.9 ± 1.2	10.1 ± 0.9	9.2 ± 0.7	8.1 ± 0.6[a]

Week 13	1/6	1/6	2/6	6/6	0/6	0/6	3/6	4/6

[a] Statistically significantly different from controls ($p < 0.05$).

24.2 After consulting with the FDA, you have determined that the hazard assessment program for your compound, *Fuzzypate,* should include subchronic toxicity testing. In a 14-day repeated-dose study with this compound in Göettingen minipigs at 5 mg/kg/day, dermal administration resulted in renal toxicity in 40% of the animals. These animals also exhibited mildly decreased body weight gain, urinary incontinence, and slightly enlarged and discolored kidneys. In the mid-dose group, 2.5 mg/kg/day, no renal toxicity was reported, and body weight of the animals was slightly lower than the untreated control group. At 1 mg/kg/day, only a statistically significant increase in serum levels of liver enzymes was observed. Efficacy testing revealed that *Fuzzypate* is effective for its intended use at 0.2 mg/kg/day. Pharmacokinetic determinations indicate that the material is excreted almost entirely in the urine and its serum half-life is 120 min. What dose levels would you select for the subchronic toxicity study? Why? In addition to the standard parameters, what special endpoints would you include for investigation during the subchronic study?

24.3 The data in Table 24.18 above were obtained during the subchronic study with *Fuzzypate*. In what dose groups is there a compound-related effect on body weight? Are liver and kidney target organs for *Fuzzypate* toxicity? If so, in which dose group(s) is there a compound-related effect? Based on the data in the table, what is the NOAEL for this study?

25 Carcinogenicity of Chemicals
Assessment and Human Extrapolation

Gary M. Williams, Michael J. Iatropoulos, Harald G. Enzmann, and Ulrich F. Deschl

CONTENTS

CHEMICALS WITH CARCINOGENIC ACTIVITY

Cancer is a leading cause of morbidity and mortality in the developed parts of the world and in many other regions [210,232]. The etiologies of most types of cancer are not known, but some are caused by exogenous chemicals, for example, lung cancer and cigarette smoke [210] and liver cancer and aflatoxin B_1 [210]. Accordingly, in the toxicological assessment of chemicals, testing for carcinogenic activity constitutes a critical component and is required under numerous governmental regulations or agreements (Table 25.1). A large database on the carcinogenic, or oncogenic, activities of chemicals in rodents has accrued [147,148,149,316] as a result of almost 100 years of basic research, as well as the output from national testing programs in several countries, particularly the United States and Japan, and regulatory studies conducted by the pharmaceutical, chemical, food, and cosmetic industries. In the United States, under the aegis initially of the National Cancer Institute (NCI) and subsequently the National Toxicology Program (NTP) [474], results of cancer bioassays in rodents, mainly mice and rats, have been reported for over 650 chemicals [324], and further testing is ongoing.

The definitive bioassay for carcinogenic activity in animals is the rodent cancer bioassay (RCB), which in its various forms is detailed here and in the previous version of this chapter [492], as well as elsewhere [177,199,200, 300,447,448,476]. The current method for the RCB is exemplified by that presently in use by the NTP [33]. This method was refined from basic procedures developed beginning in the 1960s largely by the pharmaceutical industry under guidance from the U.S. Food and Drug Administration (FDA) and by the NCI Bioassay Program [67,68,84,474]. The scientific basis for the procedures used has been recently reviewed [177]. Findings from RCB on a wide variety of chemicals have led to the recognition that results cannot be unquestioningly extrapolated to humans [305,476], in which, of course, the carcinogenic activity of a chemical is established only by epidemiological studies, involving the application of rigorous criteria [4,182,416]. Available mechanistic procedures discussed below (in the Systematic Approach to Testing section) assist in the assessment of RCB results for potential human hazard.

TABLE 25.1
Regulations, Agreements, or Their Latest Amendments and Recommendations for Carcinogenicity Testing

Legislation/Guidance	Agency	Agents of Concern
Commission Directive 318/EEC (1975) and further updates (2003)	EU	Registration of new human medicines in Europe
Commission Directive 414/EEC (1991)	EU	Plant protection products
Pesticide Registration Directive (1991)	EU	Pesticides
Commission Directive 67/EEC (1993)	EU	New notified substances
Commission Regulation 1488/EEC (1994)	EU	Existing substances
Dangerous Substances Directive (1967; amended 1992)	EU	Industrial chemicals
Commission Directive 27 (2004)	EU	Registration of new human medicines
Commission Directive 28 (2008)	EU	Registration of veterinary medicines
Commission Directive 24 (2004)	EU	Registration of herbal medicines
Federal Hazardous Substances Act (1960; amended 1988)	U.S. CPSC	Household products
Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) (1948; amended 1978)	U.S. EPA	Pesticides
Toxic Substances Control Act (TSCA) (1976; amended 1992)	U.S. EPA	Hazardous chemicals not covered by other laws, includes premarket review
Food, Drug, and Cosmetics Act (1906, 1938, amended 1992)/FDA Redbook II (1993) [447]	U.S. FDA	Food, medicines, cosmetics, food additives, color additives, new drugs, animal and feed additives, medical devices
Guidance on Toxicology Study Data for Application of Agriculture Chemical Registration (1985)	MAFF (Japan)	Agricultural chemicals
Guideline for Toxicity Testing of Chemicals (1990)	MHW (Japan)	Chemicals
Pharmaceutical Affairs Law (1980)/Guidelines for Toxicity Studies of Drugs Manual (1990)	MHW (Japan)	Medicines
Guidelines for Toxicity Studies of New Animal Drugs (1988)	MHW (Japan)	Animal medicines
Technical Requirements for the Registration of Pharmaceuticals for Human Use (1995)	ICH	Medicines

Chemical Carcinogenic Activity

Carcinogenicity is not an intrinsic property of a chemical; rather, it is an activity of the chemical under specific conditions. Carcinogenic activity has been defined in various ways. A committee of the International Federation of Societies of Toxicologic Pathologists (IFSTP) adopted the definition of a chemical carcinogen as a "substance that causes a cell or group of normal cells, which would not otherwise have shown this property, to change its biological behavior and demonstrate progressive growth of a malignant character" [118]. In an RCB, the carcinogenic activity of a test substance (TS) is best documented by the finding of unequivocal evidence in either sex of the experimental animal of induction of a type(s) of malignant neoplasm not seen in contemporary controls [492,500,513], and above that recorded in databases of background neoplasms (see Table 25.7), thereby indicating *ab initio* induction of neoplasia. A marginal increase in a very rare malignancy also can incriminate a TS. Another generally used criterion is an increase in the incidence of a type of malignant neoplasm present in controls, especially if the incidence(s) in dosed animals exceeds the range of historical controls. The malignant neoplasm can be of any histological type, epithelial or mesenchymal, and, although a clear increase in the incidence of a malignant neoplasm is most persuasive, an increase in the combined incidence of benign and malignant neoplasms of the same cell type of origin, where the latter is not significantly increased, is generally accepted as reflecting carcinogenic activity [198,290]. The evidence of malignancy is best established by the presence of invasion or metastasis. For most rodent neoplasms, however, the diagnosis of malignancy is typically made histologically on evidence of cellular atypia. This can be problematic since some diagnoses are controversial, as discussed in the following sections on anatomic pathology and cancer hazard evaluation. The finding of an increase in only benign neoplasms, especially if the type of neoplasm is not established to be premalignant, does not constitute sufficient evidence for carcinogenicity, but does provide some limited evidence. In addition to these criteria, an increase in the multiplicity of neoplasms above that in controls or a reduction in the latency period for the development of neoplasms has also been considered [513]. Although these latter findings can indicate an influence of the chemical or stress/toxicity produced by it on the development of neoplasia, they can reflect modulation of host control of background neoplasia and are less definitive evidence of carcinogenic activity. These criteria apply to findings in any species, strain, or sex. An effect in more than one sex or species, in more than one dose group or in independent experiments, of course, strengthens the evidence. For regulatory RCB, assessment of results is ultimately made by the responsible expert body using criteria deemed appropriate (see Assessment and Classification of Evidence of Carcinogenicity section), a process often influenced by a high level of concern for hazard identification in the interests of public health protection. It must be kept in mind that carcinogenicity in a rodent study is not proof of a cancer hazard to humans, as discussed below. Ultimately, in assessing human hazard (which is the reason why animal tests are done), scientific judgment is used in evaluating all the information available, including, importantly, mechanism (or mode) of action, including any known pharmacologic activity.

Types of Carcinogens

A wide variety of organic and inorganic chemicals has exhibited carcinogenic activity in rodents [147,148,149,201,206,207]. This diversity reflects the fact that the multistep process of

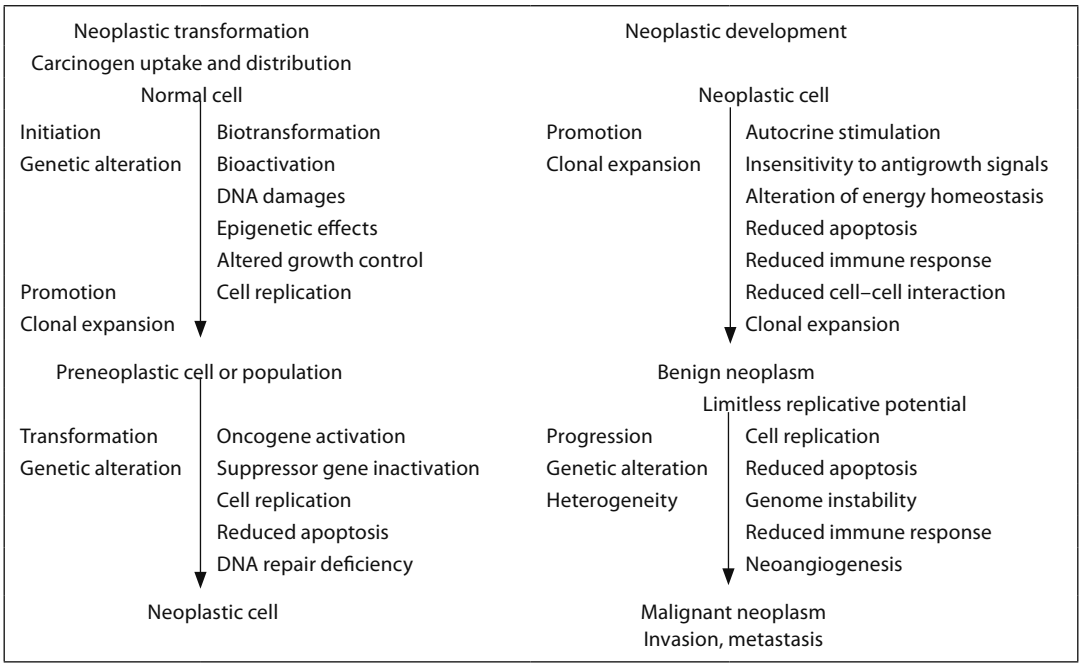

FIGURE 25.1 Sequence of oncogenesis.

oncogenesis (Figure 25.1) can be influenced by chemicals in various ways, mainly involving either chemical reactivity and genotoxicity as a key event in effecting neoplastic transformation (initiation [IN]) or epigenetic effects leading to either neoplastic transformation or enhancement of cell growth facilitating neoplastic development (promotion [PM]). Thus, chemicals can give rise to increases in neoplasms through a variety of modes of action (MOAs) that have been broadly characterized as either DNA reactive or epigenetic (Tables 25.2 and 25.3) [488,492,497]. A DNA-reactive carcinogen can be defined as an agent that reacts with DNA in the target somatic cell of carcinogenicity under conditions of carcinogenicity to produce mutations that lead to neoplastic transformation and IN of neoplasia [364]. The critical genes affected are known as oncogenes and tumor suppressor genes [43]. An epigenetic carcinogen can be defined as an agent that under conditions of its carcinogenicity produces a non-DNA-reactive cellular effect in the target tissue of carcinogenicity, which either indirectly results in DNA alteration (e.g., DNA oxidation, aberrant methylation) leading to a procarcinogenic mutation or facilitates the

TABLE 25.2
Classification of Substances with Experimental Carcinogenic Activity

A.	DNA-reactive chemicals	
	1. Activation independent	Alkylating agents: nitrogen mustards, ethylnitrosourea, cyclophosphamide
		Epoxides: ethylene oxide
	2. Activation dependent	Aliphatic halides: vinyl chloride
		Aromatic amines, aminoazo dyes, and nitro-aromatic compounds: *o*-toluidine, 2-amino-1-methyl-6-phenyl-imidazo[4,5-*b*]pyridine (PhIP), polycyclic 4 aminobiphenyl, benzidine, dimethylaminoazobenzene, 1-nitropropane (nitroalkane)
		Polycyclic aromatic hydrocarbons: benzo(*a*)pyrene
		N-nitroso compounds: dimethylnitrosamine, *N*-nitrosonornicotine
		Hydrazine derivatives: 1,2-dimethylhydrazine, azoxymethane, methyl-azoxymethanol
		Mycotoxins: aflatoxin B1, pyrrolizidine alkaloids, ochratoxin
		Pharmaceuticals: chlorambucil, tamoxifen
		Triazines (diazoamino compounds): 3,3-dimethyl-1-phenyltriazene
B.	Epigenetic chemicals	
	1. Promoter	Liver enzyme-inducer-type hepatocarcinogens: chlordane, DDT, pentachlorophenol, phenobarbital, polybrominated biphenyls, polychlorinated biphenyls
		Urothelial cell proliferation enhancers: saccharin
	2. Endocrine-modifier	Estrogenic hormones: estrogens, diethylstilbestrol, and hormone modifiers atrazine and chloro-*S*-triazines
		β_2-Adrenoreceptor agonists in female rats: soterenol, salbutamol
		Antiandrogens: finasteride, vinclozolin
		Antithyroid thyroid tumor enhancers: thyroperoxidase inhibitors (amitrole, sulfamethazine); thyroid hormone conjugation enhancers (phenobarbital, spironolactone)
		Gastrin-elevating inducers of gastric neuroendocrine tumors: omeprazole, lansoprazole, pantoprazole, alachlor, butachlor
		Neuroleptics (dopamine inhibitors), gonadotropin-releasing-hormone-like drugs (goseline)
	3. Immunomodulator	Purine analogues: azathioprine
		Cyclosporine
	4. Cytotoxin	Forestomach toxicants: butylated hydroxyanisole, propionic acid, diallyl phthalate, ethyl acrylate
		Nasal toxicants: chloracetanilide herbicides (alachlor, butachlor)
		Renal toxicants: potassium bromate, nitrilotriacetic acid
		Male rat $\alpha_{2\mu}$-globulin nephropathy inducers: D-limonene, *p*-dichlorobenzene
	5. Peroxisome proliferator-activated-receptor α/γ agonist	Hypolipidemic fibrates: ciprofibrate, clofibrate, gemfibrozil
		Phthalates: di(2-ethylhexyl) phthalate (DEHP), di(isononyl) phthalate (DINP)
		Miscellaneous: lactofen
	6. Inducer of urine pH extremes	Melamine, dietary phosphates, carbonic anhydrase inhibitors
C.	Inorganic compounds[a]	
	1. Metal or metal salt	Beryllium, cadmium, chromium, nickel, silica
	2. Fiber	Asbestos
D.	Unclassified	Acrylamide, acrylonitrile, benzene, dioxane, dioxin, furan, methapyrilene, nucleoside analogues (entecavir, zidoriudine, zalcitabine)

[a] Some are categorized as genotoxic because of evidence for damage of DNA; others may operate through epigenetic mechanisms such as alterations in fidelity of DNA polymerases.

TABLE 25.3
Classification of Chemicals and Mixtures Considered Carcinogenic to Humans by the International Agency for Research on Cancer

Aflatoxins	**Melphalan**
DNA reactive	
4-Aminobiphenyl	MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone)
5-Azacytidine	2-Napththyamine
Benzidine	Nickel and nickel compounds
Betel quid with tobacco	Phenacetin-containing analgesic mixtures
bis(Chloromethyl)ether	Soot
1,4-Butanediol dimethanesulfonate (myleran)	Sulfur mustard
Chlorambucil	Tobacco smoke and products *o*-Toluidine
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (methyl-CCNU)	
Chromium compounds, hexavalent	Triethylethiophosphoramide (thiotepa)
Coal tars	Vinyl chloride
Cyclophosphamide	
Diesel engine exhaust	
Ethylene oxide[a]	
Epigenetic	
Azathioprine	Oral contraceptives
Cyclosporine	Tamoxifen
Diethylstilbestrol	2,3,7,8-Tetrachloro-dibenzo-*p*-dioxin (TCDD)[a,b]
Estrogens, steroidal, conjugated	
Unclassified	
Alcoholic beverages	Mineral oils
Arsenic and arsenic compounds; gallium arsenide	Shale oils
Benzene

[a] Based on evidence for a relevant mechanism in humans.

[b] Based on overall increase in neoplasia.

development of a normal or preexisting preneoplastic cell into a neoplasm. A DNA-reactive carcinogen can also produce epigenetic effects, usually at higher doses than required for DNA reactivity, which facilitate neoplastic development.

The types of organic chemicals that can be assigned to these two categories of carcinogens, as well as inorganic carcinogens, are given in Table 25.2 and have been discussed in detail elsewhere [477,497]. Carcinogens are both naturally occurring (e.g., aflatoxins) and synthetic (e.g., vinyl chloride).

Of the many chemicals with carcinogenic activity in RCB, few are associated with cancer in humans, as assessed by the World Health Organization (WHO) and International Agency for Research on Cancer (IARC) (Table 25.3). Thus, the specificity of the RCB is obviously low, detecting many *rodent-only* carcinogens, whereas its sensitivity is high in that it can detect all substances that really are established to be carcinogenic in humans. Most of the known human carcinogens are of the DNA-reactive type [500], indicating the importance of this MOA in human hazard. As a further indication of the significance of this MOA, several DNA-reactive carcinogens have been carcinogenic transplacentally in rodents [373] and in primates [418]. Human contacts with, or intake of, DNA-reactive carcinogens occur mainly with tobacco use and as contaminants in food, and also in the workplace or as therapeutic interventions [477,515]. Human contacts with these types of carcinogens are usually substantial compared to those resulting from trace levels of environmental chemicals (e.g., pesticides). A variety of neoplasms is induced in humans by such chemicals, including notably lung (tobacco smoke, bischloromethyl ether), urinary bladder (benzidine, tobacco smoke), hematopoietic system (benzene, chlorambucil), and liver (aflatoxin B_1, vinyl chloride). The few human epigenetic carcinogens [500] are mainly pharmaceuticals, and these are associated with cancer increases only at therapeutic doses that produce the cellular effect that underlies their carcinogenicity in rodents, mainly hormonal perturbation or immunosuppression. With hormonal agents, responsive target tissues include endometrium (e.g., tamoxifen), while with immunosuppression, risk of lymphatic tissue neoplasia (e.g., cyclosporine) is greatly increased. Thus, a

primary objective of cancer hazard assessment is to identify chemicals with DNA reactivity and those with epigenetic effects known to be relevant to human hazard.

Because of the significance of DNA reactivity and the reliability with which it can be identified, agents of this type are generally not considered for uses in which there is any intentional human contact, apart from chemotherapeutic alkylating agents. In contrast, agents that elicit rodent neoplasm increases by epigenetic MOA are widely used; for example, as of 1995, more than 80 approved medicines were oncogenic in RCB [82], and the number has increased [18]. Generally, epigenetic carcinogens have not been carcinogenic in primates [398,418]. An important aspect of safety assessment is to elucidate any MOA that might underlie an increase in neoplasia in an RCB to guide mechanistic research for informed hazard evaluation [505].

Potency

The magnitude of carcinogenic activities in rodents of chemicals with respect to dose varies more than 10 million-fold [147]. The most extensive compilation of quantitative indices of carcinogenic potency is the Carcinogenic Potency Database [147,148], which uses TD_{50} values as its metric, defined as the daily dose rate required to halve the probability of an experimental animal remaining tumor free at the end of its standard life span [354]. A simplified method of expressing potency proposed for use in the regulatory setting in Europe is the TD_{25}, defined as the chronic dose rate in mg per kg body weight per day, which will cause neoplasia in 25% of the animals at a specific site, after correction for the spontaneous incidence, within the standard lifetime of that species [97]. Potency can also be reflected in reduced latency or increased multiplicity of neoplasms compared to controls. Specifically, for DNA-reactive carcinogens, a general, but not exact, relationship exists between carcinogenicity and DNA binding, which differs over several orders of magnitude [343,346] reflecting the fact that not all DNA binding is necessarily mutagenic [462] or carcinogenic [326].

REQUIREMENTS FOR TESTING

Testing of chemicals in experimental animals for carcinogenic activity is done to assess potential human cancer hazard under conditions in which humans might have contact with the chemical. The U.S. federal government has enacted numerous laws that establish requirements for carcinogenicity testing of substances for which human contact or environmental release occurs (Table 25.1). Other countries have similar provisions (Table 25.1). The requirements for testing of industrial chemicals in the United States and the European Union (EU) have been undergoing revision.

Food substances generally require technical evidence of safety [461]. The procedures have been detailed by the U.S. FDA [447]. Food substances, such as flavors, many of which are naturally occurring and which are used at extremely low levels, if evaluated by a group of qualified experts can be deemed "generally recognized as safe" and do not require premarket approval [461].

Cosmetics usually do not require carcinogenicity testing. Moreover, under the seventh amendment to the EU cosmetics directive [113], since 2009, the use of animals in the safety assessment of cosmetic ingredients is not permitted [165].

For pharmaceuticals, circumstances requiring carcinogenicity studies have been agreed upon by the International Conference on Harmonization (ICH), a tripartite body comprised of regulatory scientists from North America, Europe, and Japan. The requirements are available on the Center for Drug Evaluation and Research (CDER) website (http://www.fda.gov/cder). In general, candidate medicines with positive genotoxicity findings, or which are intended for chronic use (>6 months), usually require carcinogenicity testing.

The requirements for the testing of biopharmaceuticals present specific issues [395] for which the FDA has provided guidance (http://www.fda.gov/cber). Several nucleoside analogues have been found to be carcinogenic in rodents [515], possibly through perturbation of nucleotide pools leading to errors in DNA synthesis [357]. Growth factors and immunosuppressive antibodies are noted as raising concern for carcinogenic potential. Normal hormones or growth factors that are intended to correct deficiency states (e.g., insulin) may not need to be tested, unless they are structurally modified, are administered at doses exceeding the physiological levels, or are given by a route that results in substantially increased exposure in some tissues. Modified proteins with new biologic properties require testing, because, for example, it was found that a modified insulin [408] with an increased affinity for the insulin-like growth factor 1 (IGF-1) receptor produced mammary tumors in rats [92]. Also, a portion of parathyroid hormone with bone trophic activity produced bone neoplasms in rats [356]. Certain modifications of proteins to improve bioavailability, such as with conjugation to polyethylene glycol, have not raised carcinogenicity issues.

An aspect of regulatory concern is potential photochemical carcinogenicity [188], discussed below in the section Photochemical Carcinogenesis. Indications for the possible need for photochemical carcinogenicity testing include (1) long-term exposure of the skin to a chemical that can undergo photoactivation, (2) alteration of the structure of the epidermis, (3) sensitization of the skin to ultraviolet radiation (UVR), and (4) exacerbation of suspected UVR-induced carcinogenesis [454].

Nanosized particles (NSPs; <100 nm) are increasingly being used in medical and other applications [21,27,115,286,301,460]. NSP can have inflammatory, prooxidant, and antioxidant activities [286,333], which raise concern. Several regulations require the toxicity assessment of NSP products [115,460].

Thus, for the uses of many types of chemicals, RCBs are required, usually in both rats and mice. For chemicals with negligible human contact, similar to food contact materials [340], application of the threshold of toxicological concern (TTC) (see Risk Assessment) can be utilized [25,136,264,314,451]. Also, expedited approaches have been proposed to provide the assessment of potential carcinogenic activity rapidly and economically, with minimal use of

experimental animals, in order to delineate potential hazard before extensive development or significant contacts with humans takes place. These are discussed in the next section Systematic Approach to Testing.

SYSTEMATIC APPROACH TO TESTING

The goal of a systematic approach to testing is to obtain reliable data enabling the evaluation of the TS at the earliest possible stage for potential human hazard. An approach that incorporates the mechanistic concepts described earlier is the decision point approach (DPA) [475,476], which is presented here as a general framework for the concept (Table 25.4). Such an expedited approach to testing can assist in prioritizing from the large reservoir of existing untested chemicals and in selecting for progression new molecular (or chemical) entities, both small and large (e.g., protein) molecules.

The endpoints detailed later provide guidance in identifying a potentially carcinogenic TS, but negative results do not preclude carcinogenicity, and, in any event, carcinogenicity testing ultimately may be required. Recently, an analysis of data on 182 pharmaceuticals reported that a positive finding for either genotoxicity, histopathological changes indicative of preneoplasia, or hormonal perturbation could be highly predictive of carcinogenic activity [400], supporting the value of critical data prior to carcinogenicity testing. A review of the FDA/CDER database of pharmaceuticals, however, revealed that short-term toxicity studies, including in transgenic mice, do not accurately and reliably predict neoplastic findings in long-term assays [225].

Implications of Chemical Structure (Stage A)

From the classes of DNA-reactive organic carcinogens given in Table 25.2, the types of electrophiles that are involved in chemical reactivity and hence DNA binding are well known (Figure 25.2). Such molecular features also have been referred to as structural alerts [12]. In general, a relationship exists between DNA binding and carcinogenicity [455,462], although not all DNA binding is necessarily mutagenic [462] or carcinogenic [326], since adducts can be unstable or involve sites on bases that are not involved in base pairing. Among both DNA-reactive and epigenetic carcinogens, numerous classes have common structural features within the class. The presence of one of these features in a new molecular entity of unknown carcinogenicity suggests potential activity. The FDA Center for Food Safety and Nutrition (CFSAN) has grouped food substances into classes by chemical structure, estimating their potential toxicity [447,450], similar to the Cranmer classes [75]. These structural classes are used for assignment to levels of concern. Substances with functional groups of high probable toxicity are assigned to Category C; substances of intermediate or unknown toxicity are assigned to Category B; and substances of low probable toxicity are assigned to Category A. The recognition of potential toxicity can provide a guide to potential epigenetic carcinogenicity. Several artificial intelligence systems (in silico) for assessing potential toxicities related to structures are available [43,69,257].

TABLE 25.4
Decision Point Approach in Carcinogen Testing

Stage A. Structure of chemical
1. Possible electrophiles
2. Relation to known carcinogens

Stage B. Short-term genotoxicity assays
1. In vitro: Bacterial mutagenesis; hepatocyte DNA repair test
2. In vivo*:* Micronucleus test

Decision Point 1: Evaluation of findings in stages A and B

Stage C. Assays for epigenetic effects
1. Cultured cells
   - Mitogenesis
   - Induction of cytochrome P450 (CYP)
   - Peroxisome proliferation
   - Gap junction protein downregulation
   - Inhibition of cell–cell communication
   - Hormone modulating effect
   - Altered gene expression
2. In vivo
   - Increased cell proliferation
   - Reduced cell apoptosis
   - Induction of cytochrome P450 (CYP)
   - Peroxisome proliferation
   - Hormone homeostasis disruption
   - Gap junction protein reduction
   - Enhancement of preneoplastic lesions
   - Immunosuppression
   - Altered gene expression

Decision Point 2: Evaluation of results from stages A through C

Stage D. In vivo assays
1. DNA reactivity
2. Limited bioassays
3. Preneoplastic lesions (rat liver, mouse skin, mouse lung, rat breast)
4. Transgenic mice

Decision Point 3: Evaluation of results from stages A to C and selected tests in stage D

Stage E. Carcinogenicity bioassays
1. Accelerated bioassays
2. Long-term bioassays

Decision Point 4: Final evaluation of all results and cancer hazard assessment

Short-Term Assays (Stage B)

In Vitro

A large number of short-term assays for various genetic endpoints is available [43,177,485,253], and all regulatory agencies have specific testing recommendations or requirements, which may extend beyond the intent to predict potential carcinogenicity. For pharmaceuticals, a core battery

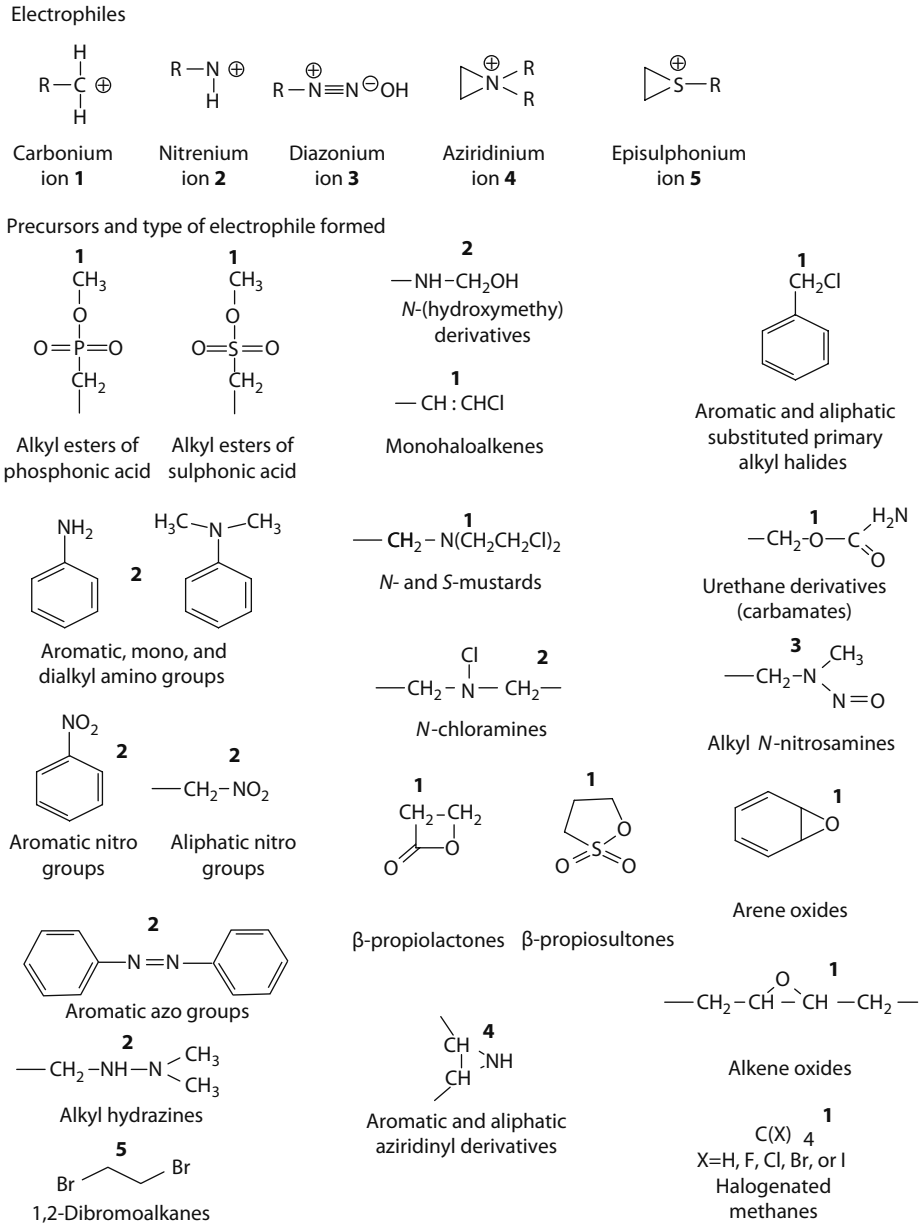

FIGURE 25.2 Structure of reactive electrophiles and precursors.

including both in vitro and in vivo assays has been agreed upon by the ICH [79,216]. For cosmetics, more extensive testing has been proposed in the EU [391], because animal testing of cosmetics was eliminated in 2009 [113]. Nevertheless, an expedited approach may still be possible [254]. These batteries generally include a bacterial mutagenicity assay (Ames), a mammalian cell mutagenicity/chromosome aberration assay, and an in vivo mutagenicity/chromosome aberration assay [252,43,216]. Each of these tests can yield false-positive and false-negative results in relation to carcinogenicity [253].

The predictivity of most genotoxicity assays (i.e., the percentage of positive chemicals that prove to be carcinogens) is limited largely to DNA-reactive carcinogens as a consequence of the fact that DNA alteration is the MOA of this class of carcinogen. Nevertheless, some assays, such as mammalian cell transformation, appear to respond to both DNA-reactive and epigenetic agents [269].

A bacterial mutagenicity assay [147] is required in all testing batteries and has reasonably high predictivity for carcinogenicity [43,519]. A substantial number of bacterial mutagens, however, are noncarcinogenic [251], for example, quercetin. Also, the NTP has found that certain in vivo effects, such as increased liver weight and hepatocellular hypertrophy (for both mice and rats) and hepatocellular necrosis (for mice), are better predictors for liver carcinogenesis than bacterial mutagenicity [9]. The ability of *Salmonella* mutagenicity to differentiate carcinogens is not increased by certain other standard in vitro assays, such as mammalian cell mutagenicity and chromosome aberration assays [137,519]. To reinforce

assurance of the predictiveness of a positive *Salmonella* mutagenicity finding in the DPA (Table 25.4, Stage B), another well-established assay, the hepatocyte/DNA repair synthesis assay [504], can be used. Positive results in the two assays in one substantial data set provided essentially perfect predictivity for the detection of DNA-reactive carcinogens [503]. Other assays for DNA damage include binding of radiolabeled TS, the alkaline single-cell gel electrophoresis (comet) assay [119], the nucleotide postlabeling (NPL) assay [366], and increases in the expression of DNA damage response genes [23]. The features of these assays have been reviewed [184]. The utility of hepatocytes is that they provide intrinsic bioactivation for both phase I and II metabolism. Also, hepatocytes from various species [295], including humans [296], can be used. Clear positive results in both of these assays, therefore, raise serious concerns for potential carcinogenicity. Other combinations of tests comprising the Ames and in vitro micronucleus tests have been found to be sufficient to detect rodent carcinogens and in vivo genotoxins [251].

Genetic toxicity studies unfortunately are not particularly informative for biopharmaceuticals because the large molecules are unlikely to enter the cells used in assays, particularly bacteria. Moreover, it is exceedingly improbable that such macromolecules would produce genetic effects. An issue with impurities is unlikely because chemical synthesis is not involved in most cases.

The FDA/CDER has issued a guidance for the integration of results from genetic toxicology studies [457]. If testing at this level, however, yields equivocal findings, in vivo assays for DNA reactivity can be used (see below).

In Vivo

In vivo genotoxicity assays are undertaken, as indicated in Table 25.4, at Stage D, if a suspicion of potential DNA reactivity for the TS has not been resolved by in vitro assays. Where possible, it is desirable to conduct these assays in rats, as most toxicity and pharmacokinetic studies will be performed in this species. Some assays included in recommended batteries, such as the bone marrow micronucleus assay [390], are not specific for DNA reactivity and assess only a single tissue, which in the case of bone marrow is of low chemical biotransformation capability. Moreover, systemic effects, such as hypothermia, hypoxia, and increased erythropoiesis, can yield positive findings [11,39,152,431]. DNA binding can be assessed if radiolabeled TS is available [278]; otherwise, assays for DNA damage, as mentioned earlier, that can be applied include the comet assay for DNA breakage [387], which is gaining acceptance [38], nucleotide postlabeling for adduct formation [355], and the in vivo/in vitro hepatocyte DNA repair assay [47]. Positive results in these DNA damage assays, if considered insufficient, direct the need for a radiolabeled chemical binding assay, which should include the demonstration of any adducted DNA base [387].

A model under development for in vivo detection of DNA damage uses avian eggs [352,511], which can also be used for the assessment of carcinogenic activity (see the following). An advantage of the in ovo model is that it employs an intact organism that is not a live animal and hence can be used for situations where use of animals is undesirable or precluded.

In addition to conventional in vivo mutagenicity assays, such as the bone marrow micronucleus assay and the bone marrow chromosome aberration assay, other models for in vivo mutagenicity include transgenic animals such as the Muta™ Mouse and Big Blue® transgenic constructs [43,309,514]. These latter assays allow for the detection of mutations in various tissues and can provide information on the molecular nature of induced mutations.

Assays for Epigenetic Effects (Stage C)

Histopathological findings in standard toxicity assays can indicate potential carcinogenicity. For example, liver enlargement is associated with a probability of liver carcinogenicity [9,54]. Specific assays for epigenetic effects (Table 25.4) are applied selectively depending on the properties of the chemical (i.e., structure, biologic/pharmacologic action, and toxicity). These assays provide evidence for an epigenetic mechanism that could result in an increase in neoplasms in rodents with long-term dosing. Many can be conducted in cultured cells, particularly hepatocytes, which provide intrinsic bioactivation. Even when applied in vivo, the experiments are of short duration, except for assays for promoting activity, the detection of which is described further in the Limited Carcinogenicity Bioassays section. Positive results indicate potential oncogenicity, in which case the potency relative to that of established carcinogens with a similar mechanism and organotropism provides a guide to hazard assessment. A particularly valuable endpoint to monitor is cell proliferation, because many nonspecific alterations in proliferation can lead to an enhancement of neoplasia [48,62].

Technologies are available for screening for effects on gene expression and function, including assays for RNA (genomics) and protein (proteomics) levels [1,18,43,91,248]. The increased expression of specific genes, such as hepatic acyl-CoA oxidase (increased by peroxisome proliferator–activated receptor-alpha (PPARα) liver carcinogens) or hepatic cytochrome P450s (increased by a variety of liver neoplasm promoters), is linked to epigenetic carcinogenesis, and thus these methods have utility for screening.

Limited Carcinogenicity Bioassays (Stage D)

Limited carcinogenicity bioassays (LCBs) are based on either neoplasms or established preneoplastic lesions as their endpoint [104,106,490]. These can be applied as IN assays, in which the TS is tested for its ability to induce the endpoint lesion, or as PM assays, in which the TS is administered after an agent that induces the endpoint lesion to determine the ability of the TS to enhance development of the lesion [423].

Neoplastic Initiation (IN)/Promotion (PM)

In early experimental studies of IN of skin carcinogenesis, IN was achieved with a single administration. Although this is possible with potent DNA-reactive agents, repeated exposure is

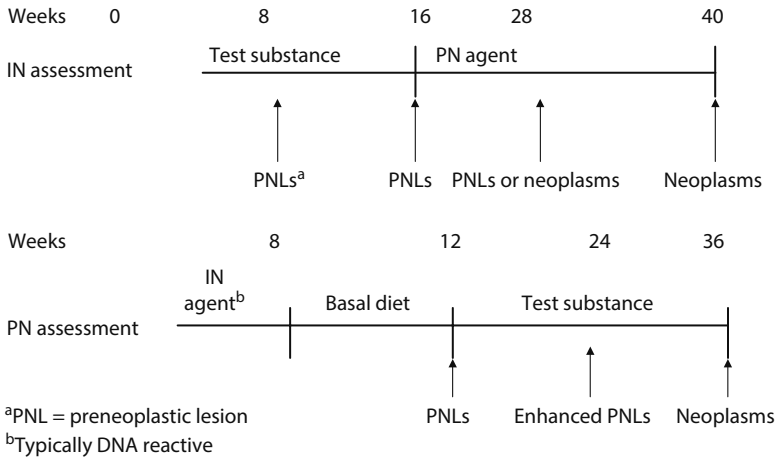

FIGURE 25.3 Limited bioassays for initiation and promotion in rodent liver.

required for an adequate assessment of IN by a TS. Because PM requires an even longer time for expression, more extensive dosing, up to 6 months, is required for an adequate test. Essentially, an assay for IN activity is directed largely toward assessing potential in vivo genotoxicity of the TS, whereas the assay for PM activity assesses an epigenetic MOA. Accordingly, assays for PM activity can also be deployed in the DPA at Stage C in vivo assays for epigenetic effects (Table 25.4).

An outline for IN and PM assays is shown in Figure 25.3. The most extensively validated and used model for an LCB is the rat liver hepatocellular focus assay [95,104,106,397]. This assay in the liver takes advantage of the extensive capability of chemical biotransformation in this organ and the availability of sensitive and reliable markers for preneoplastic lesions. Other commonly used LCBs are the mouse skin papilloma/carcinoma, the mouse lung adenoma/carcinoma, and the rat mammary gland adenoma/carcinoma assays [104,106,476]. These have advantages for specific types of chemicals, for example, mouse skin is very responsive to polycyclic aromatic hydrocarbons and is appropriate for the assessment of topical products.

Positive findings for IN are highly indicative of potential carcinogenic activity [208]. In fact, it has been calculated that an IN/PM assay (of 40-week duration) can be as sensitive as the 2-year chronic bioassay in detecting carcinogenic activity [510]. PM activity also suggests a likelihood of carcinogenic activity [208]. In either case, it is possible to establish dose–effect data and no-effect levels (NELs) for the design of chronic bioassays or risk assessment.

Transgenic Mice

Another type of LCB, increasingly in use, employs transgenic mice [114,279] in which the principal genetic targets in the transgene are specific oncogenes (H-ras model), tumor suppressor genes (p53 model), or the entire genome in DNA-repair deficient animals ($XPA^{-/-}$ deficient model). Four models that have received the greatest attention are the p53 heterozygous mouse ($p53^{+/-}$), the Tg.AC mouse, the CB6F1-Tg ras H2 mouse, and the $XPA^{-/-}$ mouse. Other models, such as Min, p53/XPC double mutant, Eμ-pim-1, and ARF-deficient, have shown responsiveness to carcinogens but have not been adopted for regulatory studies [114]. The studied transgenic models have responded appropriately to a number of carcinogenic and noncarcinogenic agents [219]; they have been introduced as alternatives to the RCB in mice and accepted as providing evidence of carcinogenicity [208,279].

Three of the commonly used models are based on alterations in genes that are relevant to gene changes in many human and rodent neoplasms (e.g., the p53 tumor suppressor gene and the H-ras oncogene), while the $XPA^{-/-}$ model provides an enhanced response to DNA damage as a consequence of the elimination of nucleotide excision repair. Each model has specific features. Mice heterozygous for p53 differ in response depending on the strains used as parents; for example, the C57BL mouse, which is the most widely used [94], has a low incidence of background liver cell neoplasms, whereas liver neoplasms in unexposed controls are more frequent in C3H mice. The Tg.AC model carries a v-Ha-ras oncogene fused to the promoter of ζ-globin gene in the FVB/N mouse strain [270], a strain not commonly used in toxicology and which is susceptible to audiogenic seizure. The Tg ras H2 mouse carries five to six copies of human c-H-ras gene integrated in tandem array in the genome of F1 mice of transgenic male C57BL/6J mice and normal female BALB/cByJ mice [381]. The C57BL/6J is not very susceptible to hepatocarcinogenesis or lung carcinogenesis, whereas the BALB/c is susceptible to lung carcinogenesis [345]. Currently, the $p53^{+/-}$ and Tg.AC mice are widely available, but the Tg ras H2 is less accessible outside Japan, where it was developed.

Although any route of exposure can be used with these models, most data have been obtained by the oral route for the $p53^{+/-}$ and Tg ras H2 assays, whereas topical application is the preferred route for the Tg.AC. In these models, neoplasms can be elicited within 6 months with few or no neoplasms in controls. Beyond 6 months, these animals begin to develop a high incidence of genetically determined neoplasms as follows: the $p53^{+/-}$ with a C57BL parent develops lymphomas and sarcomas [282]; the Tg.AC develops odontogenic tumors, erythrocytic leukemia, and salivary gland and ovarian neoplasms [281,282]; and the H-ras2

develops benign and malignant lung neoplasms, splenic hemangiosarcomas, and forestomach papillomas [381]. The evaluation of increases in any of these neoplasm types must consider whether the increase is attributable to induction of neoplasia as opposed to acceleration of neoplastic development. The XPA-deficient mice do not show appreciably increased incidences of background neoplasms (only some liver neoplasms in the C3H-derived strain) [90,466]. All of these models respond primarily to DNA-reactive carcinogens, although the Tg.AC model has the potential to identify epigenetic skin carcinogens [93,279,407], and the Tg ras H2 has also responded to epigenetic carcinogens [279,518].

The $p53^{+/-}$ mouse, in the studies available so far, clearly responds with accelerated development of thymic lymphomas (e.g., phenolphthalein, cyclophosphamide, and melphalan [219]), but compared to the wild-type background, it has not exhibited an accelerated response to DNA-reactive carcinogens targeting liver (diethylnitrosamine) [244], mammary gland (9,12-dimethylbenz(*a*) anthracene), colon (1,2-dimethylhydrazine), or lung (urethane) [244,345]. This may reflect the fact that p53 mutation is not an early event in murine carcinogenesis for some tissues. Also, this model has, on occasion, failed to respond to the positive control *p*-cresidine [219,279,409]. Among candidate pharmaceuticals for which the FDA/CDER has received bioassay data, 0 of 23 yielded positive results, although some were oncogenic in rats [225]; thus, the usefulness of the p53 model for chemical screening seems questionable. In the Tg.AC model, the positive control generally used is the skin tumor promoter 12-*O*-tetradecanoylphorbol-13-acetate [219,279]. The fact that this chemical by itself elicits skin tumors in the Tg.AC mouse demonstrates the hypersensitivity of this model. A number of innocuous materials have been positive in the Tg.AC, strongly indicating that it should be avoided where possible. For all of these models, evaluation may be enhanced by the measurement of cell proliferation in critical target organs. In the case of Tg.AC, stimulated cell proliferation can be the basis for skin neoplasm enhancement.

Currently, the Tg ras H2 model seems the most promising model [310,324] and is favored by regulatory guidelines [129]. A critical aspect of application is the demonstration of assay sensitivity. An appropriate selection of the positive control is paramount, and it may be advantageous for a convincing demonstration of a relevant sensitivity to consider the use of a nongenotoxic positive control, for example, a $PPAR_{\alpha}$ agonist. A sufficiently high exposure of the animals should be demonstrated. For pharmaceuticals, the 25-fold AUC is a well-defined and accepted upper limit for the dose selection (see RCB dose selection). A positive result in any transgenic model will be usually accepted as evidence for a carcinogenic potential. Important is that a negative Tg ras H2 has been accepted by the EMA as a substitute for the long-term mouse carcinogenicity assay. Experience so far has been limited as only a minority of applications for marketing authorization has included a transgenic assay in the last few years.

Other Models

The newborn mouse is also used in LCB [122]. In this model, newborn mice of any strain are administered the TS by intraperitoneal injection or oral intubation at days 8 and 15 after birth and then held for observation for up to 1 year of age. The model exhibits high sensitivity to DNA-reactive carcinogens but is unlikely to respond to epigenetic agents because of the limited exposure that is provided.

Another model under development is the In Ovo Carcinogenicity Assessing Assay (IOCA) using turkey or chicken eggs in which effects in the embryo–fetus are assessed [41,105–109,493,511]. TS is injected into the egg, either single or repeated, and the fetuses are harvested prior to hatching for histopathological examination of the liver for preneoplastic/neoplastic-like lesions. The key histopathological features are the foci and nodules of altered hepatocytes, which have the phenotype of carcinogen-induced lesions in rodent liver [107,108,493]. An interlaboratory validation of this assay has been completed [105]. This assay is very effective in monitoring the processes of proliferation, differentiation, apoptosis, DNA damage assessment [352,511], and developmental effects [493]. It also has the advantage of being defined as a nonanimal method for carcinogenicity testing. In addition, one of the added features of IOCA is that the organisms are bacteria-free, thus excluding the factor of bacterial flora, which is present in all organs of an adult organism and which is different and more numerous in rats and mice compared to humans.

Accelerated Cancer Bioassay (Stage E)

The accelerated cancer bioassay (ACB) model can be used to develop data on carcinogenicity when there is not a requirement for an RCB or there is an urgent need to obtain data [80,492]. It also can be used as an alternative RCB for one species. The ACB is essentially a composite of six or more IN/PM LCBs for rodent organs in which carcinogenicity has been found for known human carcinogens (i.e., liver, lung, kidney, urinary bladder, stomach, hematolymphoreticular tissue (HLR), and mammary gland). The protocol involves two segments: one in which the TS is administered at an appropriate high dose (see Dose Selection Studies for Bioassay section) for 16 weeks in an IN segment followed by promoters for the relevant target organs, and a second part in which the TS is administered in a PM segment for 24 weeks after an administration of initiating agents for the target organs (Table 25.5). The TS is also given alone for 40 weeks to assess carcinogenicity.

A rat model involving partial hepatectomy and administration of the liver carcinogen 2-acetylaminofluorene to enhance liver carcinogenicity has also been developed [224]. The use of these adjuncts, however, requires extra effort, limits the doses that can be tested, and is potentially confounding.

The ACB has a number of advantages: (1) it takes less time than the RCB, as the name implies; (2) it provides mechanistic data on IN/PM; and (3) the animals exhibit much less

TABLE 25.5
Accelerated Carcinogenicity Bioassay

Initiation Segment (IN)			Promotion Segment (PM)		
Control	16 weeks		Control	24 weeks	
TS	16 weeks		Promoter	24 weeks	
				Liver	PB
				Kidney	NTA
				Bladder	NTA
				Stomach	BHA

TS	16 weeks		TS	24 weeks	

Note: AZT, azathioprine; BHA, butylated hydroxyanisole; BHBN, *N*-butyl-*N*(4-hydroxybutyl)nitrosamine; BHT, butylated hydroxytoluene; DEN, diethyl-nitrosamine; DES, diethylstilbestrol; DMBA, 7,12-dimethylbenz(*a*)anthracene; DMN, dimethylnitrosamine; EHEN, *N*-ethylhydroxy-ethylnitrosamine; HLR, hematolymphoreticular tissue; MNU, methylnitrosourea; NTA, nitrilotriacetic acid; PB, phenobarbital; TS, test substance.

age-related pathology at termination since they are less than 1 year of age at the end of the study and background rodent neoplasms occur predominately after 50 weeks (Table 25.6) [404]. The chief limitation is that the ACB is not as comprehensive as the RCB, although it has been calculated that, because of the PM stimulus of tumor development, the IN/PM model is as sensitive as a chronic bioassay [496,510]. Moreover, the ACB, with the addition of bone marrow, interrogates all target tissues affected in rodents by human DNA-reactive carcinogens (Table 25.5).

RODENT CANCER BIOASSAY (STAGE E)

Usually, rats and mice are required, although other species may be used (as discussed in the Animals and Their Environment section). For pharmaceuticals, the value of a mouse RCB has been questioned [465]; nevertheless, a mouse RCB would be indicated when (1) the biological effect of the chemical is expressed in mice, but not in rats, (2) the chemical has a pharmacologic effect on the gall bladder (absent in rats), or (3) mice are more representative of human toxicokinetics [225]. RCB are discussed in the Limited Carcinogenicity Bioassays section above.

In the EU, a comprehensive evaluation of carcinogenicity studies of medicinal products has been compiled for the years 1995–2009 [129]. Due to the high number of rodent tumor findings with unlikely relevance for humans, the value of the currently used testing strategy for carcinogenicity assessment appears questionable. Reconsideration of the carcinogenicity testing paradigm is warranted.

[a] Values reflect percent of total at the two arbitrary intervals (i.e., before and after 50 weeks).

[b] NA, not analyzed either because inappropriate or not common neoplasms.

The RCB was developed for the testing of small molecules, but is also being used to test large biological molecules. Such biomolecules were introduced into medicine beginning with vaccines and now also include hormones, oligodeoxynucleotides, genes, recombinant human proteins, humanized monoclonal antibodies, blood products, and cellular therapies. Each of these molecules presents specific issues in the conduct of an RCB. The ICH has produced a framework for preclinical safety evaluation of biotechnology-derived pharmaceuticals [217,395,452]. The limitations of genetic toxicity testing are discussed above.

Customized approaches are usually required for chronic preclinical safety assessment of biotechnology-derived pharmaceuticals and genetically engineered food products [452]. Some of these products are intended for intravenous administration, which is a challenging route of administration for an RCB. Immunogenicity presents an additional complication with proteins, because the development of neutralizing antibodies can abolish the biological activity of the protein, and the chronic antigenic stimulation can compromise carcinogenicity testing. Guidances concerning the design of carcinogenicity studies are generally based on the clinical indication or in-use exposure. Exceptionally, with these products, the possibility arises of using relevant but nontraditional species or using an animal model of the target disease [395]. Any testing should, of course, be done in a species in which the molecule has biological activity. For an immunogenic protein, one solution to this problem may be to test a homologous rodent molecule in the corresponding tolerant species.

Design

Most RCBs are performed to meet regulatory requirements, as listed in Table 25.1; otherwise, there are more efficient approaches to carcinogen identification (as discussed in the earlier Systematic Approach to Testing section). An RCB performed for regulatory requirements must follow prescribed guidelines [111,118,214,448,452] and, in particular, the regulations for good laboratory practices (GLPs; described below). Detailed descriptions of standard procedures for an RCB with chemicals have been published [298,476,495]. Aspects of the design, conduct, analysis, evaluation, reporting, and interpretation are given later.

Lifestage and Duration

Experimental transplacental carcinogenesis has been extensively studied, mainly in rats and mice [421] but also in primates [373,418]. The design of experiments ranges from dosing during embryogenesis or fetal or neonatal development [6,421] to multigenerational, involving exposure of germ cells of one or both parents and subsequently the progeny. These approaches are based on the well-established fact that younger animals because of greater rates of cell proliferation can be more sensitive to carcinogens [292,372]. It has frequently been considered whether exposures during pregnancy and lactation should be included in a routine RCB [403,421], but so far it is accepted that a conventional RCB can identify carcinogens that might have activity in developmental stages [45,177]. Thus, the approximate start of the RCB is usually around 6 weeks of age [176].

The anticipated life span for commonly used strains of rats is 24–30 months and 18–24 months for mice. The usual duration for both rat and mouse RCB is 24 months, although for a mouse RCB, 18 months can be acceptable if the strain does not have a sufficiently high survival for 24 months [67]. Some studies have been conducted with lifetime administration in which animals are allowed to die spontaneously [403]. Such a procedure, however, presents problems such as imbalances in the survival of groups and potential impairment of the quality of pathology due to postmortem autolysis.

Dosing should start shortly after weaning at about 4–6 weeks of age and should be daily. Test groups are not allowed to live longer than control groups; otherwise, late-developing background neoplasms in these groups could appear to be induced. If a high-dose group experiences high mortality (greater than 50%) due to TS administration, it should be terminated; the other test groups and controls should continue until 24 months are completed. In general, survival should not be less than 50% for mice at 15 months and rats at 18 months or 25% for mice at 18 months and rats at 24 months [67].

Feeding Procedures

During the past 20 years, increased variability in body weights, survival, and incidences of background neoplasms in Sprague–Dawley, Wistar, and F344 strain rats and CD-1 and $B6C3F_1$ mice have been observed [5,28,59,100,242,360, 369,413,414,430,470]. The changes in these parameters can confound and even jeopardize the interpretation of an RCB [28,100,240,242,322,367,394,413,414,419].

Most RCB are conducted using ad libitum (AL) feeding. To overcome the problem of overeating with AL feeding, two solutions have been proposed [59,242,322,419]. One is referred to as the caloric optimization diet (COD), which consists of limiting caloric intakes to 50%–80% of AL consumption [59,163]. The other is the diet-restricted (DR) model in which animals are fed diets limited in the offered quantity of feed sufficient to produce a 15% reduction in body weight compared to the AL controls [2,164,322]. In addition to these procedures, the use of weight-matched groups that are fed in such a way that their mean body weight is matched with that of the high-exposure AL group has been evaluated [2,322] but is not currently being used. The COD and DR procedures clearly improve the health and survival of animals, as they reduce the occurrence of age-related pathology, such as chronic progressive nephropathy and myocardiopathy in rats [175,197], and of certain background neoplasms [19,175], such as uterine polyps, pituitary gland neoplasms, and mononuclear cell leukemia (MCL; see Species and Strain section) [40,175].

In the past, dietary control was routinely used in the testing of oral contraceptives [234]. Proposals have been made for the use of dietary control for all medicinal and chemical products [5]. Differences in the incidences of neoplasias

between AL-fed and DR rodents are available for the two commonly used rat strains, Sprague–Dawley and F344, and the B6C3F$_1$ hybrid mouse [34,40,59,174,175,293,322,411,430]. In both rats and mice, especially the latter, hepatocellular neoplasia in both sexes is reduced in DR groups. Similarly, reductions in pancreatic (both acinar and islet) neoplasia (especially in male rats), pituitary neoplasia (especially in female rats), and adrenomedullary neoplasia (especially in male Sprague–Dawley rats) were achieved in both species. In general, these decreases in DR groups are due to changes in the metabolism and hormonal homeostasis. In addition, certain tumor decreases in the DR groups are present only in one species (skin fibroma in rats), one strain (thyroid C-cell, mammary gland, ovarian, and hematopoietic neoplasms in F344 rats), or one sex (pulmonary neoplasia in male mice). Also in female F344 rats, uterine polyps and pituitary gland neoplasia have been significantly reduced in feed studies with NTP-2000 diet [175], which was developed to reduce the background pathology, particularly renal, in rats. The mechanism of these decreases is not fully understood. Available information, however, on the impact of either COD or DR on response to well-studied carcinogens generally reveals a reduced response. Accordingly, detection of carcinogenic effects may be masked at sites sensitive to tumor reduction by body weight gain inhibition. Analyzing tumor incidences within body weight strata can reduce bias introduced by weight differences (see Statistical Analyses section).

Groups and Identification

After acclimatization in the test facility, animals should be assigned to groups using randomization procedures immediately prior to study initiation. Randomization eliminates bias, but if there is another source of variation, such as sex, cage position, or order of euthanasia at termination, then a stratified randomization is more appropriate. This involves separate randomization within each level of stratifying variable, such as body weight or cage position [271].

The use of two independent control groups helps to assess biological variability in incidences of commonly occurring background neoplasms [14,170]. The minimum group size is 50, which permits detection of neoplasms with incidences in the range of 5%–10%. Larger groups, if indicated by 3 month results, can be useful in allowing interim (12- or 16-month) terminations. Such information is not otherwise available when no unscheduled deaths occur due to neoplasms [135,271,404] (Table 25.6). To monitor for intercurrent diseases (see Animals and Their Environment section), a satellite group of six or nine can be used.

The groups should consist of a high-dose group (see Dose Selection Studies for Bioassay section) and at least two lower doses. Many testing laboratories, including the NTP, use only two groups with the low-dose group at half the high dose to provide sufficiently dosed animals in the event that the high dose impairs adequate long-term survival. Others space doses by one-third or one-fourth. The factor between doses should not exceed 5. Because mainly TS that are not DNA-reactive advance to an RCB, a valuable third group is one at the NEL for any epigenetic effect identified at higher doses that may lead to oncogenesis. This NEL should yield a cancer NEL, which is valuable for risk assessment. If quantitative risk assessment is envisioned, four or more dose levels will be needed to establish the shape of the dose–effect curve.

Cages must be identified with study information including study number and animal numbers. Animals must be individually identified. This can be done by tattoo or by implantation of an electronic transponder. The latter is not advisable for transgenic mice, as subcutaneous sarcomas have been induced [26].

GOOD LABORATORY PRACTICE

As regards the RCB, the main intent of GLPs is maintaining the integrity of a complex system of data management. This requires that the study be designed, conducted, evaluated, and reported according to standard operating procedures (SOPs) and that records are maintained in a manner that ensures a comprehensive and independent review. GLP must be conducted in such a way that all data can be validated. GLP is a global process that has been implemented by several national bodies [214,341,438,446]. The elements were detailed in the previous version of this chapter [126] and have been recently addressed [177].

In a GLP study, the study director plays the critical roles of moderator, catalyst, and gatekeeper and is responsible for the integrity of study data. For more details, see Williams et al., 2008 [126].

All raw data must be properly identified and stored, eventually in study notebooks that ensure the integrity of the data. All data must be entered in a permanent and legible manner. Any changes to data must be dated and identified as changes, with reasons noted for any change, as well as the identification of the scientist making the change. Further, the professionals responsible for data entry, verification, and review should also be identified. Finally, documentation of the data so described must be maintained at all times, and secure audit trails must be created for authorized changes in the database and also in the study notebook [438]. In histopathology, the most important study materials are the tissues on glass slides and their respective blocks, which require a specific trail leading from sampling records during necropsy and trimming records after necropsy [32,76,446].

To obtain proper material for pathology, tissues are prepared according to standardized procedures with respect to location, type of section (e.g., cross), and orientation on the slide. In addition, slides of lesions should include both lesion and surrounding normal tissue. Any failure to adhere to this regimen is a form of censorship and results in noncompliance. It is of paramount importance to integrate clinical (cage-side observation), structural (macroscopic and microscopic), and functional (cellular and biochemical) data. Failure to integrate these three types of data will result in compromise of data and loss of data integrity. The pathologist must keep the

study director apprised of events as they occur. The responsibilities of the study pathologist include keeping account of all the lesions reported at necropsy and performing microscopic evaluation of the normal and abnormal tissue changes. In this way, the pathologist ensures that appropriate tissues are collected, processed, and evaluated in a manner that satisfies the objective of the study. Finally, the pathologist ensures consistency in diagnosis, integration of data, and grading of pertinent lesions, avoiding diagnostic drifts and censorship. For a facility to be GLP compliant, specified environmental conditions (see the Animals and Their Environment section) must be maintained and monitored by a program applied at appropriate intervals.

The final regulatory end product for every study is the compliance statement, which is provided in the final report and signed by the study director. In this section of the report, all modifications, deviations, and amendments to the protocol are listed. A second page with a quality assurance statement is signed by the quality assurance auditor. During the last 33 years of GLP implementation, several common findings of importance (i.e., deficiencies listed in form FD-483) have been compiled by various agencies. The deficiencies noted were in all subparts of the FDA regulations (subparts A–J, 58.10–58.190). Those pertaining to pathology are detailed in the Anatomic Pathology section.

HEALTH AND SAFETY PROCEDURES

A comprehensive, rigorously followed health and safety plan is necessary for the proper conduct of an RCB. The fact that a substance is being tested for carcinogenic activity makes it, in effect, a suspect carcinogen, although information in the Material Safety Data Sheet, such as genotoxicity or reproductive toxicity, influences the stringency of the handling procedures instituted, from receipt of the chemical through disposal of animal waste and processing of tissues for histopathological examination. All measures are subject to quality control.

The safety plan [317,337] must address the responsibility within management for the development and adherence of the plan; medical surveillance for employees; employee training; safe handling practices for the chemical; animal handling; general laboratory safety; safe personnel practices; safe work area practices (e.g., spill control and decontamination); handling of air, liquid, and solid wastes; monitoring of workers and physical equipment; emergency control; recordkeeping; design of facilities; and pollution potential. Applicable regulations of the U.S. Occupational Safety and Health Administration (OSHA) provide only a minimum structure from which to work, and lessening of the hazard within the particular facility must be addressed individually and with ingenuity. Laboratory directors must appreciate that chemicals, especially highly volatile ones, may penetrate protective clothing and travel a considerable distance from their point of use [336,383–385,441,443]. Indeed, the finding of TS in the blood of control animals [329] testifies to migration.

No safety measure is unique to an RCB; it is the degree of adherence to such procedures that distinguishes the conduct of these studies from all others. It is beyond the scope of this section to address each individually. A few examples of aspects that are often inadequately addressed include the following: (1) use of a properly ventilated cage dumping area or an enclosed animal bedding disposal cabinet to prevent the inhalation of contaminated dust and aerosols by employees; (2) an air-handling system that provides decreasing gradations of air pressure from clean corridor to the animal rooms to the dirty corridor and that is periodically tested under such stress as several doors being opened at one time or with all possible chemical hoods in operation; (3) maintenance personnel, as well as scientific supervisors, following the same rules as technicians for personal protection; (4) storage facilities that protect the integrity of the TS over extended periods of time during which unused material may be held and the immediate containers checked for deterioration; (5) a breathable air line available for use with an air-supplied respirator in the TS preparation areas; and (6) workers, including weekend staff, who are familiar with emergency safety instructions within the laboratory and know whom to notify in the event of various types of potential emergency situations.

ANIMALS AND THEIR ENVIRONMENT

The use of animals in research is subject to national regulations. In the United States, the use of rats and mice is not regulated, but usually follows the guidelines for other animal use that have been provided by the U.S. Department of Health and Welfare for Care and Use of Laboratory Animals [317,318,436], the latest amendment of the U.S. Congress Animal Welfare Act [432], the U.S. Public Health Service Policy of Humane Care and Use of Laboratory Animals [318], the U.S. Department of Agriculture Animal Welfare Rules [435], the Animal Welfare Act of the National Research Council [321], and the U.S. EPA Health Effects Test Guidelines [444]. Institutional responsibilities include making available all protocols for review by a committee and providing veterinary care. More extensive coverage is provided in Chapter 20.

Species and Strain (Genotype)

In the past, large animals have been used in carcinogenicity studies for specific purposes; for example, dogs were used for the testing of aromatic amines, whose effects in the dog bladder have been shown to be related to frequency of urination [235]. Hamsters have also been used as a second rodent species when either rat or mouse exhibits high nonrelevant effects, for example, nasal toxicity [231].

For the rat RCB, several strains have been widely used. The NTP generally uses the inbred F344, although this is under evaluation [250], while the pharmaceutical and chemical industries have favored the outbred Sprague–Dawley or Wistar to obtain genetic diversity. For the mouse RCB, industry generally favors the CD-1 strain, whereas the NTP uses

the $B6C3F_1$ hybrid, which is a first-generation cross between male C3H and female C57BL/6 strains, for the purpose of reducing the high spontaneous liver neoplasm development of the C3H.

Both rat and mouse strains, including hybrids, differ substantially in their background of neoplasms and their susceptibility to the induction of tumors [60], for example, the F344 has very high incidences of several neoplasms, notably testicular (Table 25.7). Among mouse strains, those derived from the C3H (i.e., $B6C3F_1$) have high incidences of liver tumors. The A/J mouse has a high lung tumor incidence, which is taken advantage of in limited cancer bioassays. The comparative percent incidences of the principal spontaneous neoplasms from five different strains of rats and mice are given in Table 25.7.

Several factors that influence response to carcinogens differ among genotypes. Notably, biotransformation activities for certain chemicals differ considerably. In addition, sex-dependent differences in xenobiotic biotransformation are most pronounced in rats. The differences involve mainly cytochromes P450 (CYP), sulfotransferases, glutathione transferases, and glucuronyltransferases [311,312,325]. Thus, it is critical that strains used are obtained from providers that follow procedures designed to minimize genetic drift in the founding colony [177].

A troublesome feature of the F344 rat and $B6C3F_1$ mouse is that their average survival has progressively decreased, and increases have occurred in the incidences of liver neoplasms in female and male mice; pituitary neoplasms in female mice; thyroid neoplasms, adrenal pheochromocytomas, and leukemias in male rats; and mammary neoplasms in female rats [368,428]. Some of these neoplasm increases are positively correlated with excessive body weight [428] resulting from overeating (a detailed discussion of this issue was presented earlier in the Feeding Procedures section). Likewise, in Charles River Sprague–Dawley rats, decreases in survival have been reported [241,242]. These changes may be due to breeding practices. Currently, the Wistar strain does not appear to present this problem [360].

The species and strains selected in combination should achieve exposure to all known human metabolites.

Feed and Water

Four major types of diets are available: (1) natural-product, unrefined, largely cereal-based formulations usually referred to as *chow-type* diets, such as NIH-07 (Purina 5018 or Purina 5001); (2) semipurified diets, formulated from refined nutrient ingredients, such as AIN76A (with sucrose) or modified AIN76A (with dextrose); (3) open-formula diets, such as NIH-31 (Purina 7017), which are formulated to contain researcher-specified quantities of nonproprietary ingredients; and (4) chemical-defined diets, which are individually specialized [258,321]. Industry generally favors the open-formula diet. In 2000, the NTP introduced the NTP-2000 diet, which was developed to reduce the background tumor burden [175]. Interestingly, the natural unrefined diet is reported to protect against the effects of several chemical carcinogens [328]. Details about various regimens of feed availability were given earlier in the Feeding Procedures section. Finally, the drinking water, which is usually municipal tap water, should be periodically monitored for microbiological and chemical contaminants.

Caging and Stratification

During the planning stage, the possibility of cross contamination of control groups [329], especially when the administered chemicals are volatile, should be anticipated. Once established in preliminary pilot toxicokinetic (TK) studies, then steps can be taken to address the issue as indicated later.

Following randomization, animals can be caged individually or with more than one animal in each cage; each approach has advantages and disadvantages. Individually caged animals tend to overeat. Multiple animal caging leads to a conflict for hierarchy in the cage and consequent cage differences. Group-caged female mice develop pseudopregnancy, which results in uterine decidual reactions, whereas wounding as a result of fighting is common in group-housed male mice. Also, group caging of mice produces almost a doubling of the lymphoma incidence in both males and females [417]. In general, group-caged rodents demonstrate higher survival rates and lower background pathology [376]. For inhalation and dermal administration studies, single housing is required. Cages used can be either metal (stainless or galvanized steel) or plastic (polycarbonate, polyethylene, or polypropylene), with a minimum stipulated cage size [436]. The floor of the cages can either be solid or wire bottom for a suspension rack. Solid-floor cages require bedding that does not have the enzyme-induction properties of, for example, hardwood bedding [468]. A problem with wire-bottom cages is foot injury. The tops of cages should be protected from airborne contaminants [479] at least by providing a microisolator filter cover. Cages and racks should be rotated periodically to balance known confounding sources of variability such as proximity to fluorescent lights [266,371]. Consequently, rodents within groups should be distributed in cage racks in such a way as to be present equally at all vertical levels of cage placement. A thorough documentation of such cage and rack rotation is mandated.

All groups should be housed in the same room to avoid nonuniform environmental influences [479].

Environment and Emergency Power

Environmental stress experienced by test animals must be minimized, particularly with mice, which are easily stressed even when maintained under conventional housing conditions and handled in the usual manner. The incidence of tumors in mice infected with viruses can be increased by chronic stress [375,393]. Standards for care are detailed in the *Guide for the Care and Use of Laboratory Animals* [321]. These include (1) 10–15 fresh air changes per hour occur in each animal room; (2) air pressure maintenance so the animal rooms are slightly

TABLE 25.7
Comparative Percent Incidence of Pertinent Neoplasia in Strains of Rats and Mice (104-Weeks Old) Used in Bioassays

positive to the *dirty* corridor and negative to the *clean* one, with minimal crossovers between the corridors; (3) adequate air filtration before it enters the animal facility and dilution or filtration after it leaves to prevent possibly toxic concentrations of the TS from entering the outside air (a process that is particularly important with inhalation studies because of the large amounts of chemical used); (4) temperature and humidity control within those ranges reported to be optimal (i.e., 23.3°C ± 1.1°C or 74°F ± 2°F) and a relative humidity of 40% ± 5% in rat and mouse rooms; and (5) automatic control systems to record both temperature and humidity at least three or four times per day. Control of lighting is essential. Usually, a 12 h continuous light interval per day is used for both rats and mice (14 h light day for hamsters). Moreover, 4 h of high-intensity light (only during cage-side observation) and 20 h of low-intensity fluorescent light are recommended to avoid blindness caused by high-intensity light. In addition, because the light and temperature gradients occur vertically, a cage-rack rotation is mandated [321]. In specific situations such as with dietary administration of TS, consideration should be given to a reversed light cycle, when blood for achieved blood levels needs to be obtained during the dark cycle when animals are awake and feeding.

An emergency power source is essential to maintain the operation of storage freezers and refrigerators, lighting, autotechnicons, and some degree of air conditioning, as well as air handling, during power failure or when personnel are unable to reach the facility. The emergency power and alarm systems should be tested on a regular schedule. In a GLP-compliant facility, all these conditions must be monitored.

Also important is control of pests by adequate facility design and sanitary procedures. Pesticides must not be allowed to contaminate the animal rooms, feed rooms, or cage washing areas and accordingly should be dispensed only in closed traps in limited areas. Detergents and cleaning agents for use on floors, cage washers, and other equipment must be nonvolatile and must not leave a residue.

The environment and welfare of animals can be enriched by providing wooden chew blocks.

DOSE SELECTION STUDIES FOR BIOASSAY

Dose Selection: The Maximum Tolerated Dose

Setting of the high dose can be based on a number of endpoints, including toxicity, toxicokinetics, saturation of absorption, and maximum feasible dose [125,214,215]. The various methods for the selection of the high-dose level have been reviewed by a working group on dose selection convened by the International Life Sciences Institute [125]. Generally, it is expected that the high-dose level in an RCB is a toxicity-based dose—the maximum tolerated dose (MTD) [406]—which is also referred to as the minimum toxic dose (or the minimally toxic dose by the NTP) [172]. Testing at the MTD ensures that potential carcinogenicity has been fully evaluated; nevertheless, it creates issues in the interpretation of positive findings, because of high-dose effects, as discussed below.

The first widely used definition of the MTD was formulated by the NCI [406] as follows: "The MTD is defined as the highest dose of the test agent during the chronic study that can be predicted not to alter the animals' normal longevity from effects other than carcinogenicity." This definition did not stipulate that any toxicity needed to be produced; hence, a slight, but significant, reformulation was introduced by the U.S. Interagency Staff Group on Carcinogens [320,449]: The MTD is "the highest dose which when given for the duration of the chronic study is just high enough to elicit signs of minimal toxicity without significantly altering animals' normal life span due to effects other than carcinogenicity." The MTD so defined is a dose used in the chronic study [10], which, of necessity, is selected from subchronic studies (normally 90-day studies). The ICH defines the MTD as the dose predicted from a range-finding study to produce minimum toxicity over the course of the carcinogenicity study [215,449]. Such a condition can be produced by alterations in physiological function that would be expected to alter survival, target organ toxicity, significant alterations in clinical pathological parameters, or no more than 10% suppression of weight gain relative to controls, calculated as the difference between the starting weights and those at the end of the study [320,449]. A fortuitously selected target MTD in the RCB should suppress weight gain by 10% or slightly greater and produce only minimal other toxicities. The ideal dose selection, however, infrequently happens, and issues arise when the high dose is either below or above what is considered by a regulatory agency to be an MTD.

TK endpoints have gained acceptance for dose setting for pharmaceuticals [128]. A dose that produces saturation of absorption is considered an MTD, and a dose that produces a plasma concentration that is 25 times greater than human exposure (a 25 to 1 exposure ratio) is considered pragmatic for TS with no genotoxicity signal [212,215,459]. When using this parameter, it needs to be determined whether among humans there are poor metabolizers who would achieve higher blood levels than the general population.

Toxicodynamic endpoints can be used to establish a high dose that will produce a cellular or tissue effect, beyond which the validity of the study would be compromised. An example is renal toxicity, which can become more severe with aging in rats as they develop chronic progressive nephropathy.

To identify the target MTD or high dose, subchronic studies are performed, as described below. If the target MTD (or the high dose) cannot be established using the criteria discussed, it is usually recommended that the high-dose level or limit dose not exceed 5% in the feed [199,299,340], which translates into approximately 3–4 g/kg/day for rats and 7–8 g/kg/day for mice. This limit is based in part on concern for the nutritional impact of high proportions of TS in the diet. Certainly, some TSs at high concentrations interfere with nutritional elements, such as impairment of vitamin K function by butylated hydroxytoluene [71,220], but such problems can be overcome by appropriate nutritional supplementation. Nevertheless, reduced food intake and, hence, caloric intake will affect the outcome of the RCB, usually reducing neoplasm incidence [2,59,255,322].

In the United States, the dose selection for pharmaceuticals should be submitted to the FDA/CDER and its Carcinogenicity Assessment Committee (CAC), which strongly favors a toxicity-based endpoint. Such consultation is not yet practiced in Europe, but the EMA, as well as several national authorities, offers various forms of scientific advice procedures. The selection of other dose levels is discussed in the Rodent Cancer Bioassay section above.

Subchronic Study

The MTD is usually identified from results of a 90-day study conducted in the species and strain selected for the RCB using the intended route of administration. It is unusual that the tested doses would exactly identify an MTD, so interpolation is usually made. When the two sexes show different toxicities, which is frequent, different sets of doses need to be administered in the RCB.

Chemical Disposition Studies

Before starting an RCB, it is helpful and, in the case of medicinal products, a requirement [128,212] to determine the time course of internal exposure to parent compound and metabolites and eventually the relationship between exposure and observed effects. The species/strain used for an RCB must provide coverage of known human metabolites. For this purpose, multiple-dose TK studies measuring both parent compound and metabolites are conducted [50,212]. Plasma protein binding of the TS in rodents and humans should be determined before the initiation of carcinogenicity studies. Should binding exceed 80%, it is advisable to express exposure (plasma TS concentration) in terms of the free fraction [56,347]. In addition, tissue distribution and accumulation data can be valuable [55,362], especially because species differ in their proportion and composition of certain tissues. For example, the liver represents 4.8% of the body weight of a rat, whereas it is only 2.8% of the body weight of a human [191]. Conversely, adipose tissue is only 11% of the body weight of a nonobese rat [143], whereas it can be over 20% of the body weight of a human [191]. Furthermore, appropriate and useful extrapolation from rodents to humans involves understanding of physiologic (Table 25.8), histokinetic, and xenodynamic considerations [57], for example, smaller species (e.g., rodents) have higher rates of xenobiotic biotransformation

TABLE 25.8
Species Physiologic Differences Important in Carcinogenicity

	Species		
Parameter	**Rat**	**Mouse**	**Human**
Life span (years)	2.5	2	70

[a] Human xenobiotic exposure of 1 month (or 0.1% of the life span) is 4.1% of the life span of rats and 5.5% of the life span of mice.

[b] Calculated ratio based on organ volume (mL) and organ plasma flow rate (mL/min).

per unit of body weight, faster rates of tissue distribution, and shorter tissue half-lives [191,194]. Tissue volume directly affects the volume of distribution of xenobiotics, bioavailability, half-lives, and systemic clearance [24,228,249]. In general, with increasing age, as occurs over the course of a carcinogenicity study, body weight increases, as does the proportion of an adipose tissue, which has a lower metabolic rate than skeletal muscle mass (Tables 25.8 through 25.10) [138]; thus, the volume of distribution decreases with age, resulting in an increased blood concentration of hydrophilic TS during distribution. In addition, the increased adipose tissue in rats, but not in mice (Tables 25.9 and 25.10), and the decreased water content in tissues can affect energy homeostasis, resulting in a deficiency in energy availability in rats compared to humans. Both influence the outcome of kinetic studies. In dose-proportional linear kinetics, half-life and clearance are independent of xenobiotic concentration. In contrast, in nonlinear kinetics, these parameters are dependent, because the various processes (absorption, distribution, metabolism, and excretion) can become saturated (Tables 25.8 and 25.9) [274].

The TK component of RCB often is carried out using satellite groups maintained in parallel and consists of at least three rodents per group, sex, and time interval, with interim sampling at least every 6 months. The time-course factor is very important in understanding how the various concentrations accumulate and result in different exposures [128]. The animals are maintained and dosed under identical conditions with the main study. Approximately four blood samples are taken from each animal over the duration of the RCB, with the blood removed not exceeding 15% of the total blood volume. If the route of administration is feed admixture, it is essential that sampling be done during the feeding (dark) phase; otherwise, unrepresentatively low values will be obtained. The parameters examined may include the maximum achieved concentration (C_{max}), the minimum concentration (C_{min}), the time to C_{max} (T_{max}), and the area under the plasma concentration time curve (AUC) [191], although only the AUC is required to establish exposure [212]. In an RCB, together with measuring the systemic concentration of exposure (AUC), determination of the total (cumulative) amount of exposure over time is also essential so that exposure can be related to induced effects [212,362]. Target site compound levels potentially connect the target site of both chronic toxicity and carcinogenicity; for example, essentially 100% of a compound absorbed from the intestine passes through the liver (portal circulation), and most biotransformation takes place in this organ (first pass). Highly lipophilic TSs enter directly the intestinal lymphatics bypassing portal circulation. To accomplish accurate extrapolation of systemic exposure over time, human time equivalent (HTE) values are employed (Table 25.8). At 12 months of dosing, these values amount to an HTE of 38 years for the mouse and 34 years for the rat; and at 24 months, to values of 76 and 64 years for the mouse and rat, respectively [191,194].

TK data are critical not only for delineating blood levels but also for understanding the effects of exposure, such as whether the parent or a metabolite is the main biologically active moiety, if the plasma concentration reflects the cellular site of action, and the nature of interspecies concentration (blood)–response (site) relationship [191,304,348]. Furthermore, biotransformation can also distort concentration–response homeostasis. Here, at high exposures, together with absorption and elimination being saturable (i.e., capacity limited), biotransformation can also significantly alter what is bioavailable at tissue target sites, including through the process of bioactivation, which is especially important in interspecies extrapolation [57]. Moreover, saturation of biotransformation and shunting through secondary routes of biotransformation should also

[b] Dry weight.

be taken into consideration [55,83,142,161]. Knowledge of disposition (including species differences in xenobiotic biotransforming enzymes) of the TS is essential to interpreting the basis for an increase in neoplasia and for extrapolating to humans.

Finally, in the conduct of TK studies, it is imperative to be aware that controls can be contaminated, and precautions to prevent such contamination, as described above, have been developed [329].

QUALITY CONTROL OF THE TEST SUBSTANCE

The TS should, of course, be identical to the final product or article in commerce and of a high quality and stability. This requires that it be manufactured in the same way and contain the same concentrations of impurities as the final product. Impurities in excess of 0.1% need to be individually identified. For pharmaceuticals, the active substance used in the preclinical and clinical tests should be preferably the same as in the marketed product. The product should have a well-defined and described scale-up process [213]. Most medicines will be formulated with excipients, and the noncarcinogenicity of these is expected to be established [458]. In other situations, as with agricultural chemicals and cosmetics, the technical-grade product or a representative technical grade of active ingredients is tested. In some instances, complex mixtures are tested (e.g., polychlorinated biphenyls). This aspect is discussed further in the Complex Mixtures section.

Test Substance

Chemicals or Small Molecules

In some situations, it is desirable or necessary to test pure chemicals, as with candidate medicines or food additives. With isomeric compounds, if the two enantiomers exhibit inversion in vivo or have the same biological activity, then they are considered one entity, and carcinogenicity testing of the racemate is appropriate.

Biopharmaceuticals

Biopharmaceuticals include recombinant human proteins, humanized monoclonal antibodies, oligodeoxynucleotides, and genes. Recombinant human proteins are being produced by a variety of techniques, often in bacteria, where glycosylation does not occur. Quality control of biopharmaceuticals, as with small molecules, is necessary to establish that they are actually what they are expected to be at all times during the study. For this purpose, all relevant information, such as synonyms, trade names, structural and molecular formulas, and weights, as well as methods of analysis and chemical and physical properties of the pure substance, should be available.

Complex Mixtures

Many human contacts with chemicals involve mixtures rather than single chemicals (e.g., polychlorinated biphenyls); yet, the scientific data for some mixtures are generated mainly from studies of individual components. Mixtures can be comprised of chemicals with several isomers, chemicals with major contaminants, hazardous waste in solid or liquid form, and air pollutants. The mixtures can either have a common source (e.g., tobacco smoke, aluminum production, and coal tars) or be formulated deliberately (coal gasification, footware-processing work exposure). Several such mixtures are recognized as human carcinogens (e.g., tobacco smoke, coal tars, and diesel engine exhaust). A daunting challenge has been to ascertain the role of individual components in the carcinogenicity of such mixtures [202]. To accomplish this, complex mixtures can be fractionated and characterized into chemically defined entities that can be individually tested. Nevertheless, in the mixture, individual chemicals can enhance or inhibit the activity of others, as discussed in the Interactive Carcinogenesis section.

Impurities or Contaminants

It is highly desirable that all TS should be pure chemicals of analytical grade, as even traces of impurities of <1% can produce confounding effects. An example of this is *o*-toluenesulfonamide, an impurity of saccharin present in the materials used in early carcinogenicity studies [313]. Impurities can occur in the starting materials to be used in the formulation or in materials used in the manufacturing process of the TS [121,229,453]. Impurities in excess of 0.1% should be thoroughly identified. If the TS with the identified impurity is intended for long-term use, such as with a high dose of active compound, then mutagenicity and multiple-dose toxicity studies (up to 3 months) should be performed. If the results of the mutagenicity assays are positive, carcinogenicity testing of the impurity should be considered [213].

Preparation of Dose

The most critical aspects in preparing a TS for dosing are the identity of all ingredients, homogeneity of the product, particle size, stability of all active ingredients, and vehicle (carrier) to be used [121,229]. All batches of dosage preparations must be analyzed for concentration to confirm accurate preparation prior to use. Homogeneity of the TS–diet mixture and the stability of the TS in diet under the intended in-study conditions should be established prior to the start of an RCB. During the conduct of the RCB, samples of the TS–diet mixture are taken approximately every 6 months for analysis and correction if necessary. It is recommended that the same batch be used for the entire RCB. This presupposes that there is a validated method of analysis for the active ingredients. Quality control data as described earlier should be provided, and monitoring should be conducted regularly throughout the duration of the study.

ROUTE OF ADMINISTRATION

The route of administration should be appropriate to potential human contact and reflect knowledge about comparative bioavailability; thus, chemical disposition data are essential

and should be used in designing the 2-year RCB [191,194]. The most common route is the oral, followed by dermal, inhalation, or parenteral administration. The selection of a delivery system is crucial for all routes as it has the potential to significantly affect bioavailability. Second, producing uniform and homogeneous TS exposure throughout the bioassay is equally important. This requires the availability of a validated analytical methodology [212,396].

Oral

The oral route of administration is generally used for medicines and food additives for which ingestion is the usual route of contact for humans. For oral administration, the TS can be admixed in the feed or given by intragastric instillation (gavage). Comparable systemic exposures can be achieved with either, but with the intragastric route, the bolus dose results in a higher blood C_{max} [259]. With feed additives, attention must be paid to possible inappetence due to poor palatability.

The concentration of TS in the diet is adjusted to compensate for changes in body weight. During the rapid growth phase, the concentrations are adjusted biweekly first, weekly, and later monthly after the growth plateau has been reached. Here, TS stability and homogeneity data are essential. Periodically during the study, samples of TS–diet mixtures should be analyzed to confirm intended concentrations and enable corrective action to be implemented. In general, this is the most cost-efficient mode of dosing with most TS.

Intragastric administration (gavage) affords the most precise oral delivery of the TS. For this route of administration, a vehicle is required, such as carboxymethylcellulose (CMC). Edible oils (corn, olive) have been used, but these present problems [50], including effects on body weight [171]. For a TS that cannot be dissolved in water or CMC, polyethylene glycol 400 or a uniform suspension in CMC can be used. For a TS that is unstable or volatile in diet, microencapsulation can be used. For more details, see the Feeding Procedures section. In general, the volume of the TS preparation in rats is 3–5 mL/kg body weight. In mice, a volume of up to 10 mL/kg has been shown to be desirable as this enables more accurate delivery of the dose. In addition, dilution enhances absorption and decreases local irritation, especially with weak bases or acids that are the form of many TSs [35]. If deaths are due to gavage accidents, then a monitoring program should be implemented. In general, the baseline rate for accidents per technician should not exceed 1 per 10,000 gavages.

Dermal

Under certain circumstances of dermal contact by humans, such as with cosmetics, TS is delivered by the dermal route. Bioactivation of activation-dependent carcinogens does occur in the skin, although not to the degree as in the liver or intestinal tract [50]. This route is also used for photochemical carcinogen testing (see the following). Dermal application is usually to the superior dorsal area of the back (interscapular), where the skin is clipped at least weekly, 24 h prior to application (unless hairless mice are used) [268]. In dermal studies, animals are routinely housed singly to minimize ingestion by other cage mates. The TS (0.25–1 mL) is applied topically over the clipped area at intervals (e.g., two or three times weekly) to allow for recovery (especially when the TS is irritating). Skin penetration varies with species, chemistry of the TS, and vehicle [388]; thus, it should be considered in dermal dosing by weight or surface area that rats are large enough to vary significantly in size, whereas mice are not. Any dermal study should be preceded by or accompanied by measurement of skin cell proliferation, because skin neoplasms can be elicited by nonspecific enhancement of cell proliferation.

Inhalation (Intratracheal)

With some TSs, inhalation administration is indicated. The TS can be delivered to animals in chambers for 8 h/day [180] or by nose-only devices for several hours [402]. After delivery, the animals can either remain in the chamber or be taken to an adjacent room. Either way, constant airflow through the chamber during and after dosing prevents the build-up of ammonia. Single-cage occupancy is recommended to avoid ingestion due to grooming and licking. The cages should be rotated within the chamber periodically. Inhalation administration is an expensive, labor-intensive route of delivery that requires frequent monitoring of achieved concentrations. Sampling should be done from several fixed locations in the chamber after documenting the homogeneity of the test atmosphere [288]. With nose-only or head-only delivery devices [402], major advantages include minimization of external contamination and effective monitoring of respiratory parameters. The major disadvantages include restraining the animals, which leads to alteration of many physiological parameters and entails substantial manpower requirements.

Intratracheal administration can be conducted under anesthesia to achieve chronic delivery (up to 2 years) directly into the bronchial passages once or twice weekly [401]. This route has been used for NSPs [27,301,333,286]. Here, in addition to environmental control group, a second control group receiving vehicle should be added.

Parenteral Injection

In special cases, such as when the TS is broken down in the gastrointestinal tract, intraperitoneal, intramuscular, or subcutaneous injections are employed. Here, factors such as molecular size and pH have the potential to affect absorption and cause irritation [15]. Again, if a carrier is used, then a second control group administered the vehicle is needed. The delivery regimen here is limited to two or three times per week with rotation of injection sites. With dermal injection, subcutaneous sarcomas have been induced by the irritant or physical properties of the TS [155]. An insulin analog, insulin glargine, which produced injection site irritation and inflammation, was found to be associated with increases in malignant fibrous histocytomas at the injection site in both rats and mice [408].

CLINICAL AND PATHOLOGICAL EXAMINATION

The RCB is not an extended chronic toxicity study; standard chronic toxicity assays (6 and 9 or 12 months, depending on requirements) involve more clinical observations than are necessary or appropriate for the RCB. In the RCB, animals should be observed at the beginning and at the end of each work day. Attention should be paid to signs of dermal irritation, as this may lead to skin neoplasia. Unwell animals should be euthanized before they become moribund or die and are lost to autolysis (or cannibalization, if group caging is used). Real-time automated programs for carcinogenicity studies have been developed [330], which allow for monitoring, at least biweekly, the appearance, location, and growth of palpable cutaneous or subcutaneous masses. Standard parameters measured in the RCB include body weight, food consumption, temperature, health status, and mortality.

Body Weight and Survival

In an RCB using an MTD, controls can show greater weight gain and often poorer survival than the high-dose group in which body weight is reduced both by stress/toxicity, and by secondary effects resulting in reduced food consumption or energy utilization [277].

Sustained body weight gain suppression can lead to stress responses resulting in general protein catabolism and concomitant upregulation of heat shock protein (Hsp) 70 in the liver [196]. Over time, this results in systemic antigluconeogenesis, fat anabolism, and reduction of intermediary metabolism [192]. Here, there is a significant species difference between rodents and humans—namely, in rodents, subtle sustained hypoglycemia resulting from systemic antigluconeogenesis does not trigger an increase in food consumption [185,422]. As a consequence, the increased protein catabolism and body temperature, with concomitant slow decrease in tissue hydration, cannot be compensated for, leading to a chronic disruption (deficit) in energy homeostasis and metabolism, and associated interference with their feedback loops.

Intercurrent Diseases

Laboratory strains of rats and mice are susceptible to a variety of diseases, both genetic and acquired. The genetically determined conditions, importantly, include predisposition to the development of neoplasms (as discussed in the Species and Strain section). Also, pathologies such as amyloidosis in mice and chronic progressive nephropathy in rats are common. These conditions increase with age and can complicate long-term studies. Acquired diseases, such as sialoadenitis and murine hepatitis, can be minimized by proper animal husbandry. Many strains of mice harbor *Helicobacter hepaticus* in the gastrointestinal tract. Infection with this organism can lead to an increased incidence of liver neoplasms, particularly in male mice [159]. In hamsters, the chronic form of proliferative ileitis (wet-tail disease) caused by *Lawsonia intracellularis,* enhances the susceptibility of the small intestine to carcinogenicity resulting even in adenocarcinomas [233,502]. Satellite sentinel animals are included in all chronic studies to effectively monitor intercurrent acquired diseases.

Clinical Pathology

Several regulatory agencies have suggested the monitoring of continuous variables including hematology, clinical chemistry, urinalysis, and organ weights [222,447]. It must be realized that, in spite of initial randomization, aged rodents are no longer homogeneous because of nonrandom attrition and development of diseases in the second half of the in-life phase. Although such measures may be helpful at times, they need not be implemented without a specific reason (e.g., hematology smears to assist in the diagnosis of leukemia).

Anatomic Pathology

Pathology is an integral part of the protocol design and plays a pivotal role throughout the conduct, evaluation, and interpretation of carcinogenicity studies (as discussed in the Good Laboratory Practice section) [33,76]. In general, emphasis is placed on routine methods, but special pathology methods may be required depending on the target organs. Whatever can be anticipated from previous subchronic and chronic studies (e.g., effects on endocrine status) should be addressed in the protocol for pathology. Furthermore, microscopic changes must be correlated with clinical observations, body weight effects, survival patterns, clinical pathology data, macroscopic findings, and other information. GLPs and statistical considerations are discussed in separate sections in this chapter.

All animals euthanized or found dead are submitted to a complete necropsy. At both unscheduled and scheduled necropsies, the pathology team should be prepared for potential outcomes by participating in a prenecropsy briefing, at which all known clinicopathological correlations are discussed. At necropsy, body weights are obtained. Examination of all recorded palpable masses constitutes an initial procedure with the examination of all body orifices and skin. A ventral midline incision, with reflection of the skin to display subcutaneous tissues, initiates the opening of the abdominal cavity, followed by the thoracic and finally the cranial cavities. All macroscopic lesions are described as to their location, size, shape, consistency, and color. In general, organs should be examined in situ as well as after removal. Artifactual tissue damage (e.g., crushing or tearing of tissues) should be avoided or minimized and noted. Tissues are cleaned by rinsing in physiologic saline solution (tap water is not acceptable because the low osmolarity damages cells). Alimentary tract hollow organs are opened for better fixation and are examined after removal of their contents (their anatomic integrity should be maintained, if possible). Individual lungs are inflated (with 10% neutral buffered formalin: ~4 mL in rats and ~2 mL in mice), taking care not to overinflate, and, if indicated, the urinary bladder also (with formalin ~0.2–0.5 mL), after which the trachea and urethra are ligated to maintain the inflated state. Lesions and neoplasms are dissected to

include regional lymph nodes, if possible, and a small portion of surrounding (normal) tissue. At least 55 standard tissues and lesions are sampled, trimmed, and processed for histopathological examination, including blood and bone marrow smears [58,133,289] and brown adipose tissue (BAT; either mediastinal or periadrenal), which is emerging as an important, but neglected, tissue [196]. Any significant deviation from these procedures amounts to censoring, which potentially compromises the integrity of the study (see the GLP and Statistical Analyses sections). Organ weights are usually not taken in carcinogenicity studies because of the variability in weights caused by disease, neoplasms, or body weight variations. In some cases, selected organs are weighed [447,448], usually including the adrenals, brain, heart, kidneys, liver, lungs, spleen, testes (with epididymides), and uterus (including horns). Where organ weights are taken, percentage organ to body weight values are calculated [133].

The preparation of routine microscopic slides should be in accordance with established SOPs. Each slide should be matched with blocks and sampled tissues or macroscopically observed findings. Special methods, such as immunostaining for proliferating cell nuclear antigen or Ki67, compatible with formalin fixation, should be either described in detail in the protocol or be part of an SOP. Increasingly, these methods have shown utility, as they are capable of identifying cell proliferation, preneoplasia, and early neoplasia [48,195,331,510].

During microscopic examination, an open slide evaluation is recommended initially [189,190,327]. It consists of evaluation of the concurrent control groups first and then the high-dose groups. After this, the remainder of the dosed groups is evaluated, and the presence or absence of a dose–effect pattern is established. Open evaluation is preferably conducted by one pathologist. If the study entails more than 1000 animals, then one pathologist could read the males and a second the females to reduce the length of time to complete the histopathologic evaluation. Open evaluation is also performed when quantitation is performed (e.g., immunohistochemical assessment of cell proliferation). Under certain circumstances, when a reevaluation of certain tissue-specific lesions is necessary, a blinded microscopic examination of selected target tissues may be performed. In this type of examination, all slides are reevaluated in a blinded manner in a random sequence by a second pathologist, preferably one not previously familiar with the slides. Also, the valuable practice of peer review can be utilized. This consists of an independent examination by a second pathologist of all tissues from a representative sampling of randomly selected animals of both sexes from the control and high-dose groups and a representative sampling of proliferative lesions to substantiate the data from the initial evaluation for neoplasms and other proliferative lesions. Here, it is also recommended that the evaluation be open and that all changes (not only microscopic) are taken into consideration.

It is vital to record all pathology data in a consistent manner and to depict them as individual data in appendices. The toxicologic pathology nomenclature employed should be in accordance with the newly adopted internationally harmonized pathology nomenclature [284]. A summary of all dosing-related data should be in tables. An appendix depicting all missing tissues is highly desirable. Neoplastic diagnoses should adhere to an accepted nomenclature of histopathologic terms, according to recommendations made by the Society of Toxicologic Pathologists [76], with particular care to distinguish among proliferative non-neoplastic lesions, benign neoplasms, and malignant neoplasms [78,117,118,151,156,290]. The pathologist integrates all clinical, structural (macroscopic and microscopic), and functional (cellular and biochemical) data. Moreover, the pathologist ensures proper accounting of macroscopic and microscopic lesions and changes (as detailed in the GLP and Statistical Analyses sections).

The pathologist also has the responsibility to classify neoplasms as incidental or fatal. This is done by giving a Peto score [353] to all tumors that occur in preterminal decedents, including palpable tumors. Accidental deaths are classified as incidental for all animals that die or are euthanized moribund. After the terminal necropsy has commenced, these animals are considered part of the terminal necropsy, but the tumors are considered incidental [353].

In pathological evaluation, the most common deficiencies in GLP are as follows: (1) Macroscopic observations are not fully provided and the exposure-related ones are not compared side by side with microscopic findings; (2) macroscopic and microscopic pathology data do not match, and no explanation is provided; (3) organ weights in the study notebook and report do not match; (4) euthanasia dates preceding completion of the study are not in the final report, and no explanation is given; (5) differences between forms of data recording by the pathologist and those in the SOPs are not explained; (6) individual animal data in the notebook and data in tabular form in the report on the corresponding animal are not the same, and no explanation is provided; (7) there is a lack of uniformity in pathology nomenclature, and no explanation is provided; (8) there is lack of lesion accountability, and important tissues are missing without any explanation being given; (9) the method of slide evaluation is not stated (e.g., open, peer-reviewed); and (10) there is a lack of initialing and dating in various records such as macroscopic data, tissue trimming, microscope evaluation, and tissue recuts. The failure to provide an explanation for any of these deficiencies can compromise the RCB and/or require convening of a Pathology Working Group to address discrepancies.

In the case of medicines, where clinical trials are often ongoing at the time an RCB is conducted, unexpected tumor findings, once substantiated by histopathology, need to be reported to the appropriate regulatory agency as soon as possible.

RODENT CANCER BIOASSAY EVALUATION

Tumor Increases or Decreases

If the RCB has been conducted properly, it should provide adequate evidence to assess whether dosing has led to identification of carcinogenic activity or not, that is, presence or absence of statistically significant (see Statistical Analyses)

increases in neoplasia. A conclusion of lack of carcinogenic activity requires survival of an adequate numbers of animals with sufficient relevant exposures, usually at the MTD, with no evidence of neoplasm increases according to the criteria discussed above in the section Chemicals with Carcinogenic Activity. A conclusion of a positive outcome is often less rigorous; that is, in the interest of a conservative approach to hazard identification, a statistical increase in neoplasms is often accepted as valid in spite of artifacts in the study such as excessively reduced body weight gain or poor or unbalanced survival. It is important to consider the possibility that a neoplasm increase can be a consequence of the stress or toxicity of the dosing conditions [155] and not of a chemical action of the TS. Moreover, it is possible that the differences occurred by chance alone. This can be controlled to some extent by the use of two control groups to document in-study random variation [14,170]. A statistically significant greater incidence in neoplasms in a dosed group that does not exceed one of the control groups can be regarded as a *numerical imbalance*, not a true increase.

A critical aspect in the evaluation is the interpretation of pathological diagnoses. Findings of increases in malignant neoplasms are universally accepted as evidence of carcinogenic activity. Combining malignant and benign neoplasms of the same cell type of origin is also widely accepted, and guidelines have been published by the NTP [290]. It should be noted that in some tissues, certain benign tumors are not related to malignancies (e.g., benign mammary fibroadenomas and malignant mammary adenocarcinomas). When evaluating increases in neoplasms, attention must be paid to pathology in the tissue that is the site of neoplasms because cell injury and compensatory cell proliferation can facilitate neoplastic development (see the Cancer Hazard and Risk Assessment section below).

When assessing the incidences of neoplasms in groups, both the incidence in animals surviving to termination and the combined incidences of decedent and terminal animals are considered. Evaluation should be made with regard to the ranges of commonly occurring neoplasms (Tables 25.11 and 25.12), as well as the percent incidence profiles expressed by time of death (i.e., the neoplasm distribution) (Table 25.6) [14,28,40,59,89,169,175,283,293,360,369,411, 413,414,430,470,307]. Among the commonly occurring neoplasms in rats, pituitary, mammary gland, and skin

neoplasms occur predominantly after 50 weeks, whereas lymphoma occurs almost equally before and after 50 weeks (Table 25.6) [404]. In mice, lung, mammary gland, and liver neoplasms occur after 50 weeks, whereas lymphoma or leukemia occurs almost equally before and after 50 weeks (Table 25.6) [404].

The primary comparator for dosed groups is the concurrent study controls, of which there can be one or two groups (see Groups and Identification). Findings also can be discussed in the context of historical or published control data (see Tables 25.11 and 25.12) [14,89,139,157,260,369,307]. For any meaningful comparison with historical data, these must be obtained from the same strain and breeder, the same test facility and source of nutrition, and housing conditions. The historical control data should not be more than 5 years older than the current study and should not show changes in tumor incidence indicative of a genetic drift. Control data from the literature usually lack the comparability and detail to add much weight to the conclusions. This is reflected in the wording of EMA's Note for Guidance on carcinogenic potential: "Data from the literature might be added if thought to be informative." Whether any true increase in neoplasia has relevance for human cancer hazard is discussed in the Cancer Hazard and Risk Assessment section.

A controversial issue is the interpretation of a reduced incidence of a neoplasm in the RCB [81], which is quite frequent [173]. One consideration is that the reduction should not be attributable to nonspecific weight gain suppression (as discussed in the Feeding Procedures section). A variety of mechanisms for specific anticarcinogenesis have been delineated (see the Anticarcinogenesis section). Also, tumor decreases may reflect a systemic effect of the TS.

Statistical Analyses

Methods for statistical analysis were detailed in the previous version of this chapter [492] and are described in Chapter 9 [134]. Authorities have provided guidance on appropriate use of statistics [140,200,445,455]. The object of statistics is to substantiate whether dosing of TS has elicited a neoplastic response. Other than dosing, two other factors can underlie a numerical imbalance in neoplasia. One is bias (a systematic difference other than what is caused by dosing), and another is chance (a random difference). As chance cannot be completely excluded, especially when 50 or more tissues are being analyzed, using two control groups can provide a measure of variation between small groups. The probability of chance can be statistically measured; the smaller the probability, the higher the confidence [271]. Of the two types of mathematical models used in statistics, the stochastic one that contains uncertainties or random variables is mainly used to analyze RCB.

Theoretically, at least, randomization eliminates nonsystematic bias, but if there is another major source of variation (e.g., sex of the same strain or batch of the same strain), then a stratified randomization is more appropriate. To achieve that, separate randomization within each level of the stratifying variable (e.g., cage position, order of weighting, order of killing at termination) can be performed [271]. There are three aspects that determine the nature of collected data: the biological system, the study design, and the methodologies applied. Censoring of any of these must be minimized. In general, dosing variables are independent, and effect variables are dependent [135,271]. To enhance the identification of a dosing effect, the dose–effect trend is examined [412]. Furthermore, if there are differences in survival, age adjustment to avoid bias is necessary. Even if there are no meaningful survival differences, age adjustment increases the power of detecting differences between groups, as well as sharpening their contrast by avoiding dilution of pivotal (key) data with less important data. Age adjustment is effective when the context of observation is taken into account, that is, the neoplasm is judged by the pathologist to be fatal or incidental [353]. Finally, when multiple comparisons are to be made with unequal numbers in the groups, a number adjustment should be employed [132].

In the past, the single most important aspect in the analysis of RCB was a simple quantal response, that is, either neoplasia occurred or it did not. Currently, the mechanisms underlying neoplasia induced by chemicals are more fully understood and must be given individual consideration. The first statistical test used should be one that makes a global assessment, not a series of pairwise comparisons. The nature of the data should be established (i.e., whether it is continuous or discontinuous, scalar, rank, or quantal), and the distribution of these data should be examined [271].

In an RCB, the time course of adverse effects is of importance; consequently, life-table or Kaplan–Meier product limit methods are employed to determine the duration of survival and time until neoplasms develop, as well as the

probability of survival or time course of neoplastic development [74,78,353]. The presentation of life-tables should depict sex and administered dose and include the time of selected interval, as well as the number of animals that were alive during the interval, excluding the animals that were either withdrawn (e.g., interim euthanasia) or died during the same interval. Tumors should be classified as incidental or fatal (*Peto score*) (see earlier in the Anatomic Pathology section) [353]. For continuous outcome measures, which can be either scalar or ranked, group means are compared against the control mean at each termination point using a one-way analysis of variance (ANOVA) followed by Dunnett's method for multiple comparisons, which is a powerful post hoc test [96]. Moreover, a square-root transformation can be added to stabilize the variance. In addition, the continuous mean outcome levels are compared among termination times at each exposure level using one-way ANOVA followed by Tukey's multiple comparison procedure [124].

To assess the course of dose–effect (its linearity), ordinary least-squares regression analysis can be used fitting the outcome level vs. exposure and squared exposure terms. For the incidence of specific site neoplasia comparing all test groups, the Pearson chi-square test followed by pairwise comparisons of each exposure group with control, adjusted for multiple comparisons, can be applied [131]. For incidence trend analysis, the Cochran–Armitage test, partitioning the chi-square statistic into the overall trend and departure from linearity (p nonlinear) can be tested [123]. Furthermore, survival data can be used by applying log-rank test for both homogeneity and exposure-related trend [167,168]. Neoplasm data can be analyzed using a survival-adjusted trend test that discriminates among fatal, incidental, and palpable neoplasms (see earlier in the Anatomic Pathology section) [353]. If one or more tumor types in a valid RCB show a significant positive trend in incidence rates, the significance level (p-value) for rare (≤1%) neoplasms would be 0.025 and for common neoplasms 0.005 [455]. For pairwise comparisons (control vs. high dose), the significance of rare neoplasms would be 0.05 and of common neoplasms 0.01 [455].

Thus, for the determination of statistical significance, decision rules have been developed by the U.S. FDA CDER [275,455]. Tumor types are classified as common (>1% background incidence) or rare (≤1% background incidence), according to Haseman [166,167], on the basis of historical background incidences. The significance levels are as follows:

	Pairwise Difference	Trend
Common tumor	$p < 0.01$	$p < 0.005$
Rare tumor	$p < 0.05$	$p < 0.025$

These significance levels can be applied only in case two standard 2-year carcinogenicity studies have been performed. They aim to limit the false-positive rate to 10% [275,455].

When animal weights differ across dose groups, as is usually the case with high-dose testing, such differences can contribute to differences in neoplasm incidence (see the Feeding Procedures section). Analyzing tumor incidence within body weight strata can reduce the bias resulting from weight differences [141]. The bioassay report (see later) must contain a critical interpretation of analyzed data. The final interpretation should be based on both biological and statistical considerations [118,452]. The outcome can indicate either positive or negative concurrence of differences.

Eight considerations have proven to be very helpful in evaluation and interpretation using statistical methodology: (1) exposure–effect relationship, (2) incidence of proliferation and preneoplastic and early neoplastic markers at the target site of neoplasia, (3) presence of sex and species similarities or differences at the target sites, (4) convergence in target sites of nonproliferative chronic toxicity and neoplasia, (5) combined neoplasia increases in tissues affected by chronic toxicity, (6) neoplasms of similar histogenetic target sites in other sexes or species, (7) concurrent and historical control data, and (8) relative survival of control and exposed groups. Statistical analysis of all these aspects helps with the final interpretation.

BIOASSAY REPORTING

The final report of an RCB is submitted to the regulatory agency under whose purview it was performed [67,84,110,111,442]. The final study report consists first of an introductory section containing the compliance statement signed by the study director, followed by the quality assurance and study identification statements. The study identification statement provides the study title and number, the TS, the testing facility, the test facility manager, the sponsor, the study director, the principal investigator of all study aspects, the exact specific study timetable, and approved signatures from all final report authors, including the study director and investigators of all aspects of the study (e.g., analytical, toxicokinetics, during-life observations, pathology, and statistics). The first part of the final report itself is the summary, which is an abstract of the entire study. It contains, in this order, an introduction, a listing of the materials and methods, the results, and the conclusions. The summary is followed by a summary table that depicts all pertinent findings in tabular form.

After the summary section, an extensive introduction explaining the origin and purpose of the RCB is provided, followed by listings of test animals, test materials, methods, results, discussion, conclusions, and references. All sections should fully describe all methods used and all data obtained. All individual data (e.g., analytical, body weight, during-life, necropsy, and microscopy) should be in appropriate appendices. All relevant summary data (e.g., analytical and body weight) should be in tables. Numerical incidences should precede percent incidences. Tables and graphs presenting special issues and arguments should be included in the text (text tables or text graphs). Appropriate statistical analysis of correlation of survival patterns, clinical observations, body weight gain pattern, and TK data with macroscopic and microscopic findings should be conducted. All of these considerations have been discussed in other sections in detail.

An effective way to summarize the findings is a format used in Europe known as the tabulated study report. All relevant data are presented in standardized tabular form without narrative. This corresponds to the summary tables of the final report described earlier.

ASSESSMENT AND CLASSIFICATION OF EVIDENCE OF CARCINOGENICITY

The findings of an RCB are subject to evaluation and classification, either by the regulatory body to which it is submitted or by other entities. In the United States, the results of RCB on pharmaceuticals tested under an investigational new drug application approved by the FDA/CDER are submitted to the Reviewing Division, which then evaluates them, often with the participation of the CDER CAC. The CAC consists of a chair, an executive secretary, and members from several divisions, the Office of Epidemiology and Biostatistics, the Office of Testing and Research, and the Office of Pharmaceutical Sciences. The Reviewing Division (of the FDA) notifies the sponsor when a CAC meeting is scheduled after all RCB studies are submitted, and the sponsor may attend. The final interpretation of the results will appear in the labeling of the medicine, if approved. The FDA normally describes the RCB data usually with the comment that human relevance is unknown and description of the multiples of exposure in the rodents compared to humans.

In the EU, the nonclinical studies on carcinogenicity of pharmaceuticals are evaluated as part of the assessment of the application or marketing authorization by the Committee for Medicinal Products for Human Use (CHMP) of the EMA. CHMP consists of one delegate from each of the 27 EU member states, one delegate each from Iceland and Norway as members of the European Economic Area, and five additional co-opted members who are elected by the delegates from the EU member states. The CHMP can decide to ask for an assessment by its safety working party. Carcinogenicity in rodents and its possible relevance for humans are considered as part of the benefit–risk assessment. The key findings will be included in the Summary of Product Characteristics and the European Public Assessment Report.

At the U.S. EPA, an ad hoc CAC of the EPA Science Advisory Committee evaluates the submitted dossier. The agency formerly used an alphabetical/numerical classification ranging from group A (human carcinogen, based on animal data) to group E (noncarcinogen) (Table 25.13) [442,444], but this has been changed to a narrative classification [443,444], which allows the incorporation of mechanistic data, similar to the IFSTP classification described below.

RCBs conducted by the NTP are reviewed by a peer review panel and published as technical reports. They are used by the EPA, FDA, and OSHA for regulatory action [442]. The NTP uses a classification system of no, limited (some), or clear evidence of carcinogenicity [322]. The NTP also publishes a biennial *Report on Carcinogens* [323].

In the EU and Japan, similar classification schemes are used by various health boards and the CHMP of the European Medicines Agency [84,97,112].

TABLE 25.13
Classification of Carcinogens

IARC	HWC	EPA	IFSTP
Group 1	Group I	Group A	Group 1
Group 2A	Group II	Group B1	Group 2a
Group 2B	Group III	Group B2	Group 2b
—	—	Group C	—
Group 3	Group IV	Group D	Group 3a
—	—	—	Group 3b
—	—	—	Group 3c
Group 4	Group V	Group E	Group 4

IARC Group 1, HWC Group I, EPA Group A, IFSTP Group 1: The agent is carcinogenic to humans. There is sufficient evidence in humans of a positive relationship between cancer and human exposure such that chance, bias, and confounding variables can be reasonably ruled out.

IARC Group 2A, HWC Group II, EPA Group B1, IFSTP Group 2a: The agent is probably carcinogenic to humans. There is limited evidence in humans of a positive relationship between cancer and human exposure, but chance, bias, and confounding variables cannot be ruled out. There is sufficient evidence of carcinogenicity in animals based on an increased incidence of benign and malignant neoplasms in at least two species or in two independent studies.

IARC Group 2B, HWC Group III, EPA Group B2, IFSTP Group 2b: The agent is possibly carcinogenic to humans. There is either limited evidence or absence of data in humans; there is either sufficient or limited and weak evidence of carcinogenicity in animals (e.g., presence of other relevant data, genotoxic agents cause only benign tumors or increases in certain spontaneous neoplasms).

EPA Group C: The agent is possibly carcinogenic to humans. There is either an absence of data in humans or limited evidence of carcinogenicity in animals (e.g., agents that cause only benign tumors, or neoplasm incidence increases are marginal and not consistent).

IARC Group 3, HWC Group IV, EPA Group D, IFSTP Group 3a: The agent is not classifiable as to its carcinogenicity in humans.

HWC Group IV: The data are inadequate for evaluation, or these agents cannot be classified in other groups.

IFSTP Group 3a: The experimental data of epigenetic carcinogens show a threshold level within the range of human exposure.

IFSTP Group 3b: The experimental data of epigenetic carcinogens show a threshold level beyond the range of human exposure.

IFSTP Group 3c: The experimental data of epigenetic carcinogens show that their mechanism of action is not applicable in humans.

IARC Group 4, HWC Group V, EPA Group E, IFSTP Group 4: The agent is probably not carcinogenic to humans. There is evidence suggesting a lack of carcinogenicity in humans (even if inadequate) and in animals (negative animal studies). In IFSTP Group 4, the suspected carcinogens have not been sufficiently tested.

Notes: U.S. EPA, U.S. Environmental Protection Agency [437]; HWC, Health and Welfare Canada [178]; IARC, International Agency for Research on Cancer [201]; IFSTP, International Federation of Societies of Toxicologic Pathologists [118]; —, no corre-spondence.

The IARC convenes working groups several times each year to evaluate groups of chemicals with published carcinogenicity data. They issue the IARC monographs and IARC biennial reports with evaluations of experimental and human data. The grouping ranges from Group 1 (carcinogenic to humans) to Group 4 (evidence suggesting lack of

carcinogenicity) (Table 25.13). A deficiency in this classification is that Group 3 contains chemicals with data that are considered not likely to be a human cancer hazard.

The IFSTP [118] has proposed a classification as follows: (1) carcinogens for humans based on epidemiological data, (2) genotoxic carcinogens for animals based on experimental data, (3) epigenetic carcinogens for animals based on experimental data, and (4) suspected carcinogens insufficiently tested. This is the only classification that explicitly incorporates mechanistic distinction (Table 25.13).

CANCER HAZARD AND RISK ASSESSMENT

The first step in cancer risk assessment is hazard identification [221,319], which involves an RCB to identify dosing-emergent neoplasms (see Rodent Cancer Bioassay Evaluation section). Using dose–effect data from the bioassay and potential human intake, a cancer risk can be assessed [319], often involving allomorphic scaling to extrapolate the rodent exposure to human [440]. To identify a potential human cancer hazard, the RCB results should be interpreted together with other mechanistic data [118].

If the tested chemical is clearly DNA-reactive, then a neoplasm increase strongly implies a potential hazard to humans [280,481,488,492]. On the other hand, it is now recognized that epigenetic carcinogens may exert the effects underlying tumorigenicity only in particular rodent species (e.g., $\alpha_2\mu$-globulin nephropathy inducers in male rats) or only at high toxic doses (e.g., nitrilotriacetic acid–induced nephropathy). Such effects either are considered to be irrelevant to human hazard [439] or can be subjected to a margin of exposure (MOE) risk assessment [444]. The MOAs of carcinogenicity of epigenetic (nongenotoxic) agents involve a variety of secondary organ and tissue target sites, with indirect interference with the organ or tissue homeostasis. Sustained adaptive effects [501] and disruption of endocrine, paracrine, nervous, and immune systems can be involved in the pathogenesis of neoplasia induced by such agents. Accordingly, the carcinogenetic effects of epigenetic agents are typically species, sex, and tissue specific.

These indirect epigenetic mechanisms involve key events such as enhancement of cell proliferation, disruption of hormonal feedback pathways, inhibition of trophic activity in tissues (including long-standing tissue ischemia), immune surveillance dysfunction, inhibition of enzymatic reaction/activation in cells, sustained exaggerated pharmacological effect, and sustained accumulation of normally low levels of endogenous products. All of these effects result in sustained cellular stress and/or toxicity, leading to compensatory proliferation, which is a common pathway through which chemicals with diverse cellular effects ultimately elicit or enhance neoplasia [62,72,195]. The effects that lead to compensatory cellular proliferation usually require high levels of exposure and exhibit no-observed-adverse-effect level (NOAEL). It is probably for this reason that, of the NCI/NTP rodent carcinogens identified, 6% had increased incidences of neoplasms that were limited to the top dose for all sites of tumor increases [172]. Examples of rodent neoplastic effects that are considered to be either not relevant, or possibly not relevant to human hazard, along with some MOA, are described in more detail in the next section.

It has been speculated that carcinogens that are highly potent (i.e., short latency, multiple tissue targets, and activity in more than one sex and species) are likely human carcinogens [12]. This reflects the fact that such chemicals are usually DNA-reactive. However, epigenetic carcinogens can also exhibit these features, and accordingly more information is needed for classification beyond the tumor profile. In this regard, understanding the chemical MOA pathway is essential to determining the relevance of tumor findings to human hazard [29,30,297,392,405].

Finally, in order to effectively extrapolate tumor findings from rodents to humans, an additional scaling factor based on the totality of the general cancer biology behavior of the rodents compared to humans is worthy of consideration. The differences in percent incidences of selected common neoplasms in all three species are provided in Table 25.14.

TABLE 25.14
Comparison of Percent Incidences of Selected Common Human and Rodent Neoplasms That Occur in All

	Humans[a]				SD Rats[b]				CD-1 Mice[c]			
	Males		Females		Males		Females		Males		Females	
Site	Percent	Rank	Percent	Rank	Percent	Rank	Percent	Rank	Percent	Rank	Percent	Rank
Lung	0.032	2	0.027	2	0.1	23	0.1	23	15	2	15	2
HLR[d]	0.011	6	0.010	5	2	10	2	11	8	3	22	1
Breast	NA	NA	0.071	1	NA	NA	58	2	NA	NA	6	3
Liver	0.004	9	0.002	13	5	6	3	6	18	1	3	5

Note: NA, not applicable.

[a] Data from American Cancer Society [232]; in humans, the percent figure reflects new cancer cases estimated from 2004 U.S. population.

[b] Data from Christian et al. [59], Giknis and Clifford [146], and McMartin et al. [293].

[c] Data from Giknis and Clifford [144]; in rats and mice, the percent figure reflects spontaneous neoplasms observed in excess of 1000 control animals.

[d] Hematolymphoreticular tissue neoplasms correspond to the diagnosis of lymphoma in humans.

For example, in humans of both sexes, lung neoplasia is a very common neoplasm, yet the percent incidence is only 0.032 M/0.027 F of the estimated cases from the U.S. population, whereas in mice it is 15%, and in rats it is 0.1%, somewhat closer to the human incidence. The interrodent percent difference (150 times) can be explained using the comparative adult tissue volume ratios (Table 25.9), which show that the mouse ratio is 33 times higher compared to the rat ratio. Thus, one should consider many species differences before ascertaining neoplasm incidences and *lifetime* risks (Table 25.14).

MODES OF ACTION

As discussed in the preceding sections, various criteria are applied to the assessment of carcinogenic activity. This includes MOA, where such information is available. Among the many established MOA (see Types of Carcinogens), DNA reactivity is widely regarded as relevant to human hazard. In contrast, for several neoplastic responses in rodents, sufficient mechanistic information has accrued to support general recognition that their underlying MOA are species specific and do not operate in humans. Others arise through MOA that are possibly or unlikely to be relevant to humans.

Modes of Action Not Relevant to Humans

Rat Gastric Neuroendocrine Neoplasm (Carcinoid) Elicited by Suppression of Gastric Acid Secretion

Hyperplasia and neoplasia of gastric neuroendocrine (NE) cells (enterochromaffin-like cells) are stimulated by gastrin in rats and to a lesser degree in mice. Elevations of gastrin are elicited by reduced gastric hydrochloric acid production, which can be caused by either gastric antisecretory medicines such as proton pump inhibitors (e.g., omeprazole) or histamine (H_2) antagonists (e.g., cimetidine) [42,300]. Chemicals that cause gastric atrophy (e.g., alachlor and butachlor) also have elicited this neoplasm (Table 25.2) [415]. Rats have a high density of gastric NE cells, achieve high levels of gastrin (over 1000 pg/mL), and are very responsive to elevation of gastrin [424]. For most hypoacidity-producing agents, female rats are more susceptible than males to the development of NE cell neoplasms. NE cell neoplasms have been observed in patients with multiple endocrine neoplasia syndrome (MEN-1), associated with elevated gastrin, but not with antiulcer therapy [300]. Significant NE cell proliferation in humans is seen only with gastrin, levels above 400 pg/mL, and this can be controlled in the clinical setting. Thus, this tumor response does not denote a practical human hazard [8,130,209].

Rat Kidney Neoplasm Resulting from $\alpha_{2\mu}$-Globulin Nephropathy

A variety of chemicals induces kidney neoplasms in male rats, especially F344, which excrete $\alpha_{2\mu}$-globulin in the urine. This protein is associated with hyaline droplet formation, atypical hyperplasia of the epithelium of the P_2 segment of the proximal tubules, and neoplasia. Male rats are proteinuric compared to humans, and no human renal protein is similar to $\alpha_{2\mu}$-globulin [439]. This MOA was confirmed with D-limonene administration to $\alpha_{2\mu}$-globulin transgenic mice [273]. Accordingly, it has been accepted that renal tubule neoplasms produced as a result of the $\alpha_{2\mu}$-globulin accumulation mechanism are not an appropriate endpoint for human hazard identification [8]. Agents associated with this neoplastic effect include D-limonene and trimethylpentane (Table 25.2) [347,415,439]. Likewise, an IARC working group concluded that an agent that acts solely through $\alpha_{2\mu}$-globulin nephropathy in the production of renal cell neoplasms alone in male rats is not a cancer hazard to humans [374].

Rat Mesovarial Leiomyoma

Smooth muscle tumors of the ovarian suspensory ligament have developed in female rats after long exposures to β_2-adrenoceptor stimulant medicines (Table 25.2) [8,243]. This neoplasm is rare in humans, and the agents that have induced it in rats (soterenol, mesuprine, zinterol, terbutaline, reproterol, and salbutamol) are not associated with cancer in humans. Hence this neoplasm is not relevant for humans.

Rat Urinary Bladder Transitional Cell Neoplasm Resulting from Luminal Milieu Modification

Many investigations have used rat models for urothelial neoplasia. In early studies, it was recognized that placement of inert pellets in the bladder lumen would elicit increases in urothelial neoplasia [60]. Rats have been shown to be more sensitive than mice to urothelial damages, apparently because the rat bladder urothelium lacks tight junctions, thus rendering the superficial layer ineffective as an intraluminal barrier and leaving the underlying layers vulnerable to chronic stimulation [193,265]. Moreover, rats, particularly males, have more intraluminal proteins, silicate precipitation, crystal formation, and urolithiasis than other species [61,63]. In particular, rats, unlike humans, develop calcium phosphate urinary precipitates [374]. The consequences of this are exacerbated by the fact that the bladder is horizontal in rodents (and dogs, which have also been used to study bladder carcinogenesis) and does not empty as effectively as the vertical human bladder, despite the fact that rats urinate frequently. Thus, rats are more prone to chronic cell damage to the bladder urothelium, which results in cell proliferation and neoplasia [62,193]. This effect does not occur in humans [62,100,506]. An IARC working group has concluded that production of bladder cancer in rats under conditions of formation of calcium phosphate–containing urinary precipitates is not predictive of cancer hazard to humans [374]. Conditions and chemicals associated with this neoplastic effect include crystalluria (PPARγ agonists—proglitazone, pioglitazone; PPARα/γ agonist—muraglitazar) and urine pH extremes (melamine, saccharin, carbonic anhydrase inhibitors, and dietary phosphates) (Table 25.2) [60–63,100,193,265,374,410].

Rat Vaginal–Cervical Granular Cell Neoplasm

A proliferative lesion of *granular* cells with granular eosinophilic cytoplasms occurs in the vaginal–uterine cervical regions of female Sprague–Dawley, Donryu, and Wistar rats [73,386]. This lesion is probably under hormonal influence, mainly estrogen. Granular cell aggregates occur rarely in the vulva of women, but no evidence suggests that the pathogenesis is similar to that of rat granular cell tumors. Thus, this lesion is considered not relevant for humans.

Rodent Liver Neoplasm Elicited by Hepatic Peroxisome Proliferator–Activated Receptor α Agonists

A wide variety of chemicals elicit increases in rodent liver tumors associated with the proliferation of peroxisomes [205]. Rodents are more susceptible to induction of hepatic peroxisome proliferation by PPARα agonists than primates or humans [53,205,498], apparently because of high expression of the PPARα in rodent liver [427]. Perhaps related to this, it has been reported that, in cultured rat hepatocytes, PPARα agonists enhanced DNA synthesis and suppressed apoptosis, whereas in human hepatocytes, DNA synthesis was suppressed and apoptosis enhanced [351]. The mechanism of carcinogenicity of PPARα agonists (Table 25.2), while not fully understood, appears to involve sustained hepatocellular proliferation as a key event [150,256]. No PPARα agonist is associated with cancer in humans, and an IARC group has recommended that a liver neoplasm response in mice or rats secondary only to peroxisome proliferation could modify the evaluation of carcinogenicity [205].

Rodent Subcutaneous Sarcoma at Injection or Implant Site

Rodents, especially males, are highly susceptible to the development of subcutaneous neoplasms, both as background and induced occurrences [154]. These neoplasms are variously diagnosed as fibrous histiocytomas, fibrous sarcomas, liposarcomas, and leiomyosarcomas. They can arise from a solid-state effect known as the Oppenheimer effect [339] with implantation of solid materials. Such sarcomas are also induced by subcutaneous injection in rodents of nongenotoxic irritant materials such as iron-dextran [154]. No material producing such an effect in rodents (including recombinant human insulin [356]) has been associated with cancer in humans [37].

Rodent Thyroid Neoplasm Resulting from Thyroid–Pituitary Feedback Homeostasis Disruption

Few DNA-reactive carcinogens elicit thyroid neoplasms, probably because bioactivation does not occur to a significant extent in this gland. On the other hand, disruption of thyroid–pituitary feedback homeostasis is a common mechanism of thyroid carcinogenesis in rodents, particularly rats [8,52,417]. Reduced thyroid hormone levels, either through inhibition of iodide uptake (e.g., perchlorate), inhibition of hormone synthesis by antithyroid agents (e.g., propylthiouracil), or increased clearance as a result of enhanced conjugation (e.g., phenobarbital), can lead to a feedback increase in thyroid-stimulating hormone levels, which produces thyroid follicular cell hypertrophy, hyperplasia, and eventually neoplasia. Species differ in their susceptibility to disruption of thyroid economy, with the rat being particularly sensitive [102]. Several inducers of hepatic thyroid hormone conjugation in rats (which often is also associated with increased liver neoplasms), as discussed in the next group of MOAs, do not affect mice [469]. Only radioactive chemical exposure is known to cause thyroid follicular neoplasms in humans [374]. Accordingly, it has been concluded that chemical-specific data on thyroid effects in rodents can be applied to risk assessment [183], and that agents (Table 25.2) that cause thyroid neoplasia through an adaptive hormonal mechanism belong to a different category from those acting through genotoxic effects or involving pathological response to tissue injury [374]. Thus, these epigenetic agents are considered to pose no cancer hazard to human [8].

Modes of Action Possibly Not Relevant to Humans

Several MOAs of epigenetic oncogenesis in rodents are possibly not relevant to human cancer hazard [8]. If only neoplasms arising through one of these MOA is elicited by the TS, then the effect is likely not relevant to humans.

Mouse Ovary Tubular Adenoma

This is a benign neoplasm with tubular, stromal, or mixed components, which occurs mainly in mice [7,51]. Tubulostromal adenomas have been observed with cytotoxic agents but are not seen in other laboratory animals or humans and are considered to be possibly not relevant to humans [7,8,51].

Mouse Urinary Bladder Mesenchymal Lesion

This lesion occurs in the posterior portion of the urinary bladder close to the trigone area and has been known under various names for some time [236]. Recently, the lesion has been referred to as a *mesenchymal tumor* [46,160]. The lesion has been found in mice given agents that bind to progesterone (mainly) and estrogen receptors (e.g., many oral contraceptives) [291]. Persuasive evidence has been provided [236,237] that the lesion represents a decidual reaction of mesenchymal cells carrying or developing progesterone receptors. No known counterpart of this lesion has been described in humans; therefore, its significance is questionable.

Rat Adenohypophysis Neoplasia

Most pituitary neoplasms are adenomas in both rodents and humans [20,156,294]. These common fatal neoplasms affect female rats more often than males and occur late in life [404] (Tables 25.6, 25.7, and 25.11). The majority of these neoplasms contain prolactin (PRL) cells suggesting that decreased dopamine content in old age is involved in the production of these neoplasms [365]. In addition, AL fed rats develop more pituitary neoplasms, at 2 years, compared to DR (by 20%) counterparts [22,425]. Furthermore, in the DR rats, PRL, estradiol, luteinizing hormone (LH), GH, and IGF-1 levels were reduced [303]. Nevertheless, the majority

of the background pituitary neoplasms contain PRL [315]. To date, neuroleptics (dopamine inhibitors), long-term dosing with estrogens, gonadotropin-releasing hormone (LHRH)–like drugs (goserelin, leuprolide, and calcitonin), as well as gonadectomy, thyroid ablation, iodine deficiency, dosing with goitrogens and ionizing radiation have been associated with increased pituitary neoplasms (Table 25.2) [149]. Based on all these, in rats, these neoplasms are the result of hormonal feedback interference, which is not operational in humans, where in women, hyperprolactinemic amenorrhea is often associated with pituitary neoplasia [13,3]. Thus, in humans, despite chronic dosing of contraceptive steroids or estrogen replacement therapy (monitored through imaging), no causal relationship has been established for these neoplasms [13,3].

Rat C-Cell Thyroid Neoplasia

Thyroid C-cells (clear, parafollicular, or calcitonin-producing cells) are more numerous in laboratory animals than in humans. C-cell neoplasia occurs both as background (Tables 25.7 and 25.11) and as exogenously induced findings in RCB with rats (most commonly), mice, or even hamsters [302,52,86,36]. Hyperplastic and neoplastic C-cells produce calcitonin as well as neurotensin and somatostatin [520,358]. C-cell hyperplasia preceding neoplasia has been observed in rats, but not in mice or hamsters [87,467]. C-cell hyperplasia in both rats and humans is accompanied by blood calcitonin elevation [302,52,36]. The C-cell medullary carcinoma variety occurs in the susceptible Long-Evans rat strain [86]. Administration of radioactive iodine, which induces follicular cell neoplasia, reduces the number of C-cell neoplasms compared to controls [342]. Finally, dosing with exenatide, an antidiabetic nongenotoxic drug given at up to 130 times the human exposure, as an s.c. injection produced benign C-cell adenomas in female SD rats [357]. Thus, C-cell hyperplasia and neoplasia, induced by nongenotoxic compounds, appear not to represent a human cancer hazard.

Rat Clitoral Gland Neoplasm

This rare neoplasm occurs sporadically and, if found in a TS group, can be a subject of concern. No chemical has been shown to reproducibly induce these tumors, and no underlying mechanism has been identified.

Rat Hibernoma (Brown Adipose Tissue Tumor)

Neoplasms of BAT occur in the mediastinum or periadrenal area of rats. This tissue is now considered to be an endocrine organ [196,246]. Several chemicals have been reported to produce a flat low-incidence pattern, mainly in male rats, including some antihyperglycemic thiazolidinediones (TZDs), imidazopyridine hypnotics [356], phentolamine (PHEN), a nonselective α-adrenergic receptor antagonist [196,361], and triazolone herbicides. To date, no chemical has been conclusively shown to induce BAT preneoplastic lesions or early (small in situ) neoplasms. Some TZDs, which have conclusively induced dose-related BAT hyperplasia in both rats and mice, do not stimulate progression of this chronic hyperplasia into preneoplasia or neoplasia after 2 years of continuous exposure [179]. Moreover, in a study with 12 month exposure to PHEN, focusing on the structure, function, and pathology of BAT in younger (6 weeks of age) and older (36 weeks of age) rats, no increased BAT hyperplasia, decreased BAT apoptosis, or preneoplastic lesions were present [196]. In addition, PHEN doses after 12 months of administration increased rectal temperature, decreased epinephrine (EPIN), and norepinephrine (NEPI) levels, but did not induce BAT hyperplasia. Temperature, EPIN, and NEPI changes were more pronounced in younger rats but were not present after 4 weeks of recovery. Hypothermia and sustained increases in EPIN and NEPI are considered important conditions for the induction of BAT hyperplasia. BAT neoplasms are very rare benign neoplasms in both rodents and humans [196]; however, this tissue has not been routinely sampled in RCB, and hence BAT neoplasms are recorded only when macroscopically evident. To date, malignant hibernomas have not been conclusively described in humans [103,245,478]. Review of TZD-induced hibernomas in rodents [179] further supports that they are also benign and as such of limited significance to humans, since gluconeogenesis, protein catabolism, intermediary metabolism, and energy (body temperature) homeostases and their feedback loops are different between rodents and humans (see in the Body Weight section).

Rat Mammary Gland Fibroadenoma

This is a benign neoplasm with a minor glandular epithelial component and a predominant pericanalicular type of proliferation of connective tissue. It bears little resemblance to the common intracanalicular type of fibroadenoma seen in women [377,380], which is hormonally responsive [16]. Fibroadenoma is the most common background breast neoplasm in all the routinely used rat strains (Tables 25.7 and 25.11), occurring usually >50 weeks of age (Table 25.6) and does not progress to malignancy. Thus, combining fibroadenomas and carcinomas is not appropriate, and fibroadenomas by themselves are of questionable human relevance. Fibroadenomas in rats are stimulated by PRL [192,17,120], whereas in humans, stimulation is also by estrogen (mainly) and progesterone [17,192,370].

Rat Mononuclear Cell Leukemia

MCL, also referred to as large granular lymphocyte leukemia, is a neoplasm that initially develops in the spleen and then in the liver, lungs, lymph nodes, and bone marrow. It occurs at over 18 months of age in high incidence (62% in males and 42% in females) in F344 rats [174] and is lethal (Table 25.7). No chemical has been demonstrated to reproducibly induce this neoplasm, so nothing is known about its pathogenesis. A number of chemicals (furan, C.I. Direct Blue 15, iodinated glycerol, diisononyl phthalate, and dimethylmorpholinophosphoramidate) are reported to be associated with increased incidences of MCL [101,276]. These have not been implicated in human cancer.

Rat Pancreatic Islet Cell Neoplasia

All species of rodents (but especially rats) develop later in life background pancreatic islet cell neoplasia (Tables 25.7 and 25.12)

consisting of insulin- (mainly) but also glucagon-, somatostatin-, and polypeptide-positive containing cells [378,517,308,88]. In humans, this neoplasm is rare (~1% of all pancreas neoplasms) [334]. Differences in endocrine and exocrine pancreas homeostases have been discussed in the Feeding Procedures, Body Weight, and RCB Evaluation sections. Namely, sustained hypoglycemia resulting from systemic antigluconeogenesis does not trigger an increase in food consumption in rodents [185,422], resulting in a chronic disruption (deficit) of energy homeostasis and metabolism. Experimentally, islet cell neoplasia has been produced in rats by streptozotocin or alloxan with or without nicotinamide or picolinamide [516], although the MOA has not been thoroughly elucidated. Probably, it is based on species-specific hormonal feedback interference, which is not operational in humans.

Rat Scrotal Vaginal Tunic Mesothelioma

This mesenchymal lesion, which includes hyperplasia and neoplasia [292], arises from the serous membranes of the scrotal tunica vaginalis testes. It is common (about 3%) in F344 rats [174] (Table 25.7). Because the scrotal lesion often arises in association with testicular neoplasms, especially the commonly occurring Leydig cell neoplasms [285], which assume a large size, an element of physical irritation may be involved in the pathogenesis. Thus, chemicals that induce only this tumor type are likely irrelevant to human hazard. Chemicals that produce increases in this tumor (e.g., acrylamide, potassium bromate, and pentachlorophenol) are structurally diverse, and no MOA has been established. In humans, none of these is associated with mesothelioma or any other cancer [211].

Rat Skin Fibromas

This subcutaneous benign, well-localized background neoplasm (Tables 25.6, 25.7, and 25.11) is difficult to distinguish from mammary fibroadenoma where glandular elements have atrophied. It is more common in males than females in all strains and occurs later (>50 weeks). If some of these have assumed malignant features, then careful examination is warranted, since recently, studies with PPARα/γ agonists have increased fibrosarcomas. Nevertheless, their human relevance is uncertain [461].

Rat Splenic Sarcomas

Following chronic administration of aniline (and aniline-based compounds), *p*-chloroaniline, *o*-toluidine, D and C Red No. 9 dyes, splenic sarcomas were observed in F344 rats [473,480]. The underlining MOA with anilines was postulated to involve methemoglobinemia, splenic erythrocyte sequestration with congestion, iron accumulation, and resulting oxidative stress, which produces increases in interleukin 1a, b, TNFα, and enhanced fibrogenesis and neoplasia [247,471]. With the antimalarial (together with pyrimethamine) and antileprosy drug dapsone (4,4′-diamino-di-phyenylsulphone) in an RCB in male rats, splenic congestion, necrosis, and sarcomas were evident [473,480]. Yet, years of therapeutic use produced no splenic sarcomas. Accordingly, this neoplasm is possibly not relevant for humans.

Rodent Adrenal Medulla Neoplasms (Pheochromocytomas)

The most common neoplasia of the adrenal medulla in rodents is pheochromocytoma (or chromaffin cell neoplasm). They occur most commonly in the hamster, followed by the rat and mouse (Table 25.7) [156,174]. In many situations, pheochromocytomas have been associated with systemic hypoxemia, which stimulates catecholamine secretion from the adrenal medulla where chronic endocrine hyperactivity may lead to compensatory adrenal medullary hyperplasia and neoplasia, and indeed in rats, pheochromocytomas are often found in a background of diffuse medullary hyperplasia [156]. Agents producing this feedback interference include lactose, sugar alcohols, and Ca^{2+} [344,420]. Pheochromocytomas elicited through this type of interference are most likely not relevant for humans [158].

Rodent Endometrial Neoplasia

Endometrial carcinoma was produced in an RCB in rats dosed with bicalutamide, a nonsteroidal antiandrogen [223]. This drug was exclusively used in men to treat prostatic cancer, and consequently the neoplastic finding in female rats was considered irrelevant. Moreover, chronic exposure to pergolide, a dopamine receptor agonist, produced endometrial neoplasia in rats and leiomyomas/sarcomas in mice. It was believed that both neoplasms reflected PRL inhibition and disruption of the estrogen/PRL feedback homeostasis [8,356], which is not operational in humans.

Rodent Forestomach Squamous Cell Carcinoma

The rodent forestomach is a portion of the stomach situated between the esophagus and glandular stomach, which is lined by squamous epithelium. It does not exist in humans. Squamous cell carcinoma of the forestomach is a rare neoplasm, with the exception of $B6C3F_1$ mice (Table 25.7). A number of DNA-reactive agents have induced these neoplasms in rodents [263], usually through direct contact from gavage administration. Mostly, nongenotoxic agents have produced increases in this neoplasm (Table 25.2). The epigenetic mechanism appears to involve chronic irritation leading to a promoting action, which requires high exposure, as shown for butylated hydroxyanisole [209,506,508]. An IARC working group [209] concluded that epigenetic agents that produce only forestomach tumors after prolonged exposure may be of less relevance to humans, since human exposure would need to surpass time-integrated dose thresholds in order to elicit the carcinogenic response. Indeed, none of these chemicals has been associated with cancer in humans.

Rodent Harderian Gland Neoplasia

Spontaneous neoplasms of this merocrine ocular gland in hamsters, rats, and more commonly mice (at an incidence of 0.5%–15%) [156,174,261]. Adenocarcinomas of the Harderian gland have been reported with a number of genotoxic

(ganciclovir-IV) [357] and nongenotoxic (zoledronic acid) agents in mice [356]. The relevance of neoplasms of this gland, which is not present in humans, is at best questionable.

Rodent Hemangioma/Hemangiosarcoma

This vascular neoplasm is a common background neoplasm in mice (Table 25.12) and less so in rats (Table 25.11) and occurs rarely in humans. In CD-1 mice, it is usually multifocal and affects many organs almost equally in males and females. The range of incidence is 6%–33% in males and 7%–32% in females [144]. Organs commonly involved (>2%) include spleen, liver, lymph nodes, testes, skin, and pancreas in males and uterus, spleen, liver, ovary, lymph nodes, and heart in females [144]. Increases in vascular neoplasia and hemangiosarcoma (HS) have been found in rodents with both DNA-reactive (e.g., vinyl chloride, vinyl bromide, and thorotrast) and epigenetic (e.g., pregabalin, elmiron PPAR α and/or γ agonists, and 2-butoxyethanol) agents [64,77,162,227,267,332]. A common MOA appears to exist for epigenetic induction of HS in rodents, consisting of convergence of key initiating events that include tissue hypoxia, hemolysis, decreased respiration, and adipocyte growth, all leading to dysregulated angiogenesis and/or erythropoiesis [64,77,267]. In humans, no comparable species-specific multifocal lesion has been reported, and no inducing agent has been established [67,77,429]. To date, chemical-induced hemangiosarcomas (primarily in the liver) are produced by vinyl halides and thorotrast (both genotoxic) in both rodents and humans [77].

Rodent Histiocytic Sarcoma

This neoplasm of histiocytes, found in older mice and less commonly in older rats, affects mainly the liver and uterus [429]. No chemical is known to produce an increase in only this neoplasm, and therefore it is possibly not relevant to humans [117,429].

Rodent Liver Neoplasm Induced by Phenobarbital-Like Enzyme Inducers

A variety of compounds elicit an increase in liver neoplasms in mice and rats through an MOA involving liver hyperplasia (Table 25.2) [489]. The prototype compound is phenobarbital [483]. Consideration of kinetic and dynamic factors led to the determination that the MOA was unlikely in humans [187,483]. Indeed, extensive epidemiologic data reveal no increased risk of cancer [338].

Rodent Osteomas/Osteosarcomas

Primary bone neoplasia in rodents and humans is uncommon. Background bone neoplasms in rodents are likewise rare [350,379]. Bone neoplasia has been induced in rodents by ionizing radiation, vinyl chloride, and nitrosamines [153,349]. Chronic administration of diethylstilbestrol (DES) or 17β-estradiol to mice also produced bone tumors [181]. Also, administration of an antiosteoporosis drug, teruoaretude/rh PTH, in an RCB in rats, produced dose-dependent hyperostosis, osteosarcomas, as well as osteomas and osteoblastomas [356,186,463,464]. In addition, hyperostosis and bone neoplasms (osteomas and osteosarcomas) have been produced in rats after 2 years of glucocorticoid administration [521]. Finally, proestrogens and prostaglandin E–like compounds in RCB have produced hyperostosis and osteosarcomas in mice [238,359]. In all these cases, with nongenotoxic and endocrine-active compounds, the initial MOA seems to be sustained (chronic) interference with endocrine feedback homeostases of bone growth patterns, which are not operational in humans.

Rodent Testicular Leydig Cell Neoplasm Resulting from Hormone Homeostasis Disruption

Leydig or interstitial cell neoplasms occur spontaneously in high incidence (>80%) in aged F344 rats (Tables 25.7 and 25.11) [174]. These tumors are invariably benign. In rats, they result from increases in LH [116] and in mice from increases in estrogen [363] or administration of estrogen agonists such as DES or tamoxifen [287,426]. The human counterpart is extremely rare, and no chemical that produces increases in rat testicular neoplasms (i.e., lactose, sugar alcohols, cimetidine, hydralazine, gemfibrozil, carbamazepine, vidarabine, isradipine, exogenous gonadotropins, LHRH analogues, flutamide, ergolines, and finasteride) has been associated with the induction of this or any other neoplasm in humans. The available information, therefore, suggests that nongenotoxic compounds that induce Leydig cell neoplasms in rodents do not represent a human cancer hazard [70].

Types of Cancer Hazards

Formerly, all rodent carcinogens were regarded as potential human cancer hazards. This concept was embodied in the Delaney Clause to the 1958 Federal Food, Drug, and Cosmetic Act (FFDCA), which provided that no chemical determined to be carcinogenic in animals could be allowed as a food additive, regardless of concentration. Subsequently, expanded understanding of mechanisms of carcinogenesis has led to refinements of hazard assessment [492]. In evaluation of drugs, the FDA and other regulatory bodies have long applied risk–benefit analysis. Beginning in 1992, the IARC accepted data on mechanisms as being relevant to the evaluation of the carcinogenic risk of a chemical to humans [203], and this has been further developed [209,374]. A critical aspect is the distinction between DNA-reactive and epigenetic carcinogens (see Types of Carcinogens section). This has been applied by the EPA in concluding that the rat kidney neoplasm response to $\alpha_{2\mu}$-globulin nephropathy inducers is not relevant to humans [439]. The potential hazards of a variety of DNA-reactive and epigenetic carcinogens were explored in detail by an international group of experts, drawing on comprehensive reviews of MOA of 10 prototype carcinogens both epigenetic and DNA-reactive [218]. These experts concluded in 1996, that the mechanism of carcinogenicity of a chemical can determine whether or not a risk to humans exists [218].

Currently, in the assessment of potential human cancer hazard, regulatory agencies often refer to findings implicating a chemical as a *genotoxic* carcinogen, usually with only an operational definition [66], namely, that the chemical produced a positive result(s) in some mutagenicity test [252]. All chemicals that are reliably positive in a variety of genotoxicity assays, especially including a DNA damage assay, are in fact DNA-reactive and thus belong to that category of carcinogen (see Types of Carcinogens). Many chemicals, however, are positive in only specific in vitro assays (e.g., phenobarbital and DES [201,208]), sometimes because of intrinsic spurious positive results [44]. Thus, the issue becomes a matter of which test results are to be accepted as evidence of genotoxicity. A scientifically sound approach is to define genotoxicity as a mechanism of carcinogenesis, that is, a genotoxic carcinogen is one that forms molecular lesions (such as DNA adducts) that lead to mutations in the cells that are the progenitor of neoplasms induced by the chemical [364]. Under this definition, genotoxic carcinogens would largely be confined to DNA-reactive agents, typically fulfilling the criterion for carcinogenic activity of an agent that induces malignant neoplasms not present in controls. Such chemicals often are multispecies carcinogens, inducing a high yield of neoplasms with short latent periods and often in several organs. For such carcinogens, assumption of human hazard is well founded, although evidence is accruing that even DNA-reactive carcinogens have thresholds at low levels of intake [496,507,510]. Moreover, some of the underlying MOAs of these chemicals are species specific and do not operate in humans because of differences in disposition (such as tamoxifen, which is poorly bioactivated and readily detoxified in humans) [31,98,335]. Epigenetic carcinogens do not directly produce DNA damage, but rather produce a cellular or systemic effect that is the basis for carcinogenicity. These generally do not constitute human hazards, as evidenced by the few associated with human cancer, notably hormones and immunosuppressants (Table 25.3), in spite of the large number of such agents with which humans regularly come in contact [207,491]. The lack of relevance stems from the fact that epigenetic effects are either rodent specific, as with the $\alpha_{2\mu}$-globulin nephropathy inducers [8,374,415,439], or require high and sustained duration exposure in rodents to elicit the cellular effect leading to carcinogenicity, as with butylated hydroxyanisole forestomach effects [218,482,483]. Epigenetic mechanisms (MOA) that either are not indicative of a cancer hazard to humans or are probably not indicative have been discussed earlier and addressed in numerous reviews [29,45,392]. These considerations should be applied in formulating hazard assessment.

Cancer Risk Assessment

In the United States, under the provision of the Delaney Clause to the 1958 FFDCA, a zero tolerance in food was established for chemicals determined to be carcinogenic in either humans or animals. This applies to residues of veterinary drugs used in food-producing animals [44,456]. Likewise, the EPA Cancer Principles of 1970 stated that no level of exposure to a chemical carcinogen could be considered toxicologically insignificant for humans. These are actually risk management approaches, rather than risk assessments. In contrast, in Europe, governmental agencies have not been required by regulations to impose standards of no exposure for carcinogenic chemicals and have used more flexible approaches than those imposed in the United States [504], although often this entails restricting external contact to that as low as reasonably achievable (ALARA), which again is a risk management procedure.

The prototype chemical safety assessment, introduced by Lehman and Fitzhugh [272] of the FDA, is the acceptable daily intake (ADI), calculated as the NOAEL divided by uncertainty factors (UFs), for example, 10 for intraspecies (individual) variation and 10 for interspecies extrapolation [496]. It is becoming increasingly accepted that for epigenetic carcinogens, even if a potential cancer hazard to humans is presumed, such a safety margin can be deployed [399,444,492]. For pharmaceuticals with animal neoplasm findings, the FDA/CDER calculates an MOE, which is the ratio of the AUC in rodents for the highest noncarcinogenic dose (nontumorigenic effect level, or NTEL) to the maximum AUC at the therapeutic dose [20,66], allowing for individuals who are poor metabolizers. Under ICH guidance [215], pharmaceuticals need not be tested for carcinogenicity at a dosage providing an exposure ratio greater than 25 [459], based on data showing that such exposure does not represent a cancer risk when the medicine is carcinogenic only at such exposure. In practice, many pharmaceuticals with carcinogenic activity at lower MOE have been approved for use [459]. It appears that the factor of 10 is generally regarded as an acceptable MOE [459].

In 1996, the FFDCA was amended by removing the zero-risk provision of the Delaney Clause and replacing it with a new standard of "a reasonable certainty of no harm" [67]. The new standard applies to pesticide residues in both raw and processed foods, allowing the presence of some residues of chemicals that have been shown to cause cancer in animals [433,434]. In the new EPA draft cancer assessment guidelines, the safety margin is referred to as an MOE using the NTEL [444]. In the EU, it has been proposed to incorporate potency considerations, including TD_{25} values, and to classify carcinogens into three potency groups for regulation [97]. The FDA CFSAN has published a *threshold of regulation* procedure for indirect food additives [451]. In this, based on a large database of chemical carcinogens, it was determined that an intake of 1.5 μg/person/day is unlikely to represent a cancer risk. This concept has been developed into a TTC [264,314]. The Joint WHO/Food and Agriculture Organization (FAO) Joint Expert Committee on Food Additives (JECFA) reviews safety studies on food additives and contaminants, and the Joint FAO/WHO Meeting on Pesticide Residues (JMPR) reviews those on pesticides to set global exposure limits. These groups develop ADI and tolerable daily intakes, respectively. The JECFA uses the TTC approach for flavors with very low intakes (up to 1800 μg/day) [230]. Health Canada in

its Human Health Risk Assessment for Priority Substances under the Canadian Environmental Protection Act applies an exposure potency index calculated as an average exposure in the population divided by the dose in experimental animals that produces a 5% incidence of neoplasms.

Several expert bodies have developed approaches to evaluating and integrating data in risk assessment [4,29,30,297,392,405]. Another approach proposes a carcinogen "toxicologically insignificant daily intake (TIDI)" as the NEL for the molecular or cellular effects that are the basis for carcinogenicity divided by a safety factor similar to UFs [487,491,492]. This actually is more conservative than using the NTEL because the NEL for molecular and cellular effects leading to cancer is a more robust endpoint and is usually lower than the dosage required to elicit cancer, as illustrated in reviews of rodent carcinogenicity of phenobarbital [483] and butylated hydroxyanisole [482]. A similar approach for nongenotoxic carcinogens proposes using toxicogenomic data to establish a point of departure for cancer risk assessment [18].

For genotoxic or DNA-reactive carcinogens, authorities regulate such agents either by prohibiting human contact (risk management) or by using a linear no-threshold model for quantitative risk assessment [437,442,512]. Currently, the concept of TTC is being considered for genotoxic contaminants of medicines [239] and food substances [264]. This recognizes the accruing evidence that even DNA-reactive carcinogens can have thresholds [510,492,496]. The TIDI concept described above can also be applied to DNA-reactive carcinogens using an NEL for DNA binding in target tissues [491].

These approaches were all developed for individual chemicals. However, there are situations in which multiple exposures can occur, and these can pose risks of interactive carcinogenesis, as discussed below.

INTERACTIVE CARCINOGENESIS

Interactive carcinogenesis comprises the enhancement or inhibition of carcinogenesis by combined or sequential exposures to more than one carcinogen or to a carcinogen and a noncarcinogen, which modifies the effect of the carcinogen [486]. Various types of interaction can occur between chemicals [49,484], including syncarcinogenesis, neoplasm promotion, cocarcinogenesis, and anticarcinogenesis, and between chemical and physical agents, as with photochemical carcinogenesis. Studies of interactive effects for regulatory purposes are being increasingly applied. Also, in the testing of complex mixtures, these types of interactions can influence the outcome and warrant consideration.

Syncarcinogenesis

Syncarcinogenesis is the enhancement of carcinogenesis produced by concurrent or sequential administration of two carcinogens [389], usually of the DNA-reactive type. This interaction in the case of DNA-reactive carcinogens represents a summation of the genetic effects of each of the chemicals. Generally, the enhancement occurs only in a target organ where both carcinogens independently produce a neoplastic effect [494,502].

Promotion

Neoplasm PM is the enhancement of neoplastic development by a second epigenetic agent given after an initiating, typically DNA-reactive, carcinogen [19], when a sufficient interval has been allowed for acute molecular effects of the carcinogen (e.g., DNA adducts) to be processed. If the second chemical is administered when molecular lesions are still present, the enhancement may be due to cocarcinogenesis (see below). Promoting agents essentially facilitate clonal expansion of initiated preneoplastic cells and their evolution into neoplasms. The growth advantage of preneoplastic populations can be achieved either by an enhanced rate of cell proliferation or by a decreased rate of apoptosis in either the tissue or incipient neoplasms. Promoting agents are usually assumed to be noncarcinogens, but in fact most are weak carcinogens under some circumstances, probably because they facilitate neoplasm development from cryptogenically initiated cells, which are the source of background neoplasms. Thus, most, if not all, promoters are epigenetic carcinogens (Table 25.2), albeit weak ones. An essential characteristic of a promoting agent is that it is not DNA-reactive and is not an initiating agent; otherwise, its enhancement of the effect of an initiating agent is likely to be due to syncarcinogenesis, described above. For experimental demonstration that promotion is the MOA of a chemical that has been shown to induce neoplasms, the exclusion of both genotoxicity and initiating activity is paramount.

Cocarcinogenesis

Cocarcinogenesis is the enhancement by a noncarcinogenic chemical of the carcinogenicity of a carcinogen when the noncarcinogenic chemical is administered prior to or concurrent with the carcinogen or when given shortly after the carcinogen at a time when molecular damage is still present [486]. Cocarcinogens can enhance the uptake of the carcinogen, enhance its tissue localization, increase the proportion that is bioactivated, or enhance the induced neoplastic transformation, usually by transiently increasing cell proliferation. Cocarcinogens do not act as promoters, although most promoters have cocarcinogenic activity, often due to enhancement of cell proliferation, when administered concurrently or shortly after the initiating agent.

Anticarcinogenesis

Anticarcinogenesis is the reduction of occurrence of neoplasia and may involve the inhibition of carcinogenicity of a concurrently or previously administered chemical. Anticarcinogens are typically noncarcinogenic, although certain epigenetic carcinogens, such as phenobarbital [65] and butylated hydroxyanisole [509], are effective anticarcinogens when administered concurrent with the carcinogen. Three operational pathways for anticarcinogenesis that have

been recognized are prevention of formation of a carcinogen, blocking of the effects of a carcinogen, and suppression of neoplastic development [472].

Photochemical Carcinogenesis

Another specific type of interactive carcinogenesis is photochemical carcinogenesis, which is the combined skin carcinogenicity of a chemical and UVR [126,127,204]. Photochemical carcinogenicity can result from several types of interactions among the chemical, UVR, and the skin. Some chemicals, such as psoralens, can be photoactivated to DNA-reactive chemical species. Others, such as fluoroquinolones, can undergo photoactivation to generate secondary reactive molecular species such as reactive oxygen [499]. Also some chemicals can affect the structure of skin, causing, for example, thinning of the epidermis in the case of retinoids, which results in the sensitization of the skin to effects of UVR. Stimulation of epidermal cell proliferation can enhance photocarcinogenesis. Finally, immunosuppression can facilitate UVR-induced skin carcinogenesis [262]. An FDA evaluation of available data found that photosensitivity and photogenotoxicity assays did not necessarily predict effects in photocarcinogenicity studies [226].

Photosafety Testing

Photochemical carcinogenicity studies can be required for topically applied medicines and even for some oral medicines, as well as for topically applied cosmetics and consumer products when the compound absorbs UVR or localizes in the skin [449,455].

The FDA has issued a guidance for cutaneous photosafety testing [454]. The test species is usually the SKH1 albino hairless mouse, which has the advantage that it does not require hair clipping and allows easy detection of UVR-induced skin tumors. In a typical protocol [85,126,127,382], the TS is applied before UVR (at 290–400 nm by a UV solar simulator) on Monday, Wednesday, and Friday and after UVR on Tuesday and Thursday for 40 weeks, followed by a 12-week observation period without exposure. This pattern of dosing allows detection of photoactivated chemicals as well as those that may modulate photocarcinogenesis. Typically, separate groups are administered low and high UVR doses in addition to the TS. The endpoints of evaluation include skin neoplasm incidence, multiplicity, and latency. Measurement of epidermal cell proliferation to monitor for nonspecific enhancement that can lead to enhancement of skin cancer can contribute to understanding of photochemical effects.

CONCLUDING REMARKS

It has been evident for 40 years or more that the carcinogenicity of a chemical could be predicted from data other than an RCB [475]. Nevertheless, for a variety of reasons, the RCB remains an essential component in the safety assessment of chemicals. The RCB appears to be highly effective in identifying human cancer hazards in as much as, to our knowledge, no chemical that was negative in a properly conducted RCB has subsequently proven to be carcinogenic in humans, although in some cases (arsenic, benzene) human carcinogenicity was noted first. The basic methodology of the RCB has changed little since its standardization in the 1980s, but refinements in both the analysis and the interpretation have evolved. Various types of neoplastic responses in rodents are now accepted as not being relevant to human safety. Moreover, responses considered to be relevant are increasingly recognized as having thresholds, and hence, safe levels of contact can be established.

ACKNOWLEDGMENTS

We thank Sharon Brana for preparation of the manuscript. Also, we gratefully acknowledge the thoughtful comments by many colleagues in the chemical and pharmaceutical industries.

QUESTIONS

25.1 What are the pertinent mechanisms of carcinogenesis operational in both rodents and humans?
25.2 What are some mechanisms of carcinogenesis operational only for rodents? Explain why.
25.3 Which neoplasms are of questionable significance to human cancer hazards? Explain why.
25.4 What are the types of cancer hazards?
25.5 What constitutes adequate exposure in a rodent cancer bioassay?

26 Principles of Clinical Pathology for Toxicology Studies

Robert L. Hall and Nancy E. Everds

CONTENTS

Clinical pathology is an integral component of nonclinical safety assessment and toxicology studies designed to identify target organ toxicity and establish dose–response relationships. In the context of these studies, clinical pathology usually consists of relatively routine hematology, clinical chemistry, and urinalysis tests. The majority of parameters evaluated are identical to those used in human and veterinary medicine because the fundamental physiology and pathophysiology of blood and major organ systems are similar in most species used in toxicology studies. There are, of course, species differences for reference intervals, some methodologies, the value or appropriateness of individual tests, and interpretation of findings. Selection of tests for a toxicology study is dependent on several factors, including study objectives, test species, regulatory requirements, and test article characteristics.

Clinical pathology tests are best characterized as screening tools to identify general metabolic or pathologic processes and target tissues. Test results narrow the possibilities and help direct further studies, although specific diagnoses and precise mechanisms for a toxic effect are infrequently identified. Clinical pathology tests can also help determine the biological importance of effects associated with test article administration. Alterations in clinical pathology test results are typically not the only evidence of adverse or pathologically significant toxicologic effects. In-life clinical observations and anatomic pathology findings usually corroborate pathologically meaningful laboratory findings.

Interpretation of clinical pathology data from a toxicology study is considerably different from the assessment of data from an individual patient suffering from an unknown illness. The most obvious difference is that data from groups of treated subjects receiving increasing dose levels of a test article are compared with data from a group of age-, weight-, and sex-matched control subjects that are concurrently exposed to the same environmental and experimental conditions. For larger laboratory animals (e.g., rabbits, dogs, monkeys), pretreatment clinical pathology data for each individual are also available for comparison with posttreatment results. Finally, clinical pathology results from a toxicology study can be correlated with carefully recorded in-life and necropsy observations, organ weight data, and histopathologic findings from an extensive tissue list. Given the uniformity of the animals studied and the analytical precision of modern clinical pathology instrumentation, data from toxicology studies can identify subtle changes that would not be apparent for an individual patient. One of the most challenging aspects of clinical pathology data interpretation for a toxicology study is differentiating potentially harmful toxic effects from changes representing homeostatic, metabolic, or adaptive responses to benign test article effects or study-related procedures. Proper interpretation of clinical pathology results from a toxicology study requires not only an understanding of the tests but also knowledge of species differences, study design, unique study-related procedures, clinical observations, anatomic pathology findings, and the test article. Interpretation of one test result is frequently dependent upon the results of another test, and pattern recognition is essential.

This chapter addresses (1) experimental design considerations, including test selection, timing and frequency of testing, sources of variability in clinical pathology test results with emphasis on preanalytical factors, and quality control; (2) basic principles of clinical pathology data interpretation, including the use and misuse of reference intervals; and (3) the characteristics and interpretation of routine hematology, clinical chemistry, and urinalysis tests used in toxicology studies. For in-depth descriptions of clinical pathology tests, including methods, the reader is referred to Refs. [1–10].

EXPERIMENTAL DESIGN CONSIDERATIONS

The value of clinical pathology in toxicology studies is heavily influenced by the experimental design and technical skill of the laboratory. Selection and timing of appropriate tests, consideration of unique study procedures, reduction of sources of variation, proper sample collection and handling, and controlled analytical technique are all factors that determine the value of clinical pathology test results.

Test Selection

The selection of appropriate clinical pathology tests for a toxicology study is ultimately dependent on the study objective or purpose (Table 26.1). If the objective is simply to screen a number of similar chemical entities for potential hepatocellular toxicity, the laboratory evaluation might be limited to a few targeted tests such as alanine aminotransferase (ALT), glutamate dehydrogenase (GDH), and sorbitol dehydrogenase (SDH) activities. Conversely, if the study is part of the package of studies required to support government approval of a new drug or other chemical entity with potential human

TABLE 26.1
Examples of Basic Tests Applicable to Most Rat, Dog, and Monkey Studies

Hematology and Coagulation	Clinical Chemistry	Urinalysis
RBC count	Glucose	Color and clarity
Hemoglobin	Urea nitrogen (or urea)	Overnight or timed volume (e.g., 16 h)
Hematocrit	Creatinine	Urine specific gravity
MCV	Total protein	Reagent strip tests: pH, protein, glucose, ketones, bilirubin, urobilinogen, blood
MCH	Albumin	
MCHC	Globulin (calculated)	Microscopic examination of sediment: cells, casts, crystals, bacteria, sperm
RDW	Albumin-to-globulin ratio (calculated)	
RBC morphology	Cholesterol	
WBC count	Total bilirubin	
WBC differential count	ALT	
Platelet count	AST	
MPV	ALP	
Blood and bone marrow smears	GGT	
PT	CK	
APTT	Calcium	
Fibrinogen	Inorganic phosphorus	
	Sodium	
	Potassium	
	Chloride	

exposure (e.g., food additives, pesticides, chemicals used in manufacturing), several tests are required or recommended in study guidelines published by the presiding governmental regulatory agencies (e.g., U.S. Food and Drug Administration [FDA], U.S. Environmental Protection Agency [EPA], Japanese Ministry of Health, Labour and Welfare [MHLW]) or professional standards organization (e.g., the European Organisation for Economic Co-operation and Development [OECD]).[11] The various published guidelines are relatively similar with respect to recommended clinical pathology tests but have several differences and instances of ambiguous or inappropriate testing requirements.

In an effort to encourage global harmonization of regulatory guidelines, a Joint Scientific Committee for International Harmonization of Clinical Pathology Testing was formed in 1992 to provide recommendations for clinical pathology testing of laboratory animals used in regulated safety assessment and toxicology studies. The committee was comprised of representatives from 10 professional organizations located throughout the world, with scientific expertise in animal clinical pathology, and was independent of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH). The committee prepared a document listing minimum recommendations for clinical pathology testing in regulated safety assessment and toxicology studies.[12] These recommendations are described in the following paragraphs, along with comments from the authors reflecting updated approaches and new methodologies.

With respect to hematology, the core recommended tests were total white blood cell (WBC) count, absolute differential WBC count, red blood cell (RBC) count, hemoglobin concentration, hematocrit (or packed cell volume), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), evaluation of RBC morphology, and platelet count. The importance of reporting absolute WBC differential counts rather than relative (percent) WBC differential counts was stressed. The method for evaluation of RBC morphology was not defined, but some laboratories examine blood smears for RBC morphologic characteristics such as size variation (anisocytosis, microcytosis, or macrocytosis), color (polychromasia), shape (poikilocytosis), and hemoglobin content (hypochromasia). Most laboratories assess RBC morphology using automated measurements such as MCV, MCH, MCHC, red cell distribution width (RDW), and hemoglobin distribution width (HDW). If automated methods are used for determination of hematology parameters, it is prudent to prepare blood smears in the event that the data indicate a need to examine the cells microscopically.

The Joint Scientific Committee did not recommend routine determination of reticulocyte count. At the time its paper was published, these counts were typically done manually and were relatively inaccurate, imprecise, and labor intensive. Accurate and precise automated reticulocyte counting is now a common feature of most hematology analyzers. Absolute reticulocyte count should be included as a standard hematology test. If a hematology analyzer is unable to perform an automated reticulocyte count, peripheral blood smears stained with a supravital dye (e.g., new methylene blue) should be prepared for possible manual enumeration of reticulocytes. Manual counts would then be indicated whenever a significant unexplained decrease in red cell mass existed.

The Joint Scientific Committee recommended that bone marrow smears be prepared at study termination for possible cytologic examination. Unexplained nonregenerative anemia, leukopenia, thrombocytopenia, and pancytopenia are possible reasons for performing bone marrow cytologic examinations.[13,14] Routine performance of cytologic examinations, myeloid-to-erythroid (M/E) ratios, or bone marrow differential cell counts is not recommended.

Prothrombin time (PT) and activated partial thromboplastin time (APTT), or appropriate alternatives such as the Thrombotest,[15] and platelet count were the core recommended tests for hemostasis assessment. If blood volume limitations or sample quality is a concern (e.g., multiple blood collections for a rat study; retro-orbital plexus/sinus collections), it may be necessary to perform PT and APTT only at study termination.

Current regulatory guidelines for carcinogenicity and oncogenicity studies recommend performing hematology tests (e.g., WBC differential counts) on some or all animals at set intervals (e.g., weeks 26, 52, 78, and 104). In contrast, the Joint Scientific Committee and a more recent best practice paper[16] recommended preparation of blood smears for all animals at unscheduled sacrifices (e.g., moribund animals) and at terminal sacrifice for possible examination as an adjunct to histopathology for the identification and differentiation of hematopoietic neoplasia. For example, if the histopathologist is unsure whether leukocytic infiltrates in multiple tissues represent leukemia or a leukemoid response (i.e., marked leukocytosis secondary to an inflammatory stimulus), the blood smear from that animal can be examined to help differentiate between the two conditions. WBC differentials at set intervals are not useful for detection of rodent hematopoietic neoplasms. These tumors become leukemic only late in the disease process,[17] so histologic evidence is sufficient for diagnosis.

With respect to clinical chemistry, the core recommended tests were glucose, urea nitrogen (or urea), creatinine, total protein, albumin, globulin (calculated from total protein and albumin), cholesterol, calcium, sodium, potassium, and selected tests of hepatocellular and hepatobiliary health and function. Measurement of at least two scientifically appropriate tests for hepatocellular evaluation (e.g., ALT, SDH, GDH, aspartate aminotransferase (AST), or total bile acids) and at least two scientifically appropriate tests for hepatobiliary evaluation (e.g., alkaline phosphatase (ALP), gamma-glutamyltransferase (GGT), 5′-nucleotidase (5′-N), total bilirubin, or total bile acids) was recommended. Because several acceptable tests are used to evaluate hepatic health and function, the Joint Scientific Committee recommended that each laboratory should have the freedom to choose those tests that best meet their individual needs and with which they have the most experience. For example, GDH is commonly evaluated in Europe, but the availability of commercial kits for this enzyme assay is limited in the United States. A recent publication from the American Society for Veterinary Clinical Pathology provides an additional description of clinical pathology indicators of hepatic injury in nonclinical studies.[18]

Core recommended urinalysis tests performed on an overnight or timed sample (i.e., approximately 16 h collection) were an assessment of urine appearance (color and turbidity), volume, specific gravity or osmolality, pH, and either the quantitative or semiquantitative determination of protein and glucose.

The Joint Scientific Committee listed several tests that are specifically not recommended for routine use in animal toxicology studies. These tests include ornithine decarboxylase, ornithine carbamoyltransferase, lactate dehydrogenase (LDH), creatine kinase (CK), serum or plasma protein electrophoresis, microscopic examination of urine sediment, and urinary mineral and electrolyte excretion (e.g., urine sodium, potassium, chloride, calcium, or inorganic phosphorus excretion). Although ornithine decarboxylase has appeared in the test lists of several regulatory guidelines, it has no value as a diagnostic clinical chemistry test.[19] This enzyme may have been included in the original FDA guidelines by mistake, and the error was repeated by other organizations. The FDA may have intended to include ornithine carbamoyltransferase, a liver-specific enzyme involved in the urea cycle that enjoyed limited popularity as a diagnostic test in the late 1970s. Ornithine carbamoyltransferase has never demonstrated a clear diagnostic advantage over other more common liver enzymes (e.g., ALT) and is rarely measured. LDH is similar to AST (i.e., nonspecific) but is generally more variable and not considered beneficial. CK may be helpful for evaluating test articles that cause muscle injury but is not considered necessary for most test articles. Blood collection techniques that potentially damage tissue and contaminate the blood sample with tissue fluids (e.g., cardiac puncture and retro-orbital plexus/sinus collection) can diminish the value of measuring muscle enzyme activities by increasing variability.

The routine use of protein electrophoresis is inappropriate for toxicology studies. As a diagnostic test for patients, serum or plasma protein electrophoresis is used to evaluate large, unexplained increases or decreases in globulin concentration. With respect to increased globulin concentration, protein electrophoresis is used to rule out a monoclonal gammopathy caused by some cancers of lymphoid origin (e.g., plasma cell myeloma). With the exception of monoclonal protein spikes due to a protein-based test article, these conditions are rare in toxicology studies. Regardless, analysis of stored serum samples can easily be accomplished if routine clinical chemistry tests indicate a need for electrophoresis.

Microscopic examination of urine sediment may be helpful for screening test articles that are known to cause severe renal or bladder toxicity, but histopathology is generally a more sensitive tool for detecting lesions of the kidney and bladder. In part, this is because the collection of high-quality urine specimens from many animals at one time is very difficult. On rare occasions, examination of urine sediment may be valuable for detecting the presence of crystals specific for a test article. Measurement of urinary mineral or electrolyte

excretion may be appropriate for test articles that are known to affect renal function (e.g., diuretics) or bone metabolism (e.g., parathyroid hormone), but as routine screening tests, these are excessive. If serum/plasma mineral and electrolyte concentrations are greatly affected by a test article and other causes for these findings are ruled out (e.g., vomiting, diarrhea, renal failure), an assessment of the renal handling of the mineral or electrolyte in question may then be valuable.

The recommendations of the Joint Scientific Committee and the requirements listed in the various regulatory guidelines should be viewed as a minimum database for screening the potential toxicity of a test article that will likely undergo extensive evaluation in studies of varying duration with multiple species before regulatory approval. Additional tests may be appropriate for the assessment of test article effects, depending on the study objectives and known characteristics of the test article. Platelet function tests (e.g., platelet aggregation and bleeding times) may be appropriate for evaluating drugs that target platelets. Analysis of methemoglobin concentration or the enumeration of Heinz bodies in erythrocytes can be valuable for assessing oxidative injury caused by a compound. Serum cardiac and skeletal troponin I and T can be useful markers of cardiac and skeletal muscle damage, respectively. Activity of plasma or RBC cholinesterase can indicate exposure to organophosphates or carbamates. Activity of brain cholinesterase is a measure of the toxic effect of these compounds. Determination of urinary enzyme activities and characterization of urinary protein excretion can be used for screening related compounds known or suspected to cause renal toxicity.[20–23] Various hormones may be measured when endocrine dysfunction is suspected, and cholesterol fractions may help define effects on lipid metabolism. Serum inorganic phosphorus and chloride concentrations are commonly measured as part of standard chemistry profiles in the United States and can be helpful when assessing changes in calcium and sodium concentrations, respectively.

The list of potentially valuable clinical pathology tests will grow because of industry and regulatory interest in developing improved biomarkers for both efficacy and toxicity. Novel parameters are being sought to provide more specific information about the status of individual organs and overall health. A nonstandard or novel test should be used for a specific purpose and only after the test has been shown to be useful for the species in question.

Frequency and Timing of Testing

Frequency and timing of clinical pathology testing are dependent on study objectives and duration, the biological activity of the test article, and the species tested. The Joint Scientific Committee made minimum recommendations[12] that may be modified because of these factors. With respect to regulated acute or single-dose toxicology studies, the regulatory guidelines have no clinical pathology requirements. Traditionally, in these studies, animals are dosed once at relatively high doses and sacrificed following a 1- or 2-week observation period to determine appropriate dose levels for future repeat-dose studies. Because the doses on these studies are higher than those of repeat-dose studies, information about acute high-dose effects can be gathered using clinical pathology tests. If clinical pathology tests are utilized, it is generally best to obtain samples approximately 48–72 h postdose. Waiting until the end of the observation period to obtain samples can allow recovery from acute effects. For example, at 2 weeks following the administration of near-lethal doses of carbon tetrachloride or mercuric chloride to rats, standard clinical pathology tests fail to recognize the effects of these compounds on the liver or kidney, respectively, because of the regenerative capacity and large functional reserve of these tissues. Occasionally, specific clinical pathology tests may be most appropriate within hours after dosing because the test article has a very short half-life or a limited duration of action (e.g., some cytokines, peptides, and organophosphates). Following administration of acute renal toxins, urinary enzyme activities tend to be greatest in the first 24–48 h postdose.[20] Alternatively, the effects of some test articles (e.g., cytotoxic chemotherapeutic agents) may take longer to reach their peak. For these test articles, it may be best to wait several days before performing clinical pathology tests or to take samples at multiple times to determine the time of greatest effect and pace of recovery (e.g., days 4, 7, 10, and 14).

Limited blood volume in mice dictates that blood sample collection for clinical pathology is usually practical only when the animals are sacrificed. Because the blood volume of a 30 g mouse is less than 2 mL, it is difficult to acquire a full milliliter of blood from a single mouse, regardless of the blood collection technique. If several tests are required or desired (e.g., full hematology and clinical chemistry profiles), it may be necessary to specify certain animals for hematology tests and others for clinical chemistry tests. An alternative is to limit the number of clinical chemistry tests to those that are the most relevant as screening tools for major organ toxicity (e.g., urea nitrogen or creatinine, ALT or another liver-specific enzyme, total protein, albumin). Pooling of blood samples is inappropriate for clinical pathology testing.

Prestudy clinical pathology testing is not recommended for rats because of the relatively large number of animals per group, homogeneity of the population, irrelevance of prestudy data due to rapid age-related changes in values for young rodents, and risk of adversely affecting the health of young animals due to blood loss or the blood collection procedure. For repeat-dose studies in rats, testing should at least be done at study termination. Interim testing may be unnecessary for long-duration studies (e.g., a 13-week study) if testing was done in short-duration studies (e.g., a 4-week study) that used dose levels not substantially lower than those of the long-duration studies. Conversely, interim testing (e.g., a week 6 testing point during a 13-week study) can be beneficial for interpretation of subtle effects. Clinical pathology testing is not routinely recommended for rodents after 52 weeks because naturally occurring geriatric conditions

(e.g., ulceration and infection of mammary gland tumors, chronic progressive nephropathy, and pituitary tumors disrupting normal endocrine function) obscure meaningful interpretation of laboratory data.

For repeat-dose studies in large animals (e.g., rabbits, dogs, and monkeys), testing should be done before initiation (i.e., prestudy or baseline), at least once during the study, and at study termination. Animals shipped from a supplier should have several days to acclimate to the new environment before baseline testing is performed. The baseline data are important for screening out animals with potential health problems or results that notably differ from those of their peers. Findings that may signal possible subclinical health problems and eliminate animals from study consideration include low values for erythrocyte parameters (e.g., RBC count, hemoglobin concentration, hematocrit, MCV), low or high WBC and neutrophil counts, low total protein and albumin concentrations, high globulin concentration, and high liver enzyme activities. There may be a specific need to eliminate otherwise healthy animals because they have findings that might complicate interpretation of test article-related effects. The criteria for which animals to eliminate from the study may be test article-dependent. For example, if a test article is expected to cause decreases in neutrophils, an animal with unusually high or low neutrophil count may be inappropriate. Similarly, an animal with high normal triglyceride concentration might be inappropriate for a study with a test article affecting lipids. Beagles with factor VII deficiency have slightly prolonged PTs. Even though these beagles are clinically normal, it may be inappropriate to include one in a study evaluating a product that targets coagulation.

Using larger test animals with greater blood volume allows more frequent clinical pathology evaluations. This advantage is offset by the low number of animals in each treatment group (often four or fewer per sex per group) and the increased variability between animals for many tests. The quality of data interpretation is enhanced by having more than one baseline interval for studies using monkeys and dogs, regardless of the number of animals per sex per group. An additional benefit to multiple baseline intervals is that the animals become more accustomed to the blood collection procedures, and variability caused by excitement or fear is generally reduced. Some range-finding studies only use one animal per sex per group, and each animal serves as its own control. In these studies, using at least two baseline intervals affords an appreciation for normal day-to-day, intra-animal variability. Two baseline intervals are also generally desirable for animals that have been surgically manipulated (e.g., placement of indwelling intravenous catheters) to avoid using animals with iatrogenic complications.

The nature of the test article often dictates the timing and number of clinical pathology intervals for repeat-dose studies in dogs and monkeys. For studies of 6 weeks' duration or less, an interim testing interval within 7 days of initiation of dosing may be useful. The primary purpose for this early interval is to detect transient changes, such as increases in serum enzyme activities, that may be absent at later intervals.[24] This information can be very important for clinical trials. For studies with cytotoxic chemotherapeutic agents, the number and frequency of hematology intervals are often considerable because common objectives are to identify the nadir for circulating leukocyte counts and the timing of hematopoietic recovery. A single-dose study of a chemotherapeutic agent in dogs might include hematology tests twice before initiation of treatment and at days 4, 7, 10, 14, 21, and 28 and clinical chemistry tests twice before initiation of treatment and at days 7 and 28.

Urinalysis testing should be conducted at least once during a repeat-dose study. It is best to conduct the urinalysis testing at the same time as other clinical pathology tests. Although not stated in the Joint Scientific Committee's document, urinalysis testing for mice is impractical and not recommended as a routine test.

Sources and Control of Preanalytical Variation

Many study design and procedural factors affect variability of the data and impact clinical pathology evaluation and interpretation, even under the conditions of a well-controlled toxicology study. To identify test article-related effects on clinical pathology test results, preanalytical sources of variation should be reduced whenever possible within the limitations of the study. Sources of preanalytical variation can be loosely categorized as physiological, procedural, and artifactual (Table 26.2). Physiological sources of variation include differences associated with age, strain, sex, diet, fasted condition, excitement, fear, stress, and time of blood collection. Procedural sources of variation include order of sample collection (i.e., group order vs. randomized or stratified), blood collection site and technique, anesthesia, and iatrogenic blood loss. Causes of artifactual or spurious results include poor-quality specimens (e.g., partially clotted hematology samples, hemolyzed serum or plasma samples), inappropriate use of an anticoagulant, and improper sample storage.

Initiation of treatment for many regulated toxicology studies occurs when the animals are relatively young and still in a growth phase (e.g., rats 6–8 weeks old, beagles 4–6 months

TABLE 26.2
Examples of Sources of Preanalytical Variation

Physiological	Procedural	Artifact
Age	Blood collection site and technique	Poor-quality sample (e.g., hemolyzed or clotted)
Sex	Order of sample collection and analysis	Improper anticoagulant
Strain	Anesthesia	Too much anticoagulant
Diet	Other study design factors (e.g., continuous infusion, vehicle, iatrogenic blood loss)	Improper sample storage
Fasted/nonfasted		
Time of sample collection		
Excitement/fear		
Stress		

old, and juvenile monkeys). As the animals mature, the results of several clinical pathology parameters change. Typical changes in most species include increasing RBC count, hemoglobin concentration, hematocrit, absolute neutrophil count, total protein, and globulin concentration and decreasing reticulocyte count, MCV, absolute lymphocyte count, ALP activity, and inorganic phosphorus concentration. Although these and other age-related changes may be subtle, they may result in inaccurate conclusions if interpretation of posttreatment data is based solely on comparisons with pretreatment or baseline data collected more than 1–2 weeks earlier. In addition to the age-related changes in growing animals, there are also age-related changes in mature animals. These changes are generally observed in rodents, especially those greater than 1 year of age, and are often due to intercurrent disease and other geriatric changes.

Strain differences, especially for rodents, are important to consider when evaluating clinical pathology data. Differences for hematology parameters tend to be the most prominent. For example, Fischer 344 rats tend to have lower leukocyte counts than Sprague-Dawley rats but are also predisposed to developing large, granular lymphocytic leukemia.[25,26] The size of RBCs of cynomolgus monkeys (*Macaca fascicularis*) differ based on geographic origin. Cynomolgus monkeys from suppliers in China and contiguous areas such as Vietnam have much larger, but fewer, RBCs than cynomolgus monkeys from Indonesia, the Philippines, or Mauritius.[27] The differences are so great that reference intervals for these animals may not overlap for parameters such as RBC count and MCV. Interpretation of hematologic effects could be compromised if monkeys from these different geographic origins were used in the same toxicology study or perhaps different studies of the same test article.[28] For targeted biotherapeutics, it may be necessary to preselect animals for toxicology studies based on appropriate polymorphisms (e.g., CD52-positive monkeys and alemtuzumab). Although not yet reported, it is possible that other differences for clinical pathology test results exist between various populations of cynomolgus monkeys.[29]

Diet affects many clinical pathology parameters. Standardized diets are used in toxicology studies to avoid small effects that might be misinterpreted as test article-related. Data from animals fed purified or unusual diets should not be directly compared with data from animals fed standard diets (e.g., historical reference ranges). Some species, such as the rabbit and hamster, are particularly sensitive to the effects of atherogenic diets, which cause them to exhibit very high cholesterol concentrations. The amount of protein in the diet affects urea nitrogen concentration and may have subtle effects on other parameters over time. Diet can be an important factor when assessing the potential of a test article to cause gastrointestinal ulceration or hemorrhage because some diets, especially for dogs, are more prone than others to cause false-positive results for fecal occult blood.

Much has been published on the effects of fasting animals prior to blood collection for clinical pathology.[30–34] Historically, fasting has been encouraged in clinical practice as a means of reducing the variability of certain parameters, most conspicuously glucose concentration, so the physician or veterinarian can more readily compare the results from a single patient with reference intervals. In toxicology studies, because the concurrent control group is much more relevant for comparison purposes than are historical reference intervals, the key principle is to treat all of the groups the same with respect to conditions prior to blood collection. Although most laboratories routinely fast dogs and monkeys overnight prior to blood collection, procedures for rodents differ among laboratories.

Fasting of mice for longer than a few hours is discouraged because mice reduce their water consumption when fasted and rapidly become dehydrated. Not only does dehydration affect many clinical pathology parameters (e.g., RBC count, serum protein concentrations, urea nitrogen concentration), it results in more difficult blood collection and can reduce sample quality and volume. Mice are sometimes fasted for a limited time before blood collection (e.g., 4 h) because blood collection from mice is usually a terminal procedure and fasting reduces hepatocyte glycogen stores and may improve histopathologic detection of hepatocellular injury or change. Care must be taken to keep the period of fasting similar for all mice, since necropsy procedures may take several hours to complete.

Most laboratories in the United States prefer to fast rats overnight to standardize the fasted/fed conditions for all animals. If animals in the high-dose group are eating poorly, providing all animals with access to feed before blood collection can have the effect of comparing fed animals (i.e., the control animals) to fasted animals (i.e., the high-dose animals). Because several differences for clinical pathology parameters exist between fed and fasted animals, it is more difficult to determine if differences between the control and high-dose groups are due to a test article effect or simply to differences in overnight feed consumption. When compared with rats having access to feed, fasted rats tend to have lower WBC counts; lower urea nitrogen, cholesterol, triglyceride, calcium, and bilirubin concentrations; and lower ALT and ALP activities.[31,33]

Excitement, fear, and stress can have pronounced effects on clinical pathology test results.[35] Excitement and fear are associated with acute endogenous catecholamine release ("fight or flight" phenomenon), and stress is associated with endogenous glucocorticoid release. Although these processes are separated for discussion, perturbation of either system generally activates the other system to some degree. Effects of catecholamines are immediate but short lasting (e.g., generally less than 30 min). Effects of glucocorticoids tend to be more gradual and long lasting. The most obvious changes observed in very excited or frightened animals are increased erythrocyte and leukocyte counts and glucose concentrations. These changes are observed occasionally with overexcited beagles and unanesthetized monkeys that are not used to handling for blood collection. Monkeys may also react to the presence of several people in the animal room performing additional study-related procedures at the

same time as blood collections. Endogenous glucocorticoids affect leukocyte counts but somewhat differently than catecholamines (see section on Leukocytes). Whenever possible, clinical pathology testing should be delayed for at least 1 week following shipping or surgical procedures to avoid stress-related changes.

Blood samples should be collected in a manner that minimizes the possibility of temporal biases. Examples of time-related biases include differences between morning and afternoon results (circadian effects), differences caused by delayed separation of serum from clotted blood, and day-to-day differences (may be preanalytical or analytical). These biases can be minimized or eliminated by randomizing the animals for blood collection and using procedures that enable blood collection and sample processing over the shortest reasonable amount of time. An alternative to true randomization is a structured pattern of bleeding such that one animal from each group is bled in succession (round-robin or stratified collection). After samples have been collected, they should be analyzed in the same order as collected. Rearranging the samples back to group order has the potential of causing false-positive findings that are actually due to analytical drift. For example, a small drift in the analysis of chloride by ion-selective electrode (e.g., an increase of 2 mmol/L over 60 samples) may be sufficient to produce a statistically higher mean chloride concentration for the high-dose animals if the groups are sufficiently large (e.g., 15 animals per sex per group), the control animals are analyzed first, and the high-dose animals are analyzed last. If animals must be bled over 2 days because of laboratory or necropsy capacity issues, the problem of day-to-day variability can be reduced by collecting and analyzing samples from males on the first day and females the next.

Randomization of animals for blood collection is occasionally impractical (e.g., if timed collections must follow intravenous administration of the test article). When animals must be sampled by group, it is better to sample the high-dose group immediately before or after the control group (e.g., mid-dose, control, high dose, low dose) than to sample the animals in consecutive group order (i.e., control, low dose, mid-dose, high dose). If it is necessary to sample the animals in consecutive group order, then procedures must be in place to analyze or process the samples in a similar time frame. When control animals are bled 1 h or more before the high-dose animals, analysis of the hematology samples and separation of the chemistry samples should not be delayed until all groups are bled. Such a delay can result in differences between the control and high-dose groups that are due solely to time-related, in vitro changes. This is most likely to occur for rodents when blood collection is one of the terminal procedures and several hours are necessary to bleed, sacrifice, and necropsy all of the animals. If clotted blood from the control group is allowed to stand an hour or more longer than that from the high-dose group before separation of serum, the high-dose group will often have statistically significant differences for several chemistry parameters, including higher glucose concentration, lower potassium and inorganic phosphorus concentrations, and lower AST and LDH activities. These differences result from in vitro changes in the control animal samples (i.e., the consumption of glucose by erythrocytes and the release of cell constituents by erythrocytes, leukocytes, and platelets). Circadian effects are another potential source of variation when blood collection is protracted; for example, rodents bled early in the morning can have slightly higher leukocyte counts than those bled in the afternoon during their normal period of inactivity.

Collection conditions, including site, technique, and use of anesthesia, are perhaps the most commonly cited procedural influences on clinical pathology test results. Many investigators have analyzed differences in data resulting from these variables,[25,31,36–48] especially for the rat. For example, total leukocyte counts are higher in samples from the retro-orbital venous plexus or sinus than those from larger vessels such as the abdominal aorta or posterior vena cava, and glucose concentrations are higher in samples from the abdominal aorta than those from other sources. Variability may also be related to differences in bleeding technique proficiency rather than the method itself.[39] With appropriate instruction and practice, any of the commonly used techniques can generate adequate results. Use of an unfamiliar or unpracticed blood collection technique introduces unnecessary variability and spurious results. To optimize the value of clinical pathology data, a single method of collection should be used throughout a study or series of comparable studies. For example, anesthesia tends to decrease interanimal variability for clinical pathology results from monkeys, especially their cell counts and electrolyte concentrations. If pretreatment or baseline blood collection is performed on animals anesthetized for physical examinations or other baseline procedures, the relatively heterogeneous data obtained from unanesthetized animals during treatment may cause confusion or be misinterpreted. Similar problems can occur when interim blood samples from rodents are collected from the tail or retro-orbital plexus or sinus and terminal blood samples collected from the heart, aorta, or posterior vena cava.

Blood collection from dogs, monkeys, and rabbits is facilitated by relatively easy access to large vessels (e.g., jugular, cephalic, and saphenous veins for dogs; femoral, cubital, and saphenous veins for monkeys; auricular artery and jugular vein for rabbits). Blood collection from mice is complicated by size and volume limitations, and terminal procedures are often used (e.g., cardiac puncture or sampling of the posterior vena cava or abdominal aorta at necropsy). Many acceptable methods are used for blood collection from rats. Jugular blood collection is used by laboratories with sufficient study load for phlebotomists to maintain proficiency and offers many advantages for toxicology studies.[49] Several high-quality blood samples can be collected from one animal, directly from a large vessel with needle and syringe, without anesthesia or expensive equipment or risk of damaging important structures such as the eye or heart. Because no time-consuming ancillary procedures are necessary (e.g., warming the tail to dilate the tail vein or anesthesia), samples can be collected quickly, and it is possible to accurately collect timed samples

(e.g., at 1, 5, 10, and 15 min postdose) from a single animal. However, compared to other techniques, blood collection from the jugular vein of rats requires regular practice to remain proficient.

Inappropriately collected or prepared samples increase variability of the data by introducing spurious or artifactual results. Fibrin or clot formation in a hematology sample always results in a spuriously low platelet count but may also cause low erythrocyte and leukocyte counts. Small clots may form because of an insufficient amount of anticoagulant (potassium ethylenediaminetetraacetic acid [potassium EDTA] for hematology samples), inadequate mixing of blood with anticoagulant, or poor blood collection technique with exposure of blood to substances from traumatized tissue. Excess anticoagulant can cause dilutional errors for cell counts and altered cell volumes, particularly for erythrocytes. The use of an inappropriate anticoagulant can cause spurious results. Intentional or accidental exposure of clinical chemistry samples to potassium EDTA results in very high potassium concentrations, very low calcium and magnesium concentrations due to chelation, and very low activities of enzymes such as ALP and CK that use magnesium as a cofactor.[50] Trisodium citrate, the anticoagulant of choice for the coagulation assays, also chelates divalent cations and will additionally increase sodium concentration if incorrectly used for the clinical chemistry sample. Excess anticoagulant in samples for coagulation assays can cause prolonged coagulation times.

Although hemolysis can be caused by test articles, it can also be caused by poor technique for sample collection, sample transport, or serum/plasma separation. Hemolysis can result in spuriously increased or decreased test results by two principal mechanisms: release of erythrocyte constituents and interference with test methodology.[50–54] Techniques and procedures should be chosen that eliminate in vitro hemolysis to the greatest extent possible.

Handling of collected blood can affect clinical pathology results. As previously indicated, prolonged contact between serum and clotted blood causes spurious clinical chemistry changes that can be controlled by prompt separation of serum from the clot.[55] Although most analytes are relatively stable for a reasonable amount of time,[6,56,57] unnecessary delay or storage of samples before analysis should be avoided. Ideally, hematology samples should be analyzed within a few hours of collection and no later than 24 h after collection. If samples for coagulation tests cannot be run on the day of collection, the plasma should be frozen at –20°C and thawed only once before analysis.[58] If samples for clinical chemistry tests cannot be run on the day of collection, the serum or plasma (lithium heparin is the recommended anticoagulant when plasma is used for clinical chemistry) should be refrigerated or frozen overnight. If there will be a long delay before analysis or the desired analyte is relatively labile, samples should be frozen at –70°C. Samples from all animals for any given testing interval (and all intervals, if practical) should be handled the same way.

Other sources of variation for clinical pathology data are possible, but the impact of each on data interpretation in toxicology studies is generally minimized by the inclusion of age- and sex-matched control groups exposed to the same environmental conditions and undergoing the same experimental procedures. Occasionally overlooked are the effects of procedures that may differ between the control and treated groups. Because toxicology studies frequently include blood collections for analyses other than clinical pathology (e.g., toxicokinetic measurements or detection of antidrug antibody), it is imperative that control animals be bled in a manner similar to that for the treated animals. The collection procedures and volume of blood taken for these tests can have a significant effect on hematology and clinical chemistry results,[59–61] and data interpretation is seriously compromised if control animals do not undergo the same procedures. Even when control animals are bled in a like manner, iatrogenic blood loss can complicate data interpretation.[62] This is especially true for rats and small monkeys.

Analytical Variation and Quality Control

In addition to sources of variation that occur before sample analysis, the analytical procedure itself is a source of variation. Analytical variation is minimized by a robust quality-control system within the clinical pathology laboratory. Detailed discussions of quality-control systems are available in many textbooks.[2,63,64] At a minimum, the quality-control system should include initial verification that a new method satisfies the goals of the laboratory for accuracy and precision for the analyte being measured; standard operating procedures for all laboratory functions necessary for analysis and reporting of test results; documentation of routine instrument calibration procedures; documentation of routine and nonroutine instrument maintenance; documentation of appropriate personnel training; proper labeling of all reagents, controls, standards, calibrators, and other chemicals in the laboratory; routine analysis of quality-control specimens and review of quality-control data for detection of systematic errors; routine review of subject data for detection of random errors; standard procedures for responding to and documenting out-of-control situations; and participation in some form of external quality control or proficiency testing with survey samples for analysis.

Analytical variation is affected by the accuracy and precision of a test procedure. Accuracy is a measure of the extent to which the mean estimate of a quantity approaches its true value, and precision is a measure of the agreement among replicate measurements (i.e., the reproducibility of a test result). Accuracy is generally determined in a prescribed way when a new method is introduced into the laboratory, and it is continually reassessed by means of proficiency testing. Most analytical procedures exhibit a small amount of systematic bias or inaccuracy that is either constant or proportional. The mean estimate of the quantity of analyte is always in error in the same direction, either higher or lower, than the true quantity. Precision of a test can be assessed within a single run (e.g., 20 consecutive analyses of the same sample for within-run precision) and from day to

day (e.g., the same sample analyzed several days in a row for between-run precision) and is reflected by the coefficient of variation (CV) of a test. The CV expresses the error or variability of replicate test results as a percentage of the mean value: (standard deviation/mean) × 100; the lower the CV, the greater the precision or repeatability of the test.

Accuracy and precision are desirable independent qualities for a clinical pathology test. Tests can be accurate but imprecise or inaccurate but precise. In the context of most toxicology studies, where results from groups of treated animals are compared with results from concurrent control groups and their own pretreatment results, precision is more valuable than accuracy. This is in contrast to the clinical setting, where the physician or veterinarian evaluates individual patients under less controlled conditions and uses broad historical reference intervals for making decisions. In a toxicology study, an imprecise test, regardless of accuracy, is less useful in detecting small differences between the control and treated groups. If the true mean glucose concentrations for four control dogs and four treated dogs are 100 and 115 mg/dL, respectively, but the standard deviations for the groups are large because of imprecision, then it is unlikely that the observed difference between the means (i.e., 15 mg/dL) will be considered a real difference. A precise test, regardless of a systematic bias or inaccuracy, is better able to identify small test article-related differences between the groups. In the same example, if the glucose test had a positive bias but was more precise, the means of the two groups might be 110 and 125 mg/dL, respectively, with smaller standard deviations. The improved precision permits a more accurate interpretation of the same 15 mg/dL difference between group means. Currently used hematology analyzers have very high within-run precision (CVs for most parameters between 0% and 2% with slightly higher CVs for differential WBC counts); clinical chemistry analyzers have similar within-run precision (CVs of 1%–2%) and between-run precision (CVs of 1%–4%).[65]

Clinical pathology laboratories that analyze animal samples frequently use tests that are optimized for accuracy using human samples. It is likely that many of these tests have small systematic biases when used for animal specimens. In most cases, however, the excellent precision afforded by using standardized commercial reagent kits, standards, and calibrators is preferable to time-consuming, costly efforts to optimize the accuracy of a test for different animal species by using in-house formulated reagents that likely undermine precision.

Although most clinical pathology tests can be used across animal species, some tests require specific reagents. Measurement of albumin in rabbits requires the use of a rabbit-specific calibrator. Immunoassays utilizing monoclonal or polyclonal antibodies raised against human substances (such as hormones) are usually inappropriate for use on animal specimens. Hematology analyzers that enumerate and differentiate blood cells must be validated as appropriate for laboratory animal species because of differences between animal and human cell morphology.

For human hospital laboratories, federal regulations allow each laboratory to set its own policies for assaying control materials as long as at least two control samples of different concentrations (i.e., normal and abnormal levels) are assayed every 24 h. The data from each quality-control analysis are used to make decisions about the validity of the patients' data. In the setting of nonclinical toxicology studies, it may be beneficial to assay control samples with each study run if a laboratory has a small study load (e.g., only one or two studies each day). For laboratories with a high study load, the frequency of control sample testing may more closely resemble that of a hospital setting, and control samples might be assayed only at regular intervals (e.g., before every 8 h shift). If results from a control sample are found to exceed the allowable limits for one or more analytes, then steps must be taken to resolve the problem. Actions that may be taken include, but are not limited to, the following: check for problems such as reagent levels, clots, or mechanical fault; repeat the assays on control samples using fresh aliquots; repeat the assays using newly reconstituted control samples; recalibrate the instrument for the analytes in question and then reassay the control samples; change the reagents, recalibrate, and reassay the control samples; and perform maintenance, recalibrate, and reassay the control samples.

Principles of Data Interpretation

Interpretation of data from toxicology studies begins with the identification of differences between control and treated groups and ends with an assessment of toxicological or biological relevance. In simple terms, the questions to be answered are: Do real differences exist between the groups, and if so, are those differences bad? Interpretation of clinical pathology data requires an understanding of each test's characteristics, species differences, and principles of internal medicine. Factors that influence the interpretation of a potential effect include study design and conditions, clinical observations, other clinical pathology results, anatomic pathology findings, and the test article itself. Interpretations of many clinical pathology findings are interdependent, and pattern recognition is critical. With the exception of early range-finding studies, appropriate dose selection usually precludes large, dramatic effects on clinical pathology test results. Most clinical pathology effects are relatively mild and often appear secondary to small alterations in metabolic or homeostatic mechanisms. Effects on clinical pathology results are rarely the only evidence of biologically important or adverse toxic effects. Clinical observations or anatomic pathology findings usually corroborate biologically important laboratory findings.

Statistical Comparisons

Statistical analysis of clinical pathology data is commonly performed in toxicology studies and often results in identification of several statistically significant differences between control and treated groups. However, all test article effects

caused by a test article need not be statistically significant, and all statistically significant differences do not necessarily represent test article-related effects. If used, statistical tests should be viewed as a tool to help identify differences between groups and not as the principal justification for decisions concerning potential test article effects.[66,67] It is important to remember that the number of animals per group affects the power of a statistical test. Using fewer test subjects increases the likelihood that statistical tests will fail to identify a true effect. Because the number of animals per group is usually quite small for studies with dogs or monkeys (e.g., four or fewer per sex per group), it is imperative that the data for each animal at the different test intervals be examined to look for patterns of change over time among the treated animals that are absent among the control animals. As the number of animals per group increases, the frequency of identifying statistically significant differences of very small magnitude increases. In rat studies with 15 or more animals per sex per group, it is common to observe statistically significant differences that represent very small test article-related effects but are not toxicologically relevant.

TABLE 26.3
Factors to Consider for Determining Whether Differences between Control and Treated Groups Are due to the Test Article

Magnitude of the difference
Dose dependency
Consistency over time
Consistency between sexes
Correlative findings
Number of animals tested (e.g., 2/sex/group vs. 15/sex/group)
Number of animals affected (i.e., group or individual differences)
Statistical significance
Timing of the difference with respect to dosing
Known characteristics of the test article/vehicle
Potential sources of preanalytical variability (e.g., expected variability for species, age, and tests in question; effects of study-related procedures such as route of administration, toxicokinetic sampling, and anesthesia)

Is an Apparent Difference Real?

When faced with an apparent difference between control and treated groups, the first question the investigator must answer is whether or not that difference represents a true test article-related effect or an incidental finding. Many factors can influence the answer (Table 26.3). A large difference is more likely to be real than a small one. Additional factors that suggest that a difference is test article-related include dose dependency, consistency over time, consistency between sexes, correlation with clinical observations (e.g., low chloride concentration and emesis), correlation with other clinical pathology findings (e.g., low hematocrit and high reticulocyte count), correlation with anatomic pathology findings (e.g., high globulin concentration and lymph node hypercellularity), presence in a large number of animals (e.g., 15/sex/group vs. 3/sex/group), and consistency with previously identified effects of the test article or related compounds. With large animals, it may be possible to determine whether an apparent difference was present before treatment was initiated and is, therefore, incidental. The chronology of an apparent difference is also important for interpretation; for example, following a single administration of most test articles, it is more likely that a real difference will occur within a few days rather than only after 2 weeks. Following chronic repeated administration of most test articles, it is more likely that a real difference will be apparent after a few months of treatment rather than only after a longer treatment period. For example, it would be unusual for a real difference at 6 months to be completely absent at 3 months.

With regard to specific tests and test species, the amount of expected analytical, interanimal, and intra-animal variability can influence the interpretation of apparent differences. For example, because ALT activity has much greater interanimal and intra-animal variability for monkeys than for dogs, a relatively small difference for this enzyme between control and treated groups is less likely to be a true effect for monkeys. Interanimal variability increases dramatically for older rodents (e.g., >1 year of age) because of naturally occurring age-related conditions, so small differences between groups of older rodents are less likely to be true effects of a test article.

Procedural factors such as the route of test article administration, blood collection technique, animal handling, and randomization for blood collection also affect variability and must be considered. For example, continuous intravenous infusion increases interanimal variability for several tests (e.g., WBC count, hematocrit, and serum proteins), and interpretation of small differences in results of these tests is difficult. Blood collection by cardiac puncture affects variability of muscle enzymes such as CK and AST. The potential for spurious findings associated with lack of randomization for blood collection was discussed previously.

Is a Real Difference Bad?

If a difference between control and treated groups is clearly real, the next question the investigator must answer is whether or not that difference represents a bad or adverse effect. Does the finding itself (e.g., low hemoglobin concentration) or the condition that caused the finding (e.g., blood loss from gastrointestinal erosions or ulcerations) represent a toxic effect that compromises the animal's health? The answer is often ambiguous and quite subjective. Although a large difference for a given parameter is more likely to be adverse than a small difference, it is impossible to define set limits for each test that represent an adverse effect. Many other factors must be considered. The same magnitude of change for a given test can have completely different connotations depending on the mechanism for that change, correlative findings, study design and procedures, test species, animal age, and the test article itself (e.g., a clinical pathology parameter may be the target for the pharmacological activity of a drug). Urea

nitrogen may be markedly increased because of dehydration (e.g., mice that have been fasted too long before blood collection or animals that refuse to drink water containing test article) but only mildly increased in the early stages of renal toxicity. Increased ALT activity associated with histopathological evidence of hepatocellular degeneration and necrosis is likely more important toxicologically than the same level of increase for which no correlative findings exist. Because of species differences for interanimal variability, a threefold increase for ALT activity for dogs (i.e., treated vs. control group means) is more likely to represent an adverse condition than the same increase for monkeys. A 10% decrease in hemoglobin concentration is less likely to represent an adverse condition in animals bled repeatedly during a study or that received the test article by continuous intravenous infusion than in animals that were not bled repeatedly or were treated by oral gavage. Very high neutrophil counts would normally reflect an adverse condition, but if the test article was a granulocyte colony-stimulating factor, high neutrophil counts would be a desirable effect.

Some measured analytes are critical to good health (e.g., neutrophil count, hemoglobin concentration, glucose concentration, calcium concentration, potassium concentration), and correlative in-life observations (e.g., bacterial infections, lethargy, weakness, weight loss) may help determine whether an observed effect on that analyte has impacted the animals' health. Other measured analytes are markers for effects best evaluated by histopathologic examination (e.g., ALP, urea nitrogen). All clinical pathology tests can be altered by more than one process or mechanism, and some mechanisms have worse implications than others; for example, a 10% decrease in hemoglobin concentration associated with poor food consumption and reduced body weight gain is of less concern than the same decrease caused by Heinz body hemolysis (oxidative injury). When determining the biologic or toxicologic significance of an effect on a clinical pathology test result, consideration must be given to the analyte's normal function for maintaining health, correlative findings that may better define the overall impact of the test article on health, and the mechanism that brought about the change. All study data must be considered.

Reference Intervals

Reference intervals are constructed with values obtained from reference individuals. In most clinical pathology laboratories used for toxicology studies, the reference individuals are control animals from previous studies and clinically healthy animals that have not received treatment (e.g., monkeys or dogs that have clinical pathology tests performed before initiation of dosing). In human medicine, the National Committee for Clinical Laboratory Standards recommends that reference intervals be estimated by the nonparametric method and that a minimum of 120 values from reference individuals be used.[68] Test results from the reference individuals are subjected to statistical treatment such that rare values at both ends of the distribution are eliminated; for example, if the lowest and highest 2.5% of the values are eliminated, the resulting reference interval represents the central 95% of the distribution of values. If the distribution is Gaussian, the interval corresponds to the mean ± 1.96 SD. By definition, when the central 95% is used as the reference interval, 5% of the results from normal individuals (1 of 20) are outside of the reference interval for any given test. Clearly, a value outside of the reference interval does not necessarily indicate an abnormality.[69]

Like statistical comparisons, historical reference intervals can be used as a tool when assessing apparent differences between control and treated groups. The value of reference intervals for data interpretation is sometimes overestimated, and the potential for their improper use is great.[70–72] It is tempting to invoke historical reference intervals when trying to decide whether apparent differences for clinical pathology results are true or adverse effects. While historical reference intervals can be helpful for establishing some perspective concerning what is typical or expected, the conditions of every toxicology study are unique, and it is inappropriate to use a reference interval as the primary reason for dismissing an apparent difference between control and treated animals as being incidental or biologically insignificant. It can be equally inappropriate to use a reference interval as the primary reason for determining that an apparent difference is real or adverse. As detailed in the previous sections, many factors must be considered when evaluating the nature of an apparent test article effect.

The suitability of a historical reference interval for data interpretation for a given study is a function of the parameters or *partitioning factors* that define the reference population used to construct the interval. Many potential partitioning factors exist with respect to toxicology studies (Table 26.4). The most commonly used partitioning factors are species, strain, sex, and age; in other words, a typical reference population might be defined as male Wistar rats from 8 to 10 weeks of age. Many other partitioning factors, however, can influence the reference interval and make it broader, narrower, higher, or lower. These factors include animal supplier, site of blood collection, use of anesthetic, type of anesthetic, diet, fasting status, time of sample collection, housing (single or group), and sample matrix (e.g., serum or plasma). If control animals are used for the reference population, additional partitioning factors include route of administration (e.g., dietary, oral gavage, or intravenous infusion), vehicle or control article administered (e.g., sterile water or corn oil in a gavage study; sterile saline or 5% dextrose in an intravenous infusion study), and whether or not the animals were bled repeatedly for toxicokinetic analyses, multiple clinical pathology intervals, or other tests. Finally, laboratory considerations include instrumentation or techniques used to analyze the specimen and sample storage conditions (e.g., storage temperature and time interval between collection and analysis). Ideally, whenever a new instrument or reagent system is introduced, a new reference interval

TABLE 26.4
Examples of Partitioning Factors for Constructing Reference Intervals

General Factors	Factors for Control Animals	Laboratory Factors
Species	Route of administration	Instrument
Strain	Vehicle/control article	Reagents/methodology
Age	Study-related procedures prior to clinical pathology (e.g., blood collections, anesthesia, therapeutic treatments)	Sample storage (length and temperature)
Sex		
Supplier		
Site of blood collection		
Use and type of anesthesia		
Diet		
Fasted/nonfasted		
Time of sample collection		
Matrix (i.e., serum or plasma)		

is constructed. In practice, laboratories often rely on evidence that demonstrates relative consistency between the old and new analytical methods to avoid complete replacement of old intervals.

The number of partitioning factors used to define a reference interval has a direct impact on the number of reference individuals available, and obtaining enough data for meaningful reference intervals, applicable to a given study, can be difficult or impossible. Because of this, laboratories often ignore many partitioning factors and lump data together from control animals of dissimilar types of studies or from samples that have been handled differently. The result is broader reference intervals with less relevance to data interpretation.

Even when reference intervals are appropriate for a given study (i.e., the partitioning factors match the study animals, conditions, and procedures), it is wrong to assume that a difference between control and treated groups represents a true or adverse effect simply because values for the treated group fall outside of the reference interval. Concurrent control animal data for a given study are never a perfect reflection of the historical reference data; they do not exhibit the same means and distribution. The mean for the control group may be higher or lower than the mean for the reference interval, and the distribution of results for the control group is almost always narrower than that of the reference interval. Depending on the location of the control group data within the reference interval, a very small, incidental difference for the treated group may fall outside of the reference interval, and a relatively large, adverse test article-induced difference may fall within the reference interval. A small difference, within the reference interval, may represent a very significant adverse effect; for example, dehydration can result in normal RBC counts and protein concentrations in anemic, hypoproteinemic animals. Loss of an entire subpopulation of lymphocytes is not necessarily enough to cause the absolute total lymphocyte count to fall below the reference interval. When reference intervals are broad, as occurs when few partitioning factors are used or normal interanimal variability is great (e.g., ALP activity for monkeys), significant toxicity can occur without individual test results exceeding the limits of the intervals. Investigators must understand the limitations of reference intervals with respect to data interpretation. By themselves, reference intervals do not determine whether or not an apparent difference is real or adverse. They are simply an adjunct to sound scientific judgment.

Regardless of the many pitfalls affecting their use for data interpretation, historical reference intervals do have other important functions. They serve as a nonspecific measure of quality control that can detect changes over time in assays, study conditions, or animal characteristics. For example, it may be noticed that liver enzyme activity in mice has increased over time, and the cause of this finding might be traced to changes in handling practices or animal supplier. Reference intervals also serve as a nonspecific measure of analyte variability. The cause of seemingly excessive variability might be inadequate assay precision, nonstandardized preanalytical procedures, or true interanimal variability. Finally, reference intervals can be valuable when only treated animals are tested at an unscheduled interval because of signs of toxicity or when very few animals are used for small investigational studies with no concurrent control group. Reference intervals may help to determine that animals acquired for a small study have preexisting problems that could confound data interpretation.

Hematology Tests and Interpretation

Hematology tests most often performed for toxicology studies evaluate erythrocytes, leukocytes, platelets, and coagulation. Technological advances by manufacturers of hematology and coagulation analyzers have increased the availability of highly sophisticated instruments to perform tests on animal blood with precision and accuracy suitable for nonclinical safety assessment studies. Automated hematology methods are a necessity in toxicology because manual methods are unacceptably imprecise, labor intensive, and slow. Regardless of the method of analysis, however, absolute WBC and reticulocyte counts (cells/unit of volume)

should always be reported rather than relative counts (percent of total). Relative counts are irrelevant for interpretation of effects.

Hematology and Coagulation Analyzers

Many currently marketed hematology instruments are capable of measuring or calculating all of the routinely recommended tests using less than 300 μL of anticoagulated whole blood. The instruments typically use a combination of two or more principles including electrical aperture impedance, laser light scatter, and differential staining characteristics to determine cell number (RBC, WBC, and platelet counts), cell type (WBC differential count and reticulocyte count), and cell size and size distribution (MCV, mean platelet volume [MPV], and RDW). Hemoglobin concentration is measured directly. From the previously mentioned parameters, hematocrit, MCH, and MCHC are calculated, and a few less common parameters may also be determined. Because the blood cells of laboratory animal species differ morphologically from human blood cells, only instruments with software validated for animal samples should be used.[73]

Coagulation analyzers measure the time required for fibrin clot formation after the reagent is added to a plasma sample. Clot detection can be accomplished by evaluating changes in conductivity, physical resistance, light scatter, or optical density. Most instruments can be programmed to permit detection of clot formation at times appropriate for animal specimens; these times can be much shorter (e.g., PT for dogs) or longer (e.g., PT for guinea pigs) than those for human samples.

Erythrocytes

Effects on erythrocyte parameters typically reflect a change in the balance between RBC production and RBC loss or destruction. Changes in plasma volume (e.g., dehydration or volume expansion) can also indirectly affect erythrocyte parameters. Although mechanisms for effects on erythrocyte parameters may be obvious, such as hemorrhage from gastric ulceration, they are often relatively obscure. Even when the exact mechanism is unclear, the effects can usually be described in terms of broad mechanistic categories and impact on health. RBC count, hemoglobin concentration, and hematocrit are measures of red cell mass. These parameters may or may not change proportionally, depending on the cause of the change and whether or not cell size and hemoglobin content are affected.

Decreased Red Cell Mass

Decreases in red cell mass must be differentiated from anemia. Anemia is defined clinically as a condition characterized by a hemoglobin concentration below the lower reference limit but can also be defined functionally as a decrease in red cell mass sufficient to cause decreased oxygen delivery to peripheral tissues. Decreased oxygen delivery may result in clinical signs such as pallor, weakness, exercise intolerance, tachycardia, or tachypnea. Humans generally have no clinical signs of anemia until hemoglobin concentration decreases below 8 g/dL.[74]

In many toxicology studies, animals in a treated group have lower RBC counts, hemoglobin concentrations, or hematocrits than those for the control animals, but the differences are less than those necessary to cause clinical signs or affect tissue oxygenation and are, therefore, not indicative of anemia. Unless the differences for RBC count, hemoglobin concentration, and hematocrit are quite large, it is preferable to simply discuss the magnitude of the differences between the control and treated groups and avoid using the term *anemia*. For example, reductions from control values for these parameters up to approximately 10% are relatively mild and probably do not have an adverse effect on the health of the animal. Reductions from approximately 10% to 30% may be considered a moderate effect and may or may not be clinically adverse. Reductions of more than 30% are generally marked and clearly represent a clinically adverse anemic condition. Although a 5% reduction in hemoglobin concentration may be insufficient to adversely affect health, the cause of the reduction (e.g., liver toxicity, gastric ulceration, or immune-mediated red cell destruction) may be an adverse process.

An animal's response to decreased red cell mass can be broadly categorized as regenerative or nonregenerative. A regenerative response is characterized by an appropriate increase in RBC production (erythropoiesis), and a nonregenerative response is characterized by the absence of an appropriate increase. The most important parameter for determining whether the response is regenerative or nonregenerative is the absolute reticulocyte count. For proper interpretation, the absolute reticulocyte count (i.e., reticulocytes/μL) should always be determined by multiplying the relative reticulocyte count (i.e., percent of erythrocytes) by the RBC count. If an animal is severely anemic, its relative reticulocyte count may be increased, yet its absolute reticulocyte count (most relevant because it measures the erythropoietic response) may be decreased.

Conditions Characterized by a Regenerative Response

Regenerative responses result from two general causes of reduced red cell mass: blood loss (hemorrhage) and accelerated erythrocyte destruction (hemolysis). Following acute blood loss or hemolysis, new erythrocytes (i.e., reticulocytes) begin to increase in number in peripheral blood within 3–4 days. Reticulocytes are larger and contain less hemoglobin per volume than do mature RBCs. During a strong regenerative response, the increased number of reticulocytes usually increases MCV and decreases MCHC. In practice, increased MCV is more commonly observed than decreased MCHC, especially for dogs and monkeys. In addition, the presence of variable cell size (anisocytosis) often results in increased RDW. Reticulocytes stain slightly more basophilic than mature erythrocytes with Romanowsky-type stains typically used for assessing RBC morphology and doing manual WBC differential counts (e.g., Wright or Giemsa stain). During a strong regenerative response, erythrocyte morphology

evaluated microscopically is described by the terms *anisocytosis* (variable size) and *polychromasia* (variable color) because of the increased numbers of reticulocytes. Greater numbers of nucleated RBCs, also called *metarubricytes*, and Howell–Jolly bodies (small pieces of nuclear material not cleared from the erythrocyte) may also be observed microscopically during a regenerative response.

During a strong regenerative response, erythrocyte production, as measured by reticulocyte count, can increase as much as sixfold to eightfold over normal levels. As long as the accelerated erythropoiesis is able to match erythrocyte loss or destruction, red cell mass parameters will remain relatively stable. If the cause of loss or destruction is removed or if erythropoiesis exceeds loss or destruction, the red cell mass will return to normal. When recovery periods are included in toxicology studies with compounds causing regenerative responses, affected animals occasionally exhibit transiently increased red cell mass parameters, during or following recovery, compared with control animals. Although the impetus for increased erythropoiesis is removed at the beginning of the recovery period, committed erythrocyte precursors continue to mature into RBCs, resulting in this rebound effect.

Blood Loss

Blood loss occurs secondary to a variety of conditions or study-related procedures and should always be considered when a decrease in red cell mass is accompanied by a similar decrease in serum protein concentration. The source of the blood loss may be identified by clinical observations (e.g., dermal ulceration, melena, epistaxis), necropsy findings (e.g., gastrointestinal ulceration or cystitis), or other laboratory tests (e.g., fecal or urine occult blood tests). Blood loss associated with serial blood collection for pharmacokinetic investigations, clinical pathology tests, or other study-specific requirements may also cause effects on erythrocyte parameters. Blood loss typically results in increased reticulocyte count, MCV, and polychromasia unless the loss is very recent (i.e., within the previous 2 or 3 days) or complicating factors affect erythropoiesis (see Indirect Causes of Nonregenerative Conditions).

Hemolysis

Hemolysis is characterized by premature elimination of RBCs from the circulation and is classified as either intravascular or extravascular. Hemolysis is considered intravascular when RBCs are destroyed directly within circulation and extravascular when RBCs are phagocytized, most commonly in the spleen and liver, by cells of the mononuclear phagocyte system (i.e., macrophages). Of the two, extravascular hemolysis is more commonly encountered in toxicology studies and usually results from oxidative or immune-mediated injury to RBCs.[75] Regardless of the underlying mechanism, extravascular hemolysis is usually accompanied by splenomegaly, bone marrow hypercellularity, and/or extramedullary hematopoiesis (more pronounced in rodents). Histologically, increased pigment is generally observed in the spleen and sometimes other organs, indicating increased red cell turnover and processing of hemoglobin. Increased serum bilirubin (bilirubinemia) and urine bilirubin (bilirubinuria) are less common correlative findings. Intravascular hemolysis is characterized by the presence of free hemoglobin in plasma or urine. Processes resulting in intravascular hemolysis generally occur rapidly and may cause rapid and profound changes in red cell mass. Some hemolytic processes have both extravascular and intravascular components.

Extravascular hemolysis secondary to oxidative injury is sometimes identified by the presence of Heinz bodies. Heinz bodies are particles of irreversibly denatured hemoglobin attached to the inner surface of the RBC membrane. They result when test articles with oxidative properties cause disulfide bonds to form between sulfhydryl groups of hemoglobin. RBCs containing Heinz bodies may be removed from circulation by macrophages and/or become morphologically distinct (e.g., ghost and blister cells) following selective removal of the Heinz bodies. Although Heinz bodies can be difficult to detect with the Romanowsky-type stains, they stain prominently with supravital stains (e.g., methylene blue) used for manual reticulocyte counts. The number of cells containing Heinz bodies can be determined in the same manner as that for manual reticulocyte counts. The size and number of Heinz bodies are dependent on the causative agent, dose, and time after exposure. Acute exposure to a potent oxidative agent typically causes acute anemia characterized by the observation of many RBCs containing a single, large Heinz body or, less frequently, multiple, small Heinz bodies. Ghost cells, blister cells, and other morphologic abnormalities may be present. Increased reticulocyte counts (reticulocytosis) develop within 3–4 days. Chronic, low-level exposure to an oxidizing agent usually does not cause a significant reduction in red cell mass but may cause increased reticulocytes. Under these conditions, the number of RBCs containing Heinz bodies is generally low, and the condition may go unrecognized if not looked for specifically. Identification of test articles that cause Heinz body formation is particularly important clinically because a deficiency of the erythrocyte enzyme glucose-6-phosphate dehydrogenase is relatively common in humans and results in greater susceptibility to oxidant-induced hemolysis.[76]

Oxidant test articles that cause Heinz body formation may also cause methemoglobinemia and vice versa.[77] Methemoglobin is hemoglobin in which the iron has been reversibly oxidized from the ferrous state (Fe^{2+}) to the ferric state (Fe^{3+}). Cells containing increased methemoglobin concentrations are not more susceptible to hemolysis but transport less oxygen than normal. The clinical signs of significant methemoglobinemia, therefore, are those of hypoxia.[78] Mucous membranes become cyanotic at methemoglobin concentrations above 10%. Lethargy and weakness occur at concentrations of approximately 30% or more. At greater than 80%, methemoglobinemia may be fatal. Blood containing a high concentration of methemoglobin appears brown. Accurate and efficient measurement of methemoglobin concentration can be accomplished with instruments

called *hemoximeters* or *cooximeters*. These multiwavelength, microprocessor-controlled photometers are designed to measure hemoglobin pigments such as carboxyhemoglobin and methemoglobin as well as the percentage of hemoglobin oxygenation. Samples collected for methemoglobin determination should be analyzed quickly (e.g., within 30–60 min) because methemoglobin is normally reduced by the erythrocyte enzyme methemoglobin reductase. The combination of a sensitive, precise instrument and a well-executed toxicology study allows detection of test article-induced methemoglobin formation at concentrations well below those necessary to cause clinical signs.[79] Among laboratory animals, the mouse is a poor model for studying the potential of test articles to cause methemoglobinemia because their erythrocytes have very high methemoglobin reductase activity.[80] Test article-induced methemoglobin in mice is quickly reduced to hemoglobin and, therefore, is more difficult to detect than in other species.

Immune-mediated RBC destruction has been associated with many drugs[81] but is largely a nondose-related idiosyncratic phenomenon and is detected infrequently in nonclinical toxicology studies. When it is observed, only one or two animals are typically affected, and they may or may not be in the high-dose group. In contrast to hemolytic conditions that occur soon after exposure to the test article, immune-mediated hemolysis is typically not observed until the test article has been administered for at least 1 week. Three general mechanisms exist for immune-mediated hemolysis: (1) the test article acts as a hapten bound to the RBC membrane; (2) the test article elicits an antibody response, and the resulting antigen–antibody complex binds to the RBC; and (3) the test article causes the immune system to mistakenly recognize normal RBC membrane antigens as foreign, and true autoantibodies are produced. Cells of the mononuclear phagocyte system, especially in the spleen, recognize antibody-coated RBCs and either phagocytize the entire cell or remove a portion of its membrane, creating morphologically distinct cells called *spherocytes*. On rare occasions, immune-mediated hemolysis is complement-mediated and occurs intravascularly. In a blood film, spherocytes appear smaller and denser than other RBCs; they are round and lack central pallor. Although small numbers of spherocytes can be observed with other conditions, they are the predominant morphologic feature of immune-mediated hemolysis. RBC autoagglutination is occasionally observed in the blood film, especially if the antibody response is primarily immunoglobulin M (IgM). Alternatively, autoagglutination may be detected in a wet mount of fresh blood diluted with saline or by special evaluation of automated hematology analyzer parameters. Direct antiglobulin tests may be used to confirm the presence of antibody or complement on RBCs, but species-specific anti-immunoglobulin or anticomplement must be used.[82] Animals with test article-induced immune-mediated hemolytic anemia can become severely anemic with repeated test article administration; however, they usually exhibit a strong regenerative response and will generally recover if test article administration is stopped. Confirmation that the anemia was test article induced can be accomplished by rechallenging the animal following recovery. Upon rechallenge, hemolysis should be evident within 1–2 days. Immune-mediated hemolytic anemia, unrelated to test article administration, is an unusual finding in all species used in toxicology studies, with the exception of Fischer 344 rats; immune-mediated hemolytic anemia often occurs as a sequela to large granular lymphocyte leukemia.[26]

Additional mechanisms associated with extravascular hemolysis include processes that result in RBC structural changes recognized as abnormal by the mononuclear phagocyte system. These include effects on RBC membrane lipids and proteins, intercalation of test article into the cell membrane bilayer, and effects on RBC metabolic processes. In addition, numerous biotherapeutics have been shown to cause activation of the mononuclear phagocyte system, resulting in extravascular hemolysis.[83] Direct damage to the RBC membrane is most commonly caused by test articles administered intravenously. The lipid bilayer of the cell membrane is sensitive to test articles with detergent-like properties, and intravascular hemolysis can occur rapidly when RBCs are exposed to high concentrations of the test article at the site of intravenous infusion (e.g., the tip of the catheter or needle). Administration of a very hypotonic solution, as might occur if sterile water is inappropriately chosen as the vehicle for a low-concentration solution, is another potential cause of acute intravascular hemolysis. Water passively enters erythrocytes because of the ionic concentration gradient, and the cells swell and rupture. Intravascular administration of hypertonic solutions typically does not cause hemolysis. If the amount of released hemoglobin exceeds the carrying capacity of circulating haptoglobin, unbound hemoglobin passes through the glomerulus and is excreted in the urine. Visible hemoglobinuria (red-tinged urine) may be observed within a few hours of treatment, and a regenerative response is detectable within 3 or 4 days of treatment. Intravenously administered test articles that cause extensive intravascular hemolysis are usually associated with local damage to endothelium. The effect of the vascular damage may be observed grossly (e.g., tail lesions in rodents treated via the tail vein) or histologically. Additional histopathologic evidence of intravascular hemolysis is the presence of hemoglobin pigment within renal tubular epithelial cells and hemoglobinuric nephrosis. Compounds administered by other routes rarely cause significant intravascular hemolysis.

Whenever regenerative anemia is identified in a nonhuman primate study, the role of the hemotropic parasite *Plasmodium* must be considered as a possible contributing cause. Many imported monkeys, even though they are captive bred, harbor subclinical infections with this organism that causes malaria.[84,85] The readily identifiable intracellular organism is frequently observed in blood films from healthy animals that have no signs of anemia.[86] Parasitemia is inconsistent or cyclical, however, and multiple blood samples may be examined from an animal before the organism is identified. On rare occasions, test article administration or the stress of shipment and study-related procedures precipitates a hemolytic crisis. When this occurs, the parasitemia is usually quite obvious in the blood film.

Another infrequent cause of hemolysis in toxicology studies is mechanical fragmentation or microangiopathic hemolysis. This form of hemolysis typically occurs when RBCs are forced to pass through small, fibrin-obstructed vessels in highly vascular tissue. The resulting fragmented RBCs are called *schizocytes* (helmet cells) and are easily identified microscopically. Disseminated intravascular coagulation (DIC) is the best example of a condition causing microangiopathic hemolysis, but widespread vascular injury in tissues such as lung, liver, or intestine also causes some degree of fragmentation. These conditions, especially DIC, are generally so severe that an animal may fail to mount a significant regenerative response before it dies or is humanely euthanized. Test articles that target endothelial growth factors and/or cause less severe vasculopathies may also result in RBC fragmentation.

Nonregenerative Conditions

Nonregenerative conditions are characterized by the absence of appropriately increased erythropoiesis in the presence of declining red cell mass. This can result in progressively decreased red cell mass over time because red cells that are normally destroyed or lost are no longer replenished. Erythrocyte morphology in nonregenerative conditions is characterized by the absence of changes observed with regeneration (e.g., anisocytosis, polychromasia, increased MCV, decreased MCHC). Most often, erythrocytes appear normocytic (normal size) and normochromic (normal color), and the MCV is unchanged (large animals) or decreased (rodents). Absolute reticulocyte count is unchanged or decreased, depending on whether the problem is simply an inability to adequately respond to increased needs or, more significantly, failure of erythropoiesis. Nonregenerative conditions result from indirect or direct causes.

Indirect Causes

A common finding in nonclinical toxicology studies is mildly decreased red cell mass (i.e., RBC count, hemoglobin concentration, and hematocrit) without a regenerative response and without an obvious mechanism for the effect. Red cell mass is usually no more than about 10% lower than that of the respective control group (e.g., mean control group hematocrit = 44%; mean high-dose group hematocrit = 40%). Slightly lower MCV is sometimes observed, especially in rodents. The animals may or may not exhibit clinical signs of poor health (e.g., poor grooming habits or decreased activity) or reductions in body weight, body weight gain, or, less frequently, feed consumption. In some cases, no clinical signs are observed. Potential concurrent effects on other clinical pathology test results include mildly decreased serum total protein and albumin. These relatively mild, nonspecific findings for red cell mass are identified most frequently in rat studies where the number of animals per group is high, the dose levels used are typically higher than those for dog or monkey studies, and the normal interanimal variability of hematology data is relatively low. In addition, because the circulating life spans of mouse and rat erythrocytes (approximately 25–40 and 45–65 days, respectively) are shorter than those for dogs (approximately 100–120 days) and nonhuman primates (varies with species; for rhesus monkeys, approximately 85–100 days),[4] reductions in RBC production of similar magnitude will become apparent more quickly in rodents. In many cases, specific mechanisms for these changes are not identified; however, they suggest a generalized reduction of anabolic processes, including those of hematopoietic tissues. Anything that affects the normally brisk pace of RBC production (in humans, approximately 100 billion new cells per day) will ultimately be reflected in the test results. It is also possible that decreased physical activity and correspondingly decreased tissue oxygen demand may contribute to reduced erythropoiesis.

Indirect effects on erythropoiesis are relatively common in toxicology studies and result from toxic effects on other tissues or organ systems. Collectively, they are sometimes referred to as *anemia of chronic disease*. Chronic inflammatory diseases[87–89] and significant kidney,[90] liver,[91] and endocrine dysfunction (e.g., hypothyroidism and hypoadrenocorticism)[92] negatively affect erythropoiesis and erythrocyte survival, and all of these conditions can be associated with this type of mild to moderate reduction in red cell mass. With chronic inflammatory conditions, the causes of reduced erythropoiesis are thought to be decreased availability or transfer of iron to developing erythrocytes, decreased responsiveness of the bone marrow to erythropoietin, and decreased red cell life span. With renal disease, reduced erythropoiesis is attributed to decreased renal production of erythropoietin and the effects of uremic toxins. Liver disease is sometimes associated with acanthocytosis, a morphologic abnormality of erythrocytes characterized by several blunt cytoplasmic projections resembling pseudopodia. The acanthocytes are thought to result from the accumulation of free, nonesterified cholesterol in the RBC membrane. Acanthocytes are relatively inflexible and removed prematurely from circulation by cells of the mononuclear phagocyte system, indicating that extravascular hemolysis plays a role in some decreases in red cell mass due to chronic conditions. Small reductions in circulating red cell mass are observed with hypothyroidism and may result from reduced basal metabolic rate and cellular requirements for oxygen. Changes in thyroid metabolism may play a role in the mild erythrocyte effects observed in some animals with reduced food consumption because caloric malnutrition can result in decreased T_3 and decreased responsiveness to T_3, which may, in turn, lead to reduced production of erythropoietin. These indirect effects on the erythron tend to be relatively mild and are not as toxicologically important as the direct effects on the primary target tissue.

Chronic iron deficiency, most commonly associated with chronic blood loss or inadequate dietary iron, is relatively rare in toxicology studies and is characterized by microcytic (low MCV), hypochromic (low MCHC) erythrocytes.

Direct Causes

Sustained direct toxic effects on the development and maturation of erythrocytes result in severe anemia because

senescent erythrocytes are not replaced. Rodents become anemic faster than dogs or monkeys because of the short circulating life span of their erythrocytes. In contrast to most toxicities that indirectly affect erythropoiesis, direct toxic effects markedly reduce absolute reticulocyte count.

Direct injury to pluripotent hematopoietic stem cells or their stromal microenvironment causes failure of blood cell production, resulting in the condition called *aplastic anemia*.[93,94] Aplastic anemia is characterized by varying degrees of pancytopenia—decreased erythrocytes, leukocytes (primarily neutrophils), and platelets—and hypocellular bone marrow. Because leukocytes are affected, decreased resistance to bacterial infections usually causes severe illness or death before the anemia becomes life-threatening. Irradiation is a classic model of stem cell injury and is used therapeutically as part of the process for bone marrow transplantation. In addition to irradiation, several chemicals and drugs are known to cause aplastic anemia in humans. These include benzene, toluene, lindane, pentachlorophenol, chloramphenicol, phenylbutazone, penicillamine, gold salts, and acetazolamide. Chemotherapeutic drugs such as alkylating agents (e.g., busulfan and cyclophosphamide), antimetabolites (e.g., fluorouracil and methotrexate), and cytotoxic antibiotics (e.g., doxorubicin and daunorubicin) have the potential to cause aplastic anemia because of their pharmacologic activity. Normally, however, their effects are reversible following completion of each treatment cycle.

In toxicology studies with test articles such as these, decreased WBC and platelet counts are typically recognized earlier in the study (generally 5–10 days after initiation of treatment) than decreased RBC counts because the circulating life spans for neutrophils (12–24 h) and platelets (7–10 days) are much shorter than that for erythrocytes. Conversely, absolute reticulocyte count can be a sensitive indicator of hematopoietic injury and may be better than WBC or platelet counts for identifying the onset of toxic effect and subsequent recovery. This is most apparent in rodent studies because the normally high absolute reticulocyte counts for young rodents facilitate identification of decreases, while their normally low neutrophil counts make neutropenia more difficult to recognize. Furthermore, reticulocyte counts are not compromised by poor blood collection technique that may cause increased interanimal variability for platelet count.

The timing of sample collection following administration of a test article that temporarily interrupts hematopoiesis will dictate the findings in peripheral blood and can impact interpretation. During the peak effect, reticulocytes, neutrophils, monocytes, eosinophils, platelets, and often lymphocytes are decreased in number, and histopathologic examination of the bone marrow reveals hypocellularity. Once the effect ends, hematopoietic tissue usually mounts a strong recovery, often called a *rebound effect*, that is characterized peripherally by increased counts for reticulocytes, platelets, and sometimes neutrophils. Increased extramedullary hematopoiesis in the spleen, especially for rodents, is often apparent before the bone marrow repopulates. Because the time to peak effect and the duration of effect vary for different test articles, it is necessary to perform hematology tests at multiple intervals for proper interpretation.

Pure red cell aplasia, a condition in which only the production of red cells fails, is rarely observed in toxicology studies, even though several drugs are known to cause the disorder in humans.[95] Because most drug-induced pure red cell aplasias are idiosyncratic and may be immune mediated, recognition of this toxic effect is low in animal studies using a limited number of test subjects. Furthermore, it would be very difficult to prove that unexplained nonregenerative anemia in a single animal was a direct test article effect. Pure red cell aplasia has been observed in animals dosed with recombinant human erythropoietin because the animals produced neutralizing antibody that cross-reacted with and neutralized endogenous erythropoietin. The lack of erythropoietic stimulation caused red cell aplasia.

Megaloblastic anemia is a nonregenerative reduction in red cell mass characterized by macrocytic erythrocytes (increased MCV), asynchronous maturation of cytoplasm and nucleus in hematopoietic precursors, and hypersegmented or giant neutrophils.[96] In humans, it is associated with a variety of disorders that cause folate or vitamin B_{12} deficiency (e.g., sprue, alcoholic cirrhosis, and pernicious anemia) and drugs (e.g., methotrexate) that impair DNA synthesis. Macrocytosis results because developing erythrocytes undergo fewer divisions before maturation. Megaloblastic conditions are rarely identified in laboratory animals, perhaps due to differences in uptake and metabolism of folate and vitamin B_{12}. On the other hand, nonhuman primates have been used frequently as animal models for folate and vitamin B_{12} deficiency.[97] Some antiviral drugs impair cellular DNA synthesis and cause mildly increased MCV that may or may not be associated with decreased red cell mass.

Finally, nonregenerative anemia is a feature of some hematopoietic tumors and leukemias. Nonregenerative anemias caused by neoplastic processes are due to a combination of factors, including blunted response to erythropoietin, excessive cytokine release (IL-1, IL-6, and TNFα) suppressing erythropoiesis, hemolysis, nutritional deficiencies, and competition for bone marrow space.[98,99] It is not unusual in carcinogenicity studies to observe severe anemia secondary to naturally occurring leukemia.

Leukocytes

Leukocytes are evaluated by counting the concentration of WBCs in peripheral blood and differentiating them into specific cell types: neutrophils, lymphocytes, monocytes, eosinophils, and basophils. Hematology analyzers capable of automated differentials provide more accurate data than manual counts and enable the detection of changes in even minor leukocyte types (e.g., decreased eosinophils). When interpreting and reporting differential WBC count results, it is essential to evaluate the absolute cell counts (i.e., cells/μL). Relative or percent counts are simply a means for determining the absolute counts and have little or no inherent value for assessing an animal's condition. For example, a

50% neutrophil count in a dog could be normal, increased, or decreased, depending on the total WBC count. As with changes in red cell mass, small changes in leukocyte counts should generally not be described using diagnostic terminology. When changes are pronounced, diagnostic terminology for increases and decreases in leukocytes may be used. These clinical terms include *leukocytosis* and *leukopenia*, *neutrophilia* and *neutropenia*, *lymphocytosis* and *lymphopenia*, *monocytosis* and *monocytopenia*, *eosinophilia* and *eosinopenia*, and *basophilia*. Neutrophils and lymphocytes are the most numerous WBC types in peripheral blood and are usually the cells affected when peripheral blood leukocyte counts change due to toxicity. Indirect effects on these two cell lines are often observed in response to study-related procedures or test article effects on other tissues. Direct test article effects on these two cell lines can occur but are less common than indirect effects.[100]

Physiological Leukocytosis

Physiological leukocytosis occurs in excited or frightened animals secondary to endogenous catecholamine release. Increased heart rate, blood pressure, and muscular activity shift leukocytes from the marginal pool (i.e., cells that adhere to the endothelium of small vessels or are sequestered in vascular beds of tissues such as the spleen) to the circulating leukocyte pool. Physiologic leukocytosis may cause the total WBC count to double. The specific cell type predominantly responsible for the increase varies because of species-dependent differences in the normal distribution of leukocyte types. Increased neutrophil count is the most prominent change for dogs, while increased lymphocyte count is most conspicuous for rats. Physiological leukocytosis of nonhuman primates generally results in a relatively similar increase in neutrophils and lymphocytes. Because physiological leukocytosis is most frequently observed in animals not accustomed to handling or blood collection, it is common for a few animals to have notably high WBC counts only at the first blood collection interval for a study. Recognition of this phenomenon is critical in studies using few animals (usually dogs or monkeys) and only one pretreatment interval. Overinterpretation of data from a study using this design might lead to the false conclusion that a test article has a myelosuppressive effect because posttreatment WBC counts, determined when the animal is more accustomed to being handled, may be much lower than pretreatment counts. For this reason, strong consideration should be given to acquiring at least two pretreatment hematology samples to facilitate proper data interpretation, especially if peripheral leukocyte counts are critical endpoints.

Steroid- or Stress-Induced Leukocyte Response

This leukocyte pattern occurs following exogenous glucocorticoid administration or when stressful conditions result in increased production of endogenous glucocorticoids. It is characterized primarily by increased neutrophil count (immature neutrophils, such as bands, are absent) and decreased lymphocyte and eosinophil counts. Increased monocyte counts may or may not be present. Differentials measured by an automated instrument are generally necessary to detect decreases in eosinophil count. Even though study-related procedures or test articles appear to create conditions generally considered stressful, this pattern is typically exhibited by individual animals and not entire groups. The changes are common in animals exhibiting significant toxicity. Leukocyte changes consistent with stress can be integrated with in-life and other clinical and anatomic pathology endpoints to develop a weight-of-evidence approach to determine that animals experienced stress.[35]

Increased and Decreased Neutrophil Counts

Increased neutrophil counts are usually caused by increased production or decreased margination but can also be caused by increased circulating life span. Increased production is generally the result of signals prominent in inflammatory conditions, with or without the involvement of an infectious agent. The signal for increased neutrophil production may be an inherent property of the test article (e.g., cytokines or hematopoietic growth factors) or may be secondary to a toxicity (e.g., intravascular hemolysis or tissue necrosis) or study-related procedures (e.g., chronic catheterization or repeated injections). Various cytokines and hematopoietic growth factors developed as therapeutic agents directly affect neutrophil kinetics and may result in mild to marked neutrophilic leukocytosis. The term *left shift* refers to an increased number of immature neutrophils (e.g., band neutrophils) in circulation, usually in response to an inflammatory lesion with a significant demand for neutrophils or administration of inflammatory cytokines. Inflammatory lesions resulting in left shifts or marked neutrophilia are usually identified either by physical examination, other diagnostic tests, or at necropsy. The term *degenerative left shift* describes the combination of a normal or decreased absolute neutrophil count with more immature than mature neutrophils. This pattern indicates that the production of neutrophils is insufficient to meet the peripheral need for neutrophils. It generally reflects a very severe infection as might occur with aspiration pneumonia, gastrointestinal perforation, or septicemia associated with bacterial contamination of an indwelling intravenous catheter. In conditions such as these, *toxic neutrophils* may be observed. These neutrophils have distinct morphological characteristics including cytoplasmic basophilia, vacuolation, and granulation and the presence of Döhle bodies (small, bluish-gray cytoplasmic inclusions made of aggregated rough endoplasmic reticulum). The term *toxic neutrophils* is a misnomer in that these cells only indicate greatly accelerated neutrophil production, regardless of cause; for example, toxic neutrophils may be observed following the therapeutic administration of hematopoietic growth factors. Increased neutrophil count due to decreased egress may occur with glucocorticoid therapy or test articles that inhibit the normal processes of egress from the vasculature.

Decreased neutrophil counts can be due to decreased production, increased margination, or increased egress from circulation. Leukocyte effects of cytotoxic or antiproliferative

agents are typically observed in most or all of the animals in groups receiving toxic dose levels. Because mice and young rats normally have very low neutrophil counts (e.g., less than 1000/μL), recognition of neutropenia is more difficult for these species than for others. In addition, although a neutrophil count below 500/μL is generally considered an indicator of risk for bacterial infection in humans, monkeys, and dogs, low neutrophil counts in rodents are generally not associated with increased incidence of infection. For noncytotoxic drugs, the observation of severe neutropenia, with or without a left shift or toxic neutrophils, is generally limited to one or two individuals that have severe complications secondary to test article toxicity or study-related procedures.

Single or short-term administration of a potent cytotoxic agent is usually characterized by neutropenia within a few days to a week of treatment, followed by a recovery that may include the presence of immature neutrophils for a short time and may result in a rebound neutrophilia. Detection of these changes is dependent on the timing and frequency of hematology testing. Similarly, the appearance of the bone marrow, whether hypocellular or hypercellular, is also dependent on the timing of sample collection. Hematology findings for test articles that directly injure pluripotent stem cells or rapidly dividing committed precursor cells are usually characterized by decreased numbers of reticulocytes, platelets, neutrophils, monocytes, eosinophils, and, possibly, lymphocytes. Selective damage of granulocyte precursors without affecting erythropoiesis or thrombopoiesis is unusual.

Immune-mediated reductions in neutrophil counts are relatively rare but can occur.[101–103] Like immune-mediated hemolytic conditions, however, they are often idiosyncratic and difficult to identify in nonclinical safety studies using limited numbers of test subjects.

Increased and Decreased Lymphocyte Counts

Lymphocytes are responsible for a wide variety of immune system functions. Lymphocytes are relatively long-lived compared with other leukocytes and have the ability to leave the vascular system through venules in lymph nodes and eventually reenter the blood via the thoracic duct. Automated hematology analyzers and light microscopy only determine total lymphocyte counts; subpopulations of lymphocytes must be determined by other methods such as flow cytometry. Increased lymphocyte counts can be caused by increased production, decreased margination, or redistribution. Physiological leukocytosis (i.e., excitement causing decreased margination) should be considered whenever increased lymphocyte count is present in only a few animals. Cynomolgus monkeys occasionally exhibit markedly increased lymphocyte counts (e.g., >60,000/μL) of unknown etiology; these are generally transient but can obfuscate test article-related findings. Increased lymphocyte count is an uncommon test article-related effect, although it may be observed in conjunction with compounds that cause chronic inflammatory lesions, especially in rodents, or with administration of test articles that are antigenic and elicit an immune response by the test animals. Increased lymphocyte count may be a pharmacodynamic effect of immunomodulatory drugs designed to alter lymphocyte trafficking.

Decreased lymphocyte counts can be caused by decreased production, increased margination, or redistribution. Decreased lymphocyte count is most frequently observed as part of the stress- or glucocorticoid-induced leukocyte response. Marked lymphopenia is commonly observed in moribund animals. Cytotoxic test articles often cause decreased absolute lymphocyte counts, but the magnitude of the decrease is usually less prominent than that for neutrophils in nonrodent species. In rodents, it is generally easier to detect effects on lymphocytes because of the normally high number of lymphocytes compared with neutrophils. During recovery from effects of cytotoxic test articles, lymphocyte counts may remain decreased longer than neutrophils and typically do not exhibit a prominent rebound response. Because of the many subpopulations of lymphocytes, it is difficult to gauge the biological importance of small decreases in absolute lymphocyte count. Selective reduction or elimination of a subpopulation may occur (e.g., selective decreases in B lymphocytes by belimumab, a BLyS antagonist) without greatly affecting the total lymphocyte count.[28] Evaluation of corollary information (e.g., overall health and findings that might suggest immunosuppression) is essential to putting small changes in lymphocyte count into context.

Monocytes, Eosinophils, Basophils, and Large Unstained Cells

Although absolute counts for these cell types are generally quite low (e.g., <1000/μL), test article-induced effects can often be detected using analyzers that do automated differential counts. As with neutrophils and lymphocytes, increases in circulating numbers of these cells are generally secondary phenomena unless the test article is a hematopoietic growth factor or other cytokine that directly stimulates cell production (e.g., interleukin-5 increases eosinophil count).

Monocytes phagocytize and digest particulate matter such as senescent cells and necrotic cell debris. They also serve as precursors to cells of the mononuclear phagocyte system and as a source of macrophages in inflamed tissues. Monocytes participate in modulation of the inflammatory response through cytokine production and antigen processing and presentation to lymphocytes. Increased monocyte counts may occur secondarily to any condition with substantial tissue destruction, such as widespread inflammation, tumor-associated necrosis, or hemolytic anemia. Decreased monocyte counts may be identified following administration of a cytotoxic chemotherapeutic agent.

Eosinophils are part of the body's defense against helminthic parasite infections, and eosinophilia is occasionally observed in nonhuman primates with a heavy parasite load. Increased eosinophil count is sometimes observed secondarily to hypersensitivity reactions. In addition, platelet clumps may be erroneously counted as eosinophils by some hematology analyzers.[104] Decreased eosinophil count may be identified as part of the stress-induced leukocyte pattern or following administration of cytotoxic chemotherapeutic agents.

Basophils may play a role in some hypersensitivity reactions. Effects on basophil counts under the condition of a toxicology study are rare. Large unstained cells are counted by automated hematology analyzers manufactured by Siemens Corporation (previously Bayer). These cells cannot be classified by the instrument into one of the five major cell types but generally are thought to represent lymphocytes, monocytes, or some immature cells. Changes in large unstained cell counts are typically observed with changes in the other cell types.

Leukemia

In most 2-year carcinogenicity studies using rodents, some of the animals will develop leukemia, a neoplastic proliferation of a hematopoietic cell line. The diagnosis of leukemia is best made by histopathologic examination of tissues infiltrated with the neoplastic cells. The odds of correctly identifying animals with leukemia are much greater by doing routine histopathology than by doing periodic hematologic examinations at regularly scheduled intervals. Although leukemias are sometimes characterized by markedly elevated WBC counts and the presence of neoplastic cells (e.g., blasts) in circulation, many animals with leukemia exhibit neither of these characteristics. Even when neoplastic cells are present in peripheral blood, it is often difficult to determine from which cell line they were derived (e.g., granulocytic, lymphocytic, myelomonocytic) because immature, anaplastic, or blast-stage cells from different cell lines can be indistinguishable by light microscopy using standard staining techniques.

Lymphocytic leukemias are the most commonly observed leukemias in laboratory rats and are occasionally observed as an incidental finding in 90-day toxicology studies.[17] Fischer 344 rats may develop large granular lymphocyte leukemia (also called *mononuclear cell leukemia*) at incidences of 30%–40% in the second year of a carcinogenicity study.[26] This neoplasm appears to arise in the spleen and commonly infiltrates other tissues, particularly the liver. Affected rats develop an immune-mediated hemolytic anemia and often exhibit hyperbilirubinemia and elevated liver enzyme activities in the serum. Neoplastic cells in peripheral blood appear as large, immature lymphocytes and may contain prominent azurophilic granules. Erythrophagocytosis by the neoplastic cells is occasionally observed.

Platelets

Platelets play a key role in primary hemostasis. When blood vessels are damaged, platelets quickly adhere to the subendothelium, undergo a shape change, and begin to aggregate, forming a primary platelet plug that is sufficient to control bleeding from minor injuries to small vessels. These activated platelets secrete a variety of substances that stimulate vasoconstriction and promote fibrin formation. Fibrin serves to cement the aggregated platelets into a stable hemostatic plug. Healthy endothelial cells in close proximity to the damaged vessel release inhibitors of platelet aggregation and fibrin formation in order to limit the clot size.

Increased Platelet Count

Increased platelet counts are caused by increased production by megakaryocytes or release of sequestered platelets. Extremely high platelet counts have the potential to increase the risk of thrombosis in humans, but increases in platelet count are generally asymptomatic in laboratory animals. Increased platelet counts in toxicology studies are usually indirect or secondary responses, but they can occur as a direct test article effect.

Increased platelet count as an indirect effect occurs in conjunction with generalized bone marrow stimulation as observed with hemolysis, blood loss, and many types of acute and chronic inflammation. These increases are generally of small magnitude and unlikely to have any biological significance; they have been termed *reactive* or *secondary thrombocytosis*. Release of hematopoietic growth factors such as erythropoietin and cytokines such as interleukin-6 and interleukin-11 may be at least partially responsible for the increased platelet production in some of these conditions.[105,106] Acute but transient increases in platelets may occur in association with physiological leukocytosis because catecholamine-induced splenic contraction releases platelets sequestered within the sinusoids of the spleen. A rebound thrombocytosis often follows recovery from significant thrombocytopenia caused by test articles such as chemotherapeutic agents that reversibly inhibit platelet production.

A few test articles directly stimulate platelet production and the release of platelets from megakaryocytes. These test articles include hematopoietic growth factors such as thrombopoietin and erythropoietin and small molecules such as vincristine.

Decreased Platelet Count

Decreased platelet count can be caused by decreased production or increased consumption/sequestration. Clinical signs associated with decreased platelet count include petechial and ecchymotic hemorrhages (most commonly observed in mucous membranes or at mucocutaneous sites), epistaxis, melena, menorrhagia, and prolonged bleeding from small wounds such as venipuncture sites. These signs typically do not occur spontaneously unless the platelet count is very low (e.g., less than 20,000/μL) or there is some type of hemostatic challenge (e.g., surgery).[107] Because of their protected environment, animals in toxicology studies are less prone to exhibit signs of hemorrhage when their platelet counts are extremely low.[108]

Decreased platelet counts are relatively common spurious findings associated with difficult venipuncture or inadequate anticoagulation of blood samples and subsequent in vitro platelet aggregation. In vitro aggregation can generally be confirmed by the observation of platelet clumps at the feathered edge of the blood film or by the characteristic scattergram produced by some automated hematology analyzers. Although typically observed for individual mice and rats, platelet clumps and spuriously low platelet counts can sometimes appear group-related because animals receiving

the test article may be more difficult to bleed as a result of poor health, dehydration, or small size relative to the control animals.

Decreased platelet counts due to decreased production can be caused by chemotherapeutic agents. These drugs reduce erythroid and myeloid cell production and frequently inhibit production of platelets by megakaryocytes as well. Moderately to markedly reduced platelet counts tend to occur a few days after reductions in neutrophil and reticulocyte counts because the circulating life span of platelets is longer, about 5–10 days.

Decreased platelet counts due to increased consumption of platelets can occur secondarily to acute lesions of highly vascular tissues (e.g., the gastrointestinal tract) or result from extensive hemorrhage, especially from multiple sites. If lesions affecting blood vessels are severe and widespread, DIC may develop, and platelet counts will be markedly decreased. Test articles may also stimulate immune reactions against platelets. Immune-mediated thrombocytopenia, like immune-mediated hemolysis, has been associated with many drugs[109] but is usually an idiosyncratic phenomenon and is, therefore, detected infrequently in nonclinical toxicology studies. When observed, only one or two animals are typically affected, and these animals may or may not be in the high-dose group. Immune-mediated thrombocytopenia and immune-mediated hemolysis may occur together. Antiplatelet antibody can be detected using flow cytometry; however, the best evidence that thrombocytopenia is immune mediated may come from a rechallenge exposure with the test article following cessation of treatment and recovery. Upon rechallenge, platelet count should drop acutely if the mechanism is an immune-mediated destruction. Compounds may also result in activation of platelets, which leads to their premature removal from circulation.[108] Activated platelets can be detected in some species by flow cytometric evaluation of activation markers.

Like immature red cells, young platelets have residual RNA that stains with nucleic acid dyes. Using methods analogous to those used for erythrocytes, these reticulated platelets can be counted using flow cytometry. Decreased platelet production is associated with inappropriately decreased concentrations of reticulated platelets, while platelet consumption is usually associated with increased reticulated platelet counts. Young platelets also tend to be relatively large, and MPV often increases during times of increased platelet production in response to platelet consumption.

Platelet Function

Test articles that affect platelet function have the potential to cause the same clinical signs as marked thrombocytopenia, but the tendency to do so is much less because of the complexity of platelet function and the presence of alternative or redundant pathways in vivo for the various platelet functions. Platelet function tests such as bleeding time and platelet aggregation may be beneficial when evaluating safety of therapeutic agents related to coagulation and platelet function, but it is important to recognize the considerable analytical and interanimal variability for these tests. Group results may be less meaningful than assessment of results from individual animals before and after test article administration. In addition, an effect noted in vitro may have no in vivo relevance.

Bone Marrow Smear Evaluation

The most important aspect of bone marrow smear evaluation is understanding when it should and should not be performed.[13] Although preparation of smears is advisable for most repeat-dose toxicology studies, evaluation of those smears is usually unnecessary. The standard hematology tests provide considerable information concerning bone marrow function, and if results from these tests are unaffected, it is extremely unlikely that bone marrow evaluation will provide any additional knowledge concerning potential significant test article effects on the hematopoietic system. Likewise, if the effects observed in peripheral blood are relatively small, it is unlikely that bone marrow smear evaluation will be beneficial.

Even when hematology test results are affected by test article administration, bone marrow evaluation has no benefit if mechanisms for the hematology findings are clear from the peripheral blood data and other findings. For example, decreased red cell mass parameters associated with increased absolute reticulocyte counts indicate a normal regenerative erythropoietic response to hemorrhage or hemolysis. In this example, bone marrow evaluation would simply confirm the presence of increased erythroid cellularity/production and provide no new information. Likewise, increased absolute neutrophil count in response to an inflammatory condition is normal, and bone marrow evaluation would only confirm increased granulocytic cell cellularity/production. Bone marrow smear evaluation is also not warranted following administration of a cytotoxic chemotherapeutic drug that predictably causes myelosuppression and can be monitored by peripheral blood tests.

The main indications for bone marrow smear evaluation in toxicology studies are moderate to marked nonregenerative anemia, leukopenia, or thrombocytopenia (or any combination of the three) of unknown etiology or significant morphological abnormalities of peripheral blood cells. The primary objective of the bone marrow smear evaluation is to assess the relative numbers and maturation of precursor cells to explain peripheral blood changes. Miscellaneous observations, including increased iron stores, plasma cell hyperplasia, and excessive cytophagia may also be recognized. Because bone marrow smears are relatively poor indicators of the actual cellularity of the bone marrow, it is necessary to consider the histopathologic findings for sections of sternum, rib, or femur. Although histologic sections generally are inadequate for evaluating individual cell types and abnormal cell morphology, they provide a good assessment of overall cellularity and are useful in providing estimations of cell density (e.g., for megakaryocytes or mast cells).

There are three major approaches to bone marrow smear evaluation. Regardless of the approach taken, the results of

the bone marrow evaluation (both bone marrow smear and histologic evaluation) must be interpreted in conjunction with peripheral blood test results. The most simplistic and least informative bone marrow evaluation is to determine the M/E ratio by counting a certain number of nucleated cells (usually between 200 and 500 cells) and classifying cells as either granulocytic or erythroid. The results generally are not useful in interpretation of peripheral blood changes and generally do not help to understand the underlying problem. For example, increased M:E ratio is consistent with increased granulocytic cellularity/production, decreased erythroid cellularity/production, or a combination of both. If peripheral blood data indicate a high neutrophil count and normal hematocrit, then an increased M:E ratio likely indicates increased granulocytic cellularity/production. If peripheral blood data indicate a normal neutrophil count and a nonregenerative anemia, then an increased M:E ratio likely indicates decreased erythroid cellularity/production. In both cases, the outcome of the M:E ratio could have been predicted from the peripheral blood results, and bone marrow evaluation provided no additional information. If an animal is neutropenic and has a nonregenerative anemia, an increased M:E ratio only indicates that there are relatively more granulocytic cells than erythroid cells and has not increased understanding of the process.

The most time-consuming and labor-intensive bone marrow evaluation is to perform a bone marrow cell differential count by differentiating the cell type and stage of development of at least 500 cells. When completed, an M:E ratio can be calculated from the results if desired. This thorough evaluation yields more information but at a very high cost. Differential counts provide numeric information concerning the relative numbers of different precursor cells and whether a cell line is maturing normally. Unusual or abnormal morphologic characteristics of the cells must be described separately. Techniques for conducting bone marrow differentials using flow cytometry have been described and have the potential to rapidly provide more accurate information than manual 500-cell differential counts.[13,110]

The most cost-effective and informative approach to bone marrow evaluation is the subjective cytological examination. In this approach, the bone marrow smear is examined in much the same manner as a morphologic pathologist examines a histologic section of liver, and a diagnosis or interpretation is recorded. The person performing the examination, usually a veterinary anatomic or clinical pathologist, assesses the quality and cellularity of the smear, the presence and relative number of precursors for each of the three major cell lines (erythrocytes, granulocytes, and platelets), and the maturation of each of the cell lines. Abnormal morphology is noted, as well as unusual numbers or characteristics of other cell types such as lymphocytes, plasma cells, monocytes, macrophages, and mast cells. A diagnosis or interpretation is rendered based on the examination of the smear and the peripheral blood tests results.

Regardless of the method used for evaluation of bone marrow smears, the end goal of the evaluation is to assess any negative impact of the test article on the number or maturation of hematopoietic cell precursors.[13,111,112] Conclusions from the bone marrow evaluation should address the relationship between the bone marrow findings (from both smears and histologic sections) and peripheral blood changes. For example, if a test article causes decreased platelet count, the absence of megakaryocytes in bone marrow smears and sections indicates that the decrease is due to failure of platelet production rather than increased platelet consumption peripherally. Likewise, if bone marrow evaluations find increased numbers of morphologically normal megakaryocytes, the results indicate that thrombocytopenia is due to a consumptive process.

Coagulation

The clotting mechanism or cascade has traditionally been divided into two pathways. In vivo, the intrinsic pathway begins with the activation of zymogen factor XII following exposure to negatively charged subendothelial components such as collagen. Factors XI, IX, and VIII are also part of the intrinsic pathway. The extrinsic pathway begins with the activation of zymogen factor VII following exposure to tissue factor (also called *tissue thromboplastin*) expressed by cells deep in the vessel wall. Both pathways share the same terminal sequence of events including the activation of factor X, conversion of prothrombin to thrombin, and conversion of fibrinogen to fibrin. It is thought that the extrinsic pathway is the primary initiator of coagulation in vivo.[113] The extrinsic and intrinsic pathways are routinely evaluated by the one-stage prothrombin time (OSPT; generally referred to as PT) and APTT, respectively. An alternative test, the activated coagulation time (ACT) test, is a simple, rapid measure of the intrinsic pathway that does not require a coagulation analyzer.[114–116] These three coagulation assays are relatively insensitive and nonspecific. Activity of a single clotting factor must be reduced to approximately 30% of normal before noticeably prolonged times are detected for an individual animal. When the results from groups of animals are compared, statistically significant differences are occasionally observed that are smaller than what would generally be considered an important change for an individual animal (e.g., less than 2 s of difference between the means for the control and high-dose groups). The toxicologic significance of differences such as these is sometimes difficult to determine. Although they clearly do not represent an effect likely associated with a bleeding diathesis for individual animals, they may be an indication of an important change in coagulation homeostasis. It may be valuable to design a longer study or increase the dose level to see if the effect is repeatable, dose related, and associated with clinical signs.

Under the conditions of most toxicology studies, where animals are exposed to high concentrations of a test article for a prolonged period of time, any major effect on the production of a clotting factor will likely result in a clinically obvious, bleeding diathesis. The administration of vitamin K antagonists such as dicumarol or the ingestion of synthetic or poorly absorbed fat substitutes is associated with bleeding

and prolonged PT and APTT because the fat-soluble vitamin K is required by the liver for production of functional forms of factors II, VII, IX, and X. In theory, PT will be affected before APTT because factor VII has the shortest half-life of the clotting factors. Although the liver synthesizes nearly all of the clotting factors, PT and APTT are insensitive measures of liver function. Because of the liver's large functional reserve, liver injury must be relatively severe before coagulation times are noticeably affected. DIC is characterized by depletion of all clotting factors, including fibrinogen, and moderately to markedly prolonged coagulation times. In many cases of DIC, the plasma samples fail to clot during the coagulation assays. These changes are observed in conjunction with decreased platelets (discussed previously).

Similarly to platelet count, coagulation times can be spuriously prolonged by difficult blood collection or poor collection technique. The combination of low platelet count, prolonged coagulation times, and/or low fibrinogen concentration, in an otherwise healthy animal, is an indication of poor sample quality. Inherited factor VII deficiency affects a small number of laboratory beagles.[58] These animals can usually be distinguished during pretreatment screening by PTs that are 2 or 3 s longer than those of the other animals acquired for the study. Although the deficiency rarely causes a clinical problem, it would be inappropriate to use these animals if the test article is known or suspected to affect coagulation. PT and APTT can both be artifactually prolonged because of excessive sodium citrate anticoagulant in the plasma sample.[117,118] This can occur if insufficient blood volume is added to standardized collection tubes or if the animal's hematocrit is elevated because of hemoconcentration (e.g., dehydration) or drug-induced polycythemia. Normal coagulation times vary from one laboratory animal species to another. Among the notable differences are the relatively fast PTs for dogs (e.g., 6–8 s) and slow PTs for guinea pigs (e.g., 30–40 s). It is not unusual for normal coagulation times to change slightly when a new reagent lot is introduced.

Although fibrinogen is occasionally measured along with PT and APTT as a coagulation assay, its primary value is as an acute-phase protein produced in response to inflammation. Increasing fibrinogen concentration almost always indicates an inflammatory process.

Clinical Chemistry Tests and Interpretation

Routinely performed clinical chemistry tests provide information concerning hepatocellular and biliary integrity and function, renal function, carbohydrate, lipid and protein metabolism, and mineral and electrolyte balance. Modern clinical chemistry analyzers require very small sample volumes; less than 250 μL of serum is needed to perform as many as 20 tests. It is possible, therefore, to obtain complete biochemical profiles from rats at multiple time points during a study without excessive blood collection. Most of the common clinical chemistry assays developed for human testing are applicable, without modification, to animal clinical chemistry testing.

Hepatocellular and Hepatobiliary Integrity and Function

Many routine clinical chemistry tests can be affected by liver toxicity because of the critical metabolic, synthetic, and excretory functions of the liver and the abundant enzymatic machinery required to perform these functions.[119,120] Conversely, a significant loss of liver tissue with little or no detectable change in routine tests is possible because of the liver's large functional reserve. No single test is superior for detecting all of the various types of liver toxicity, but the pattern of abnormal findings in a battery of tests may help characterize the location and severity of liver lesions.[121]

Liver Enzymes

Serum activities of liver enzymes are used primarily to identify hepatocellular injury and cholestasis, with or without hepatobiliary injury. Although sometimes referred to as liver function tests (or LFTs), they do not provide specific information about liver function. The liver can be severely dysfunctional in the absence of effects on serum liver enzyme activities. Animals with end-stage liver cirrhosis, for example, can exhibit normal serum enzyme activities. Conversely, focal lesions causing marked elevation of certain liver enzyme activities may have no appreciable effect on overall hepatic function because of the large functional reserve of the liver.

The specificity, sensitivity, and predictive value of liver enzyme tests are largely dependent on the models of hepatotoxicity used to make those determinations. This fact is at least partially responsible for the practice of including multiple liver enzymes in the clinical chemistry test panels for toxicology studies. The apparent absence of changes in liver enzyme activities does not necessarily rule out the possibility of hepatotoxicity. Possible reasons for this include suboptimal timing of clinical pathology testing and excessive variability of control animal results, especially for mice and monkeys.

Serum activities of many enzymes present within hepatocytes are increased following hepatocellular injury (i.e., degeneration or necrosis). The utility of a particular enzyme for the identification of hepatocellular injury depends on factors such as relative specificity to liver, intrahepatic location, intracellular location, the concentration gradient between the hepatocyte and serum, serum half-life, in vitro stability, and economy of measurement.[122–124] The most frequently used enzymes to assess hepatocellular injury are ALT, formerly serum glutamic pyruvic transaminase (SGPT), and AST, formerly serum glutamic oxaloacetic transaminase (SGOT).[18] SDH, GDH, and LDH are measured less frequently.

ALT is the most useful enzyme for the detection of hepatocellular injury in the majority of laboratory animal species. Although the enzyme is present in many tissues, its greatest concentration in most species is within hepatocytes, and significant elevations of serum ALT activity usually indicate release of ALT by hepatocytes. Species for which ALT is less useful because of relatively low hepatocyte concentrations include the guinea pig[125] and large domestic animals

such as pigs (including minipigs), goats, sheep, cows, and horses.[36,123,126,127] Because ALT is primarily cytosolic, and its concentration within the cell is up to 10,000 times greater than that in the serum, ALT may enter the serum in any condition that sufficiently alters cell membrane integrity. In addition to release from degenerating or necrotic cells, there may be other mechanisms (e.g., blebbing) for movement of the enzyme across the cell membrane[128] because high serum activities of ALT are occasionally observed with no evidence of cell death. The magnitude of serum activity elevation is generally proportional to the number of affected hepatocytes and is not indicative of the reversibility of the lesion. As a general guideline, test article-related ALT increases in excess of 200 IU/L are usually accompanied by histopathologic evidence of hepatocellular injury, while activities below this level may or may not have correlative findings.

Following an acute but reversible hepatotoxic event, serum ALT activity increases relatively rapidly, peaks within 1 or 2 days, and then declines over the next few days. Significant hepatotoxicity can go undetected if clinical pathology tests are delayed for 1 or 2 weeks following a single administration of the test article. Prolonged elevations following a single insult may reflect increased concentrations of ALT in regenerative liver tissue or continued loss of ALT from cells in close proximity to the primary lesion that undergo degenerative changes as a result of the altered microenvironment.

Increased serum ALT activity does not always indicate primary hepatocellular injury. Biliary disease or toxicity and bile duct obstruction may cause increased serum ALT activity at least in part due to the effect of retained bile salts on the cell membranes of neighboring hepatocytes. Muscle damage, when severe and extensive, can increase serum ALT activity in the absence of hepatic injury.[129,130] Increased intracellular activity of ALT will cause serum ALT activity to increase proportionately. Some studies have shown an association between increased serum ALT activity and certain drugs (e.g., glucocorticoids and anticonvulsants) that may be due, at least in part, to increased intracellular activity.[128]

Assessment of hepatotoxicity using serum ALT activity in monkeys can be complicated by the presence of subclinical, enzootic hepatitis A infection.[131] Transiently increased serum ALT activity occurs concurrently with seroconversion to the virus and periportal inflammation. Because animals entering a facility may not have been exposed to the virus previously, it is possible to observe transiently increased ALT activities (e.g., up to approximately 300 IU/L) for a few individual monkeys during the course of a toxicology study. Some facilities choose to bank serum collected from monkeys before a study is initiated for possible serologic testing to help clarify ambiguous ALT results. Interpretation of serum ALT activities for mice can be complicated by considerable interanimal variability. In toxicology studies using mice, it is relatively common for a few animals, including control animals, to have much higher serum ALT activities than those of the majority (e.g., 200 vs. 40 IU/L). One cause of these high activities is thought to be physical damage to the liver or possibly muscle, especially when mice are handled by grasping the body.[132] Restraint of rats, dogs, and nonhuman primates can also result in increased ALT, generally with concurrent AST.

Serum SDH and GDH activities have been recommended as good indicators of hepatotoxicity in laboratory animal species[12,121,133,134] because increased serum activities are liver specific and relatively sensitive. SDH is a cytosolic enzyme, and GDH is located in mitochondria. Elevations in serum SDH activity generally return to baseline levels faster than for other liver enzymes because of a short serum half-life. The addition of either of these tests to a standard clinical chemistry profile is a good choice if potential liver toxicity is of particular interest. SDH is routinely used in large animal veterinary practices, and GDH enjoys popularity in Europe. Because neither enzyme is used in human medicine in the United States, assay test kits are less available and may be difficult to obtain.

Serum AST and LDH activities tend to parallel serum ALT activity with respect to liver damage but are much less liver specific because of high concentrations in muscle and other tissues. Compared with larger animals, rodents tend to exhibit more interanimal variability for these enzymes. The variability may be due to contamination with muscle tissue during blood collection procedures such as cardiac puncture and rupture of the retro-orbital plexus or sinus. There is little advantage to determining both AST and LDH. Generally, only AST is determined, as LDH has greater interanimal variability and does not improve identification of hepatocellular injury. Elevations in serum AST activity caused by hepatotoxicity are usually less pronounced than concurrent elevations in serum ALT activity. Because a portion of intracellular AST is located in mitochondria, a more severe injury may be necessary for the release of like quantities of AST. As with ALT, drugs such as corticosteroids and anticonvulsants may increase intracellular activity of AST.

Decreased serum activities of ALT and AST are occasionally observed in toxicology studies. Among the potential causes for these findings are decreased hepatocellular synthesis or release of the enzymes, inhibition or reduction of enzyme activity, and assay interference. The most widely recognized of these causes involves an effect on pyridoxal 5′-phosphate (vitamin B_6), a coenzyme cofactor required for full catalytic activity of the aminotransferases. If a test article negatively affects this cofactor, directly or indirectly, serum aminotransferase activities may decrease.[135–137] This phenomenon is occasionally observed in monkeys that develop chronic watery diarrhea and may result from loss of the water-soluble cofactor. Because the aminotransferase assays can be run with or without additional pyridoxal 5′-phosphate in the reagent system, a test article-related effect on pyridoxal 5′-phosphate can be identified by analyzing for enzyme activity with and without excess cofactor. Regardless of the mechanism involved, decreased serum activities of the aminotransferases are generally not associated with toxicologically significant effects on the liver.

Several enzymes that originate from hepatocytes and biliary epithelial cells are increased in serum as a result of increased synthesis or release following intrahepatic or

extrahepatic cholestasis or in conjunction with biliary hyperplasia. These include serum ALP, GGT, and 5′-N. Of these, the most commonly measured are ALP and GGT.

A variety of related enzymes contribute to total serum ALP activity. In humans, at least four genes have been identified that code for different ALP isoenzymes: tissue nonspecific (found in liver, bone, and kidney), intestinal, placental, and germ cell. In most laboratory animals, only two ALP genes have been identified; these code for the tissue-nonspecific and intestinal isoenzymes. Tissue-nonspecific ALP enzymes originating in the liver, bone, and kidney are the product of the same gene and are, therefore, isoforms rather than isoenzymes. The isoforms can be distinguished because of differences in degree of posttranslational glycosylation and tissue of origin.[138,139]

The contribution of each isoenzyme and isoform to total serum ALP activity is dictated by tissue production and serum half-life. Because bone ALP is produced by osteoblasts, bone ALP activity is highest in young, growing animals, regardless of species, and decreases as animals mature. In puppies, the bone isoform may be responsible for up to 95% of total serum ALP activity. In adult dogs, the liver isoform is most prevalent. Bone ALP is responsible for approximately 60% of serum ALP activity in 6-week-old rats.[138]

In rats, serum activity of the intestinal ALP isoenzyme increases after feeding and is reduced with fasting.[140] Dog intestinal ALP is rarely identified in serum due to its short half-life. Diseases of the intestine are not typically associated with increased serum ALP. Kidney ALP may be found in urine but is not released into blood to any significant extent and has a short serum half-life. In response to glucocorticoids (either administered or endogenous), dogs can produce a unique hyperglycosylated form of the intestinal ALP isoenzyme (corticosteroid-induced ALP isoenzyme) from the liver. Corticosteroid-induced ALP activity is absent from the serum of most dogs.

In spite of the different ALP isoenzymes and isoforms, serum ALP activity is most often a measure of cholestasis. It is a sensitive indicator of cholestasis in the dog and usually increases well before other markers such as GGT and total bilirubin. Primary hepatocellular toxicities of mild to moderate severity often cause enough intrahepatic cholestasis to elevate serum ALP activity because of cell swelling and pressure obstruction of small bile ductules. Periportal effects result in higher activities than do centrilobular effects. Extrahepatic cholestasis, as might occur with pancreatitis, biliary calculi, or complications of bile duct cannulation, results in higher serum ALP activity than intrahepatic cholestasis. The value of serum ALP activity for identifying cholestatic lesions is less in monkeys than dogs or rats because of marked interanimal variability.

Alterations in serum ALP activity can be the first indication of an effect on bone formation. Elevations of serum ALP activity due to increased osteoblast activity tend to be less pronounced than those due to cholestasis (e.g., generally no greater than twofold to threefold higher than control animals). If the test article is administered for sufficient duration, the effect on ALP activity is usually accompanied by clinical or histopathologic evidence of bone changes. If a test article has concurrent liver and bone effects, bone-specific ALP measurement may be indicated.

Drugs such as anticonvulsants and glucocorticoids can induce synthesis of liver ALP, with or without evidence of hepatobiliary disease. Following corticosteroid administration to dogs, serum activity of liver ALP increases within a few days, while that for corticosteroid-induced ALP does not increase noticeably for about 10 days.[141] Increased corticosteroid-induced ALP activity has been observed in dogs with a variety of chronic disease conditions[73] and may be related to increased endogenous corticosteroid release, but this dog-specific isoenzyme has not been closely evaluated in toxicology studies.

Measurement of serum GGT activity gained popularity because it is more specific than ALP and was shown to be effective in certain models of biliary toxicity in the rat.[142] Although the highest tissue concentrations of this membrane-localized enzyme are in the kidney and pancreas, serum elevations have been reported only with hepatobiliary toxicity and following induction by drugs that stimulate microsomal enzyme production.[119,143] Unlike ALP, GGT is unaffected by bone growth or disease, and its serum activity is less likely to increase secondary to primary hepatocellular toxicity or intrahepatic cholestasis due to hepatocellular swelling. Serum GGT activity is often undetectable in rodents, and even small increases may be significant.

Serum 5′-N activity has been investigated as an alternative to ALP and GGT but has not found general acceptance.[121,144]

Bilirubin

In contrast to serum liver enzyme activities, serum total bilirubin concentration is primarily a function test. In the absence of hemolysis, increased serum bilirubin concentration indicates an effect on uptake, conjugation, secretion, or excretion of bilirubin by the liver. However, serum total bilirubin concentration is a relatively insensitive marker of hepatotoxicity because of the large functional reserve of the liver.

Bilirubin results from the breakdown of heme by cells of the mononuclear phagocyte system. Hemoglobin from senescent erythrocytes accounts for approximately 85% of all serum bilirubin. When macrophages release bilirubin into circulation, it is known as free, unconjugated, prehepatic, or indirect bilirubin. It is water insoluble and circulates bound to albumin. Hepatocytes efficiently remove unconjugated bilirubin from plasma and prepare it for elimination from the body by a four-step process that includes uptake, conjugation, secretion, and excretion. Secretion of conjugated bilirubin across the canalicular membrane is the rate-limiting step, and small amounts of conjugated or direct bilirubin escape into plasma. Conjugated bilirubin is not bound to albumin and is freely filtered through the glomerulus. In most species, conjugated bilirubin is completely reabsorbed by renal tubular epithelial cells unless the amount of filtered bilirubin is excessive. In the dog, the renal threshold is low and traces of bilirubin are normal in concentrated urine.

Conjugated hyperbilirubinemia occurs as a result of impaired secretion of bilirubin, cholestasis, or both. Because bilirubin secretion is the rate-limiting step, any disease that damages enough hepatocytes can potentially increase serum conjugated bilirubin concentration. Periportal lesions cause higher serum bilirubin concentrations than do centrilobular lesions, and extrahepatic cholestasis causes higher serum bilirubin concentration than does intrahepatic cholestasis. When increased bilirubin concentration results from cholestasis, serum ALP activity is generally elevated, particularly in the dog.

Unconjugated hyperbilirubinemia usually occurs as a result of relatively severe, acute hemolysis. If hepatocytes cannot process the large amount of unconjugated bilirubin produced by macrophages during a hemolytic episode, serum bilirubin concentration increases. A hemolytic event sufficient to overload a normal liver always produces other findings indicative of hemolysis. It is possible, however, for relatively modest hemolysis to cause unconjugated hyperbilirubinemia if hepatic function is already compromised. Although a number of nonhemolytic, unconjugated hyperbilirubinemia syndromes are known, these syndromes are usually due to hereditary defects in the uptake and conjugation of free bilirubin.

Unconjugated (or indirect) bilirubin can be differentiated from conjugated (or direct) bilirubin by the Van den Bergh test. The test is used clinically to help distinguish prehepatic causes of hyperbilirubinemia, such as hemolysis, from hepatic or posthepatic causes such as hepatitis or biliary obstruction. In well-designed toxicology studies, the combination of clinical observations, other laboratory data (e.g., hematocrit or liver enzyme activities), and anatomic pathology findings (e.g., hemosiderin accumulations in splenic macrophages or periportal hepatocellular necrosis) is usually more than sufficient to determine the primary mechanism for any observed hyperbilirubinemia. In addition, the correlation between bilirubin conjugation state and the underlying process is often inconsistent for very small increases observed in some nonclinical toxicology studies. For these reasons, laboratory determination of direct and indirect bilirubin is not recommended as part of the routine panel of tests performed in toxicology studies. Bilirubin fractionation may be useful if total bilirubin concentration is greatly increased in the absence of correlative findings because test article inhibition of uridine diphosphate glucuronosyltransferase, the bilirubin-conjugating enzyme, can substantially increase serum unconjugated bilirubin in the absence of other liver effects.[18,145]

Increased bilirubin can occasionally result from interference by the test article or its metabolites with the enzymatic assay generally used to measure bilirubin concentration. In these cases, use of an alternate assay such as the vanadate assay can be useful to assess true bilirubin concentrations.[146]

Decreased serum bilirubin concentration is occasionally associated with administration of test articles that induce microsomal enzyme production.[143] Human patients receiving phenobarbital therapy have lower serum bilirubin levels than the general population as a whole.[147] Enzyme induction apparently enhances the metabolism and excretion of bilirubin and could potentially mask an otherwise elevated bilirubin level.

Other Liver-Related Parameters

Like serum bilirubin concentration, total serum bile acid concentration is a measure of hepatic function. Bile acids are synthesized from cholesterol by hepatocytes, conjugated to an amino acid, secreted into the biliary system, and excreted into the intestine, where they facilitate fat absorption. Bile acids undergo efficient enterohepatic circulation, with most reabsorption occurring at the level of the ileum. Portal blood conveys the bile acids to the liver for uptake, reconjugation, and resecretion. Liver toxicity has the potential to alter bile acid metabolism at any of multiple steps and cause increased serum bile acid concentration. Unfortunately, although it is considered a sensitive and specific test for hepatobiliary disease in clinical veterinary medicine,[148] measurement of total serum bile acids has not proven effective at increasing the identification of hepatotoxicity beyond that of the standard battery of tests routinely performed in toxicology studies. Like total bilirubin, increased serum bile acid concentration does not discriminate between different types of hepatic lesions. In addition, serum bile acid concentrations tend to exhibit relatively high inter- and intra-animal variability, further decreasing their utility.

The liver is wholly or partially responsible for the synthesis of many substances including glucose, cholesterol, urea, and a variety of proteins. Severe hepatocellular dysfunction can cause decreased serum urea nitrogen concentration, hypoglycemia, hypocholesterolemia, hypoproteinemia (especially hypoalbuminemia), and prolonged coagulation times. Liver disease can also result in hypercholesterolemia and hyperglobulinemia. The patterns of change in clinical pathology tests caused by different types of liver toxicity, whether primary (e.g., chloroform-induced hepatic necrosis) or secondary (e.g., hypoxia-induced centrilobular necrosis), are often overlapping. Examination of the entire biochemical profile, along with other clinical pathology and anatomic pathology findings, is necessary to properly evaluate data for potential liver toxicity.

Renal Function

Serum urea nitrogen (or urea) and creatinine concentrations, in conjunction with measures of urine concentration (urine specific gravity or osmolality) and volume, are the most common tests used to evaluate renal function.[149–153] These tests are easy and inexpensive to perform but are relatively insensitive to small effects on the kidney and can be affected by nonrenal factors.

Urea is synthesized by the liver from ammonia that is absorbed from the intestine or produced by endogenous protein catabolism. Urea is freely filtered through the glomerulus and excreted in urine. Some urea is reabsorbed passively with water in the proximal tubule; the amount reabsorbed is

inversely related to the rate of urine flow through the tubule. Serum urea nitrogen concentration is, therefore, affected by rate of urea production, glomerular filtration rate (GFR), and flow rate of urine through the renal tubule. Mechanisms for increased urea nitrogen (also called azotemia) are categorized as prerenal, renal, or postrenal.

Prerenal causes for increased urea nitrogen are increased urea synthesis and decreased renal blood flow. Increased urea synthesis results from consumption of high-protein diets or conditions that increase protein catabolism such as starvation, fever, infection, tissue necrosis, or high gastrointestinal hemorrhage. Decreased renal blood flow decreases GFR and may be caused by conditions such as dehydration (the most common cause of increased urea nitrogen in toxicology studies), cardiovascular disease, or shock. Changes in urea nitrogen concentration caused by increased urea synthesis are typically small. Changes caused by decreased renal perfusion may also be small, but if GFR is severely affected, the increase in urea nitrogen is indistinguishable from that which would occur due to primary renal failure. When increased urea nitrogen is due to prerenal causes, renal concentrating ability is typically maintained. If the prerenal condition is dehydration, urine volume is reduced and urine concentration is increased as kidneys attempt to conserve water.

Increased urea nitrogen due to renal causes results from diseases or toxicity of the renal parenchyma. Like the liver, kidneys have a large functional reserve capacity. In clinical practice, it is commonly said that serum urea nitrogen concentration does not increase notably until approximately 75% of the kidneys' nephrons are nonfunctional. In nonclinical toxicology studies, however, it is likely that differences between control and treated animals can be detected prior to that degree of impairment. When the cause of increased urea nitrogen is primary renal disease or toxicity, renal concentrating ability may be impaired, and urine specific gravity may be isosthenuric (i.e., the same as the glomerular filtrate; approximately 1.008–1.012). Increased urea nitrogen due to renal causes is generally accompanied by histopathologic evidence of renal damage (e.g., proximal tubular nephrosis or chronic progressive nephropathy), and animals may exhibit signs of poor health such as inappetence, weight loss, or inactivity.

Postrenal causes of increased urea nitrogen reduce GFR by obstructing outflow of urine. Obstruction by naturally occurring urinary calculi is occasionally an incidental finding in rodent studies, but test articles that promote urinary calculi formation can also be responsible for this condition.

Creatinine is a nonprotein nitrogenous waste product formed at a relatively constant rate by the nonenzymatic breakdown of creatine. Creatine is a breakdown product of phosphocreatine, a molecule that stores energy in muscle. Serum creatinine concentration is, therefore, influenced by muscle mass and conditioning, but it is relatively independent of dietary influences and protein catabolism. Creatinine is freely filtered by the glomerulus, but unlike urea, it is not reabsorbed by the tubules. Following alterations in renal blood flow, renal function, or urine outflow, changes in serum creatinine concentration tend to parallel those for serum urea nitrogen concentration. The timing and magnitude of the changes for serum creatinine may lag behind those for serum urea nitrogen. This usually occurs as a result of the tubular reabsorption of urea, especially when urine flow is slow or when there is increased formation of urea. Serum creatinine is usually a better reflection of glomerular filtration than serum urea nitrogen because it is influenced by fewer factors. However, the most commonly used method for determining serum creatinine concentration, the Jaffe reaction, is nonspecific, and interfering compounds called *noncreatinine chromagens* can affect its accuracy. Although noncreatinine chromagens are typically of insufficient quantity to complicate data interpretation, other analytical methods for creatinine (e.g., enzymatic) can be used to investigate the possibility of interferences when serum creatinine concentrations are increased in the absence of correlative effects on serum urea nitrogen or renal histopathology. Endogenous creatinine clearance is sometimes used as a noninvasive measure of GFR because blood levels of creatinine are relatively stable over short intervals, creatinine is freely filtered, and creatinine is not significantly secreted or reabsorbed.[149,154] Unfortunately, this test is better suited for individual patients because it requires procedures (e.g., emptying the bladder before and at the end of the urine collection period) that are difficult in a toxicology study. Serum cystatin C concentration is being used more commonly in human medicine as an indicator of GFR because it is affected by fewer extrarenal factors than urea nitrogen or creatinine,[155,156] and it may see increased use in toxicology studies as more is learned about its performance in animals.

Other clinical chemistry findings sometimes observed when renal function is significantly impaired include increased serum inorganic phosphorus concentration and decreased serum sodium and chloride concentrations. Whereas increased inorganic phosphorus is primarily due to reduced filtration, decreased sodium and chloride result from loss of tubular function and normal reabsorption.

Proteins, Carbohydrates, and Lipids

Serum Proteins

Serum total protein concentration is a measure of all plasma proteins with the exception of those consumed in clot formation such as fibrinogen and other clotting factors. Serum total protein concentration is, therefore, about 0.3–0.5 g/dL lower than plasma total protein concentration. Albumin is the most abundant serum protein and is largely responsible for maintaining intravascular osmotic pressure. Albumin serves as a storage reservoir of amino acids and as a transport protein for plasma constituents that do not have a specific transport protein. Many test articles bind to and are transported by albumin. Globulins are a heterogeneous population of proteins that include specific transport proteins (e.g., transferrin for iron, lipoproteins for lipids, haptoglobin for hemoglobin, and thyroxine-binding globulin for thyroxine), mediators of inflammation (e.g., complement), acute-phase

proteins, clotting factors, enzymes, and immunoglobulins. Globulins are loosely categorized by their electrophoretic migration pattern as α, β, and γ globulins. Several different globulin proteins are present in each region of the electrophoretic pattern.[157] The regions can be further subdivided (e.g., most species have two α regions), but serum protein electrophoresis cannot distinguish specific globulin proteins. Immunoglobulins are generally thought of as γ globulins, but some, particularly IgM, extend into the β regions of the electrophoretogram.

The liver synthesizes albumin and most of the globulin proteins, while lymphocytes and plasma cells synthesize immunoglobulins. Serum total protein and albumin concentrations are measured directly, and serum globulin concentration is calculated by subtracting albumin from total protein. Hydration status must be considered for proper interpretation of changes in serum protein concentrations. Low serum protein concentrations, like low red cell mass, can be masked by dehydration.

In toxicology studies, the most frequent reason for increased serum total protein concentration is reduced hydration of treated animals relative to control animals. Serum albumin and globulin concentrations increase proportionately when simple dehydration occurs. The effect on hydration status of treated animals may or may not be detectable as clinical dehydration. Possible correlative clinical observations include gastrointestinal fluid losses (e.g., vomiting, diarrhea, excessive salivation), polyuria, and reduced water consumption. Because water consumption in rodents is closely associated with food consumption, any cause of decreased food consumption in rodents has the potential to cause dehydration. In short-term dietary studies, for example, palatability problems may result in higher serum protein and urea nitrogen concentrations for treated animals because of differences in hydration; however, if decreased food consumption is protracted and body weights or body weight gains are affected, serum protein concentrations will typically decrease over time.

Other common causes for increased serum total protein concentration in toxicology studies are inflammatory conditions that stimulate production of globulins called *acute-phase proteins* (e.g., fibrinogen, haptoglobin, α_2-macroglobulin, C-reactive protein) and/or immunoglobulins.[158–160] A concurrent decrease in serum albumin concentration often occurs because albumin is a negative acute-phase protein. The opposite direction of changes in albumin and globulin concentration may result in the absence of a change in total protein concentration. However, albumin-to-globulin ratio will be reduced. This serum protein pattern is commonly observed in animals affected by complications of long-term intravenous catheterization.

Decreased serum protein concentrations result from either decreased protein synthesis or increased protein loss. Protein synthesis can be negatively affected by decreased food consumption, maldigestion or malabsorption, and hepatic dysfunction. Although the functional reserve capacity of the liver is quite substantial and hepatic injury must be relatively severe before protein synthesis is notably diminished for individual patients, small differences between control and treated groups in large studies may be apparent with relatively modest hepatotoxicity. Loss of both albumin and globulin occurs with hemorrhage, exudative lesions such as burns or severe dermal toxicity, and, occasionally, severe diarrhea. Albumin may be the principal protein lost as a result of protein-losing enteropathies and glomerulopathies because of its relatively small size. Globulin concentrations may increase secondarily to enteropathies because of inflammation and increased systemic exposure to gastrointestinal toxins and bacterial flora. Decreased globulin concentrations, without concurrent or proportional decreases in albumin concentration, may be indicative of decreased synthesis of immunoglobulins. Histopathologic evidence of effects on lymphoid tissue strengthens this interpretation, and peripheral blood absolute lymphocyte counts are sometimes concurrently affected. Reduced serum globulin concentrations have been observed following prolonged administration of antibiotics (e.g., 4 weeks) to young animals, perhaps as a result of inhibition of normal bacterial flora and subsequently reduced antigenic stimulation.

A small decrease in serum albumin concentration is one of the most frequent findings in animals given poorly tolerated test articles. Like small decreases for other parameters (e.g., hematocrit, glucose concentration, cholesterol concentration, body weight, and body weight gain) that may occur concurrently, decreased albumin due to nonspecific causes is usually considered an indication of the animals' poor overall condition. Decreases in serum albumin concentration are more commonly observed for rodents than for larger species. Although this may be due simply to higher numbers of animals per group, faster turnover of albumin in smaller species may also be a factor[157]; for example, the half-life of albumin is approximately 2 days for mice, 8 days for dogs, and 16 days for baboons.

Serum Glucose

Serum glucose concentration is a reflection of intestinal glucose absorption, hepatic glucose production, and tissue uptake of glucose. The balance between hepatic production and tissue uptake is influenced by many hormones, including insulin, glucagon, glucocorticoids, adrenocorticotropic hormone, growth hormone, and catecholamines. In oversimplified terms, insulin promotes uptake of glucose by tissues, glucocorticoids and glucagon stimulate hepatic gluconeogenesis, and catecholamines and glucagon stimulate glycogenolysis.

The most frequently encountered causes of increased serum glucose concentration in toxicology studies are failure to fast an animal and catecholamine release secondary to excitement or fear. Moribund animals occasionally exhibit marked hyperglycemia, probably as a result of both glucocorticoid and catecholamine release. Glucose concentration decreases at a rate of approximately 7–10 mg/dL/h when serum is not separated from the blood clot. If blood collection is performed in group order (starting with the control group)

and samples are not processed promptly, the high-dose group may appear to have higher serum glucose concentrations than those of the control group because of greater glucose consumption by erythrocytes in the control group's samples. Infrequent causes of increased serum glucose concentration in toxicology studies include some relatively common clinical conditions such as diabetes mellitus, pancreatitis, hyperadrenocorticism, and steroid therapy. Test articles can also cause increased glucose by affecting the sensitivity of cells to insulin (insulin resistance).

In toxicology studies, test article-related decreases in serum glucose concentration are most commonly observed in animals that fail to thrive and gain body weight, with or without a concurrent decrease in food consumption. When this occurs, the difference for serum glucose concentration between control and treated animals is usually no more than 10 or 15 mg/dL. Although a precise mechanism for decreased glucose is typically undetermined, the difference may reflect the overall process that has caused the animals to do poorly and is frequently accompanied by small decreases in circulating red cell mass and serum protein concentrations. Clinical conditions that cause decreased serum glucose include intestinal disease with malabsorption, severe hepatic disease, endotoxemia, and some tumors, in particular insulinomas and hepatomas. Test articles can cause decreased glucose as a primary or secondary effect; frequent monitoring of large animals using glucometers and supplementation of the diet may be necessary to avoid severe hypoglycemia with some glucose-lowering test articles.

Serum Lipids

The two major serum lipids are cholesterol and triglycerides. Cholesterol is utilized for synthesis of cellular membranes, bile acids, corticosteroids, and some sex steroid hormones, and triglycerides are an important source of energy. Serum cholesterol and triglycerides are derived from dietary intake and endogenous synthesis, primarily by the liver. Cholesterol and triglycerides circulate as components of chylomicrons and lipoprotein particles: high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL).[161] Chylomicrons are produced by intestinal cells after ingestion of a fatty meal and are rich in triglycerides. Hepatocytes synthesize VLDLs, particles with less triglyceride but more cholesterol than chylomicrons. Triglycerides in chylomicrons and VLDLs are broken down to free fatty acids and monoglycerides by lipoprotein lipase attached to the surface of endothelial cells, especially in capillaries of adipose tissue and muscle. Adipocytes tend to reesterify fatty acids for storage as triglycerides. Myocytes tend to oxidize fatty acids for energy. Loss of triglyceride transforms VLDL to LDL. In humans, LDLs transport about two-thirds of serum cholesterol. In contrast, HDL is responsible for a significant majority of cholesterol transport in most laboratory animal species. For example, cholesterol of rats and mice is carried almost exclusively by HDL particles. Clinical chemistry analyzers can determine the amount of cholesterol associated with HDL and LDL particles (i.e., HDL cholesterol and LDL cholesterol). Species differences in lipid metabolism cause difficulties in correlating lipid effects in animal models with potential effects in humans.[162] In addition, some of the commonly used HDL and LDL cholesterol assays for clinical chemistry analyzers have species-specific biases, depending on the underlying methodology (Wescott, Everds, unpublished observations). Hamsters, some rabbit strains, and genetically engineered mice have been used as animal models for lipid research.

Small changes in serum cholesterol and triglyceride concentrations, both increases and decreases, are relatively frequent findings in toxicology studies. The changes are generally believed to represent minor alterations in lipid metabolism that do not adversely affect the animals' health. Unfortunately, exact mechanisms for the changes are rarely identified. Factors to consider include alterations in food consumption and assimilation, body weight and composition, liver function, and hormones.

Serum triglyceride concentration is elevated postprandially, while serum cholesterol concentration is relatively stable. When fat is mobilized to meet energy requirements because of significant anorexia, starvation, malabsorption, or maldigestion, serum triglycerides are usually increased, sometimes markedly. Cholesterol levels, however, are variable. Clinical conditions that often increase both serum cholesterol and triglyceride concentrations include hypothyroidism and diabetes mellitus. Lipoprotein lipase activity is reduced in both conditions. In most species, hypercholesterolemia is more prominent in hypothyroidism, and hypertriglyceridemia is more prominent in diabetes mellitus. Cholestasis and other forms of liver disease can increase serum cholesterol concentration because the liver is the major excretory pathway for cholesterol. Conversely, liver disease may also be associated with hypocholesterolemia. Hypercholesterolemia, increased urinary protein excretion (due to glomerular disease), and hypoalbuminemia are characteristics of nephrotic syndrome. Young rats (e.g., 7–20 weeks of age) usually exhibit less interanimal variability for cholesterol and triglyceride concentrations than dogs and monkeys. It is, therefore, more common to detect subtle effects on serum lipid concentrations in short-term rat studies versus large animal studies, especially because the number of animals per group is typically much higher for rat studies. Serum cholesterol and triglyceride concentrations are extremely variable for older rats because of a number of naturally occurring diseases.

Minerals and Electrolytes

Serum Calcium and Inorganic Phosphorus

Serum calcium concentration is controlled primarily by parathyroid hormone, calcitonin, and vitamin D and reflects a balance among intestinal absorption, bone formation and reabsorption, and urinary excretion.[163] Serum inorganic phosphorus concentration is affected by the same hormones but is more sensitive to changes in dietary intake and urinary excretion. Approximately 50% of serum calcium is in its biologically active, ionized form. Ionized calcium is critical

for neuromuscular activity, bone formation, coagulation, and other biochemical processes. Approximately 40% of serum calcium is bound to albumin, and the remainder is complexed to anions such as phosphate and citrate.

Although many disease conditions are associated with hypercalcemia,[163] increased serum calcium concentration is relatively uncommon in toxicology studies unless the test article specifically targets bone or calcium metabolism or has properties of either parathyroid hormone or vitamin D. Because approximately 40% of serum calcium is bound to albumin, mildly increased serum calcium concentration is occasionally observed when serum albumin concentration is increased. This change is physiologically appropriate, not adverse. Rare causes of increased serum calcium in toxicology studies include primary hyperparathyroidism, pseudohyperparathyroidism (a paraneoplastic syndrome), hypervitaminosis D, and renal disease.

Mildly decreased serum calcium concentration, as a result of decreased serum albumin concentration, is a frequent finding in toxicology studies. Signs of toxicity secondary to decreased calcium, such as neurological and neuromuscular abnormalities, are absent because ionized calcium is relatively unaffected. Rare causes of decreased serum calcium in toxicology studies include hypoparathyroidism, nutritional hyperparathyroidism, acute pancreatitis, bone effects, and renal disease.

Young, rapidly growing animals have high serum inorganic phosphorus concentrations (e.g., greater than or equal to serum calcium concentration) that decrease with maturity. Serum inorganic phosphorus concentration is affected by GFR, and increased concentrations parallel changes in serum urea nitrogen and creatinine and should be interpreted in conjunction with those parameters. Rare causes of increased serum inorganic phosphorus in toxicology studies include hypoparathyroidism, nutritional hyperparathyroidism due to excess dietary phosphorus, and hypervitaminosis D. Decreased serum inorganic phosphorus concentration observed in toxicology studies is most commonly associated with reduced food consumption.

Serum Sodium, Potassium, and Chloride

Sodium, the major extracellular cation in plasma, is the principal determinant of extracellular fluid volume. Chloride, the major extracellular anion in plasma, supports fluid homeostasis and balances cation secretion. Potassium is the major intracellular cation and has a critical role in neuromuscular and cardiac excitation. Reference intervals for electrolyte concentrations for animals on toxicity studies tend to be much narrower than the range of values obtained clinically. For this reason, it is common to observe very small, but statistically significant, differences between control and treated groups with no apparent mechanism or effect on animal health. Many of these differences are likely incidental, but others may represent subtle homeostatic effects or uncontrolled preanalytical influences. Changes in serum sodium and chloride concentrations tend to parallel each other when they are associated with relative water content, but serum chloride concentrations are disproportionately affected in disorders affecting acid–base balance.

Significant increases in serum sodium are rare in toxicology studies. Increases in serum chloride are occasionally observed secondarily to metabolic acidosis resulting from diarrhea. In this condition, renal tubular reabsorption of chloride is increased because of decreased availability of bicarbonate. Approximately proportional decreases in serum sodium and chloride concentrations can occur with gastrointestinal losses (e.g., vomiting or diarrhea), renal losses (e.g., renal failure), diuretic effects, and hypoadrenocorticism (rare in toxicology studies). Vomiting may cause decreased serum chloride concentration without affecting sodium because stomach secretions are rich in chloride.

Increased serum potassium concentration may be observed with a variety of conditions causing acidosis because extracellular hydrogen ions are exchanged for intracellular potassium ions. Severe tissue necrosis and anuric or oliguric renal failure are infrequent causes of increased serum potassium. Serum potassium may be falsely elevated because of hemolysis (either technique- or test article-related) in species that have high intraerythrocytic potassium (e.g., nonhuman primates). Marked thrombocytosis and thrombocytopenia can be associated with increased and decreased serum potassium, respectively, because potassium is released from platelets during clot formation. Serum potassium is very sensitive to potassium intake, and decreased concentrations are often associated with anorexia. Similar to effects on sodium and chloride, decreased serum potassium is sometimes associated with gastrointestinal losses and polyuric renal losses. Disorders resulting in alkalosis (e.g., persistent vomiting) may cause decreased serum potassium because intracellular hydrogen ions are exchanged for extracellular potassium ions.

Miscellaneous Serum Chemistry Tests

Serum CK activity is measured primarily as a marker for skeletal muscle toxicity. Test article-related increases in CK activity can be detected only if complicating factors or study-related procedures do not obscure results. For example, intramuscular injections, surgical procedures, and poor venipuncture technique can all give rise to marked elevations in CK that preclude identification of meaningful differences between control and treated animals. Serum aldolase activity is a less frequently used marker for skeletal muscle injury. The utility of additional markers of skeletal injury is currently under investigation.

Several tests have been used with varying degrees of success in human medicine as markers of acute myocardial injury,[164] and cardiac troponins I and T have emerged as cardiotoxicity markers of choice for toxicology studies designed specifically to evaluate myocardial injury.[165–179] Cardiac troponin I is the more readily available assay, and there appears to be no need to measure both cardiac troponins in a given toxicology study. Although cardiac troponins are best used to assess myocardial injury within a day or two of toxic insult,

they are sensitive enough to detect subclinical myocardial toxicity in long-term studies.

Amylase and lipase activities are measured clinically to diagnose diseases causing acute pancreatic necrosis. These enzymes have limited value in toxicology studies, especially repeat-dose studies, because toxin-induced pancreatitis will cause severe illness and have prominent, unmistakable morphologic consequences. Amylase and lipase are not sufficiently sensitive to be markers for test articles with specific action against pancreatic islet cells.

URINALYSIS AND URINE CHEMISTRY TESTS AND INTERPRETATION

Urinalysis

Urinalysis has traditionally been considered part of the minimum laboratory database for evaluating patients. Although urinalysis provides specific information about the urogenital tract and general information regarding some systemic conditions, it is not particularly well suited for most toxicology studies. The cost-to-benefit ratio is poor because sample collection and analysis are labor intensive and relatively few toxicities produce detectable effects on urinalysis parameters. Technical difficulties associated with collecting a large number of urine specimens from small laboratory animals or uncooperative large animals can impact test results. If a test article is known or suspected to affect the urinary system, then measures can be taken to provide appropriate specimens for urinalysis (e.g., by catheterization, cystocentesis, or carefully collected fresh voided samples). Usually, however, when a large number of animals are being administered a test article of unknown toxic potential, the most efficient method of urine collection (in a collection vessel at the bottom of a metabolic cage) can produce artifacts that affect test results and complicate interpretation. Preservatives and methods for keeping the urine chilled may help limit artifactual changes, but these procedures are not without cost and other issues.

The standard urinalysis includes measurement of physicochemical properties and microscopic evaluation of urine sediment. The physicochemical properties include volume (for timed collections), color, clarity, specific gravity or osmolality, and reagent strip tests (pH, protein, glucose, ketones, bilirubin, urobilinogen, and blood). Some reagent strips have additional tests for nitrite (indicates presence of nitrite-producing bacteria) and leukocyte esterase, but these are screening tests normally used to decide whether to examine urine sediment or culture urine from human patients and are not particularly valuable for animal specimens, especially those collected overnight.[180] Urinary sediment evaluation is a semiquantitative microscopic measure of the presence of cells (urogenital epithelial cells, WBCs, and RBCs), casts, bacteria, crystals, and other formed elements. This is the most expensive component of the urinalysis and, in most instances, the least informative or necessary.[181] In general, disorders that increase the number of cells or casts in urine sediment will be better characterized by histopathologic examination of the kidneys and bladder. Occasionally, however, test article-specific crystals that might otherwise go undetected are identified by urine sediment examination.

Urine Volume and Concentration

Timed urine volume and a measure of urine concentration (urine specific gravity or osmolality) can be valuable in assessing renal function because they demonstrate concentrating ability. Loss of urine-concentrating ability usually precedes development of azotemia as a consequence of chronic renal disease. Timed urine volume (e.g., 16 or 24 h) and a measure of urine concentration are probably the most beneficial of the routine urinalysis tests. Urine concentration generally varies inversely with urine volume and is most commonly assessed by measuring urine specific gravity. Urine specific gravity determined by refractometry is an approximation of urine solute concentration. Although urine osmolality (usually determined by freezing-point depression osmometry) is a more accurate estimation of urine solute concentration, it is more expensive and labor intensive and measured infrequently. Reagent strip specific gravity measurements are not sufficiently accurate for use in nonclinical toxicology studies and should not be used. Animals with impaired ability to concentrate urine due to renal disease have decreased urine specific gravity or osmolality and increased urine volume. With advanced renal disease, urine specific gravity may become fixed in a range from approximately 1.008 to 1.012 (termed *isosthenuria*). Isosthenuria and hyposthenuria (i.e., urine specific gravity below 1.008) are particularly meaningful when serum urea nitrogen concentration is elevated. This combination usually indicates primary renal dysfunction. Test articles with diuretic activity or that cause increased water consumption also produce dilute urine and increased urine volume, but serum urea nitrogen is usually unaffected. Increased urine concentration (e.g., urine specific gravity greater than 1.030 in dogs) indicates that the kidneys have functional concentrating ability. Very high urine concentrations may be observed in dehydrated animals because kidneys attempt to conserve water. In toxicology studies, urine specific gravity is sometimes high in treated animals, particularly rodents, that are anorectic and consequently not drinking normally. Problems with watering systems can create interpretive issues because faulty sipper tubes or animals that habitually play with their water source may result in very dilute, water-contaminated urine, while dysfunctional systems that limit water availability may result in dehydrated animals.

Reagent Strip Tests

Reagent strip tests provide a semiquantitative biochemical evaluation of urine. When one of the following tests indicates a test article effect, a more quantitative determination of that parameter may prove valuable. Because urine reagent strip reactions are usually measured by reagent strip readers that use a grayscale system, highly concentrated (dark) or abnormally colored urine may interfere with test results. In these cases, reagent strips can be manually evaluated, and some parameters can be measured by alternate methods.

Urine pH can be affected by diet, test article pH, and sample handling. Animals consuming high-protein meat diets tend to produce urine of lower pH than do animals consuming cereal or vegetable diets. If administered in large enough quantities, an acid or alkaline test article can affect urine pH. Urine pH is often artifactually elevated in samples collected overnight for two reasons: urease-producing bacteria cause ammonia formation, and carbon dioxide is lost from open containers. Urine pH is generally not a good indicator of acid–base balance.

A low concentration of protein is a normal finding in the urine of most animals, especially if the urine is concentrated. A high concentration of protein is not generally observed in younger animals, especially in dilute urine. Increased urine protein concentration may result from glomerular injury, defective tubular reabsorption, hemorrhage, inflammation, or proteinaceous secretions from the lower urogenital tract in voided specimens. Sediment examination may help identify the cause of proteinuria. Older rats, particularly males, may develop marked proteinuria as a consequence of chronic progressive nephropathy, a common, naturally occurring disease of rats. Highly alkaline urine and quaternary ammonium disinfectants can cause false-positive findings for urine protein measured by reagent strips. Urine protein can be determined quantitatively by automated clinical chemistry analyzers.

The finding of glucose in urine is abnormal. Under normal conditions, renal tubules reabsorb all glucose filtered through the glomerulus. If the glucose load is excessive as a result of markedly increased serum glucose (e.g., >180 mg/dL for the dog), glucose spills into urine. Urine glucose may be observed with renal toxins that target proximal tubular epithelial cells because of failure to adequately reabsorb filtered glucose. Drugs developed for diabetes mellitus that specifically target tubular reabsorption of glucose are typically associated with marked glucosuria and secondary osmotic diuresis that may negatively affect reabsorption of other urinary constituents. If urine glucose is considered an important endpoint for a study, precautions should be taken to avoid false-negative findings resulting from a proliferation of bacteria that consume glucose. Diabetes mellitus is the most frequent clinical disease associated with glucosuria, but it is rarely observed in toxicology studies.

Ketones are normally not present in urine of most animals, but fasted monkeys occasionally and male rats usually have trace to 1+ urine ketones. Ketonuria can also be observed in anorectic animals and animals that have been fasted for a prolonged period of time. Ketonuria usually indicates that energy metabolism has shifted from gluconeogenesis to incomplete oxidation of fatty acids. False-negative findings for urine ketones occur as a result of bacterial degradation and loss of volatile ketones from open containers.

Bilirubin is normally absent in the urine of most laboratory animals. A small amount, however, can often be measured in the urine of male dogs, especially in concentrated urine. Increased urine bilirubin results from the same conditions that cause increased serum bilirubin and may precede the change in serum. False-negative findings for urine bilirubin occur from prolonged exposure of urine to light, causing oxidation of bilirubin to biliverdin.

Urobilinogen is normally present in the urine of animals. Theoretically, urine urobilinogen tests for patency of the bile duct. Intestinal bacteria convert conjugated bilirubin to urobilinogen, a portion of which is reabsorbed by the intestine. Because a small amount of the reabsorbed urobilinogen is normally excreted in the urine, a negative urine urobilinogen is purported to indicate obstruction of the bile duct, an extremely rare occurrence in toxicology studies. The test has little value and is generally determined only because it exists on the same reagent strip as the other tests.

Blood is occasionally present in the urine of normal animals. Although the origin of the blood is usually unknown, estrus is a common source in female dogs and monkeys. Reagent strips do not effectively discriminate among erythrocytes, hemoglobin, and myoglobin, but examination of the urine sediment may help differentiate hematuria from hemoglobinuria. Hematuria may result from bleeding disorders or inflammation, trauma, or neoplasia of the urogenital tract. Hemoglobinuria as a result of significant intravascular hemolysis (typically associated with test articles administered intravenously) is usually associated with concurrent hematologic evidence of hemolysis, and hemoglobinuric nephropathy may be detected microscopically.

Urine Sediment Evaluation

Cells, casts, and crystals are poorly preserved in urine during overnight or 24 h collections; for example, it is common to find no erythrocytes in the urine sediment even though the reagent strip blood test is positive and hemolysis has been ruled out. If sediment detail is deemed an important endpoint for a study, other means of urine collection (e.g., cystocentesis or free catch) should be considered.

Small numbers of erythrocytes, leukocytes, and epithelial cells are normal findings in urine sediment obtained from voided urine specimens. Large numbers of these cells may or may not be abnormal, and gross or histopathologic correlates are necessary to determine their origin. Increased numbers of large epithelial cells (i.e., squamous and transitional cells) generally do not indicate a significant abnormality, but increased numbers of small epithelial cells (i.e., renal tubular cells), especially in conjunction with granular or cellular casts, are indicative of kidney disease.

Urinary casts are infrequently observed in the urine of normal animals. A cast is the cylindrical mold of a segment of renal tubule formed by protein alone or protein and cells. Casts are generally classified as hyaline, cellular, waxy, or broad. Hyaline casts are made of protein alone, and increased numbers are sometimes observed with glomerular disorders that cause excessive proteinuria. An occasional hyaline cast is normal. Cellular casts (erythrocyte, leukocyte, or epithelial) usually indicate renal tubular lesions but are rarely observed in animal urine. If not moved rapidly into the urine, cellular casts become granular casts as the cells degenerate and take on a granular appearance. Waxy casts represent the final stage of degeneration of the cellular cast and indicate

prolonged intrarenal urine stasis. Granular and waxy casts, therefore, may also be an indication of renal tubular disease. Broad casts are identified by their width and represent casts formed in collecting ducts or pathologically dilated portions of the nephron. Broad casts also indicate intrarenal urine stasis. Although the origin of individual cells in urine cannot always be determined, increased numbers of casts (cylindruria) indicate that renal tubular injury has occurred proximal to the renal pelvis.

Bacteria are a consistent finding in the urine of normal animals, given the routine methods used to collect urine during toxicology studies. If the test article is an antibiotic, a test article-related decrease in the number of bacteria may be observed.

Crystals are common in the urine of laboratory animals. The type of crystals observed is dependent on urine pH and the test article. Crystals observed frequently in alkaline urine include triple phosphate, amorphous phosphate, calcium carbonate, and ammonium urate crystals. Urate and oxalate crystals are associated with acid urine. Although rarely observed, ammonium biurate crystals are associated with liver failure. In addition to the previously mentioned crystals that occur naturally, test article-specific crystals will occasionally form when a test article or metabolite is highly concentrated in the urine. These crystals may be pathologically significant if they obstruct renal tubules or lead to the development of calculi. Urine crystals may be important in the establishment of rodent-specific mechanisms of bladder carcinogenesis. Mechanistic studies with specific urine collection techniques may be designed to evaluate urine crystals for this purpose.[182]

Quantitative Urine Chemistry Tests

Because serum urea nitrogen and creatinine and standard urinalysis tests are relatively insensitive markers of renal injury, several urine chemistry tests have been proposed as better methods for identifying and quantifying early renal injury or dysfunction. For the most part, these tests are impractical as part of the general screen in routine, regulated toxicology studies; however, they may be valuable as tools for assessing early renal toxicity at dose levels below those that cause histopathologic lesions and for determining the intrarenal location of the earliest toxic insult. Some of these tests are also well suited for acute screening studies to determine the relative nephrotoxicity of different analogues of a compound with known nephrotoxic action for lead candidate selection.

Urinary Enzyme Activity

Many urinary enzymes have been evaluated for use as early markers of nephrotoxicity,[20,23] and several have been proven effective in specific models of nephrotoxicity.[22,183–187] Perhaps the two most frequently measured urinary enzymes are GGT and *N*-acetyl-β-D-glucosaminidase (NAG) because they are relatively stable at room temperature and have somewhat different cellular locations; GGT is located in the brush border of proximal tubular epithelial cells, and NAG is a lysosomal enzyme with apparently greater distribution along the nephron. Other enzymes that have been evaluated as indicators of nephrotoxicity include ALP (another brush-border enzyme), LDH, ALT, and AST (all primarily cytosolic enzymes). Urinary enzyme activities should be corrected for variations in urine concentration by calculating the total activity excreted per unit time or the ratio of urinary enzyme activity to urinary creatinine concentration. Urinary enzyme activities are most effective for assessing acute renal injury. They appear to have much less utility for assessing chronic conditions (e.g., repeat-dose studies of several weeks' duration) and, like liver enzymes, do not provide information concerning renal function.

Urinary Proteins

Quantitative measurement of urinary protein excretion has historically been used to evaluate protein-losing nephropathies. A variety of chronic renal diseases can result in significant proteinuria.[188–191] Nephrotoxins that produce readily identifiable proteinuria typically exhibit correlative histopathologic findings for glomeruli, tubules, or both. As with urinary enzyme activities, urine protein excretion should be corrected for urine concentration by calculating the total amount excreted/unit time (e.g., mg/16 h) or the ratio of urinary protein concentration to urinary creatinine concentration. Although glomerular disorders (increased protein filtration) tend to exhibit greater proteinuria than tubular disorders (decreased protein reabsorption), the exact source of the protein loss cannot be determined by simply quantifying total urinary protein.

β_2-Microglobulin is a low-molecular-weight plasma protein that is freely filtered through the glomeruli and almost completely reabsorbed (>99%) by proximal tubular epithelial cells. Immunoassays for urinary β_2-microglobulin have been developed and used to differentiate glomerular from tubular protein loss and assess tubular function.[192–194] Unfortunately, antibodies specific for animal β_2-microglobulin are not commercially available, and the structure of the protein appears to be highly species specific.[151] The use of sodium dodecyl sulfate–polyacrylamide gel electrophoresis has been proposed as a means of classifying renal injury by the molecular weight pattern of excreted urinary proteins.[21] An increase in high-molecular-mass proteins (e.g., >69,000 Da) is associated with glomerular injury, and an increase in low-molecular-mass proteins (e.g., 12,000–60,000 Da) is associated with tubular injury.

Numerous biomarkers have been proposed for monitoring renal toxicity in nonclinical studies. Several of these have undergone extensive qualification under defined conditions in rats and are being used more frequently to detect injury.[195–204]

Urinary Electrolytes

Urinary electrolyte concentrations (sodium, potassium, and chloride) from timed urine collections are the most commonly performed quantitative urine chemistry tests for regulated toxicology studies because they have been listed in the study guidelines for nonclinical evaluation of new pharmaceutical

products by Japan's MHLW.[11] Unfortunately, these tests have a very poor cost-to-benefit ratio as screening tools for nephrotoxicity. If only concentrations are assessed, they offer little advantage or information beyond that obtained from urine specific gravity or osmolality. Additional information can be obtained by calculating the total amount of each electrolyte excreted per unit time (e.g., mmol/16 h) or the fractional clearance of each electrolyte. In contrast to effects on urinary enzyme activities or protein concentrations, effects on urinary electrolyte excretion are most often a reflection of the normal homeostatic mechanisms required to maintain electrolyte and fluid balance in the face of changes in intake (e.g., anorexia) and output (e.g., gastrointestinal losses from diarrhea) rather than specific measures of renal injury or dysfunction. Of course, increased excretion of urinary electrolytes can occur secondarily to administration of many nephrotoxins and compounds with diuretic activity, but routine tests are typically more sensitive and cost-effective for detecting test article-related changes. One reason for the relative insensitivity of urinary electrolyte measurements is that they tend to exhibit considerable interanimal variability.

With respect to the effect of diuretic agents on urinary electrolyte excretion, the period of time for which the urine is collected has a major impact on the results obtained. For example, if a diuretic is administered in the morning, fluid and electrolyte excretion may be quite high during the first several hours postdose. But, if the urine sample collection is performed overnight, after the effect of the diuretic has subsided, electrolyte excretion may appear decreased because of compensatory electrolyte reabsorption to counteract the loss of fluid during the day.

QUESTIONS

26.1 Time-related biases are sources of preanalytical variation. Give at least three examples of time-related bias, and describe how these biases might affect interpretation of several different clinical pathology test results.

26.2 Describe how reference intervals are constructed, and compare their uses with those of concurrent control groups and correlative findings for a given toxicology study.

26.3 Differentiate regenerative from nonregenerative conditions as they relate to decreased red cell mass and give examples of each.

26.4 Describe how the common tests of hepatocellular and hepatobiliary integrity and function are used to characterize hepatotoxicity.

27 Dermatotoxicology

Benjamin B. Hayes, Esther Patrick, and Howard J. Maibach

CONTENTS

Human skin, a dynamic multilayered organ comprising approximately 10% of the normal adult body, has numerous functions essential for terrestrial life, including thermoregulation, sensory perception, nutrient storage, vitamin synthesis, and barrier protection [226,227,270,301]. Resiliency and tensile strength protect against physical injury, pigmentation protects against ultraviolet light, barrier properties protect against the entry of environmental chemicals into the body, and the growth pattern and surface characteristics protect against microbial colonization and invasion. The regenerative capacity following wounding and the numerous processes by which skin can deal with environmental insults provide strong evidence of the importance of healthy skin to the organism. The psychological value of healthy skin has led in part to the development of multibillion-dollar cosmetics and personal care industries.

The policies of agencies such as the Occupational Safety and Health Administration, Department of Transportation (DOT), Consumer Product Safety Commission (CPSC), and Food and Drug Administration (FDA) in the United States and the Organization for Economic Cooperation and Development (OECD) and European Economic Community (EEC) internationally indicate that the identification of chemicals hazardous to the skin and the protection of society from exposure to those chemicals should be given high priority. These agencies mandate specific assays to evaluate the effects of skin exposure prior to registration, transport, and marketing of chemicals of formulated products. Adverse skin responses associated with repetitive low-dose exposure to industrial chemicals and consumer products all too often are not accurately predicted by the required assays. The need to market products with low risk of producing dermal and systemic injury to increase consumer satisfaction has led to the development of numerous assays to rank chemicals for their ability to injure the skin. Although these assays are not mandated by regulatory agencies, the frequency with which they are conducted and their utility warrant attention.

The discipline of dermatotoxicology evaluates the toxic effects of chemicals on the skin and includes both the pharmacokinetics of epicutaneously applied chemicals and assays that evaluate the development of neoplasms, trigger an immune response, directly destroy the skin (corrosion), irritate the skin, produce urticaria (hives), and produce noninflammatory painful sensations. The inflammatory responses of skin are the most common chemically induced diseases in humans.

SKIN STRUCTURE AND FUNCTION

To understand the variety of adverse responses to skin and the basis for the predictive assays for skin injury, some understanding of skin anatomy and physiology is necessary. Approximately 2 m^2 (20,000–23,000 cm^2) of skin cover the body of an adult human. Skin is heterogeneous. Its characteristics (e.g., sweat glands, hair follicles, sebaceous glands, and the thickness of skin) vary by body region [138,331];

TABLE 27.1
Regional Variation of Skin Thickness in Humans

Region	Thickness (μm)[a]	Reference
Stratum corneum of abdomen	8.2	Holbrook and Odland [139]
Abdomen	46.6	Whitton and Ewell [333]
Stratum corneum of back	9.4	Holbrook and Odland [139]

[a] Values are for full-thickness skin unless stratum corneum is specified.

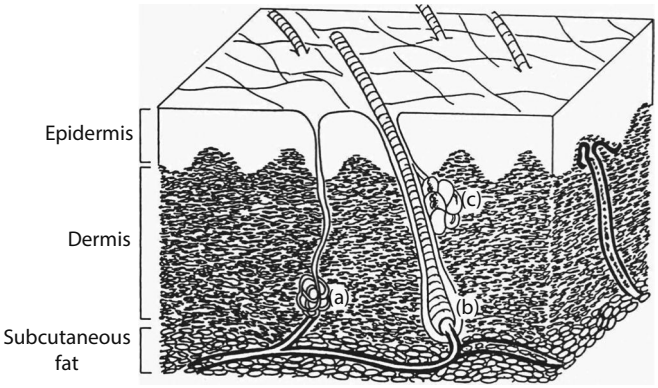

FIGURE 27.1 Schematic of human skin. (a) Eccrine sweat glands are located in the dermis; a duct transports sweat through the epidermis to the surface. (b) Hair follicles are located deep in the dermis; each hair extends through the skin via an epithelized channel. (c) Contents of sebaceous glands are released into the follicular channel as the sebocytes die. Each skin appendage has its own blood supply. Plexuses formed in the upper dermis (shown in the drawing to the far right) supply nutrients to the upper epidermis and upper dermis.

for example, the thickness of the skin of the eyelid is approximately 0.51 mm, whereas that of the palm and sole is approximately 4.1 mm (see Table 27.1).

A film composed of triglycerides, phospholipids, esterified cholesterol, and other materials released by holocrine sebaceous glands, as well as salts and water released by eccrine sweat glands, normally covers the outer surface [234]. This surface film has been referred to as an *acid mantle*; the pH of the skin normally varies between 4.2 and 5.6. Micrococcinae and *Corynebacterium* species normally colonize the skin surface [192,226]. Changes in surface film composition (e.g., changes caused by inflammatory conditions or occlusion) may result in a 1000-fold increase in the absolute number of microorganisms colonizing the area and a shift in flora present [28,29]. The surface film penetrates the outermost cellular layers of the skin.

Based on the structure and embryonic origin, the cellular skin layers are divided into two distinct regions (Figure 27.1): epidermis and dermis. The outer region, the epidermis, develops from embryonic ectoderm and covers the connective tissue; the dermis is derived from the mesoderm [137,139,220]. The epidermis accounts for approximately 5% of full-thickness skin [191,227]. For descriptive purposes, the epidermis is subdivided into five to six layers based on cellular characteristics (Figure 27.2). Layers of keratinocytes are formed by the ordered differentiation of cells from one layer of mitotic basal cells. The number of distinguishable layers varies by anatomical site.

Basal layer keratinocytes are metabolically active cells with the capacity to divide. Some daughter cells of the basal layer move upward and differentiate. Cells adjacent to the basal layer contain large mitochondria; the Golgi apparatus and rough endoplasmic reticulum (RER) are well developed. These cells produce lamellar granules (intracellular organelles) that later fuse to the cell membrane to release neutral lipids believed to form a barrier to penetration through the epidermis [82,83,293,326]. Microscopically, the desmosomes and bridges connecting adjacent cells resemble spines, and the three- to four-cell thick layer of cells above the basal layer is referred to as the *stratum spinosum*. The spines connecting adjacent cells are temporary structures; keratinocytes dissociate from neighboring cells and form new associations as they move upward, individually, in the epidermis [227]. Cells of the third subdivision of the epidermis, the stratum granulosum, are characterized by the presence of keratohyalin granules, polyribosomes, large Golgi apparatus, and RER. Cells of the granular layer are the uppermost viable cells of the epidermis. Here, the lamellar granules are released at the cell surface. An intermediate zone of cells separates the cornified layers of the outer epidermis from the viable granulosum. In the palms and soles, the stratum lucidum, or clear cell layer, lies above the stratum granulosum. This layer is indistinguishable in skin sections from other areas. Cells of the intermediate zone may contain enzymes capable of metabolizing exogenous chemicals but have lost the ability to synthesize proteins. The outermost cornified layer, the stratum corneum, consists of cells that have lost their nucleus and all capacity for metabolic activity. The dominant constituent of these cells is keratin, a scleroprotein with chains linked by both disulfide and hydrogen bonds that are synthesized and stored in the deep epidermal layers. The intracellular attachments between these cells gradually break, and the outermost cells are sloughed.

In addition to the visible intercellular and metabolic changes observed during keratinocyte differentiation, their size and shape have also changed. Cells derived from basal cuboidal cells approximately 5 μm in diameter have elongated and flattened to approximately 30 μm [191]. Four

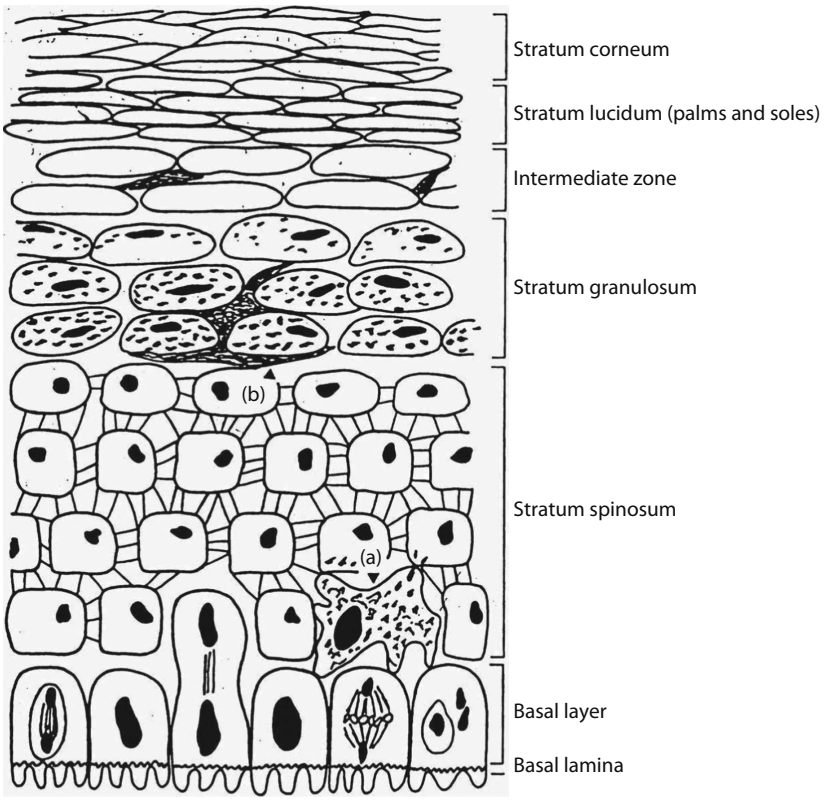

FIGURE 27.2 The epidermis, showing all possible cell layers and locations of the two dendritic cell types: (a) melanocytes and (b) Langerhans cells.

differentiated cornified cells of the stratum corneum (2 × 2) cover the same area as 100 basal keratinocytes (10 × 10). Each basal cell has the capacity to cover itself many times with modest mitotic rates. The pattern of papillae (ridges and grooves) of the basal layer formed by accessory structured from the dermis to the skin surface increases the area of germative layer relative to surface area. This provides a large reserve in capacity to cover the area. Estimates of normal turnover rate for keratinocytes vary considerably [73]. Early investigators [256] estimated normal turnover to be 28 days, with considerable increases in disease states. Since then, the turnover rate has been calculated to be between 17 and 71 days [90]. Turnover varies by anatomical site (e.g., 32–36 days for the human palm vs. 58 days for the anterior surface of the forearm). Recent studies utilizing deuterated H_2O support these observations [359].

The epidermis also contains two dendritic cell types: melanocytes and Langerhans cells. Between 460 and 1000 melanocytes and Langerhans cells per square millimeter of glabrous nonspecified skin is normal [191,236]. Melanocytes, derived from embryonic neural crest cells, lie directly adjacent to the basal layer. Melanocytes produce melanin, the principal pigment of human skin, which is then transferred to basal layer keratinocytes in granules. The dendrites of the melanocyte allow one cell to supply melanin to many basal cells. Langerhans cells express Ia (immune recognition) antigen and receptors for IgG and C3 on their surface. Like cells of the monocyte/macrophage lineage that bear these markers, Langerhans cells are derived from the bone marrow mesenchyme. They process low-molecular-weight haptens during induction of immune responses [134,290]. Although this function has been questioned, Langerhans cells take up small molecules (nonlipid) and increase in number in areas that have developed allergic reactions [289]. Note that Langerhans cells lie in epidermal layers containing enzymes that can metabolize exogenous chemicals. In some cases, metabolites of the agent applied to the skin cause allergic contact dermatitis.

The dermis and epidermis are separated by a basal lamina. The dermis is attached to this membrane by fine fibers of connective tissue. Cells of the basal layer are anchored to the lamina by anchoring proteins. This area of attachment, called the *marginal layer*, is identified histologically by periodic acid Schiff reaction. There are occasional breaks in the attachments. Large breaks are observed in exfoliative skin conditions [37,191]. The dermal connective tissue enclosed by the epidermal papilla is referred to as the *papillary dermis*, and the area below the papilla is the *stratum subpapillare* or *reticular dermis*. Fibers of the papillary dermis are finer than those of the reticular dermis. The reticular dermis contains thick collagen bundles, especially in areas adjacent to blood vessels and skin appendages. Connective tissue fibers are separated by the ground substance, an amorphous material consisting of proteins and glycosaminoglycans, such as chondroitin A sulfate and hyaluronic acid. Constituents of ground substance are derived from both fibrocytes and

blood plasma. The physical behavior of the dermis, including elasticity, is determined by the fiber bundles and ground substance. Variations in plasma content of ground substance may alter physical properties substantially.

The dermis contains all tissue types, except cartilage and bone. Skin appendages originate in the subpapillary dermis. Eccrine sweat glands, sebaceous glands, and hair follicles with their erector muscles are found in the skin of most anatomical sites; however, the number of each varies significantly by site [272,291]. Sebaceous glands normally are adjacent to hair follicles, and the hair shaft serves as an excretory duct. The axillae, anogenital region, eyelid, and external ear contain apocrine sweat glands [265,286]. These glands develop at puberty and form odorless secretions that are decomposed by bacteria to produce characteristic odors. The dermis also contains nerve cells with highly specialized sensory endings in some areas, fat lobules, migratory white blood cells, and mast cells. Mast cells are indistinguishable from fibroblasts in size or appearance; however, they contain granules that stain metachromically with agents of a thiazine group. Mast cells are most numerous in areas adjacent to blood vessels, skin appendages, and nerves. The precise function of mast cells is unknown; however, they appear to be involved in the pathogenesis of some inflammatory conditions [296,320]. Their granules contain histamine, heparin, and other vasoactive agents that may be released upon stimulation of the cell surface by IgE cross-linking 48/80, activated serum compounds, and some enzymes. Release of these mediators is accompanied by formation of other agents, such as the metabolites of arachidonic acid [296], which are inflammatory mediators in some conditions.

The dermis and fascia of muscles are separated by the subcutis, a layer of fatty tissue. The extent and development of subcutis depend on sex, age, diet, and body region. Blood vessels supplying the skin arise from the subcutis. Vascular plexuses are formed in the transition zone of the subcutis and dermis adjacent to coils of the eccrine sweat gland. Arteries extend upward to mid dermis, forming anastomoses there. Similar, but independent, plexuses form at the base of the hair shaft and sebaceous glands. A third vascular network is formed from arteries branching off from vessels at the level of eccrine sweat glands that branch into finer vessels that form plexuses in the papillary dermis. Plexuses of the papillary dermis supply the upper dermis, including the upper hair shaft, and the epidermis with nutrients. The adjacent but separate vascular units in the dermis sometimes react differently in pathological processes (i.e., follicular rash).

A simple visual comparison allows one to conclude that the skin of humans and animals varies considerably. The most obvious difference is hair coat covering the skin. In lower mammals, each hair shaft may contain several follicles, a large follicle arising from the subpapillary dermis and several accessory follicles arising from the papillary dermis. In humans, sebaceous gland density varies from 100 to 900 glands per square centimeter; in other mammals, sebaceous glands are more evenly distributed [286]. Human sweat is produced by eccrine sweat glands. Apocrine sweat glands are the dominant sweat gland of animals. Eccrine sweat glands open directly to the skin surface, whereas apocrine glands empty into the hair shaft. Apocrine sweat is less acidic than eccrine sweat, and the pH of the skin surface of animals usually is somewhat higher than that of humans [180]. The thickness of skin also varies extensively by species and body site. Differences in the content of granules of mast cells from different species have been reported [320], as have differences in sensitivity to various inflammatory mediators applied to the skin. These differences undoubtedly contribute to the lack of correlation between the results of some animal and human predictive assays [252]. The lack of correlation justifies predictive skin testing in humans after preliminary screening in animals if the risks to subjects are minimal.

Pharmacokinetics Following Application of Chemicals to the Skin

Until the beginning of the twentieth century, skin was considered a relatively inert barrier to chemicals that might enter the body [274]. We now know that this view is incorrect. Although the barrier properties of the skin are impressive, many chemicals penetrate the skin, and the skin can metabolize exogenous compounds. Because of its large surface area, skin may be a major route of entry into the body for some exposure situations. Delivery of drugs through the skin to treat systemic conditions has become almost commonplace. Interest in cutaneous pharmacokinetics has increased as the skin has been reconsidered to be a route for systemic administration of drugs and chemicals, as well as a route of entry for toxins. A variety of assays, both in vivo and in vitro, for measuring absorption through the skin have been developed [9,10,328,329], and many factors that govern absorption through the skin have been determined (Table 27.2).

The stratum corneum is a major diffusion barrier of the skin [129,271]. Removal of the stratum corneum by tape stripping increases the rate of absorption of some chemicals [29]. Absorption of chemicals through shunts, openings of skin appendages, and gaps in the stratum corneum associated with these structures has been considered [121,273,300,332]. Because of the relative surface area of these shunts (0.1%–1.0% of the total area), they may not play a decisive role in absorption [273]; however, they may be important initially after the application of the penetrant [275], and sebaceous glands may act as a drug reservoir for some materials [129,141,271]. The stratum corneum is not viable and has no capacity for active transport processes; therefore, absorption can be described as passive diffusion across this membrane: $J = K_m \times C_v \times D_m \times y$ [77], where J is the rate of absorption, K_m is the partition coefficient between the vehicle and stratum corneum, C_v is the concentration, D_m is the diffusion constant of the penetrant in the stratum corneum, and y is the thickness of the stratum corneum. Skin from different animals or sites of different thickness from the same animal will vary in barrier properties to absorption.

The concentration term is concentration at the skin surface. Application of suspensions of penetrant with slow dissolution

rates, emulsions, or penetrants in vehicles in which the diffusion rate is slow will alter the surface concentration and may control the rate of penetration [41,49,56,136,344,345]. This principle has been used in designing slow-release transdermal delivery devices. Other factors that affect thermodynamic activity of the solution at the skin surface, such as pH and temperature, may alter the absorption rate [274,275]. The influence of the vehicle cannot be overstated for a specific concentration of drug; thermodynamic activity may vary by 1000-fold from one vehicle to another. Some vehicles may promote penetration by altering the characteristics of the stratum corneum [174]. Other factors that affect percutaneous absorption include the condition of the skin [95], age [132,204,268], surface area to which the material is applied [329], penetrant volatility, temperature and humidity [104], substantivity, wash and rub resistance to removal from the skin, and binding to the skin [245]. Skin may become saturated by a penetrant and thus resist penetration from subsequent applications.

In an intuitive sense, it has been assumed that multiple applications would provide significantly greater mass transfer; however, dermatopharmacokinetics studies demonstrate that, in any one given day, multiple applications may or may not add little transfer. This may explain why many dermatologic drugs can be successfully dosed on a once-daily basis. Over many days of topical application, however, this unique dermatopharmacokinetic phenomenon does not appear to continue [69,327].

When a chemical has gained access to the viable epidermal layers, it may initiate a local effect, may be absorbed into the circulation and produce an effect, or may produce no local or systemic effects. Viable epidermis contains many enzymes capable of metabolizing exogenous chemicals [21,22,212,235,352], including cytochrome P450 isoenzymes, mixed-function oxidases, and glucuronyl transferases. Enzymes have been identified in three compartments [8,61]. Skin enzymes are inducible by systemic phenobarbital, rifampin, and 3-methyl cholanthrene [313] and by topical 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [257], 3-methyl cholanthrene, and Aroclor® 1254 [68].

Early studies indicated that enzymatic activity in skin was only a fraction of the activity of the liver. Those studies were conducted in vitro using whole skin; the enzymatic activity is in the epidermis, which makes up less than 5% of whole skin [235]. When enzymatic activities of the epidermis were calculated, activities ranged from 80% to 240% of those in liver. In some cases, different metabolites are formed in liver and skin from the same parent compound.

The list of enzymes isolated from skin continues to grow, but the skin does not have the capacity to metabolize all chemicals; for example, topically applied hexachlorophene does not appear to be metabolized. At present, it is not possible to predict metabolic pathways or rates following topical application; these must be determined experimentally. Comprehensive reviews of the metabolic capability of skin have been published [8,158].

In Vivo Percutaneous Absorption Assays

Percutaneous absorption can be determined by applying a known amount of chemical to a specified surface area and then measuring the level of the chemical in the urine or feces. To correct for excretion of the material through the lungs, sweat levels (of retention in the body) measured following topical administration usually are expressed as a percentage of levels following parenteral administration of the chemical [39,328]. Because the analytical techniques to measure the chemical are not always available, and because some chemicals may be metabolized, radioactive-labeled chemicals, usually carbon-14 or tritium, are customarily used in these assays. Although studies with radiolabeled compounds accurately reflect absorption, they may not provide accurate estimates of bioavailability; for example, comparison of bioavailability from the nitroglycerin (unmetabolized drug) level and the level of radioactive tracer indicates that use of the tracer overestimates available drug by as much as 20%. This corresponds to the metabolism of the drug to an inactive form.

In vivo studies have been conducted in humans and in a number of species [9,10]. Comparison of the absorption rates of a number of compounds shows that absorption rates in the rat and rabbit tend to be higher than in humans and that the skin permeability of monkeys and swine more closely resembles that of humans (Table 27.3). Although these differences are not predicted by any single factor, such as epidermal thickness, they are not unexpected in light of differences in skin characteristics. There are interspecies differences in

TABLE 27.3
Species Differences in In Vivo Absorption (% Dose Absorbed)

Compound	Rat	Rabbit	Pig	Squirrel Monkey	Human	Reference
Haloprogin	95.8	113.0	19.7	—	11.0	Bartek et al. [9]

Malathion	64.6	—	15.5	19.3	8.2	Bartek and LaBudde [10]

routes of excretion of some chemicals as well. This may be due in part to metabolism of the chemical, and the metabolic capabilities of the species should be considered when selecting an animal model and designing the experiment. Ingestion of the test material by the animal must be prevented, and this may require restraint of the animal or design of specialized protective apparatus for the site of application. Because urine and feces are collected for analysis, specialized cages are also required.

The difficulties in conducting these types of pharmacokinetic assays, such as collecting excrement for relatively long periods (24 h), requirements for specialized cages and protective apparatus, and the increased space requirements for housing animals individually, have led to the use of other in vivo assays and to the development of in vitro models. Loss of radioactive material from the skin surface has been used to estimate in vivo percutaneous absorption [207]. The difference in applied dose and residue on the skin is assumed to be absorbed. The characteristics of the radioisotope, penetrant, and vehicle may limit the usefulness of this procedure. Volatile materials leave the surface without penetrating, and it is difficult to recover all materials from the skin surface. In addition, skin may retain a reservoir of the penetrant that has not entered the circulation.

A clear relationship exists between the mass of a chemical residing in the stratum corneum that has been washed 30 min after application and the eventual penetration that can be measured in urine or blood. This principle has led to a facile method for estimating percutaneous absorption in animals and humans. The approach of determining the stratum corneum content via cellophane tape sampling is also used for bioequivalence determination [39].

In vivo biological responses, such as vasoconstriction assays to estimate the absorption of corticosteroids [218] and changes in blood flow being used to study penetration through various types of skin and under diverse conditions [127,128], have been used to estimate penetration rates. These endpoints are complicated biological processes and may vary with the ability of the tissue to produce the response. For example, application of histamine produces increased blood flow; however, the degree of change would depend not only on the rate of penetration but also on the reactivity of receptors at that time. Most exogenous chemicals produce their vascular effects by triggering the formation and release of endogenous mediators; thus, the usefulness of penetration studies using biological endpoints is limited to comparisons between closely related chemical structures that can be assumed to trigger the same process.

In Vitro Percutaneous Absorption Assays

The excised skin of humans or animals can be used to measure penetration of chemicals. In vitro assays utilizing excised skin use specially designed diffusion cells [10,40,102]. The skin is stretched over the opening of a collecting receptacle, epidermal side up. The chemical to be studied is applied to the epidermis, and fluid from the receptacle is assayed to measure the penetration of the chemical. Chemicals usually are radioactively labeled. Some investigators have used diffusion cells in which the epidermis was covered with fluid containing the chemical; however, the preferred method for toxicological relevance is a one-chambered cell in which the stratum corneum is exposed to the air and the underside of the skin is bathed in saline or other receptacle fluid. Because diffusion through a membrane depends on relative concentrations on each side, some chambers have been designed to allow periodic replacement of the receptacle fluid. Fluid in the receptacle base usually is constantly stirred and maintained at a physiological temperature. Either full-thickness skin or epidermis alone may be used in in vitro assays. With relatively hairless skin, epidermis can be separated from the dermis by heat treatment.

This type of in vitro assay offers advantages over in vivo assays. Highly toxic compounds can be studied in human skin. Several cells can be run simultaneously. Diffusion through the membrane, eliminating other pharmacokinetic factors, can be studied. In addition, these assays may be less expensive and easier to conduct; however, these assays do not mimic human exposure in some important areas. Because excised skin must often be stored prior to use, it cannot be assumed that the skin will retain full enzymatic activity. This may alter the metabolic profile of compounds entering the receptacle. In intact skin, chemical penetrating the epidermis would

enter the circulation through vessels and lymphatics located just below the epidermis. In excised full-thickness skin, the dermis is also involved in the absorptive process. The influence of the dermis can be minimized by using heat-separated epidermis or by removal of the skin with a dermatome at the level of the upper dermis. In the intact animal, the chemical enters the peripheral circulation in plasma; the collecting fluid of diffusion chambers is usually saline or water. The relative solubility of hydrophobic and hydrophilic chemicals in these collecting fluids may alter the rate at which they leave the skin. Surface conditions of excised skin may vary from normal skin; changes in the surface emulsion occurring during storage have not been studied. Storage conditions and procedures for preparing the tissue may affect skin absorption and metabolism. The suitability of each specimen of excised skin should be verified by measurement of penetration of a standard tritiated water through the tissue prior to its use to study the penetration of other chemicals. Comparisons of penetration rates obtained from in vitro and in vivo assays have been made [10,40]. Often a good correlation between the two methods has been obtained; however, with some compounds, correlation of the methods is poor. Differences between in vivo and in vitro results for some compounds can be explained because of solubility in the receptacle fluid and blood. Differences observed for other compounds cannot be explained.

In vitro penetration rates through skin of various species have also been compared (Table 27.3). Skin of the weanling pig and miniature swine appears to serve as good in vitro models for most compounds [9]. The skin of monkeys seems to be a good model, as well [328]. For most compounds, mouse and hairless mouse skin appears more permeable than the skin of other species. Rat skin appears to be a good model for some compounds; however, when differences have been noted, they have been large.

A few investigators have estimated percutaneous absorption using *model* membranes, including excised stratum corneum, and physiochemical data have been used to predict absorption. Lipid/water partition coefficients have been correlated with skin permeability. Smaller molecules (molecular weight ~400) are more readily absorbed than large molecules. Molecules with polar groups, in general, do not penetrate as well as nonpolar molecules [270]. The addition of hydroxyl groups also lowers the permeability. Substitutions that increase lipid solubility may increase penetration, depending on the vehicle in which the chemicals are applied [274]. Electrolytes do not penetrate the skin well [275]; shunt diffusion through skin appendages for these molecules may be important.

The presumed simplicity of in vitro penetration assays has led to their universal acceptance for preclinical and other screening purposes. This acceptance and wide-scale use have resulted in many variations in how studies have been conducted. It is not surprising that confusion regarding the interpretation of data generated by variations of this method occurs. Bronaugh [40] collated the experimental variables leading to discrepancies, and his text provides a catalog of variables that, properly considered, can lead to experimental designs that may have in vivo relevance, especially for hydrophilic materials.

Government agencies and individual investigators utilize quantitative structure–activity relationships (QSARs) based largely on in vitro datasets to estimate penetration when actual flux data are not available. Faramind and Maiback[360] compared several such models to in vivo human data and noted significant under- and overflux estimations.

Neoplastic Response of Skin

The skin is the most common site of cancer in humans. Both benign and malignant tumors may be derived from viable keratinocytes and melanocytes of the epidermis, and rarely from skin appendages, blood vessels, peripheral nerves, and lymphoid tissue of the dermis [191,192]. Historically, basal cell and squamous cell carcinomas, which develop from keratinocytes, account for 60% and 30%, respectively, of all skin cancer. The remainder includes malignant melanoma and the rare tumors developing from other cell types; however, the incidence of malignant melanomas appears to be increasing. Melanomas often metastasize, and the prognosis for patients with this disease is poor. Only 4%–5% of squamous cell carcinomas are metastatic, and basal cell tumors rarely metastasize. The relatively noninvasive nature of the common forms of skin cancer accounts for a cure rate of over 95%. Skin cancer accounts for less than 0.3% of all cancer deaths.

The association between exposure to environmental carcinogens and the development of basal cell and squamous cell carcinomas is strong [284]. Epidemiological studies demonstrate a strong correlation between exposure to ultraviolet radiation and development of skin cancer [86]. Clinical experience leaves little doubt that radiographs can also produce cancer of the skin. Both forms of radiation have induced tumors in experimental animals [38]. The association between environmental chemicals and skin cancer was first demonstrated by Sir Percival Potts in 1775. Following Potts's association between skin cancer of the scrotum and soot exposure, experimental studies in animals revealed that polycyclic aromatic hydrocarbons such as benzo(*a*)pyrene are the carcinogens in soot, coal tar, pitch, and various cutting oils [93]. The same types of experiments demonstrated that skin cancer development is a multistage process [37,38].

Despite abundant experimental evidence that chemicals can produce skin cancer, few chemicals have been associated with increased incidences of skin cancer in humans (http://www.iarc.fr/). Epidemiological studies have demonstrated associations between polycyclic aromatic hydrocarbons and arsenic and the increased incidence of benign precancerous lesions and basal cell and squamous cell carcinomas [148]. The ability to establish relationships between chemical exposure and the development of skin cancer by epidemiology is minimized by many confounding factors, including exposure to ultraviolet light, high background incidence rates, long latency periods for the development of cancer [93], and incomplete reporting due to the nonlethal nature of the disease. Even without strong epidemiological evidence, the

experimental evidence that exposure of the skin can lead to tumor development and the degree of dermal exposure to chemicals in the workplace justifies the practice of evaluating carcinogenic potential by dermal exposure. Furthermore, it is likely that certain internal tumors (bladder cancer from occupational aniline exposure) result from chemicals absorbed through the skin.

In vivo skin carcinogenesis studies are generally conducted using Sprague–Dawley rats, but mice have also been used frequently. Differences in species sensitivity to various agents have been demonstrated [38,247], and a review of the data suggests that when differences in species were noted, rats tended to be more sensitive. The design of carcinogenesis assays has been reviewed in other texts [100,101,146,194,244] and is described in Chapter 25. The method, in brief, is daily application of the test material to the clipped skin of up to six groups of animals (untreated, vehicle control, and up to four dose groups) for 104 weeks. The dose is generally administered at a constant volume of 1.0 mL/kg body weight to 5%–10% of the animal's body surface. Typically, 70 male and 70 female animals are included in each group, with additional groups dosed on the same schedule used for periodic blood analysis and for evaluating the toxicokinetics of the test material. Two variations of standardized skin carcinogenicity studies have also been reported. In the first, the skin is treated with the chemical of interest. Then, a promoting agent, such as tetradecanoyl phorbol acetate (TPA), may be applied to reduce the latency period. In the second, the skin is treated with a noncarcinogenic dose of a carcinogen, such as dimethyl benzanthracene, followed by repeated doses of the agent under study. These approaches may be helpful in elucidating the mechanisms of action of the chemicals.

Numerous factors may influence the outcome of dermal carcinogenic assays, and the choice of what to test is crucial in such assays. Although it is tempting to evaluate pure chemicals, it should be remembered that other agents in mixtures could act as promoting agents; for example, coal tar and pitch may contain catechol and pyrogallol, which are promoters of the carcinogen benzo(*a*)pyrene found in these mixtures. Wounding increases the number of tumors that spontaneously develop, and severe inflammatory responses may cause tissue destruction. Care should be taken in selecting an appropriate nonirritant dose.

Epidemiology and experimental studies have shown that sunlight (ultraviolet light) is a skin carcinogen [88,89]. Various investigators [305] have shown that exposure to some chemicals in combination with a dose of ultraviolet light increases the number of tumors or decreases the latency period for tumor development following exposure to the chemical or ultraviolet (UV) light alone. No standard protocol has yet been put forth by any regulatory agency, and typically regulatory agencies request to review specific protocols prior to study conduct [100,101,146]. In general, the studies have involved repeated intercurrent exposures to simulated sunlight and the test article. The endpoint is the time required for UV radiation (UVR) to produce skin cancer. Two doses of UVR are used as a control: a high dose that will result in a short latency period for tumor development and a lesser dose that would result in a lower tumor yield and longer latency period. The interaction of the test article and the lesser dose of UVR is compared to each control and to a vehicle control group irradiated with the lower dose of UVR. Complete details of a typical protocol have been published by Forbes et al. [101,102].

The FDA has expressed concern that some topical drugs and cosmetic ingredients may promote neoplastic changes in the skin induced by other agents, such as sunlight. Although, to date, there is no epidemiological evidence for such an occurrence, the exploration of this possibility will require developing new approaches to conventional assays for carcinogenicity.

A number of in vitro assays for studying chemical carcinogenesis have been developed [147]. Of particular interest for dermal carcinogenesis is the ability to cultivate epidermal keratinocytes of rats, mice, and humans [181]. Cultured human keratinocytes can metabolize polycyclic aromatic hydrocarbons, and chemical transformation using human fibroblasts has been achieved [181]. The establishment of human epidermal lines for in vitro carcinogenesis testing will provide an important new predictive tool.

Taken together, the clinical and public health implications of positive animal assays remain an incompletely understood science. Many dermatologies (systemic, topical, and over-the-counter [OTC]) are tumorigenic in animals. New approaches and insight into hazard and risk management regarding such dermatologies based on such data are needed.

Skin Allergy (Delayed-Type Hypersensitivity)

Since the turn of the twentieth century, certain forms of eczema have been recognized as allergic in nature. Jadassohn [150,151] demonstrated that in some patients, dermatitis was due to increased sensitivity following repeated contact with a substance, not the toxic (irritant) properties of the material [148,149]. By 1930, a procedure for producing this hypersensitivity to chemicals in guinea pigs had been developed [30]. The pioneering work of Landsteiner and his colleagues demonstrated that low-molecular-weight chemicals conjugate with proteins to form an antigen that stimulates the immune system to form a hyperreactive state [190]. They demonstrated that immunogenicity is related to chemical structure [189] and that two types of immunologic response exist, one transferable by serum and another transferred by suspensions of white blood cells [188].

Most cases of allergic contact dermatitis are of the cell-mediated type, transferable by lymphocytes. This type of skin response is often referred to as *delayed-contact hypersensitivity* (DCH) because of the relatively long period (approximately 24 plus hours) required for the development of the inflammation following exposure.

Some understanding of the processes by which this hypersensitivity develops is helpful in selecting and interpreting results of predictive sensitization tests. During ontogenesis, stem cells from the yolk sac, fetal liver, and bone marrow

migrate to the central lymphoid organs, the thymus, and bone marrow in mammals. After birth, stem cells derive from bone marrow. In the central lymphoid organs, stem cells differentiate into immunocompetent lymphocytes. This results in two classes of lymphocytes: thymus-processed T lymphocytes and B lymphocytes processed in bone marrow. B lymphocytes are precursors of antibody-producing cells responsible for immune responses transferable by serum. T lymphocytes are responsible for producing delayed-type hypersensitivity (DTH) and for the regulation of the immune system. This regulation is accomplished by subsets of T cells (i.e., T helper and T suppressor cells). Lymphocytes leaving the lymphoid organs are programmed to recognize a specific chemical structure via receptor molecules. If, during circulation through body tissues, a cell encounters the structure it is programmed to recognize, an immune response may be induced. The ability to develop and express a hypersensitivity response is determined by the relative activities of the T helper and T suppressor cell types [258].

To stimulate an immune response, a chemical must be presented to lymphocytes in an appropriate form [189,190]. Chemicals usually are haptens that must conjugate with proteins in the skin or other tissues to be recognized by the immune system. Haptens conjugate with multiple proteins to form antigens that may stimulate an allergic response by stimulating T lymphocytes with different recognition capabilities [259].

Hapten–protein conjugates are processed by macrophages, Langerhans cells, or other cells expressing immune-response Ia proteins on their surface. Although the exact nature of this process is not completely understood, it is known that physical contact between macrophage and T cells is required [60,304], suggesting that receptor interactions are necessary. Physical interaction is accompanied by the release of interleukins, a family of soluble regulatory proteins that stimulate cell division, act as growth factors, and increase expression of immune proteins on the surface of some cells [94,143,224,228].

Following antigen stimulation in the skin, lymphocytes enter the lymphatic system and migrate to the draining lymph nodes. Disruption of lymphatic drainage prevents sensitization of an animal [103]. Stimulated cells settle in the paracortical regions of the lymph nodes, and T lymphocytes differentiate into immunoblasts. This differentiation involves interaction with other cell types. Immunoblasts eventually give rise to T effector cells, which enter the systemic circulation and, upon encountering the antigen that they are programmed to recognize, release lymphokines that initiate a local inflammatory response. Immunoblasts also give rise to memory cells that enter the systemic circulation. These memory cells are capable of similar activities as the processed T lymphocytes; they recognize antigen and can be stimulated to divide. Memory cell production is essentially an expansion of the number of cells capable of recognizing a given antigen. The lymphokines released by primed effector cells that encounter their stimulating antigen directly and, indirectly, by stimulation of other white blood cells produce a local inflammatory response. Actions of lymphokines include direct tissue damage, chemotactic factors, stimulation of mitosis, increased phagocytic activity of macrophages, and factors that inhibit migration of some cell types from the area [67]. Only a small percentage of lymphocytes in an area of skin exhibiting a delayed hypersensitivity response are specifically stimulated by antigen [231]. Most cells in the lesion are recruited by lymphokines. Histologically, the response has been described as a hyperproliferative epidermis with intracellular edema, spongiosis, intraepidermal vesiculation, and mononuclear cell infiltrate by 24 h. The dermis shows perivenous accumulation of lymphocytes, monocytes, and edema. No reaction occurs if the local vascular supply is interrupted, and the appearance of epidermal changes follows the invasion of monocytes. Vascular changes (i.e., increased blood flow) occur early (2–6 h) in the response.

The histology of the response varies somewhat by species; for example, a higher proportion of polymorphonuclear cells in the cellular infiltrate have been observed in DTH reaction sites of mice than in guinea pigs or humans [151]. These differences may be due, in part, to mixed immune responses. Mice develop both antibody and DTH responses to haptens applied to the skin [5]. Exposure via the skin is believed to preferentially lead to DTH in guinea pigs and humans. Pichler has provided detailed immunologic information [355].

The biological processes necessary for producing hypersensitivity in predictive tests are often grouped into two phases: induction of the capability to respond and elicitation of a response. Induction has been referred to as the *afferent phase*, the initial exposures through clonal expansion and the release of memory cells that enter the system circulation. Elicitation, referred to as the *efferent phase*, consists of local recognition of the antigen by the memory cells, their release of lymphokines, and the activity of inflammatory mediators that are generated locally, which produce the dermatitis. All standardized predictive tests in guinea pigs and some early tests in mice [5,113,206] use the efferent phase response as an indication of immune reactivity to the chemical. The local lymph node assay (LLNA) in mice uses stimulation of lymphocytes [163–165] in local draining lymph nodes during the afferent phase as the endpoint.

Modulation of the development of DTH in experimental animals and in humans is complex. The intrinsic biological variables controlling sensitization can be influenced by the selection of animals likely to be capable of mounting an immune response to the hapten. The extrinsic variables of dose, vehicle, route of exposure, adjuvant, etc., can be manipulated to develop sensitive predictive assays. The method of skin exposure is important. Keratinocytes produce interleukins [67], important regulatory proteins for the induction of DTH. Langerhans cells express Ia antigen and may act as antigen-presenting cells [60,267,304]. Intradermal injection in animals bypasses the processes but ensures entry of the chemical into the skin.

Vehicle plays an important role in percutaneous penetration and hence presumably in sensitization. The theory, at least with regard to flux, should be simple: maximum

solubility leads to maximum thermodynamic activity and enhanced flux. The experimental literature only partially documents this presumed truth. Analysis of the relevant literature provides a partial interpretative key to this fundamental area [203]. Increasing the dose per unit area increases the sensitization rate. Upadhye and Maibach [306] reviewed in detail the influence of area application on the development of human sensitization. When early publications viewed as dogma were examined with statistical methods, the findings failed to be significant, yet dose per unit area and occlusion [198,199] appear to be highly important variables.

Application of haptens to damaged skin (i.e., irritated, tape-stripped) increases the sensitization rate, perhaps partially by increasing penetration. Although effects of vehicle, dose level, and damaged tissue have been studied more extensively in guinea pigs and humans than in mice, until conclusive studies are reported, it is prudent to consider their influence in the design of all studies. Repeated applications to the same site are more effective for inducing sensitization than applications to new sites each time [91,198]. The incidence of sensitization increases with increased number of exposures [198], and an interval between exposures of 2–6 days increases the sensitization rate [5,165,198]. This may be due to the booster effect of memory cells. Materials such as Freund's complete adjuvant (FCA) nonspecifically enhance the development of immune responses but may selectively trigger humoral immunity in some species [47]. Treatment of animals with adjuvant, either simultaneously or shortly after hapten exposure, increases sensitization rates [199,201]. The development of DTH is under genetic control; within the human and guinea pig populations, all individuals do not have the capability to respond to a given hapten [198]. The status of the immune system will determine if an immune response can be induced; for example, animals may become tolerant to a hapten, and pregnancy may suppress expression of the allergy [177].

Appropriate planning and execution of predictive sensitization assays are critical. All too often, techniques are discredited when, in fact, the performance of the tests was inferior or the study design (e.g., choice of vehicle or dose) was inappropriate. The first priority is to choose an appropriate experimental design. Often the assay to be used is chosen on a pro forma basis without realizing the inherent weaknesses and strengths of the method. A common error in choosing an animal assay is using FCA when one wishes to determine dose–response relationships. The adjuvant provides such sensitivity that dose–effect relationships are muted.

Choice of dose and vehicle appropriate to the assay and the study question is the second priority. Although dose must be sufficient to ensure penetration, it must be below the irritation threshold at challenge to avoid misinterpretation of irritant inflammation as allergic. For example, quaternary ammonium compounds, such as benzalkonium chloride, rarely sensitize, but they have been identified as allergens in some guinea pig assays. Knowing the irritation potential of compounds allows the investigator to appropriately design and execute these studies. Vehicle choice determines, in part, the absorption of the test material and can influence sensitization rate, ability to elicit response at challenge, and the irritation threshold. Inappropriate selection of vehicle and dose effectively invalidates studies.

Sensitization assays often are assigned to novices when they should be performed and read by persons experienced with the method being used. Experienced investigators will recognize marginal reactions that should be further investigated and positives that may be irritant in nature, and they will be able to assist in the estimation of risk associated with the proposed use of the material. Working with laboratories and personnel with extensive experience greatly decreases errors and increases the reliability of all of the standard assays described later [140,160,161,169,264].

Data from various sensitization assays have been broadly used to determine the likelihood of induction of clinical allergic contact dermatitis in populations to be exposed. Interpretation of these assays requires experience, judgment, and sophistication because each assay has its own strengths, weaknesses, and limitations. Central to the issue of interpretation is the definition of allergic contact dermatitis in humans and animals; for example, in the mouse, the endpoint is documented reliably only by measuring ear swelling. In humans, the patch test, albeit a highly valuable bioassay, has often been misinterpreted. Guidance for proper interpretation is found in the original references for many of the assays discussed later; for human repeat insult patch tests, guidance is found in a review article by Stotts [292]. Several authors and groups are refining criteria for allergic contact dermatitis that are operational rather than mechanistic. Fundamentally, each of the systems acknowledges the complexity of the biological process. Each parameter is qualitative or quantitative and is multifunctional; for example, in humans, it is necessary to have a pertinent history, carefully performed patch test results with appropriate virgin controls, and sufficient follow-up to define that removal of the allergen improved clinical status [156,317].

Guinea Pig Sensitization Tests

Predictive animal tests to determine the potential of substances to induce delayed hypersensitivity in humans are conducted most often in guinea pigs. Several tests have been described. Each offers its own advantages and disadvantages; most have many features in common. All use young (1–3 months old or 250–550 g), randomly bred albino guinea pigs. To reduce the possibility of seasonal variability in reactivity, animals are maintained in facilities with a temperature of approximately 20°C ± 1°C, a relative humidity of 40%–50%, a 12 h automatic light cycle, a standard vitamin C-supplemented chow, and water available at all times. Test sites are clipped free of hair with electric clippers; some assays specify chemical depilation as well. Almost all evaluate the response as the production of visible dermatitis, using descriptive scales for erythema and edema. Because of genetic influences, sensitivity to a common chemical, such as dinitrochlorobenzene (DNCB), is usually confirmed periodically for animals from each vendor. There is disagreement as to which sex, if either, is more susceptible to sensitization.

Males are more aggressive and may damage the skin of cage mates. Some assays specify use of one sex or half of each sex. The tests differ significantly in route of exposure, use of adjuvants, induction interval, and number of exposures. Table 27.4 summarizes the principal features of the most commonly used assays to predict sensitization and assays acceptable to regulatory agencies [58,87,92,152,232,264].

Draize Test

The Draize sensitization test (DT) [75,153,166] was the first predictive sensitization test and is still widely used. One flank of 20 guinea pigs is shaved and 0.05 mL of a 1% solution of test material in saline, paraffin oil, or polyethylene glycol is injected into the anterior flank on day 0. The next day, and every other day through day 20, 1.1 mL of the test solution is injected into a new site on the same flank. Challenge follows a 2-week rest period. The opposite untreated flank is shaved, and 0.05 mL of test solution is injected into each animal. Twenty previously untreated controls are injected at the same time. The test site is visually evaluated 24 and 46 h after injection. The intensity of the responses of test animals is compared with that of controls. A larger more erythematous response than that of controls is considered a positive response. Results are expressed as the percentage of animals positive or as the ratio of positive animals tested.

Open Epicutaneous Test

The open epicutaneous test (OET) [160,166,167] simulates the conditions of human use by using topical application of the test material. The procedure determines the dose required to induce sensitization and to elicit a response in sensitized animals. The irritancy profile is evaluated by testing various concentrations (typically, undiluted, 30%, 10%, 3%, and 1%) in ethanol, acetone, water, polyethylene glycol, or

petrolatum. In six to eight guinea pigs, 0.025 mL of the dosing solutions is applied to 2 cm^2 areas of the shaved flanks. Vehicle solubility and use conditions (e.g., direct application to skin or dilution during normal use) are considered when selecting the concentrations to be tested. Test sites are visually evaluated 24 h after the application of test solutions for the presence or absence of erythema. The dose not causing a reaction in any animal (maximum nonirritant concentration) and the dose causing a reaction in 25% of the animals (minimal irritant concentration) are determined. During induction, 0.10 mL of test solution is applied to an 8 cm^2 area of flank skin of six to eight guinea pigs for 3 weeks or five times a week for 4 weeks. As many as six groups of animals are treated with different doses; a control group is treated with vehicle only. The highest dose tested usually is the minimal irritant concentration; lower doses are based on usage concentration or a stepwise reduction (e.g., 30%, 10%, 3%, and 1%). Solutions are applied to the same site each day unless a moderate inflammatory response develops. Each animal is challenged on the previously untreated flank 24–72 h after the last induction treatment. The minimal irritant concentration, the maximum nonirritant concentration (from the irritancy screen), and five solutions of lower concentrations are applied (0.025 mL to a 2 cm^2 area). Skin reactions are read on an all-or-none basis at 24, 48, and 72 h after the applications of the solutions. The maximum nonirritating concentration in the vehicle-treated group is calculated. Animals in test groups that develop inflammatory response to lower concentrations are considered sensitized. The dose required to sensitize is determined by comparing the number of positive animals in the test groups. The minimal concentration necessary to elicit a positive response in a sensitized animal is apparent from the challenge responses.

Buehler Test

The Buehler test [45–47,106,166] also employs topical application of the test material. An absorbent patch—20 × 20 mm Webril®, backed by Blenderm™ tape and saturated with 0.4 mL of the test material—is placed on the shaved flanks of 10–20 guinea pigs. The test concentration varies from undiluted to usage levels. An optimum concentration that produces slight erythema is selected based on an irritancy screen conducted in other animals. The patch is held in place by wrapping the animal with an occlusive wrapping. The animal is then placed in a special restrainer fitted with a rubber dam to maintain even pressure over the patch for a 6 h exposure period. This procedure is repeated 7 and 14 days after the initial exposure. A control group of 10–20 animals is patched with vehicle only. Two weeks after the last induction patch, animals are challenged with patches saturated with a nonirritating concentration of test material applied to both flanks and with the vehicle (if other than water or acetone). Wrapping and restraint are as during induction. After 6 h, the patch is removed, and the area is depilated. Test sites are visually evaluated 24 and 48 h after removal. Animals developing erythematous responses are considered sensitized (if irritant control animals do not respond). The incidence of positive reactions and the average intensity of the response are calculated.

Freund's Complete Adjuvant Test

FCA test is an intradermal technique incorporating test materials in a 50/50 mixture of FCA and distilled water. The test has been significantly modified since originally described [166]. The latest published description [167] is summarized here. A 6 × 2 cm area across the shoulders of two groups of 10–20 guinea pigs is shaved and used as the injection site. Animals of one group are injected with a 5% solution of the test material in FCA/water; injection volume is 0.1 mL. Control animals are injected with FCA/water. Injections are repeated every 4 days until three injections are given. The minimal irritating and maximum nonirritating concentrations following topical application of 0.025 mL solutions to a 2 cm^2 area of skin are determined in a minimum of four naive guinea pigs (see OET procedure). Twenty-one days after the first induction injection, 0.025 mL of the minimal irritant concentration, the maximum nonirritant concentration, and two lower concentrations is applied to 2 cm^2 areas of the shaved flank. Test sites are not covered and are evaluated for the presence of erythema at 24, 46, and 72 h after application. The minimum nonirritating concentration in FCA/water-treated controls is determined. Animals injected with the test material during induction that respond to lower doses are considered sensitized. The incidence of sensitization and the threshold of concentration for elicitation of the response in these animals are calculated.

Optimization Test

The optimization test resembles the DT but incorporates the use of adjuvant for some induction injections and both intradermal and topical challenges [166,167,217]. Injections during induction are 0.1 mL of 0.1% concentration of test material in 0.9% saline or in 50/50 FCA/saline. In total, 10 injections are given. On day 1 of the first week, one injection into the shaved flank and one into a shaved area of dorsal skin are given. Two and four days later, one injection into a new dorsal site is given. The test material is administered in saline during the 1st week. During the 2nd and 3rd weeks, test material is administered in FCA/saline every other day to a shaved area over the shoulders. Twenty test animals are treated; 20 controls are injected with saline during week 1 and FCA/saline during weeks 2 and 3. The intensity of the 24 h responses during week 1 is calculated as reaction volume. Thickness of a skin fold over the injection site is measured with a caliper (mm), and the two largest diameters of the erythematous reaction are recorded (mm). The reaction volume is calculated by multiplying fold thickness times both diameters and is expressed as microliters. The mean reaction volume of each animal to the intradermal injections using saline as a vehicle (week 1) is calculated. Animals are challenged with 0.1 mL of 0.1% test material in saline 35 days after the first injection. The challenge reaction volume for each animal is calculated and compared to the mean reaction volume for that animal. Any animal developing a reaction

volume at challenge greater than the mean plus one standard deviation during induction is considered sensitized. Vehicle control animals are injected with saline at challenge. A second challenge is conducted 45 days after the first injection. A nonirritating concentration of the test material in a suitable vehicle is applied to the flank skin, away from injection sites; 0.05 mL is applied to an area of approximately 1 cm^2.

The area is covered with a 2 × 2 cm piece of filter paper backed by an occlusive dressing, which remains in place for 24 h. Reactions are visually evaluated using the four-point erythema scale of the Draize primary irritancy scale (see Table 27.9). The control animals are patched with vehicle alone. The number of positive animals in the test group is statistically compared with the number of pseudo-positive animals in the control group using the exact Fisher test. Separate comparisons of intradermal and epicutaneous challenges are made. A p-value of ≤0.01 is considered significant. To classify materials as strong, moderate, weak, or nonsensitizers, a classification scheme has been devised using results of the exact Fisher test and number of positives detected (Table 27.5)

Split Adjuvant Test

The split adjuvant test [166,200,201] uses skin damage and FCA as adjuvants; application of the test material is topical. An area of back skin just behind the scapulas of 10–20 guinea pigs is clipped, shaved to glistening, then treated with dry ice for 5–10 s. A dressing of a layer of loose mesh gauze and stretch adhesive with a 2 × 2 cm opening over the shaved area is placed around the animal and secured by adhesive tape. This dressing remains in place throughout induction. Approximately 0.2 mL of creams or solid test material or 0.1 mL of liquid is spread over the test site and covered with two layers of #2 filter paper backed by occlusive tape and attached to the dressing by adhesive tape. The concentration tested varies by irritancy potential, use conditions, etc. Two days later, the filter paper is lifted from the test site, the test material is reapplied, and the filter paper covering is replaced. On day 4, the filter paper cover is removed; two injections of 0.075 mL FCA are given into the edges of the test site, the test material is reapplied, and the site is resealed. On day 7, the test material is reapplied, and on day 9, the dressing is removed. Twenty-two days after the initial treatment, animals are challenged by topical application of 0.5 mL of test material to a 2 × 2 cm area of the shaved mid-back. The test site is covered by filter paper backed with adhesive tape, held in place by wrapping the animal with an elastic adhesive bandage secured with adhesive tape. A group of naive controls (10–20 animals) is treated by the same procedure at challenge. The dressing is removed 24 h after application, and the test site is evaluated visually at 24, 48, and 72 h, using a seven-point descriptive visual scale. Sensitization of individual animals is indicated by significantly stronger reactions than reactions of controls.

Guinea Pig Maximization Test

The guinea pig maximization test (GPMT) [166,198,199,316] combines FCA, irritancy, intradermal injection, and occlusive topical application during the induction period. The shoulder regions of two groups of 20–25 guinea pigs are shaved. Two identical sets of intradermal injections of 0.1 mL 50/50 FCA/water; test material in water, paraffin oil, or propylene glycol; and the same dose of test material in FCA/vehicle are placed in a 2 × 4 cm area. Seven days later, the test article is placed on filter paper over the injection site. The filter paper is covered with approximately 4 × 8 cm occlusive surgical tape and secured in place with an elastic bandage wrapped around the animal. If the test material is nonirritating, the test site is pretreated with 10% sodium lauryl sulfate (SLS) in petrolatum on day 6 to provoke an irritant reaction. If a vehicle other than petrolatum is used for topical application of the test material, the filter is saturated with the solution. Control animals are patched with the vehicle alone. The dressing is removed from the animals 48 h after application. Test and control animals are challenged on the shaved flank with the highest nonirritating concentration, with approximately one half of the highest nonirritating concentration, and with the vehicle. Solutions are applied to 1 × 1 cm pieces of filter paper secured in place as during induction; patches are removed 24 h later. The challenge area is shaved, if needed, 21 h after patch removal. Reactions are evaluated visually 24 and 48 h after patch removal. The intensity of responses to test material and vehicle in the test group is compared to the responses in controls. Reactions are considered positive when they are more intense than the response to vehicle and the responses to the test material in controls. Based on the incidence of positives in the test group, test materials are rated as weak to extreme sensitizers (Table 27.6).

TABLE 27.5
Classification Scheme for the Optimization Test

Interdermal Positive Animals (%)	Epidermal Positive Animals (%)	Classification
NS, 0–30	NS, 0	Nonsensitizer
S, 30–50	NS, 0–30	Weak sensitizer
S, 50–75	S, 30–50	Moderate sensitizer
S, >50	S, >75	Strong sensitizer

Note: S, statistically significant; NS, not statistically significant by exact Fisher test.

TABLE 27.6
Classification of Materials by Maximum Test

Sensitization Rate (% Responding at Challenge)	Grade	Classification
0–8	I	Weak
9–28	II	Mild
29–64	III	Moderate
65–80	IV	Strong
81–100	V	Extreme

Sensitization Tests in Mice

Although guinea pigs have been the animal of choice for predictive sensitization assays for 50 years, interest and activity in developing and validating standardized predictive assays in mice have been intensive during the last 10 years. Classical guinea pig sensitization assays are relatively costly and time consuming. All use subjective endpoints, and data interpretation is prone to difficulties. Manipulations of the animals are sufficiently stressful in some assays to alter normal physiological parameters. With the development of new techniques for studying DTH [36] and evaluating cellular response [115], it has become possible to study the response in other laboratory animals [5,64,65] in shorter time frames. Numerous less subjective techniques for evaluating the allergic response have been proposed, including changes in the water content of challenged ears [36], measurement of ear thickness with an engineer's micrometer [7,307], and responses of lymphocytes [7,222,223,253]. Although numerous approaches to developing a predictive sensitization assay in mice have been proposed, only two methods have been sufficiently developed to warrant consideration as standardized assays. The test site for each is the mouse ear, yet these methods employ distinctively different approaches. The mouse ear swelling test (MEST) uses both topical and injection exposures for induction and a topical challenge of the pinnae in which visual evaluation is replaced by measuring ear thickness with an engineer's micrometer. The LLNA consists of a topical induction followed by measurement of the mitotic activity of the draining lymph node. LLNA is unique out of all predictive assays in evaluating the response of the efferent phase of the response. A third mouse sensitization assay, the vitamin A enhancement test (VAET), has been used for the evaluation of ingredients of consumer products but has not been used by a sufficient number of laboratories to be considered standard. In the VAET, the reactivity of the immune system is heightened by maintaining animals on a diet with high doses of vitamin A for a preconditioning period and throughout induction and challenge. Challenge is topical and is assessed by measuring ear thickness. These assays are contrasted in Table 27.7.

Local Lymph Node Assay

Kimber and colleagues [162–164,238] investigated measuring lymphocyte proliferation as an alternative approach to visual evaluations or measurement of edema of the mouse ear. They found that exposure of the dorsum of the ear pinnae to sensitizers produced hyperplasia of T cells in auricular lymph nodes. A dose divided into three exposures over three

consecutive days produced a more intense response than the same dose delivered in a single exposure [165]. In a limited trial, Balb/c mice were more sensitive than other strains [164]. Initial studies used 24 h cultures of excised lymph node cells labeled with ^{3}H-thymidine, with or without exogenous IL-2 [163,164]; however, to simplify the assay, the method was modified to expose proliferating cells to ^{3}H-thymidine in situ via intravenous injection. The method described is the final method used in intralaboratory validation studies that have been reported [13,276]. A complete list of references was made available in 1999 by an independent review evaluation of the method sponsored by the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) [233]. Several new reviews have recently been published [346–348].

The LLNA employs multiple topical in vivo doses of the material of interest to the mouse ear. This is followed by in vitro evaluation of mitotic activity of cells from draining lymph nodes. At least three dose levels are evaluated in separate groups of four CBA/ca mice. Experimental animals between 8 and 12 weeks of age are used. Either males or females may be used, but each assay should use only a single sex.

Vehicle selection and test concentration are based primarily on the solubility and viscosity of the solution or suspension. Investigators ascertain that the doses selected are nontoxic to the animals. Vehicles shown to be acceptable include 4:1 acetone/olive, methyl ethyl ketone, dimethylformamide, propylene glycol, dimethyl sulfoxide, and 2.5% hydroxypropyl cellulose in methanol. Investigators have proposed testing three consecutive concentrations from the series 100%, 50%, 25%, 10%, 5%, 2.5%, 1.0%, 0.5%, 0.25%, 1.0%, 0.05%, and 0.001%.

For three consecutive days, 25 μL of the appropriate test solution or the vehicle alone is applied to the dorsal surface of the pinnae. Five days after the first exposure, 250 mL phosphate-buffered saline (PBS) containing 20 μCi methyl thymidine is injected via the tail vein of each animal. Five hours after injection, animals are euthanized by carbon dioxide asphyxiation. Draining auricular lymph nodes are excised and pooled with nodes from other animals in the same group. A single-cell suspension is prepared by gently passing the nodes through stainless steel, 200-mesh gauze with the plunger of a syringe. The cell suspension is centrifuged at 190 × g for 10 min, and the pellet then washed twice with 10 mL PBS. Cells are resuspended in 3 mL of 5% trichloroacetic acid (TCA) and incubated overnight at 4°C. The precipitated macromolecules are recovered by the centrifugation, the supernate is removed, and the precipitate is resuspended in 1 mL 5% TCA. The suspension is transferred to 10 mL scintillation fluid, and disintegrations/min are counted using a β scintillation counter. Disintegrations per lymph node are calculated for each experimental group and the control group. The ratio of ^{3}H-thymidine incorporation into the test group and the control is calculated for each dose. Some investigators prefer to pool the lymph nodes from all animals in the dosage group. If the ratio is 2–3 for any dose, the material is considered a sensitizer.

Several groups have reported comparisons of the LLNA with various guinea pig assays and have suggested variations of the method [11,12,144,161,162,276]. It is clear that LLNA is not as stringent as some guinea pig assays; however, it is expected to retain utility as a rapid screening assay for materials with strong sensitization potential, as it offers advantages in the low number of animals used, lower cost, and less time required for conducting the assay. A validation meeting to review the strengths and weaknesses of the assay has been reported [233]. Certain materials, such as metals, have not been reliably identified as allergens. The validation attempt matched LLNA results with guinea pig Buehler and maximization assays. Both have false positives and false negatives. No attempt was made to determine the clinical relevance of the LLNA data, nor the benchmarks used. Key to the clinical relevance of this assay will be a more precise series of databases that permit clinical collaboration between the LLNA and human experience; that is, how does one relate the LLNA data with the frequency of allergic contact dermatitis in humans?

Mouse Ear Swelling Test

Gad and coworkers [113,114] used ear thickness measured with a caliper-type engineer's micrometer to evaluate the response of mice after challenge with potential sensitizers. They optimized a protocol in which tape-stripped skin sites that had been injected with FCA were topically exposed to the test material each day for 4 days. Seven days after the last topical exposure, animals were challenged by topical application of the test material to one ear. Early work also showed that Balb/c, CF-1, or SW mice could be used in the assay. Females were selected because their less aggressive behavior allows group housing with minimally damaged ears. Responses of animals less than 5 weeks old or more than 13 weeks old were weaker than animals 6–10 weeks of age. Administration of induction doses to the stomach region yielded a higher rate of sensitization than application to the back of the animals. The efficacy of the induction method was increased somewhat by both tape stripping and preinjection of the test site with FCA. Exposure via occlusive patches during induction did not increase the sensitivity of the assay, and in some cases, the response was diminished when the patching system was employed. Their final protocol incorporated these findings.

For the MEST, 6- to 8-week-old CF-1, Balb/c, or SW female mice are gang housed in direct bedding cages. Following a 5- to 7-day quarantine period, the fur of the abdomen is shaved by electric clippers from 10 to 15 test animals and 5 controls. Animals with damaged pinnae are excluded from testing at this time. After the area is shaved, it is tape stripped with Dermaclear®, a surgical adhesive tape, until the skin appears glossy. Then a divided dose of 0.05 mL FCA is injected intradermally with a tuberculin syringe fitted with a 30-gauge needle. The FCA is injected into two sites within the shaved area but along the borders. Following the injection of adjuvant, 100 μL of vehicle containing the test material or vehicle alone (controls) is applied to the center of the shaved area. The abdomen is allowed to dry, and the mouse is then returned to its cage. The process of

tape stripping and application of appropriate material to the abdomen is repeated daily for the next 3 days.

Vehicle is chosen based on solubility and chemical compatibility with the test substance. Acetone, methyl ethyl ketone, or 70%, 80%, and 95% ethanol in water have been shown to be acceptable vehicles. Mixed ethanol/olive oil systems are not satisfactory. The dose selection is based on dermal irritation toxicity range-finding studies prior to testing each compound. Four groups of two mice each are subjected to the induction procedure, including shaving, tape stripping, and application of the test material, and the ears are then exposed as during challenge. At least four concentrations are evaluated in the range study. Minimally irritating or nonirritating concentrations are selected for the induction application. The highest nonirritating concentration is used at challenge.

Challenge is performed 7 days after the last topical induction application by applying 20 μL of the test material in vehicle to one ear of each animal (test and control) and 10 μL of the vehicle to the opposite ear. Ear thickness is measured before application of the challenge dose and 24 and 48 h after the challenge application. Animals are lightly anesthetized with ether, and the thickness of both pinnae is measured with an engineer's micrometer. Positive respondents are defined as animals in which the ear dosed with the test material shows at least a two- to threefold greater increase in thickness than the vehicle-treated control ear. The control group should not show greater than 10% increase in ear thickness for the test to be considered valid. If the control groups show more than a 10% increase, the study should be repeated using lower doses. The percentage of respondents is calculated. In addition, the degree of ear swelling is calculated by dividing the thickness of the ear to which the test material was supplied by the thickness of the vehicle-treated control ear. Measurements from all animals in the test group are included. No additional explanations or examples of the use of the degree of ear swelling in interpreting results are available. A later paper proposed that the data generated by MEST (and classical guinea pig assays) could be used to calculate a potency index of sensitization [112].

The original paper of Gad et al. [114] included validation studies of 72 compounds. They reported a false-negative rate of only 2% and no false positives when MSET was compared to GPMT data on the same materials. The incidence of sensitization in MSET was consistently lower than that produced by GPMT. Similar findings were reported for comparisons between the Buehler assay and MEST in the same paper; however, published guinea pig data used for comparisons included data from other topical guinea pig techniques that did not employ the restraint procedure specified by Buehler. Intralaboratory validation of the method includes a comparison of test results for eight materials tested in five laboratories [114]. That report indicates that MSET did not identify weak sensitizers in two of three laboratories. Other studies have confirmed that the incidence of positive response in MEST is consistently lower than in GMPT, and weak and moderate sensitizers are not identified correctly [63,78]. The MEST has been accepted by the Environmental Protection Agency (EPA) for registration of chemicals under the Toxic Substances Control Act [59].

Although not reported in papers describing this method, the type of micrometer used may affect interpretation of the test results. Van Loveren [309] compared the use of spring-loaded, caliper-type instruments with screw and friction thimble micrometers. Spring-loaded instruments were best. Electronic instruments have been used in other types of immunological investigations. In our experience, the use of anesthetic can be eliminated by operator training prior to handling animals.

Vitamin A Enhancement Test

Miller and colleagues [206,209,221] decreased the dose of strong sensitizers required to induce sensitization by maintaining the animals on diet supplemented with high levels of vitamin A acetate. The mechanism of the increase in response was studied using radioisotopes, but because of ease in performing the assay, ear thickness measurement was selected for use in the predictive assay. Principal features of the test included a preconditioning period for the diet of 28 days, six exposures to the shaved abdomen and thorax during the 12-day induction period, and challenge 4 days later. Results from the test group were compared statistically to those of the controls, and a 50% increase over the response to controls was observed that indicated sensitization. The minimally irritating concentration was used for induction, and the highest nonirritating dose was used at challenge (determined by dose response in separate groups of mice). The vehicle was selected based on nonirritancy and solubility of the test substance. An obvious difficulty with the method was the long conditioning period required prior to the study. General comments concerning choice of micrometer for MEST also apply to VAET. The test was never widely adopted or submitted to formal validation procedures.

Human Sensitization Assays

Chemicals can be tested for their ability to induce contact hypersensitivity in panels of human volunteers from whom informed consent is obtained. Human studies should be undertaken only after the results of predictive tests in animals are available if the test material is a new compound or if it contains significantly increased levels of common ingredients. Testing higher doses in animals provides some margin of safety for potential human subjects. Generally, materials identified as sensitizers in animals are not tested on humans; however, if the potential benefit of the material warrants, a small group of human subjects may be tested with materials inducing sensitization in animals. Such situations should be reviewed by an institutional review board (IRB). Test subjects should be informed of the risks, and the number of subjects should be limited (additional subjects can be exposed if members of a small group do not respond).

Subjects should be randomly selected; however, some precautions are indicated. Some investigators believe intact draining lymph nodes adjacent to the application site are

the preferred site to induce sensitization, and patches should not be placed on areas adjacent to mastectomies. Persons with unilateral mastectomy who wish to participate may be tested by applying patches to the opposite sides of the body. Test materials should not be applied on scar tissue. Recurrence of skin conditions in remission (e.g., psoriasis and eczema) has been associated with patch testing and other minor physical traumas. Subjects at risk should be informed of this possibility and encouraged to consult their dermatologist prior to testing. Subjects should not be tested with materials to which they are known to be allergic (demonstrated by diagnostic patch test or in previous predictive assays). It is prudent to routinely question potential subjects concerning their history of dermatologic disease and allergies. Allergic contact dermatitis to materials already in commerce is sometimes detected by early induction patches. This indicates that, under patch conditions, the material may elicit a response in presensitized individuals. Although the incidence of preexisting sensitization to the material should be considered in risk assessment decisions regarding marketing, detection of preexisting sensitization may not be helpful in evaluating the ability of a material to induce sensitization. Records of previous responses of individuals participating in multiple predictive assays should be reviewed prior to testing to eliminate subjects presensitized to components of the product.

Although numerous variations have been reported, four basic predictive human sensitization tests are in current use: (1) single induction/single challenge patch test, (2) repeated insult patch test (RIPT), (3) RIPT with continuous exposure (modified Draize), and (4) maximization test. The principal features of human sensitization assays are summarized in Table 27.7. As originally described, all methods used customized patches, and patch selection was governed by available adhesive systems. Description of customized patches would be of historical interest only; as currently conducted, most human assays use similar patches. Occlusive patches, consisting of a nonwoven pad (usually Webril®) of four-ply gauze sponges backed by an occlusive surgical tape, such as Blenderm™, are available commercially or may be custom made in strips of four or five pads. Acceptable alternatives include the Hill Top Chamber® [157], which contains a Webril pad inside an occlusive plastic disk backed by porous tape; the Duhring chamber [109], a stainless steel disk that contains a Webril pad; and the large Finn Chamber®. Duhring and Finn chambers usually are secured in place by porous surgical tape. Occasionally, semiocclusive patches made of Webril backed by porous tape may be used. Semiocclusive patches are decidedly inferior to occlusive patches in the induction of sensitization.

For assays other than maximization, usually 150–200 subjects are tested. Henderson and Riley [136] showed statistically that, if no positive reactions are observed in 200 randomly selected subjects, as many as 15/1000 of the general population may react (95% confidence). As the sample size is reduced, the likelihood that the test will not correctly predict adverse reactions in the general population increases.

Results of the RIPT, modified Draize test, and human maximization tests have been accepted as valid by regulatory agencies; however, some sponsors routinely use one of the methods described and defines its use as the *standard of the industry*. This is a simplistic view of the methods and their strengths and weaknesses. As for most toxicity endpoint, the method used should provide a reasonable exaggerated exposure over the anticipated exposure from use of the product. The device group of the FDA held several meetings to review details of sensitization procedures. These deliberations led to a guidance document [55] for evaluating skin sensitization to chemicals in natural rubber products. The modified Draize procedure is recommended. Tests guidance for transdermal products evaluated by the FDA is available on the FDA website (www.fda.gov/ohrms/dockets/98fr/990236Gd.pdf).

Schwartz–Peck Test (and Modifications)

A single application induction patch followed by a single application patch test was described by Schwartz [277,278] and Schwartz and Peck [279] with a usage test of 1 month after challenge to verify patch results. The test has been modified by some to eliminate the usage test [43], to eliminate patching altogether, and to place a usage period between induction and challenge patches [299]. The term *complete Schwartz–Peck method* refers to a single induction patch, usage period, and single challenge patch test. This may also be referred to as the *Traub–Tusing–Spoon method*. Incomplete Schwartz–Peck tests do not incorporate a usage period. A patch saturated with the test material, diluted if necessary, is applied to the outer upper arm of 200 test subjects and remains in place for 24–72 h. The dose tested and duration of patch contact vary with intended use. Cosmetics may be tested without a covering (open application) or with semiocclusive patches. The test site is visually evaluated at patch removal and at 24 and 48 h after removal for erythema and edema. A 4-week normal usage period follows the induction patch in the complete Schwartz–Peck test, with a challenge patch applied to the same site on the upper arm at the conclusion of the usage period. For the incomplete Schwartz–Peck test, a second patch procedure is performed 10–14 days after the induction patch. Duration of contact and evaluation of the site are similar to those during induction. The development of dermatitis at challenge that is much stronger than during induction signifies sensitization.

Schwartz originally described the incomplete Schwartz–Peck test. A usage test was to be conducted after the challenge patch using 1000 different subjects. Although Schwartz and Peck referred to their assay as a *prophetic patch test*, experience has shown that only potent haptens will induce sensitization in this assay [169]. In fairness, it should be noted that the test was originally designed to evaluate the effect of nylon garments on the skin. It was intended to detect adverse effects, irritation, and secondary irritation (sensitization). The mechanism of skin allergy was not understood when the test was designed. Although the test was useful for its original purpose, unfortunately, its use was expanded without considering new information generated by immunologists. Clearly, the assay

is inferior to all other predictive human sensitization assays; however, a few groups continue to use the method.

Repeat Insult Patch Test

Three major variations on the RIPT are in common use: (1) the Draize human sensitization test [74,75], (2) the Shelanski–Shelanski test [279–281], and (3) the Voss–Griffith test [45,122,123,315]. Although the Shelanskis first published a description of a RIPT, they based its development on a verbal description of a method Draize was revising [281]. Voss modified the Shelanski–Shelanski test [316], and his assay was later modified by Griffith [123]. As one would expect, the three assays have much in common. However, there are significant differences in the assay as originally described. Several groups at the FDA evaluated various RIPT protocols, leading to guidances that are published on their websites (see www.FDA.gov, medical devices section).

In the Draize human sensitization test, an occlusive patch containing the test material is applied to the upper arm or upper back of approximately 200 volunteers. The patch remains in place for 24 h and is then removed. The test site is evaluated at patch removal for erythema and edema. A second patch test is applied to a new site 24 h after the first patch is removed. This process is repeated until 10 patches are applied. For convenience, the test may be run on a Monday-to-Friday schedule, with subjects removing their own patches on Saturday (72 h between Friday and Monday applications). Ten to fourteen days after the application of the last induction patches, subjects are challenged via a patch applied to new sites. Duration of contact is 24 h, and sites are visually evaluated at removal of the patch. The response at challenge is compared to the responses to patches applied early in induction, and the incidence of sensitization is reported.

Like the Draize RIPT, the Shelanski–Shelanski test employs occlusive patches that remain in contact with the skin of the upper arm for 24 h. The patching cycle is the same; however, patches are placed on the same test site each time, and a total of 15 sets of patches are applied during induction. The test site is evaluated before application of a new patch to the site. If inflammation has developed, the patch is placed on an adjacent uninflamed site. Two to three weeks after the induction period, subjects are challenged by the application of a patch that remains in place for 48 h. Test sites are evaluated at patch removal for erythema and edema, and the incidence of positive response is reported. Patch responses during induction were considered by Shelanski and Shelanski to be evidence of *skin fatigue* (cumulative irritation); the time of development (i.e., number of patches) was reported as a fatigue index. Voss [316] reduced the number of 24 h patch exposures to nine over a 3-week period. At challenge, 2 weeks after the last induction patch, duplicate patches applied to the original test site are worn for 24 h. Patch sites are evaluated 48 and 96 h after patch application. A pilot group of 10–12 subjects was tested prior to exposing the full panel of 60–70 subjects.

Griffith later published more method details [122,123]. A maximum of four dissimilar materials was tested simultaneously, and duplicate challenges were applied to the sites of induction and to the opposite arm, thus testing areas drained by different regional lymphatics. The concept of a rechallenge of subjects with reactions difficult to interpret was also introduced. The number of subjects was increased to 200 by conducting tests on multiple panels. Stotts [292] presented detailed examples of proper interpretation of human repeat insult patch tests. Sensitization is characterized by challenge reactions stronger than reactions early in the induction phase, by persistence of responses through delayed readings, by delayed appearance of response, or by weak responses in a few subjects when the material has not produced irritation in the panel. Examples of patterns of responses indicating presensitization and weak responses that warrant rechallenge are also presented in the paper.

As currently conducted, the differences in the Draize and Voss–Griffith RIPTs are minimal. Many investigators apply patches to the same site during induction and refer to the procedure as a Draize RIPT. The value of multiple grades at challenge is widely recognized. Multiple test materials are tested simultaneously in all RIPTs for reasons of efficiency and economy. Although the distinctions between the Draize and Voss–Griffith procedures have blurred with common usage, the Shelanski–Shelanski test, with five to six more induction applications, remains distinct.

Marzulli and Maibach [215,216] have suggested modifications to the RIPT that provide advantages in compliance. Instead of having the volunteers remove the patch, laboratory staff performs this function. Typical application remains at thrice weekly, but the patch remains in place for 48, 48, and 72 h cycles. Hence, chemical/skin exposure is continuous for 3 weeks rather than three 24 h exposures per week. An additional modification involves dosing several groups at ascending doses to allow the determination of the minimal induction concentration.

Human Maximization Test

Kligman [170] reviewed the common human predictive sensitization test methods in use in 1966 and found them to be unsatisfactory in inducing sensitization to nine clinical allergens. In panels of 200 subjects, the Shelanski–Shelanski method induced sensitization to four materials, the original Draize test and the complete Schwartz–Peck test induced sensitization to two allergens each, and the incomplete Schwartz–Peck test failed to induce sensitization to any allergen. Kligman concluded [171] the following:

- Emphasis must shift from prophecy to the more practical objective of identifying potential allergens.
- Once the allergenic potential is known with reasonable certainty, a judgment of risk might be ventured after examining all the pertinent variables.

This represented a profound change in the intent of predictive sensitization assays. Based on his studies of factors affecting rates of sensitization in predictive assays [168,175], Kligman designed the human maximization test [175].

He later modified the procedures somewhat to reduce the difficulties in performing the test and in interpreting the test [175]. The maximization test uses irritancy as an adjuvant. During induction, irritating compounds are tested at a concentration that produces moderate erythema within 48 h. If materials are nonirritating, the test site is pretested with a 24 h patch of 5% SLS. Additional pretreatment SLS patches may be applied before each patch application until a brisk erythema is produced. Induction concentrations are at least five times higher than use levels; petrolatum is a preferred vehicle. Often, custom-made Webril/Blenderm™ patches or plastic or metal chambers are used. Patches are applied to the outer aspect of the arm or lower back, and up to four dissimilar materials may be tested at one time. Wrapping with extra tape is often necessary to ensure occlusion. Bandage sprays may be used to ensure sealing of the test site. Five sets of patches are worn on the same site for 48 h each, with a 24 h rest period between removal and reapplication.

Following a 2-week rest period, an SLS provocative patch is applied to prepare the skin for challenge. A patch saturated with a 2.5%–5.0% solution of SLS is applied to previously untreated sites on the lower back. SLS concentration is based on the season and on individual subject response. The SLS patch is removed after 1 h, and a patch containing the test material is applied. A control site is patched with SLS (1 h) and petrolatum (48 h) to aid in interpretation of the results. The patch is removed 48 h after application, and the test sites are evaluated. Test sites are reexamined 24 and 48 h after patch removal. The number of subjects developing a positive response is reported, and a sensitization index based on percentages of subjects responding is assigned to the test material. In common practice, the human maximization procedure is performed on either the outer upper arm or the back. Although it is clear that the maximization test is a sensitive tool for the detection of allergenicity, the skin damage produced is dramatic and unacceptable to many subjects. This assay is little used today for this reason and because the 25 subject panel has been shown incapable of identifying some allergens.

Modified Draize Human Sensitization Test

The RIPT procedure was modified to provide for continuous patch exposure. Materials are applied to the outer upper arm each Monday, Wednesday, and Friday until 10 patches have been applied during a 3-week period [213,214]. Patches remain in place until approximately 30 min before the application of a fresh patch. This brief rest period allows some clearing of responses to tape and facilitates grading. Fresh patches are applied to the same site unless moderate inflammation has developed; the patches are placed on adjacent, noninflamed skin, should inflammation become pronounced. This produces a continuous exposure of 504–552 h (some investigators apply only nine patches) compared to a total exposure period of 216–240 h for RIPT of comparable induction applications. In addition, induction concentration was increased to levels above usage exposure. Two weeks after induction, subjects are challenged by exposure of a new site to a patch of 72 h duration at a nonirritating concentration. Test sites are evaluated at patch removal and 24 h after removal. Jordan and King [155] proposed modifying the challenge procedure to two consecutive 48 h patch periods. The modified Draize test has been selected as the test of choice for chemicals in natural rubber products [55]. However, numerous causes of false positive predictive allergenic contact dermatitis exist and are beyond the province of this chapter. Lachapelly and Maibach [358] provide extensive information that helps separate false and true positives.

In Vitro Assays for Allergic Contact Dermatitis

As our understanding of cell biology of DCH has increased, in vitro assays to replace diagnostic patch testing and as early screening predictive assays have been proposed. Much of the work toward diagnostic procedures has centered on measuring the effect of cytokines released by sensitized lymphocytes on target cells as a marker for allergy. Proposals for in vitro predictive assays have focused on the afferent phase of antigen binding and stimulation of target cells. To date, neither approach has proved satisfactory, but some limited experimental successes have been reported.

Migration inhibition of peritoneal exudate cells from capillary tubes has been reported to be inhibited by the antigen to which donor guinea pigs were sensitized [116]. Inhibition of macrophage migration is medicated by soluble factors produced by sensitized lymphocytes in the presence of sensitizing antigen [76]. This factor, identified as migration inhibition factor (MIF), has been shown to aggregate macrophages, increase macrophage adherence to glass, and decrease macrophage mobility [70]. Rocklin et al. [269] reported that MIF was produced by highly purified populations of proliferating T cells. Moorehead et al. [230] later demonstrated that MIF production is dependent on Ia/T cell subsets. Mitogenic factors, such as phytohemagglutinin, initiate mitotic activity and transform lymphocytes in their blast forms. Pearmain et al. [255] demonstrated that tuberculin produced the same effect in peripheral blood leukocyte cultures from sensitive patients but not from unsensitized patients. Similar work experiments were conducted in nickel-sensitive subjects [6]. Lymphocytes from unsensitized controls also underwent blast transformation when exposed to nickel. The nonspecificity of nickel and mercury transformation was confirmed by numerous investigators [248,253,258]. Using ^{14}C-thymidine uptake to measure blast transformation, MacLeod et al. [193] demonstrated transformation in over half of the nickel-sensitive subjects and no unsensitized controls.

Experimental studies of blast transformation in which animal or human subjects were intentionally sensitized have been somewhat more successful. Investigators [115,222] have demonstrated that lymphocytes from guinea pigs sensitized with DNCB and incubated with dinitroflurobenzene (DNFB) were transformed to a greater degree than cells from unsensitized controls (note that a dinitrophenyl group would attach to protein using either material). Tritiated thymidine was used to measure blast formation when exposed to DNFB conjugated to epidermal protein. Similar responses were demonstrated

using human volunteers and epidermal extracts for conjugation [223]. Miller and Levis [222] produced the same effect using leukocyte and erythrocyte membranes for conjugation.

Cytotoxicity consistent with that produced by lymphotoxin has been demonstrated in experimentally induced allergic contact dermatitis [72]. Peripheral lymphocytes from DNFB-sensitized guinea pigs were incubated with DNFB-coated radiolabeled chick erythrocytes. Increased radioscope leakage was produced by lymphocytes from sensitized animals than produced by controls. Similar effects were demonstrated using epidermal cells [295].

The use of exclusively in vitro assays for predicting sensitization potential of various schemes has been proposed. In one hypothetical system [36], binding to Langerhans cells would be measured. If no binding occurred, the activation state of the Langerhans cell would be evaluated. If no activation was detected, the material would not be considered to induce sensitization. If Langerhans cells were activated, an autologous lymphocyte blastogenesis assay would be preformed. Current commercial activity in producing skin recombinants may make this type of approach feasible. Blomberg et al. [31] reviewed the use of in vitro assays to study mechanisms of contact dermatitis. There is great enthusiasm for developing such assays to serve as substitutes for testing on animals and humans [349,350]. Taken together, the extensive experimental literature on in vitro assays provides hope that one of several of these methods will not only be *validated* but also sufficiently developed to provide not only hazard information but information to support risk assessment of such materials as well.

Skin Irritation and Corrosion

Historically, skin irritation has been described by exclusion as localized inflammation not medicated by sensitized lymphocytes or antibodies (e.g., that which develops by a process not involving the immune system). The application of some chemicals destroys tissues directly, producing skin damage (including necrosis) at the site of application. Chemicals producing necrosis that result in the formation of scar tissue are described as *corrosives*. Chemicals producing inflammation after a single exposure are termed *acute irritants*. Some chemicals do not produce acute irritation from a single exposure but may produce inflammation following repeated application to the same area of skin. The cumulative irritation from repeated exposures was originally called *skin fatigue*, but the term *cumulative irritation* prevails [279]. Because of the possibility of skin contact during transport and the wide use of many chemicals, regulatory agencies have mandated that chemicals be screened for their ability to produce skin corrosion and acute irritation. These studies have been conducted in animals using standardized protocols; however, recent efforts to replace animal studies with in vitro or human assays have had some success. It is not appropriate to conduct screening studies for several acute irritation or corrosion in humans. Acute irritation can be evaluated in humans after animal studies have shown that the risk of systemic toxicity is low and if the material is known to be noncorrosive. Tests for cumulative irritation in both animals and humans have been reported. In general, cumulative irritation is evaluated in humans unless the toxicity of the material necessitates testing in animals (pesticides, industrial chemicals).

The processes that result in any form of skin irritation are not well understood. In addition to destroying tissue directly, chemicals can disrupt cell functions or trigger the release, formation, or activation of autocoids. Autacoid that are generated following exposure of tissue to some chemicals produce low increases in blood flow, increase vascular permeability, attract white blood cells in the area, and damage cells indirectly. The additive effects of the autocoid mediators would result in local skin inflammation. No agent has yet met all the criteria to establish it as a mediator of skin irritation [261]; however, histamine, 5-hydrotryptamine, prostaglandins, leukotrienes, kinins, complement reactive oxygen species, and products of white blood cells [246] have been strongly implicated as mediators of some irritant reactions.

We have studied the process by which chemicals produce acute skin irritation following open topical applications to the ear of the mouse [228,250,252]. The time course of the inflammatory responses varied from compound to compound and was independent of vehicle and applied dose. Because the differences in time course could not be attributed to differing rates of penetration, this suggested that the materials tested triggered different inflammatory processes. Differences in the irritation process triggered by three chemicals were confirmed by histology, albumin leakage, and changes in the rate of blood flow. Using a series of pharmacological antagonists of putative mediators of irritation, enzyme inhibitors to prevent the formation of suspected mediators, and agents that deplete the body of serum mediators, we confirmed that different pathways of mediator involvement existed for skin irritation. The implications for this finding are clear. A battery of in vitro assays would be required to screen materials for skin irritation; no single assay would be effective.

Many factors may modulate the development of skin irritation (Table 27.8). As with DCH, these factors have been classified as extrinsic or intrinsic [186,205,216,333]. Some extrinsic factors have been shown experimentally to be important considerations in designing predictive tests for skin irritation. A few investigators have also considered intrinsic variables when designing studies.

Like other toxic responses, skin irritation is related to dose. If the duration of contact and the dosing procedure are held constant, the intensity of the response increases as the concentration of the solution increases. Under patch test conditions, the rate of increase in intensity decreases as the concentration increases [335]. The type of appliance, chamber, and tape used to secure patches in place influence the intensity of irritant responses [58,169,179]. More intense inflammatory responses are produced as the degree of occlusion is increased. The search for good techniques of occlusion ultimately led to the development of the Finn, Duhring, and Hill Top chambers now routinely used in patch testing.

TABLE 27.8
Factors Influencing Sensitivity of Skin to Development of Irritation

Variables	References
Extrinsic	
Degree of occlusion	Magnusson and Hersle [196,197]
Choice of vehicle	Patrick et al. [254]
Frequency of dosing	Kligman and Wooding [177], Frosch and Kligman [109]
Duration of exposure	Wooding and Opdyke [337]
Dose (concentration)	Patrick et al. [254], Kligman and Wooding [177]
Temperature	Rothenborg et al. [271]
Environmental conditions	Hannuksela et al. [132], Carter and Griffith [54]
Altered barrier function (including abrasion)	Frosch and Kligman [106]
Chemical damage	Finkelstein et al. [97,98], Patrick and Maibach [251]
Tape stripping	Kligman [172]
Intrinsic	
Anatomical site	Magnusson and Hersle [196,197]
Concomitant disease	Skog [285], Bjornberg [25]
Species differences	Davies et al. [71]
Age	Rockl et al. [268]
Gender (effect disputed)	Wagner and Purschel [317], Bjornberg [26], Frosch and Kligman [107]
Race	Weigand et al. [325], Weigand and Gaylor [324]

Increases in occlusion may be accompanied by local increases in surface temperature, and increased temperature is believed to predispose subjects to irritation. The temperature of solutions used in immersion assays is usually around 105°F [124,155,242]. Although systematic studies demonstrating that those temperatures were necessary were not presented, increased temperature has been shown to be necessary to reproduce irritant dermatitis in some instances [269].

The influence of vehicle in diagnostic patch testing for allergy is well recognized. Similar effects are seen when irritation is studied. These effects are demonstrated convincingly in open systems; for example, a dose of croton oil that produces no measurable edema in the mouse ear when applied in olive oil produces the maximum response when applied in acetone [252]. Patch occlusivity and interactions between vehicles and adhesives used in patch systems also influence the intensity of response and make it more difficult to demonstrate vehicle effects under patch conditions. In most predictive irritation tests, the choice of solvent is related to conditions, and water is the solvent often used.

Dosing schedules have been developed that maximize the development of the responses of interest. In general, the longer the duration of contact to the same dose of a given chemical, the greater the intensity of the response. Multiple exposures at frequent intervals are the basis for most cumulative irritation assays, although there is some disagreement on the optimal time between exposures. In developing the soap chamber test (discussed later), Frosch and Kligman [110] varied both the frequency and the duration of exposure in order to produce a more sensitive test.

The seasonal variability in human response to normal exposure to irritants is well documented [131]. Conducting usage studies in late fall and winter increases the discriminating ability of the test [54]. Some investigators have demonstrated similar effects using patch test procedures [168] and small-scale exaggerated exposure tests [155]. Although the basis for this variability is not well understood, it is believed to be due in part to changes in the barrier properties of the skin. Investigators have experimentally altered the barrier properties of skin to develop assays that are more sensitive. Alterations vary from the abrasion of Draize-type tests [76] and the chamber scarification test [106] to tape stripping to remove the outer surface of the epidermis [172]. Pretreating the test sites with damaging agents increases the reactivity of the skin to other chemicals [96,97,251]. Although these extrinsic factors modify the barrier function, intrinsic factors governing barrier properties are also important [211]. Barrier function would be expected to contribute to responses observed in screening tests used to identify sensitive subjects [107,111]. The demonstration that persons with some skin disease develop more intense response to irritants [25,283] and have diminished barrier function [309] was not unexpected. Susceptibility to the development of irritant responses is presumed to be under genetic control. The prevalence of irritant responses in atopic individuals supports this theory. The response to identical patches applied to different sites is convincing evidence of regional variation in susceptibility to irritants. The reactivity of the various sites appears to correlate to the ability of chemicals to penetrate the skin in that area. Regional differences in skin response are not limited to humans [311].

Susceptibility to irritation is believed to vary by age, gender, and race. Children may develop inflammatory responses to lower levels of a variety of chemicals than adults [266]. The inflammatory response to some materials is decreased in the elderly [173,294]. The skin of women may be more sensitive to irritants than men [315]; however, sex differences in reactivity were not confirmed by other investigators [26]. Higher doses of irritants are required to produce inflammation of black skin [322,323]. This difference in reactivity disappeared when black skin was tape stripped, leading some investigators to hypothesize that black skin forms a more efficient barrier. Berardesca and Maibach [18] questioned whether these differences are more real than apparent.

The principles of toxicology should be remembered when designing and conducting any animal (and human) assay for skin irritation. One should consider dose–response relationships. Draize scores require careful interpretation; they are best interpreted by comparison to related compounds of formulations with a history of human exposure. Knowledge of intended human use (and foreseeable misuse) permits a more rational interpretation. With occlusive application techniques,

remember that occlusion increases the permeability of some but not all moieties. Although there is a consistent, reasonably good correlation between responses in rabbits and humans, occasional inconsistencies have occurred [117]. Different species exhibit widely varying reactivity under identical test conditions, especially in substances with only minor irritant potential; thus, the accuracy of the Draize test and other animal testing as it relates to humans has been questioned [117,135,159,252]. In addition, results from the animal methods differ due to the subjective visual test scoring. These differences occur most frequently in the assessment of the toxicity of mild irritants and colored material [241]. Wise investigators conduct carefully planned and executed tests in humans when rabbit tests indicate that materials are possible irritants. This is particularly true when one wishes to compare the irritancy potential of mild irritants. One should follow the guidelines of the National Academy of Science (NAS) committee [232] when this course of action is taken. The clinical and basic knowledge of what is now called the *irritant dermatitis syndrome* continues to advance, and interest in irritant dermatitis has led to an international symposium being held approximately every 3 years. Several textbooks summarize current advances [85,308,351].

Irritation Tests in Animals: Draize-Type Tests

Primary irritation and corrosion are most often evaluated by modifications described by Draize and colleagues in 1944 [76]. The Federal Hazardous Substances Act (FHSA) adopted one modification as a standard procedure [57]. The backs of six albino rabbits are clipped free of hair.

Each material is tested on two 1 in^2. sites on the same animal; one site is intact and one is abraded in such a way that the stratum corneum is opened but no bleeding produced. Abrasion can be performed using the tip of a hypodermic needle drawn across the skin repeatedly or commercial instruments such as the Berkeley scarifier [130].

Materials are tested undiluted, and 0.5 mL liquid or 0.5 g solid or semisolid material is applied. In some cases, the skin may be moistened to help solids adhere to the site, or an equal volume of solvent may be used to moisten the material.

Each test site is covered with two layers of 1-inch square surgical gauze secured in place with tape. The entire trunk of the animal is then wrapped with rubberized cloth or other occlusive impervious material to retard evaporation of the substances and to hold the patches in one position. The wrappings are removed 24 h after application, and the test sites evaluated for erythema and edema using a prescribed scale (Table 27.9). Evaluations of abraded and intact sites are recorded separately. Test sites are evaluated again 48 h later (72 h after application) using the same scale.

The reproducibility of the FHSA procedure [311,324] and the relevance of test results to human experience have been questioned [71,140,216,260,288]. Numerous modifications to the Draize procedure have been proposed to improve its prediction of human experience. Proposed modifications include changing the species tested [230], reduction of the exposure period, the use of fewer animals, and testing on intact skin only [80,126,226]. A few investigators have supplemented visual evaluation with other techniques [219,220], but these additions have not been considered essential for the standard method. Several governmental bodies have used their own modifications of the Drake procedure for regulatory decisions. The FHSA, DOT, Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), and OECD guidelines are contrasted to the original Draize methods in Table 27.10. Cruzan et al. [66] proposed a composite test that meets requirements of major agencies.

Summaries and evaluations of the scores vary. Draize reported values for individual animals at each time point, combined the erythema and edema values at each time point, and then averaged the 24 and 72 h evaluations for intact and abraded sites separately. He also calculated a primary irritation index (PII) of averaged intact and abraded sites. Agents producing a PII of 2 were considered only mildly irritating, 2–5 moderately irritating, and more than 5 severely irritating. The primary irritation calculated for the FHSA is essentially the PII of Draize. A minimum PII of 5 defines an irritant by CPSC standards. The method of the National Institute of Occupational Safety and Health does not combine responses of abraded sites and includes probable effects on normal and damaged skin in their evaluation.

Although vesiculation, ulceration, and severe eschar formations are not included in the Draize scoring scales, all Draize-type tests are used to evaluate corrosion as well as irritation. When severe reactions, which may not be reversible, are noted, test sites are observed for a longer period. Delayed evaluations usually are made on days 7 and 14; however, evaluations have been made as late as 35 days after

TABLE 27.9
Draize Scoring System in Albino Rabbits[a]

Description	Score Assigned[b]
Erythema and eschar formation	
No erythema	0
Very slight erythema (barely visible)	1
Well-defined erythema	2
Moderate-to-severe erythema	3
Severe erythema (beet redness) to slight formation (injuries in depth)	4
Edema formation	
No edema	0
Very slight edema (barely perceptible)	1
Slight edema (edges of area well defined by definite raising)	2
Moderate edema (raised approximately 1 mm)	3
Severe edema (raised more than 1 mm and extending beyond the area of exposure)	4

[a] The scale as defined by Draize and adopted by various regulatory agencies.
[b] The primary irritation index (PII) is calculated by averaging the erythema values and averaging the edema values from all animals and then combining the averages (maximum PII = 8).

TABLE 27.10
Comparison of Skin Irritation Tests Based on the Draize Method

Feature	Draize	FHSA	DOT	FIFRA	OECD[a]
Number of animals	3[b]	6	6	6	3
Abrasion	Abraded and intact	Abraded and intact	Intact	2 abraded and 2 intact	Intact
Dose liquids	0.5 mL undiluted	0.5 mL undiluted	0.5 mL	0.5 mL undiluted	0.5 mL
Dose solids	0.5 g	0.5 g in solvent	0.5 g	0.5 g moistened	0.5 g moistened
Wrapping materials	Gauze and rubberized cloth	Impervious material	—	—	Semiocclusive
Length of exposure	24 h	24 h	4 h	4 h	4 h
Evaluated at[c]	24 h, 72 h	24 h, 72 h	4 h, 48 h	0.5 h, 1 h, 24 h, 48 h, 72 h	0.5 h, 1 h, 24h, 48 h, 72 h
Treatment at removal	Not specified	Not specified	Skin washed	Skin wiped, not washed	Skin washed
Excluded from testing	—	—	—	Materials with pH < 2 or >11.5	Materials with pH < 2 or >11.5

Note: DOT, Department of Transportation; FHSA, Federal Hazardous Substances Act; FIFRA, Federal Insecticide, Fungicide, and Rodenticide Act; OECD, Organization for Economic Cooperation and Development.

[a] Although other species are acceptable, the albino rabbit is the preferred species.

[b] Draize tested four materials on six rabbits. Three abraded and three intact sites were tested with each material.

[c] Times listed are after removal for FIFRA and OECD. Times listed for Draize, FHSA, and DOT are after the application of the test material.

application. The EPA bases interpretations on 7-day observations. The basic exposure procedures of the OECD guidelines for skin irritation or corrosion have been further modified to test for corrosion during shorter periods [243]. Under a directive of the EEC, a shorter 3 min exposure was added (with no wrapping procedure). The United Nations' recommendations for the transport of dangerous goods are based on exposure times of 4 h, 1 h, and 3 min, with the recommendation that the 1 h exposure be conducted first. Evaluations are made 1, 24, 48, and 72 h and 7 days after dosing.

The Draize method has generally erred on the side of safety in that it overpredicts the severity of skin damage produced by chemicals, thus providing a safety factor for those exposed. One criticism often repeated is that the test is not sensitive enough to separate mild from moderate irritants. The purpose when designing the Draize test was to identify chemicals that posed a severe hazard to the public, not to compare products. Criticisms of the Draize test have been embraced by groups supporting the elimination of animal testing as they serve to demonstrate that use of the method is unwarranted. These criticisms overlook the tremendous value the test has provided in warning consumers, workers, and manufacturers of potential dangers associated with specific chemicals so appropriate precautions can be taken. Although Draize-type tests may be replaced by in vitro assays at some time in the future, we have no widely accepted in vitro substitutes at present [261]. Although a few assays have been validated as reproducible, chemical relevant data are often minimal.

Non-Draize Animal Studies

Animal assays to evaluate the ability of chemicals to produce cumulative irritation have been developed [255]; however, they are not required by any regulatory agency. The impetus for their usage is largely the development of products that are better tolerated by consumers and industrial workers. Although many such tests have been described, few are used extensively enough to summarize here. Even those used more often are not as well standardized as Draize-type tests, and many variables have been introduced by multiple investigators.

Repeat application patch tests using several species where diluted materials are applied to the same site each day for 15–21 days have been reported [255]; the guinea pig or rabbit is most commonly used. Patches used vary considerably, with gauze-type dressings and metal chambers being the extremes. Some authors recommended testing the materials with no covering, presumably with a restraining collar to prevent grooming of the area and ingestion of the material. A material of similar use or that produces a known effect in humans is included in almost all of the repeat application procedures as a control. The degrees of inflammation produced by the materials in a single assay are compared. Test sites are evaluated for erythema and edema using the scales of the Draize-type tests or more descriptive scales developed by the investigator. Although interpretation ratings such as *slight*, *moderate*, or *severe* irritant are not usually made, the data from cumulative irritancy assays in rabbits have been used to predict reactions in humans. Other investigators have used multiple applications with shorter time periods to evaluate materials [155].

A 5-day dermal irritation test in rabbits was used to compare consumer products [193]. After the animals' backs were shaved, 0.5 mL of test materials was spread over a 5 × 4.5 cm area of skin. The test sites were protected from grooming by placing the animals in a leather harness or Elizabethan collar. After 4 h, sites were cleaned and graded using the Draize scoring system. This procedure was repeated daily for 5 days. The authors showed good agreement between this assay and 21-day human patch tests of liquid detergents, after-bath colognes and hair preparations; the technique was less satisfactory for other types of materials.

The guinea pig immersion assay has been used to evaluate the irritancy of aqueous detergent solutions [41,242,326]. Ten guinea pigs are placed in restraining devices that are immersed in a 40°C test solution for 4 h. The apparatus is designed to maintain the head of the guinea pig above the solution. Immersion is repeated daily for three treatments. The flank is shaved 24 h after the final immersion, and the skin is evaluated for erythema, edema, and fissures. A photographic grading scale for this assay was presented in MacMillan et al. [194]. Only materials of limited toxic potential are suitable for this assay because systematic absorption of a lethal dose is possible. Concentrations of test materials vary somewhat but are usually below 10% to limit systematic toxicity of the agents. A second group of animals is usually tested with a reference material as a control for the material of interest.

An open application procedure in guinea pigs uses microscopic examination of skin biopsies of sites treated with weak irritants to rank materials [4]. Biopsies are taken after three daily applications of 10% of solvent or 5% aqueous test solutions to 1 cm areas of the shaved flank. Sites are evaluated visually for erythema and edema, and 3 μm histological sections are stained with May–Grünwald–Giemsa under oil immersion to evaluate microscopically epidermal thickness and dermal infiltration. A composite score reflecting the macroscopic evaluation, number of applications before the development of visible response, the epidermal thickness, and the cellular response is used to rank chemicals. Although this method provides information on pathogenesis of the response to each chemical, the extensive processing may limit its application to special studies.

Uttley and Van Abbe [308] developed a mouse ear test in which undiluted shampoos were applied to one ear daily for 4 days. The degree of inflammation was quantified visually as vessel dilation, erythema, and edema. The degree of inflammation produced by materials of interest was compared to that produced by a reference material tested on another group of mice. One confounding factor with this assay may be the use of anesthetics to facilitate performance of the procedure, which may alter the development of inflammation.

To distinguish between mild and moderate irritants in an acute exposure test, Finkelstein and colleagues [97,98] used pretreatment of test sites with an irritant and enhanced visualization of the response by injection of Trypan blue to increase test sensitivity. The technique was performed in anesthetized rabbits, rats, or guinea pigs. A circular area of the shaved abdomen was painted with a 20% solution of formaldehyde and then was allowed to dry for 5 min. This was repeated three times, and then 1 in. cotton flannel pads saturated with test material were applied to each site. A control substance of known irritancy was tested in each study. Pads were secured in place, and the entire trunk was then wrapped in polyethylene. A solution of Trypan blue was injected into subcutaneous tissue away from the dosage sites. The dye was absorbed and served as a marker for plasma leakage because it spontaneously binds to albumin. After 16 h, patches were removed and the degree of bluing at each site was evaluated on a 0%–100% scale. In light of work comparing the reactivity of dorsal and abdominal animal skin [311], one wonders if the enhanced sensitivity was due in part to choice of test site. Another study reported quantifying the amount of Evans blue dye recovered from rat skin after exposing the skin to inflammatory agents [142].

A few tests in which material is not applied topically have been developed that claim to evaluate the intrinsic irritancy of test materials. The persistence of edema in the skin of depilated juvenile white mice following intracutaneous injection of solutions has been used to assess local irritation [44,319]. The number of wrinkles observed when piercing (is there a better word?) the skin with thin pincers is counted before and at selected time points through 6 h after injection of 0.01 mL test solution. Although test animal number has varied between 8 and 25, the developers considered 20–25 optimal. An obvious limitation of this method is that materials must be administered as isosmotic solutions, which requires substantial pretest formulation. Although the developers claim this procedure has good predictive power for eye, skin, and mucosal irritation, it has not been adopted extensively, and no validation studies comparing this method to the standard assays have been published.

Justice et al. [156] described a repeat animal patch test for comparing the irritation potential of surfactants. Solutions were applied to the clipped backs of immobilized albino mice with saturated cotton-tipped applicators. Test sites were covered with rubber dams to prevent evaporation. This process was repeated seven times at intervals of 10 min. The skin was then evaluated microscopically for epidermal erosion.

Brown [42] used both open and closed exposures to rank surfactants for skin irritation potential. Tests ranged from 6 h patch exposures each day for 3 consecutive days in rabbits to daily open application to the skin of rabbits, guinea pigs, or hairless mice for up to 4.5 weeks. Good agreement among the test methods was not obtained, and none of the methods gained wide acceptance, although they are similar to techniques developed by others later.

We have used an assay in which dilute solutions of surfactants and other chemicals are applied to one ear of five or six mice each day for 4 days [251]. Ear thickness measurements at various time points after each treatment were used to quantify the degree of inflammation. Multiple groups (at least four) were tested with different doses of the material. The dose producing a 50% maximum response following a single treatment, and the slopes of the dose–response lines for the chemicals were compared. Pretreating the ear with croton oil or TPA 72 h before application of the material of interest increased the sensitivity of the assay. Although the procedure was useful for most surfactant-based products, it is not suitable for oily and highly perfumed materials because animals attempt to remove the materials by grooming. Moloney and Teal [227] also used ear thickness to quantify inflammatory changes produced by *n*-alkanes applied to the ears of mice. They dosed animals twice per day for 4 days to produce inflammation. Dithranol-induced skin irritation and the modulating effects of different pharmacological agents, such as the corticosteroid and the lipoxygenase

and cyclooxygenase inhibitor studies, were studied using the mouse ear model [310].

Human Irritation Tests

Because only a small area of skin must be tested, it is possible to conduct predictive irritation assays in humans, provided that systematic toxicity (from absorption) is low and informed consent is obtained. Although regulatory agencies do not routinely require testing in humans, human tests are preferred to animal tests in some cases because of the uncertainties of interspecies extrapolation. New materials, those of unknown or unfamiliar composition, should be tested on animal skin first to determine if application to humans is warranted [233]. Patch test responses generally heal rapidly, within a week or so. More severe reactions should be evaluated periodically over a longer period to determine how the inflammatory response is resolved. Some subjects may develop changes in pigmentation level at the test site following severe responses. It is prudent to arrange for medical consultation whenever human clinical tests are undertaken. Lamel et al. [356] summarize the minimal quantitation for hyperpigmentation [354].

Single-Application Irritation Patch Tests

Many forms of single-application patch tests have been published. The duration of patch exposure has varied between 1 and 72 h. Custom-made apparatus to hold the test material has been designed [195,280,282], and a variety of adhesives that are no longer commercially available have been used [197]. Although the individual assays provided important information to the investigators of the period, they were never standardized or gained widespread acceptance.

The single-application patch procedure outlined by the NAS [232] incorporates important aspects of assays used by many investigators. The procedure is similar to FHSA tests in rabbits. Commercial patches, chambers, gauze squares, or cotton bandage material, such as Webril, applied to either the intrascapular region of the back or to the dorsal surface of the upper arms are expected to produce equivalent reactions [174]. Patches are secured in place with surgical tape without wrapping the trunk or the arm. For new volatile materials, a relatively nonocclusive tape, such as Micropore®, Dermicel™, or Scanpore®, should be used. Increasing the degree of occlusion with occlusive tapes such as Blenderm™ or chamber devices such as the Duhring and Hill Top chambers generally increases the severity of responses. A 4 h exposure period was suggested by the NAS panel; however, it is desirable to test new materials and volatiles for shorter periods (30 min to 1 h), and many investigators apply materials intended for skin contact for 24–48 h periods. Subjects should routinely be instructed to remove patches immediately if any unusual discomfort develops. After the exposure period, the patches should be removed, the area cleaned with water to remove any residue, and the test site marked by study personnel.

Responses are evaluated 30 min to 1 h after each patch removal (to allow hydration and pressure effects to subside) and again 24 h after the patch is removed. Persistent reactions may be evaluated for 3–4 days. The Draize scale for erythema and edema (Table 27.9) has been used for grading human skin responses; however, the scale has no provision for scoring papular, vesicular, or bullous responses. Integrated scales ranging from 4 to 16 points have been published (see Table 27.11) and are generally preferred to the Draize scale. Up to 10 materials can be tested simultaneously on each subject. Skin reactivity differs by body region, and some patch sites may receive more pressure (e.g., from chairs or clothing); therefore, the location where the materials are placed on the skin (e.g., upper right back and lower left back) should be systematically varied within each study. Each study should include at least one reference material. Scores from all subjects are averaged for each material, and comparisons made between standards and other test materials. Some investigators have accepted an average difference of one unit on the grading scale as meaningful. Other investigators analyze the data by standard nonparametric statistical tests. It is also possible to test multiple doses and calculate the ID_{50} [176].

Wooding and Opdyke [337] investigated the effects of modifying some test parameters on the intensity of the response,

TABLE 27.11
Human Patch Test Grading Scales

A. Simple Patch Test Grading Scale	
0	Negative, normal skin
±	Questionable erythema not covering entire area
1	Definite erythema
2	Erythema and induration
3	Vesiculation
4	Bullous reaction
B. Detailed Human Patch Test Grading Scale	
0	No apparent cutaneous involvement
½	Faint, barely perceptible erythema or slight dryness (glazed appearance)
1	Faint but definite erythema, no eruptions or broken skin *or* No erythema but definite dryness; may have epidermal fissuring
1-1/2	Well-defined erythema or faint erythema with definite dryness; may have epidural fissuring
2	Moderate erythema, may have a *few* papules or deep fissures, moderate-to-severe erythema in the cracks
2-1/2	Moderate erythema with barely perceptible edema *or* Severe erythema not involving a significant portion of the patch (halo effect around the edges), may have a few papules *or* Moderate-to-severe erythema
3	Severe erythema (beet red). May have generalized papules *or* Moderate-to-severe erythema with slight edema (edges well defined by raising)
3-1/2	Moderate-to-severe erythema with moderate edema (confined to patch area) *or* Moderate-to-severe erythema with isolated eschar formations or vesicles
4	Generalized vesicles *or* Eschar formation *or* Moderate-to-severe erythema and/or edema extending beyond patch area

and the intensity of inflammation has been shown to increase after removal of patches in some cases [67,263]. Kooyman and Snyder [180] used 6 h exposures to 8% solutions of bar soaps and evaluated test sites 24 h after patch application. Griffith et al. [125] reported using single-application patch tests with exposures of less than 24 h to evaluate laundry detergents containing enzymes. Justice et al. [156] varied exposure time between 18 and 24 h to test bar soaps, liquid detergents, and laundry detergents. Others have suggested that 48 h patch exposures are more suitable for some products [269].

A standardized procedure for evaluating the irritation potential of new chemicals in humans as a replacement for the Draize rabbit test has been proposed [14,15,79,125,337,338]. The method has been tested in several laboratories, and results appear reasonably reproducible. The classification of irritancy is based on a comparison of the length of exposure to the chemical being tested vs. the length of exposure producing irritation following the application of a 20% solution of sodium laurel sulfate. Chemicals producing irritation after shorter exposures than used for SLS are considered irritants and would be labeled as such. Each test subject is exposed to the undiluted test material in occlusive chambers (e.g., Hill Top Chamber®) and to a 20% solution of SLS. Length of exposure begins with a 15 min exposure with evaluation at removal and at 24 and 48 h. If no response is observed, then another set of patches is applied and worn for 30 min. This process of patching, evaluation, and patching for a longer exposure interval is repeated until the subject responds to the SLS exposure or until a 4 h exposure has been completed. The test was developed for chemicals but may have used for evaluating consumer products as well. For most household chemicals and cosmetics, this cycle can probably be shortened considerably. Nixon et al. [236] used a 4 h FHSA-type procedure (including abrasion) to evaluate a range of household products.

Repeat-Application Irritation Patch Tests

The term *skin fatigue* was used to explain the development of inflammation late in the induction phase of sensitization tests without positive responses at challenge [279]. The phenomenon was also referred to as *secondary irritation* and later as *cumulative irritation*. The human RIPT for skin allergy was modified to evaluate skin irritation. As with single-application patch test, many investigators developed their own version of the repeat application patch test. Most were patterned after human sensitization studies with 24 h exposures with or without a rest period between patches. Kligman and Wooding [177] applied the Litchfield and Wilcoxon probit analysis to cumulative irritation testing with the calculation of IT_{50} and ID_{50} values, and statistical comparison of those values for different materials. Their early work forms the basis for the 21-day cumulative irritation assay, which is currently widely used.

The cumulative irritation assay, as described by Lanman et al. [191], was developed to compare antiperspirants, deodorants, and bath oils to provide guidance for product development. A 1 in. square of Webril® was saturated with liquid or up to 0.5 g of viscous substances and applied to the skin. The patch was applied to the upper back and sealed into place with occlusive tape. After 24 h, the patch was removed, the area evaluated, and a fresh patch applied. The procedure was repeated for up to 21 days. The sensitivity of the assay was increased by increasing the number of test subjects from 10 to 24. The IT_{50}, as described by Kligman and Wooding [177], was used to evaluate and compare test materials.

Modifications of the cumulative irritation assay have been reported. Intensity of response has been evaluated using other evaluation schemes, the interval between application of fresh patches has been varied, and other methods of data evaluation have been proposed [19,53,262]. The newer chamber devices have replaced Webril with occlusive tape in some laboratories. Some investigators currently use cumulative scores to compare test materials and do not calculate an IT_{50}. The necessity of 20 applications has been questioned [19]. Although the procedure came to be known as the 21-day cumulative irritation assay, the number of applications used was varied by Lanman, depending on the types of materials to be tested; 21 days was the maximum period of testing. Kligman and Wooding performed their studies on surfactants in 10 days. Lanman found that 21 applications were necessary to discriminate between baby lotions. The number of applications used to rank materials should be chosen based on the class of material being studied.

Numerous other human repeated application schedules have been used for comparing commercial products. Finkelstein et al. [97,98] described tests using either a 5–6 h or a 17–18h exposure each day for 14 days. Test sites were evaluated 1 h after patch removal. Modifications of this procedure have also been used to evaluate shaving creams and toilet soaps [285].

Repeated application patch tests on intact skin fail to predict some adverse reactions due to repeated application to *damaged* skin (e.g., acne, shaved underarms, or sensitive areas such as the face) [16]. The chamber scarification test [106,108,110] was developed to evaluate materials that would normally be applied to damaged skin. Light-skinned Caucasians who develop severe erythema with edema and vesicles following a 24 h exposure to 5% SLS in Duhring chambers applied to the inner forearm are preselected subjects. Six to eight 10 mm^2 areas on the midvolar forearm are scarified with eight criss-cross scratches made with a 30-gauge needle. Four scratches are parallel, with another four at right angles. In scarifying the tissue, the bevel of the needle is to the side and is drawn across the tissue at a 45% angle with enough pressure to scratch the epidermis without drawing blood. Duhring chambers containing the test material (0.1 g for ointments, creams, or powders or Webril® saturated with 0.1 mL for liquids) are placed over the scarified areas and are secured in place with nonocclusive tape wrapped around the forearm. Fresh chambers containing the same materials are applied daily for 3 days. The test sites are evaluated on a 0–4 scale (Table 27.12) 30 min after the removal of the last set of chambers. The responses are averaged, and materials are classified as low (0–0.41), slight

TABLE 27.12
Grading Scale for the Chamber Scarification Tests

0	Scratch marks barely perceptible
1	Erythema confined to scratches
2	Broader bands of erythema with or without rows of vesicles, pustules, or erosions
3	Severe erythema with partial confluence with or without other lesions
4	Confluent, severe erythema sometimes with edema, necrosis, or bulla

(0.5–1.4), moderate (1.5–2.4), or severe irritants. A scarification index (SI) may be calculated by dividing the score on intact skin by the score from the scarified site. The SI is used to estimate the relative risk for damaged and normal tissue; it is not used to rank test materials.

Although bar soaps produce erythema when tested by conventional patch test techniques, the typical clinical response is dryness and flaking with occasional erythema and fissuring. Frosch and Kligman [110] developed the soap test chamber test to compare the *chapping* potential of bar soaps. Sensitive subjects are preselected as described for the chamber scarification test or by ammonium hydroxide blistering time [89]. Duhring chambers fitted with Webril® pads are used to apply 0.1 mL of an 8% solution of soap to the forearm. Chambers are secured in place by encircling the arm with porous tape. Patch contact time is 24 h on day 1 (Monday) and 6 h each day for the next 4 days (Tuesday through Friday). Test sites are monitored each day before the application of fresh solutions. If severe erythema is noted, dosing is discontinued. Unless treatment was discontinued before the fifth exposure, skin reactions are evaluated on day 8 (Monday). This test has shown good agreement with skin-washing procedures but has overpredicted irritant responses to some materials [105].

Exaggerated Exposure Irritant Tests

Although patch tests have been useful in detecting differences in the irritation potential of some materials, in some cases, predicted differences were not apparent when materials were used by consumers. Exaggerated exposure tests have been developed to bridge the gap between responses occurring during product use and patch testing. Perhaps the oldest nonpatch irritancy test still in use is the arm immersion technique [179], in which the relative irritancy of two soap or detergent products is compared. As originally described, soap solutions of up to 8% were prepared in troughs. Temperature was maintained at 105°F while subjects immersed one hand and arm to just above the elbow in one test solution and the other arm in a solution containing a second product. The period of exposure varied between 10 and 15 min, three times a day, for 5 days or until observable irritation was produced on both arms.

In most volunteers, the first sign of irritation was erythema of the antecubital surface of the arm [155,179]. Later, the hands developed dryness and cracking. These observations led to the development of separate assays on the antecubital area and the hands. Numerous versions of the antecubital washing test (also known as the flex washing test and elbow crease washing test) have been used. Published methods compare two products; however, dosing regimes differ somewhat. Investigators have used two [105] or three [124,292] washing procedures per day, and some specify that lather is allowed to remain on the skin for a brief period. Erythema and edema are evaluated as endpoints for all studies. Frosch [106] used a similar procedure on the cheeks to evaluate toilet soaps. A simple 1–4 (i.e., slight, moderate, severe, very severe) grading scale is used to evaluate the severity of the response. Products can be compared in terms of the average grades or the number of washes producing an effect. Some investigators have tested up to four samples per forearm by washing in glass cylinders and then rinsing the area [144].

At least two types of hand immersion procedures have been used. In small studies (i.e., 10 subjects), relatively concentrated solutions (up to 2%) of two materials are tested. Up to four hand-dishwashing products have been compared at near-use concentrations in studies on 64 subjects using a Latin-square dosing pattern (Bannan, E. A. (1975): Personal communication.). Exposure conditions have varied from two to three 10–15 min immersions each day [124] to a single 30 min exposure each day (Bannan, E. A. (1975): Personal communication.). Grading scales for this type of assay focus on scaling and cracking as well as erythema.

Evaluation of skin conditions before and after use in the home has also been used to compare the irritation potential of various products. These tests represent skin tolerance studies, as either irritation or allergy could be detected. The clinical method published by Johnson et al. [154] has been varied to include tests of bar soaps, laundry soaps and detergents, and dishwashing detergents. Essentially, the method is a double-blind crossover study with usage periods of 2 weeks [54]. Skin condition is evaluated by a dermatologist before the study and after the use of each product. Magnification of the area is used to facilitate grading using a 0–10 scale. Tests are conducted using large panels (more than 300 subjects per product), and up to eight materials can be evaluated simultaneously using a Latin-square design. The principles used in conducting this type of large-scale usage study have been applied to laundry powders for diapers and bar soaps used in infants [84,124] and to fabric softeners in adult populations [321]. Special emphasis should be placed on the statistical design of clinical trials of this type to ensure validity of the study [1].

Use of Bioengineering Devices in Irritancy Evaluations

Measurements of biophysical parameters of skin function have been proposed as adjuncts to visual elevations of the inflammatory response [210,212,297,298,334]. In many instances, investigators constructed their own instruments to perform these measurements. As the availability of commercial instruments increases, assessment of the biophysical changes in skin has become widely used to supplement visual evaluations. The benefits of the methods vary and include more objective measurements of erythema (as change in blood flow), more precise determination of the color change, and measurement of parameters of damage that cannot be evaluated visually. When combined with various techniques

of exposure, it is possible to vastly decrease the number of subjects and probable clinical relevance of the studies.

Laser Doppler velocimetry has been used to quantify the increased blood flow to inflamed tissue. This device is an optical technique for the estimation of microcirculation, based on the Doppler principle. When the laser beam, a 632 nm helium–neon (He–Ne) laser source, is directed toward the tissue, reflection, transmission, absorption, and scattering occur. Laser light backscattered from moving particles, such as red cells, is shifted in frequency according to the Doppler principle, whereas radiation that is backscattered from nonmoving structures remains at the same frequency. Detailed guidelines for using this device are provided by the Standardization Group of the European Society of Contact Dermatitis [23].

Skin reflectance spectrophotometry has been used to measure the color change in skin associated with inflammation. Polychromatic light is directed into the skin. The reflected light is collected in an integrating sphere and guided to a monochromator, where the light is split into five bands in the spectral range of 355–700 nm. Melanin content and oxygenized and deoxygenized hemoglobin are analyzed at different spectra, and the relative changes are expressed as a percentage of chromophore content in control skin [3,24].

Changes in transepidermal water loss (TEWL) and electrical resistance have been detected before inflammatory changes are apparent. Early investigations clearly established that chemicals that provoked inflammation increased TEWL. TEWL reflects the integrity of the water-barrier function of stratum corneum as determined by the use of an evaporimeter (open chamber method, where the skin capsule is open to the atmosphere). TEWL is calculated from the slope provided by two hygrosensors precisely oriented in the chamber. Air movement and humidity are the drawbacks of this method. A report reviewing interindividual, environmental, and instrument-related variables with respect to the Evaporimeter EPI (ServoMed), its use, and good practice guidelines can be obtained from Pinnagoda et al. [258]. Malten and Thiele [211] showed that increase in TEWL occurred before visible inflammation when ionic, polar, water-soluble substances (e.g., sodium hydroxide, soaps, detergents) were used as irritants. Unionized polar irritants, such as dimethyl sulfoxide, and unionized, nonpolar, water-soluble irritants, such as hexanediol diacrylate and butanediol diacrylate, did not induce increased water loss until visible inflammation occurred. This method thus seems to be possibly valuable for detecting irritancy with no perceivable irritancy for ionizable, polar, water-soluble substances. These techniques have been used to compare the irritancy potential of soaps tested at near-use levels [133].

Water content of the skin can be estimated by electrical measurements of skin resistance and capacitance. Subtle degrees of skin damage can be measured using skin resistance before skin inflammation occurs [297]. The corneometer is used to register the electrical capacitance of the skin surface. The principle of this instrument is to decipher distinctly different dielectric constants of water and other constitutional materials (fewer than 7) with a probe applied to the skin at constant pressure. Another instrument working on similar principle is the skin hygrometer, which measures conductance of the skin using high-frequency electric current of 3.5 MHz with the help of a sensitive probe [295]. Several other devices using different frequencies and technologies have been developed to measure water content, including instruments that measure impedance, resistance, phase angle, microwave transmission, and photo-acoustic methods. Noninvasive bioengineering techniques, such as colorimetry, remittance spectroscopy, measurement of surface pH, and skin surface topography, have been reviewed by Berardesca and Maibach [17,18]. One unique new way of evaluating irritancy uses in vivo measurements of the water-binding capacity of the stratum corneum after occlusion [17]. Bioinstrumentation techniques have now also been used in in vitro studies. These techniques permit more clinically realistic bioassays that more closely mimic use experience. The five volumes on skin bioimaging (reference needed) and the volume by Serup et al. detailed experimental documentation [357].

In Vitro Assays of Skin Irritation and Corrosion

Since 1980, much effort has been expended toward developing in vitro alternatives to Draize-type tests for both eye and skin irritation. Approaches to development of an in vitro model include cell toxicity [32,34], measurement of inflammatory mediators, effect on cell recovery and survival [81,178,229], effect on cellular physiology [249], cell morphology [32,34], biochemical endpoints [225], and effect on membranes [27] and artificial membranes [118,120] constructed to release dye indicator. Some investigators have included metabolic activators in their systems [35]. Nonmammalian cells [48] have also been used.

In vitro assays for skin irritation are being explored as tools in toxicologic research and as aids in formulating mild products, as well as for replacement of the Draize-type tests. This mirrors the overall use of in vitro assays during the last 25 years [15]. Numerous proposals for the validation of the methods have been put forth; however, tests in intact animals or humans are currently the only means of assessing the potential irritation hazard from skin exposure [287]. In vitro assays for skin corrosion have been validated and accepted.

Two commercial systems, Skin2® and EpiDerm™, have been used extensively for skin irritation testing. Skin2 [99,302,303] is a three-dimensional coculture of human fibroblasts and keratinocytes. In Skin2, human neonatal fibroblasts are seeded on a nylon mesh to which they attach and lay down collagen. When the proper degree of confluence is reached, human keratinocytes are seeded onto the fibroblast culture. The epidermis is exposed to air, and a partially differentiated stratum corneum develops. Several cytotoxicity assays and assays for the release of inflammatory mediators are available for use with these systems. EpiDerm [51] consists of a multilayered cornified epithelium with no dermal element. It appears to have a well-differentiated stratum corneum. Perkins et al. [256] used these systems to evaluate skin corrosion in vitro using the dimethyltriazoldiphenyl tetrazolium-formazan (MTT) [52] cell viability assay with some success.

SKINTEX™ and Corrositex® [101–104] are described as membrane barrier/protein matrices. They are two-component systems consisting of a barrier matrix that contains an indicator dye. Dye release is expected to correlate with protein disruption and denaturation. The second compartment is a reagent system that increases in turbidity when exposed to irritants. Corrositex has been accepted by the DOT as an alternative to the Draize test for skin corrosion [145] and has been validated for limited purposes by ICCVAM [343].

Several European investigators have reported success in using excised rat or human skin to assess skin corrosivity [14,239,240,318,330] based on changes in transcutaneous electrical resistance (TER). A rubber O-ring is used to secure full-thickness skin (including dermis), epidermal surface uppermost, onto the top of small tubes. These tubes are then suspended in a larger tube containing an electrolyte solution in distilled water. Applied to the surfaces of at least three disks is 150 μg of the test material. After 24 h, the skin is rinsed, the surface is treated with ethanol, and electrolyte solution is added to the skin surface. The TER is then measured using a commercial instrument. Values above 11–12.5 kΩ/disk are indicative of corrosivity (varies by investigator and source of skin). With the judicial use of reference materials to set the threshold values for classifying materials as corrosive, this method appears to be reproducible.

Contact Urticaria and Urticaria-Like Syndromes

Circumscribed, erythematous, evanescent areas of edema involving the epidermis and superficial portions of the dermis are referred to as *urticaria* [314]. Classically, the reaction has been described as a wheal-and-flare response that develops within 30–60 min after exposure of the skin to certain agents. Symptoms of immediate contact reactions can be classified according to their morphology and severity; itching, tingling, and burning with erythema is the weakest type of immediate contact reaction. Local superficial wheal-and-flare with tingling and itching represents the prototype reaction of contact urticaria. Generalized urticaria after local contact is rare but can occur from strong urticants. Signs in other organs appear with the skin symptoms in cases of immunologic contact urticaria syndrome. Urticaria and angioedema (edematous processes in the deep dermis, subcutaneous, and submucosal tissue) may persist for up to 72 h [62]. The strength of the reactions may vary greatly, and often the entire range of local signs—from slight erythema to strong edema and erythema—can be seen from the same substance if different concentrations are used in skin tests [182]. Not only the concentration but also the site of the skin contact can affect the reaction. A certain concentration of contact urticant may produce strong edema and erythema reactions on the skin of the upper back and face, but only erythema on the volar surfaces of the lower arms or legs. In some cases, contact urticaria can be demonstrated only on slightly or previously eczematous skin, and it can be part of the mechanism responsible for the maintenance of chronic eczemas [2,202,237]. Some agents, such as formaldehyde, produce urticaria on healthy skin following repeated but not single applications to the skin. Diagnosis of immediate-contact urticaria is based on a thorough history and skin testing with suspected substances [62]. Skin tests for human diagnostic testing have been summarized [314]. Because of the risk of systemic reactions, such as anaphylaxis, human diagnostic tests should be performed only by experienced personnel with facilities for resuscitation on hand.

Contact urticaria has been divided into two main types: immunologic and nonimmunologic [183]. Several reviews list agents suspected to cause each type of urticarial response [184,185,314]. Some common urticants are listed in Table 27.13. Nonimmunologic contact urticaria occurs without previous exposure in most individuals and is the most common type. The reaction remains localized and does not cause systemic symptoms or spread to become generalized urticaria. Typically, the strength of this type of contact urticaria reaction varies from erythema to a generalized urticarial response, depending on the concentration, skin site, and substance. The mechanism of nonimmunologic contact urticaria has not been delineated, but a direct influence upon dermal vessel walls and nonimmunologic release of mast cell mediators are possible mechanisms [278]. Nonimmunologic urticaria produced by different agents may involve different combinations of mediators [183].

The most potent and best studied substances producing nonimmunologic contact urticaria are benzoic acid, cinnamic aldehyde, and nicotinic esters. Under optimal conditions, more than half of a random sample of individuals

TABLE 27.13
Agents Reported to Cause Contact Urticaria in Humans

Immunologic mechanism
Grains
Nuts
Bacitracin
Parabens
Seafood (protein extracts)
Penicillin
Butylated hydroxy toluene
Nonimmunologic mechanism
Aspirin
Balsam of Peru
Benzoic acid
Cayenne pepper
Cinnamic aldehyde
Codeine
Dimethyl sulfoxide
Unknown mechanisms
Lettuce/endive (probably immunologic)
Cassia oil
Formaldehyde

Note: More comprehensive lists and the original references can be found in Amin, S. et al., Contact urticaria syndrome, in *Dermatotoxicology Methods: The Laboratory Worker's Vade Mecum*, Marzulli, F.N. and Maibach, H.I., eds., Taylor & Francis, New York, pp. 161–176, 1998.

shows local edema and erythema reactions within 45 min of application of these substances if the concentration is high enough. Benzoic acid and sodium benzoate are used as preservatives for cosmetics and other topical preparations at concentrations from 0.1% to 0.2% and are capable of producing immediate contact reactions at the same concentrations. Cinnamic aldehyde at a concentration of 0.01% may elicit an erythematous response associated with a burning or stinging feeling in the skin [215]. Mouthwashes and chewing gums contain cinnamic aldehyde at concentrations high enough to produce a pleasant tingling or lively sensation in the mouth that enhances the sale of the product. Higher concentrations produce lip swelling of typical contact urticaria in normal skin. Eugenol in the mixture inhibits contact sensitization to cinnamic aldehyde and inhibits nonimmunologic contact urticaria from this same substance. The mechanism of the quenching effect is not certain, but competitive inhibition at the receptor level may be the explanation [109].

Immunologic contact urticaria is an immediate type 1 allergic reaction in people previously sensitized to the causative agent [314]. The molecules of a contact urticant react with specific IgE molecules attached to mast cell membranes. The cutaneous signs are elicited by vasoactive substances, including histamine, released from mast cells. The role of histamine is conspicuous, but other mediators of inflammation (i.e., prostaglandins, leukotrienes, and kinins) may influence the degree of response. Immunologic contact urticaria reactions can extend beyond the contact site, and generalized urticaria may be accompanied by other symptoms, such as rhinitis, conjunctivitis, asthma, and even anaphylactic shock. The term *contact urticaria syndrome* was therefore suggested by Maibach and Johnson [206]. The name has been accepted for a symptom complex where local urticaria occurs at the contact site with symptoms in other parts of the skin or in target organs, such as the nose and throat, lung, and gastrointestinal and cardiovascular systems. Fortunately, the appearance of systemic signs is rare, but it may be seen in cases of strong hypersensitivity or in a widespread exposure and abundant percutaneous absorption of an allergen.

Foodstuffs are the most common causes of immunologic contact urticaria. The otolaryngeal area is a site where immediate contact reactions frequently are provoked by food allergens, most often in atopic individuals. The actual antigens are often proteins or protein complexes. As a proof of immediate hypersensitivity, specific IgE antibodies against the causative agent typically can be found in the patient's serum using the RAST technique and skin test for immediate allergy. The passive transfer test (Prausnitz–Kustner test) also often gives a positive result.

Predictive assays for evaluating the ability of materials to produce nonimmunologic contact urticaria have been developed. No predictive assays for immunologic contact urticaria have been published. Lahti and Maibach developed an assay in guinea pigs using materials known to produce urticaria in humans. One-tenth of a milliliter of the material is applied to one ear of the animal; it is also applied to the opposite ear as a control. Ear thickness is measured prior to application and then every 15 min for 1 or 2 h after application. The swelling response is dependent on the concentration of the eliciting substance. The maximum response is about a 100% increase in ear thickness, and it appears within 50 min after the application of a contact urticant. In histologic sections, marked dermal edema and intra- and perivascular infiltrate of heterophilic granulocytes appear 40 min after the application of test substances. This assay is the predictive test of choice for nonimmunologic contact urticaria if animals are to be tested. Guinea pig body skin reacts with quick-appearing erythema to cinnamic aldehyde, methyl nicotinate, and dimethyl sulfoxide but not benzoic acid, sorbic acid, or cinnamic acid. Analogous reactions can be elicited in the earlobes of another animal species. Cinnamic aldehyde and dimethyl sulfoxide produce a swelling reaction in the guinea pig, rat, and mouse. Benzoic acid, sorbic acid, cinnamic acid, diethyl fumarate, and methyl nicotinate produce no response in the rat or mouse, but the guinea pig ear reacts to all of them [183]. This suggests that either there are several mechanisms of nonimmunologic contact urticaria or that differences are due to the relative sensitivity of the species to the mediators.

Materials can also be screened for nonimmunologic contact urticaria in humans. A small amount of the test material is applied to a marked site on the forehead, and the vehicle is applied to a parallel site. The areas are evaluated at approximately 20–30 min after the application for erythema or edema [314]. Differentiating between nonspecific irritant reactions and contact urticaria may be difficult. Strong irritants, such as hydrochloric acid, lactic acid, cobalt chloride, formaldehyde, and phenol, can cause clear-cut immediate healing if the concentration is high enough, but the reactions usually do not fade away within a few hours. Instead, they are followed by signs of irritation; erythema and scaling or crusting are seen 24 h later. Some substances have only urticant properties (e.g., benzoic acid and nicotinic acid esters), some are pure irritants (e.g., SLS), and some have both of these features (formaldehyde and dimethyl sulfoxide). Contact urticaria reactions are much less frequently encountered than either skin irritation or skin allergy [185]; however, increasing awareness of contact urticaria has expanded the list of etiologic agents and perhaps will lead to the development of adequate predictive assays for detecting causative agents of other forms of urticaria.

Subjective Irritation and Paresthesia

Cutaneous application of some chemicals elicits sensory discomfort, tingling, and burning without visible inflammation. This noninflammatory painful response has been termed *subjective irritation* [107,111]. Materials reported to produce subjective irritation include dimethyl sulfoxide, some benzoyl peroxide preparations, and the chemicals salicylic acid, propylene glycol, amyl-dimethylparamino benzoic acid, and 2-ethoxyethyl-*p*-methoxy cinnamate, which are ingredients of cosmetics and OTC drugs. Pyrethroids, a group of broad-spectrum insecticides, produce a similar condition that may lead to temporary

numbness, or paresthesia [9,50,177]. As in subjective irritation, the nasolabial folds, cheeks, and periorbital areas are frequently involved. The ear is particularly sensitive to the pyrethroids. Herbst et al. investigated an assay to quantify subjective irritation using a pyrethroid chemical model [353].

Only a portion of the human population seems to develop nonpyrethroid subjective irritation. Frosh and Kligman [107] found that they needed to prescreen subjects to identify *stingers* for conducting predictive assays. Only 20% of subjects exposed to 5% aqueous lactic acid in a hot humid environment developed stinging responses [107]. All stingers in their series reported a history of adverse reactions to facial cosmetics, soaps, etc. A similar screening procedure by Lammintausta et al. [188] identified 18% of their subjects as stingers. Prior skin damage, such as sunburn, pretreatment with surfactants, and tape stripping, increases the intensity of responses in stingers. Persons not normally experiencing a response report pain upon exposure to lactic acid or other agents that produce subjective irritation [107]. Attempts to identify reactive subjects by association with other skin descriptions (e.g., atopy, skin type, degree of skin dryness) have not yet been fruitful; however, data show that stingers develop stronger reactions to materials, causing nonimmunologic contact urticaria and some increase in TEWL and blood flow following the application of irritants via patches than those of nonstingers [187].

The mechanisms by which materials produce subjective irritation have not been investigated extensively. Pyrethroids act directly on the axon by interfering with the channel-gating mechanism and impulse firing [312]. It has been suggested that agents causing subjective irritation act via a similar mechanism because no visible inflammation is present. An animal model was developed to rate paresthesia to pyrethroids and may be useful for other agents [50,98]. The test site is the flank of 300 to 450 g guinea pigs. Both flanks are shaved, and animals are housed individually in observation cages. A volume of 100 µL of the test material is spread over approximately 30 mm^2 on one flank. The animal's behavior is monitored by an unmanned video camera for 5 min and at 0.5, 1, 2, 4, and 6 h after the application of the materials. Subsequently, the film is analyzed for the number of full turns of the head made to the control and pyrethroid-treated flanks. Head turns were usually accompanied by attempted licking and biting of the application sites. It was possible to rank pyrethroids for their ability to produce paresthesia using this technique. The ranking corresponded to the ranking available from human exposure.

As originally published, the human subjective irritation assay required the use of a 110°F environmental chamber with 80% relative humidity [107]. Volunteers were seated in the chamber until a profuse facial sweating was observed. Sweat was removed from the nasolabial fold and cheek. A 5% aqueous solution of lactic acid was then rubbed briskly over the area. Those who reported stinging for 3–5 min within the first 15 min were designated as stingers and used for subsequent tests. Subjects were asked to evaluate the degree of stinging as 0 = no stinging, 1 = slight stinging, 2 = moderate stinging, and 3 = severe stinging. Stinging was evaluated 10 s and 2.5, 5, and 8 min after the application of the test material. Other investigators [187] used a 15 min treatment with a commercial facial sauna to produce facial sweating. The subjects turn away from the sauna for application of the test materials, then turn back to face the sauna for the observation period. The facial sauna technique is less stressful to both subjects and investigators and produces similar results.

Advances in understanding the somatosensory processes in humans are leading to the development of more objective methods for evaluating skin sensory effects [336,339]. Although these approaches are not yet sensitive enough to warrant use in predictive assays, they have been used to study pain and itch responses to histamine [341] and to some solvents [340]. In time, these techniques will undoubtedly be applied to predictive testing.

QUESTIONS

27.1 A chemically exposed occupational worker developed generalized urticaria and shortness of breath at the work site. Differential diagnosis includes
- a. Photoirritation
- b. Allergic contact dermatitis
- c. Contact urticaria syndrome (answer)

27.2 On introduction of a revised topical formulation, complaints of acute burn, sting, and itch increase beyond the expected level. Likely diagnostic possibilities include
- a. Photoallergic contact dermatitis
- b. Sensory irritation (answer)
- c. Photoirritation

27.3 Topical formulations may be contraindicated during pregnancy because of concern regarding
- a. Irritant dermatitis
- b. Allergic contact dermatitis
- c. Percutaneous penetration (answer)

28 Inhalation Toxicology

Joseph D. Brain, Wolfgang G. Kreyling, and John J. Godleski

CONTENTS

INTRODUCTION

The respiratory tract has a unique proximity to the environment. The same thinness and delicacy that qualify the air–blood barrier for the rapid exchange of oxygen and carbon dioxide reduce its effectiveness as a barrier to inhaled microorganisms, allergens, carcinogens, and a wide variety of toxic particles and noxious gases. The surface area of the more than 300 million alveoli is typically 100–150 m^2. The thickness of the air–blood barrier—the distance between inspired air and circulating blood—is less than 1 μm. This is small compared to the barrier between blood and the external environment in the gut or in the skin. Clearly, any discussion of toxicology must include the respiratory tract as an important site for interactions between the internal and external environments.

Not only does anatomy make us vulnerable to airborne threats, so does physiology. The weight of the air breathed each day greatly exceeds the weight of ingested food and water. Adults, depending on their size and physical activity, breathe from 10,000 to 20,000 L of air each day. A wide variety of toxic particles and gases enter the body with this air and are potentially hazardous. In this chapter, we describe particle and gas exposures, discuss how particles deposit in the respiratory tract, and describe diverse physiologic mechanisms that prevent the accumulation and deleterious action of inhaled particles and gases reaching the airways and parenchyma.

It is important to remember that exposure to aerosols or gases do not define the dose produced, nor does it say anything about the anatomic distribution of that dose. Regardless of the aerosol exposure problem being studied, it is essential to quantify the dose and to know as much as possible in regard to the location of particle retention or gas uptake. Our understanding of the biologic effects of inhaled agents stems in part from our understanding of factors important to their uptake and fate. An essential tool for experimental inhalation toxicology is knowledge of how to generate and to deliver aerosols. Ultimately, at the policy level, we must better control the exposure of the public and workers to toxic aerosols and gases to prevent respiratory disease and other pathologic consequences in other organ systems.

This chapter will give the reader an overview of the principles and methods used by the inhalation toxicologist. It will emphasize the methods used in assessing the effects of aerosols and gases on the respiratory system following inhalation. A bibliography is provided for the reader who is interested in a more in-depth treatment of the topics presented here.

ANATOMY AND FUNCTION OF THE RESPIRATORY TRACT

An overview of the anatomy, function, and physiology of the mammalian respiratory system is presented to clarify issues that face the inhalation toxicologist. The respiratory system can be divided into three major components: (1) nasopharyngeal, (2) tracheobronchial, and (3) pulmonary. These components represent distinctly different functions, clearance processes, and susceptibilities to inhaled substances.

Nasopharyngeal Region

The nasopharyngeal region includes the nose, epiglottis, glottis, pharynx, and larynx. As the entry port for inspired air, the nostril openings (nares) and nasal cavity serve to remove the larger inhaled particles (through impaction in the turbinates and filtration by nasal hairs) and to condition the incoming air (by moderating the temperature and raising the humidity). Given its location, the nose is exposed to the highest concentrations of inhaled substances within the respiratory tract; accordingly, the nasopharyngeal region is the subject of considerable investigation.

Nose

The nasal airway is divided into two passages by the nasal septum. Each passage extends from the nostrils to the nasopharynx. The nasopharynx is the airway posterior to the termination of the nasal septum and proximal to the soft palate. Air moves through the nares into the nasal cavity that contains turbinates (bony structures lined by well-vascularized and innervated respiratory or olfactory mucosal tissue) covered by a continuous layer of mucus. The nasal mucus layer is moved distally by underlying cilia to the oropharynx, where it is swallowed into the esophagus. The turbinates project into the airway lumen from the lateral walls into the main chamber of the nose. These increase the inner surface area of the nose, which in humans is about 150–200 cm^2 or about four times that of the trachea (Guilmette et al. 1989).

The nose functions as both an air conduit to the lungs as well as the organ of the sense of smell (olfaction). Though there are some similarities in the nasal passages of most mammals, there are definite interspecies differences in nasal architecture (Figure 28.1). Humans have relatively simple noses with breathing as the primary function, while other mammals have more complex noses with olfaction as the primary function. Although humans (and some nonhuman primates) use both nasal and oral breathing, most laboratory rodents used in inhalation toxicology studies (e.g., rats, mice, hamsters, and guinea pigs) are obligate nose breathers due to the close apposition of the epiglottis to the soft palate. Differences in nasal airflow patterns are due to variation in the shape and complexity of the turbinates. The human nose has three turbinates: superior, middle, and inferior. These structures are relatively simple compared to turbinates in laboratory animal species, such as the dog, rat, and mouse, which have complex folding and branching patterns (Figures 28.1 and 28.2) specialized for olfactory function (Harkema et al. 2006).

The mucus lining at the air–mucosal cell interface of the nasal structures is produced by mucous (goblet) cells in the surface epithelium and subepithelial glands in the lamina propria. The surface epithelial cell populations lining the nasal passages differ among species. These differences include the distribution of nasal epithelial populations and the types of

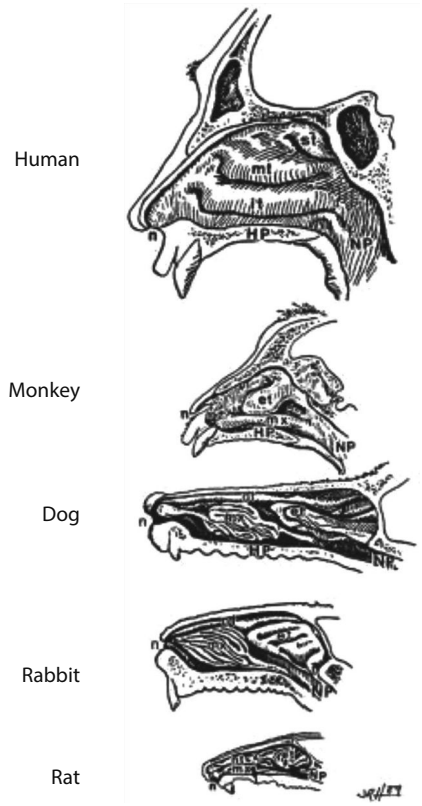

FIGURE 28.1 Diagrammatic representation of the exposed mucosal surface of the lateral wall and turbinates in the nasal airway of the human, monkey, dog, rabbit, and rat. HP, hard palate; n, naris; NP, nasopharynx; et, ethmoturbinates; nt, nasoturbinate; mx, maxilloturbinate; mt, middle turbinate; it, inferior turbinate; st, superior turbinate. (From Harkema, J.R. et al., *Toxicol. Pathol*., 34(3), 252, 2006. With permission.)

nasal cells within these populations. There are four distinct nasal epithelial populations in most animal species. These include the squamous epithelium of the nasal vestibule; ciliated pseudostratified cuboidal/columnar epithelium in the main chamber and nasopharynx; nonciliated cuboidal/columnar epithelium (transitional) lying between squamous epithelium and the respiratory epithelium in the proximal or anterior aspect of the main chamber; and olfactory epithelium, located in the dorsal or dorsoposterior aspect of the nasal cavity (Harkema et al. 2006).

The olfactory epithelium has specialized neural cells for its primary role of odor detection. Olfactory cells process odors to help identify predators, prey, and hazardous substances/conditions. The olfactory epithelium covers a much greater percentage of the nasal cavity in rodents compared to humans. About 50% of the nasal cavity surface area in F344 rats is lined by this sensory neuroepithelium (Gross et al. 1982). Olfactory epithelium in humans is limited to an area of about 500 mm^2, which is only 3% of the total surface area of the nasal cavity (Sorokin 1988). There are three cell types of olfactory epithelium: the olfactory sensory neurons, the supporting (sustentacular) cells, and the basal cells. The neurons are bipolar cells interposed between the sustentacular cells (Vollrath et al. 1985, Farbman 1994). The dendritic portions of these neurons extend above the epithelial surface and terminate into the olfactory knob from which protrude immotile cilia (Menco 1983). These cilia provide an extensive surface area for reception of odorants. The ciliary membranes contain odorant receptors responsible for chemical interaction with odors. Odorant receptors are G protein–coupled, seven transmembrane domain proteins (Buck and Axel 1991, Mombaerts 1999, 2001). The nasal cavity of a mouse has approximately two million olfactory sensory neurons (Harkema et al. 2006). The axial portion of the neurons form nerve bundles that form the olfactory nerves and travel to the olfactory bulb of the brain. Tissue spaces or lymphatic spaces along these nerves are pathways by which toxicants may directly translocate to the brain (Oberdorster et al. 2004).

The supranuclear cytoplasm of sustentacular cells has abundant smooth endoplasmic reticulum and xenobiotic-metabolizing enzymes including hydrolytic enzymes (especially carboxylesterases) necessary to detoxify inhaled substances (such as aromatic esters). Sustentacular cells also contribute to the regulation of the ionic composition of the overlying mucous layer, which may affect the chemical interactions between odors and their odorant receptors. Basal cells are the progenitor cells for olfactory epithelium. Exposure to inhaled substances may injure the epithelium leading to either temporary or permanent loss of smell (anosmia). Importantly, the olfactory cells differ from other nerve tissue cells because they have the capability to regenerate following injury, provided the olfactory epithelium and their progenitor cells are not completely destroyed (Keenan et al. 1990, Bergman et al. 2002).

In addition to the cells described previously, there are several other types of more rare scattered cells called microvillus cells, distinctive from neuronal and sustentacular cells (Menco and Morrison 2003). Bowman's glands, located in the underlying lamina propria, are simple tubular-type glands composed of small compact acini. Ducts from these glands pass through the basal lamina to the luminal surface. Bowman's glands contain neutral and acidic mucosubstances that contribute to the mucous layer covering the luminal surface of the olfactory epithelium (Harkema et al. 2006).

Transitional epithelial cells of rodents located anteriorly in the nose have no secretory granules but do have abundant smooth endoplasmic reticulum in their apices (Harkema et al. 1987). These cells also have xenobiotic-metabolizing enzymes, including cytochromes P-450. The majority of the nonolfactory nasal epithelium of laboratory animals and humans is ciliated respiratory epithelium. About 46% of the nasal cavity in F344 rats is lined by respiratory epithelium (Gross et al. 1982). These cells are responsible for the movement of mucus and the materials trapped within from the nasal surface. Nonciliated cells among the ciliated cells are rich in metabolizing enzymes. There is yet another specialized epithelium, the lymphoepithelium, in animal nasal airways that covers discrete focal aggregates of nasal-associated lymphoid tissue in the underlying lamina propria. The correlate of rodent nasal-associated lymphoid tissue in

humans is Waldeyer's ring, the oropharyngeal lymphoid tissues composed of the adenoid, bilateral tubule, palatine, and lingual tonsils (Brandtzaeg 1984). These lymphoid structures in both species have roles in immune responses.

Larynx

The larynx is found at the upper part of the trachea in most vertebrate animals, and contains the vocal cords. The walls of the larynx are made of cartilage. Sound is produced by air passing through the larynx, causing the walls of the larynx to vibrate. The pitch of the sound produced can be altered by the pull of muscles, which changes the tension of the vocal cords. The surface of the larynx is covered with squamous epithelium. There are interspecies differences among laboratory rodents in the anatomy of sensitive areas of the laryngeal mucosa. In Sprague–Dawley rats, the mucosa covering the epiglottis differs from that of the Syrian golden hamsters in that it is thinner and composed of a mixture of cell types. In contrast, the cartilage of the hamster is much more prominent and forms a distinct protrusion into the lumen at the base of the epiglottis. These anatomic differences can play a role in the use of this information in extrapolating these findings to man (Renne et al. 1993).

Tracheobronchial Airways

The tracheobronchial airways conduct inspired air through a series of branching ducts ending at the terminal bronchioles. Many differing epithelial cell types line this airway and are distinct on the basis of ultrastructural morphology, functionality, and sensitivity to inhaled materials. Considerable variation exists in the abundance of each of these cell types at defined airway levels among species. However, the tracheobronchial epithelia contains predominantly basal, ciliated mucous, Clara, and neuroendocrine cells (Jeffery 1983). Complex layers of airway mucus lines these airways. It consists of an epiphase and hypophase with scattered amounts of surface active material (Yoneda 1976) (Figure 28.3).

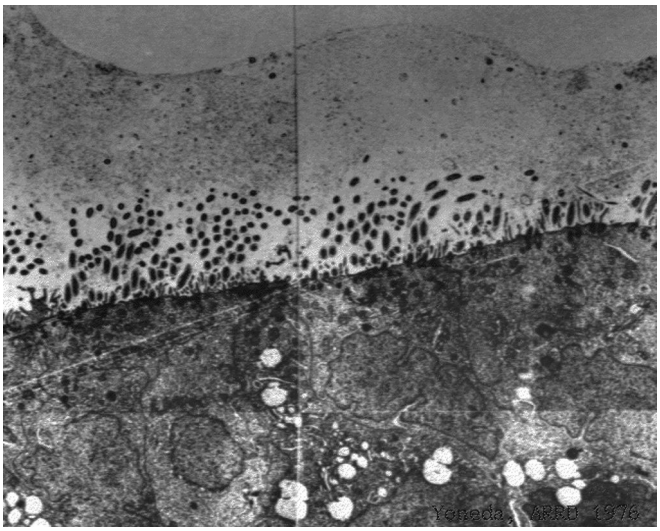

FIGURE 28.3 Large airway of a rat fixed with osmium vapor to preserve the mucous layer. The upper layer of mucous is the epiphase; it is denser and often has fragments of surface active materials. Surrounding the cilia is the watery hypophase. Cilia are seen in cross section and longitudinal sections. Airway epithelial cells make up the bottom half of the figure. (Reprinted from Yoneda, K., *Am. Rev. Respir. Dis*., 114(5), 837, 1976. With permission.)

Mucociliary clearance is a protective mechanism by which contaminants of inhaled air are trapped or dissolved in the mucous layer and then removed by ciliary transport. The two critical components of the system are the of mucus blanket and ciliated cells. Methods to define the composition of mucous include carbohydrate histochemistry and cytochemistry, autoradiography, immunohistochemistry, and biochemistry (Lamb and Reid 1969, Rose et al. 1979, Spicer et al. 1983, St. George et al. 1985). Assessment of mucociliary escalator transport function has been useful in measuring the biological response to inhaled gases and cigarette smoke in particular.

Marked species differences exist in the geometric structure of the tracheobronchial region. Typically, the branching patterns of the tracheobronchial tree are either monopodal or regular dichotomous. The monopodal pattern is characterized by long tapering airways with asymmetric, smaller lateral branches that leave the main tube at a shallow (<60°) angle as seen in cats, dogs, hamsters, horses, mice, monkeys, pigs, rabbits, and rats. In contrast, regular dichotomous branching, typical of humans, involves division of a tube into nearly identical equal-diameter smaller tubes with approximately equal branching angles. Variations in symmetry of branching, airway diameters and lengths, and number of airway generations can affect deposition of particles in the respiratory tract and can account for observed differences. Mathematical airway models suggest that the uptake kinetics of inhaled gases (oxygen, nitrogen dioxide, and sulfur dioxide) vary substantially among rats, dogs, and humans. Such variations are at least partially the result of anatomical and physiological differences in their airways (Tsujino et al. 2005).

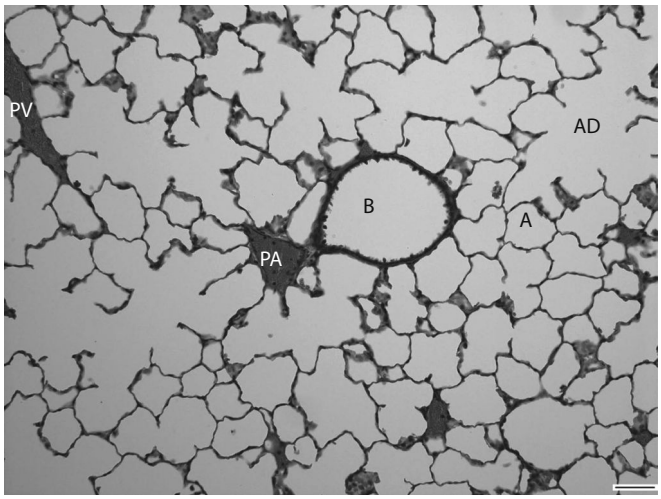

FIGURE 28.4 Histology of the pulmonary region of the rat lung illustrating the thinness of alveolar septae. B, bronchiole; PA, pulmonary artery; AD, alveolar duct; A, alveolus; PV, pulmonary vein. Bar = 50 μm.

Pulmonary Region

The pulmonary region is composed of respiratory bronchioles, alveolar ducts, and alveoli (Figure 28.4). The alveolus is the functional gas exchange unit of the lung between the air and blood compartments. The alveolus itself has walls formed by epithelial cells. Major cell types of alveolar epithelium are known as type I and type II cells. The type I epithelial cell is very thin, has a smooth surface, and covers nearly the entire alveolar surface. The type II cell contains numerous microvilli, is metabolically active, and manufactures and secretes surfactant(s), which, by reducing surface tension at the air–liquid interface (ALI) of the alveolus, reduces the tendency for alveoli to collapse.

Another important cell type in the lung is the alveolar macrophage (Brain 1985, 1988). This is a large, mononuclear cell that functions to engulf foreign particulate material deposited in this region. These cells are scavengers of inhaled particulate material, and their location on the alveolar surfaces preserves the sterility of the deep lung by keeping inhaled bacteria and particles from accumulating. Similar to the nose, larynx, trachea, and bronchi, the bronchioles are lined by ciliated mucosa with columnar goblet cells that manufacture and secrete mucus. The cilia and mucus work together in a coordinated fashion to propel particulate material entrained in the mucus away from the lungs.

Measurement of breathing pattern, lung flows and volumes, lung capacities, forced expirograms, and blood gas and pH are important in determining not only the functional performance of the lung but also are used to approximate the dose of a substance received under experimental conditions. Reliable values for these parameters can be obtained during exposures using whole-body plethysmographs (Diaz et al. 2011). A comparison of typical breathing characteristics of a number of commonly studied species is shown in Table 28.1.

TABLE 28.1
General Breathing Characteristics of Common Species

Species	Mass (g)	Frequency (Breaths/min)	Tidal Volume (mL)	Minute Ventilation (mL)
Human	70,000			
Rest		12	750	9000
Light exercise		17	1700	28,900

GENERATING AND CHARACTERIZING EXPOSURES TO INHALED PARTICLES AND GASES

National and international regulatory agencies have implemented testing guidelines regarding the conduct of inhalation toxicity studies. These guidelines attempt to standardize testing procedures so that toxicity data may be obtained and compared using a defined protocol. Test data generated in this fashion may be used in a variety of ways: (1) to investigate the relationship between exposure concentrations and adverse effects, (2) to provide information on the mechanism of toxicity and permit a reasoned extrapolation of the experimental animal data to potential human health risks, (3) to form the basis for dose-level selection for repeated-exposure studies, or (4) to categorize the inhalation toxicity of a test material relative to other substances. Such data are the foundation for establishing science-based exposure limits for the protection of human health and appropriate toxicity classification and labeling of substances.

Regulatory agencies have adopted standardized protocols for both short-term and long-term inhalation testing and are harmonizing protocols internationally. Guidance on general study design, exposure conditions, measurement frequencies, and major end points of concern have been published for acute, subchronic, and chronic inhalation toxicity testing (OECD 2006b, EPA 2006c).

Exposure Systems

Inhalation exposure systems involve the harmonious integration of several subsystems whose design, construction, and operation are critical to a safe, functional system allowing generation of meaningful results. The various subsystems are shown schematically in Figure 28.5 and include a conditioned air supply system, a suitable vapor or aerosol generator for the test substance, an atmosphere dilution and delivery system, one or more exposure chambers, an atmosphere sampling and analytical system, and an exhaust/scrubbing system. There are several inhalation modes of exposure to evaluate substances appropriate spontaneous breathing animals and ventilated animals (i.e., nose only or whole body for the former and controlled ventilation of the intubated animal for the latter). While the design, operational parameters, testing objectives, and technical requirements for these approaches are similar, there are several issues to consider when choosing one mode versus another (Table 28.2). Specific

TABLE 28.2
Testing Guidelines for Acute Inhalation Toxicity Studies

Criteria	U.S. EPA OPPTS 870.130[a]	Europe OECD 436[b]	Japan MAFF[c]
Study design			
Species[d]	Rat	Rat	Rat
Sex and number per group	≥5 of each sex[e]	3 male, 3 female	5 male, 5 female
Age	Young adult, 8–12 weeks	8–12 weeks	Young adult
Weight range	<±20% of mean weight per sex	<±20% of mean weight per sex	Not specified
Exposure time	4 h after equilibration of chamber concentration	4 h after equilibration of chamber concentration	4 h
Observation period (days)	14	14	14
Limit test (mg/L)[f]	2	5	5
Exposure conditions			
Chamber temperature	22°C ± 2°C	22°C ± 2°C	22°C ± 2°C
Relative humidity (%)	30–70	30–70	40–60
Airflow	≥10 air changes/h	Not specified	Not specified
Chamber oxygen concentration	At least 19%	At least 19%	At least 19%
Particle size distribution	1–4 μm MMAD	1–4 μm MMAD	Not specified
Chamber loading	Total animal volume <5% chamber volume	Total animal volume <5% chamber volume	Not specified
Frequency of measures			
Airflow	Monitor continuously, record >3 times/exposure	Prefer continuously	Not specified
Particle size	2–4 times/exposure	Atleast twice during each 4 h exposure	As needed to determine consistency
Exposure concentration	2–4 times/exposure	Either continuously or atleast twice during each 4 h exposure	Not specified
Temperature and humidity	Monitor continuously, record ≥3 times/exposure	Prefer continuously, or atleast 3 times during each 4 h exposure	Not specified
Nominal concentration[g]	Required but frequency not specified	Prefer continuously	Not specified
End points			
Morbidity and mortality	Yes; daily	Yes; daily	Yes
Clinical observations	Yes; daily	Yes; daily	Yes
Body weights	Yes; weekly	Yes; daily	Yes
Gross pathology	Yes; at termination	Recommended	Recommended
Histopathology	Optional; in animals with gross changes at necropsy	Discretionary	Discretionary

[a] This harmonized guideline was developed in 1998 by the Office of Prevention, Pesticides and Toxic Substances to blend the testing requirements for the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Toxic Substances Control Act (TSCA) with the Organisation for Economic Co-operation and Development (OECD).

[b] OECD Guideline for the Testing of Chemicals, Acute Inhalation Toxicity, Section 436, 1-4, 2009. At the time of publication, a revised, harmonized OECD guideline had not been issued.

[c] Requirements for Safety Evaluation of Agricultural Chemicals. Testing Guidelines for Toxicology Studies, Ministry of Agriculture, Forestry and Fisheries (Japan), Acute Inhalation Toxicity Study, 1985.

[d] Mammals are specified in the test guidelines, but rats are generally preferred.

[e] At least five experimentally naive animals are used of each concentration, and they should be of one sex. After completion of the study in one sex, at least one group of five animals of the other sex is exposed to establish that animals of this sex are not markedly more sensitive to the test substance.

[f] If exposure at the limit concentration (LC) (or where this is not possible due to the physical characteristics of the test substance) produces no observable toxic effects, a full study may not be necessary.

[g] Amount of test material delivered to the generation system divided by the air volume used during the exposure.

components typically used for test substance generation and analysis and animal exposure are shown in Figure 28.6.

Conditioned Air Supply

A sufficient amount of clean, conditioned air for chamber operation must be supplied. The availability of high-quality, contaminant-free (e.g., particles or organics) air for chamber supply is essential, especially for long-term inhalation studies. Ordinarily, ambient air is dried, filtered, and purged of organic vapors prior to adjusting its temperature and humidity to the desired levels. Where this is not practical for very small, low airflow chambers with limited numbers of animals, a commercial source of compressed purified air may be utilized. The size of the air-conditioning equipment should

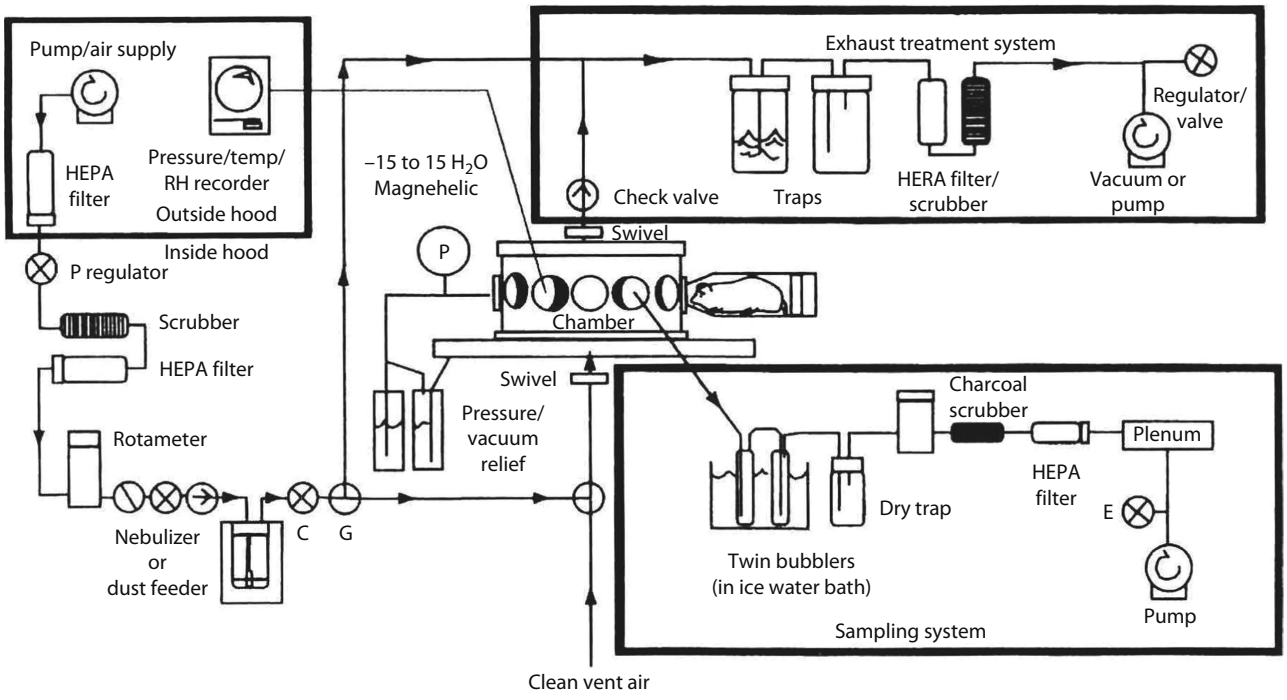

FIGURE 28.6 Details of components used for air supply and test atmosphere generation, dilution and sampling, and exhaust in a nose-only inhalation exposure system.

be scaled to allow some excess flow capacity for the required number of chambers operating at the desired flow rates.

Airflow rate, temperature, and humidity need to be maintained within fairly tight ranges to ensure environmental conditions are acceptable to the well-being of the test species. Excursions beyond the normal range could result in varying overall exposures and could lead to altered test species responses to any given concentration. Typically, environmental conditions are targeted to a temperature from 20°C to 24°C, humidity from 30% to 70%, and airflow greater than 10 air changes/h. Modern inhalation systems have been automated for chamber monitoring and exposure control, which eliminate the need for manual adjustments and data logging. It is important that these conditions remain relatively consistent for the duration of the exposure (and from exposure to exposure).

Generation of Test Atmospheres

Generation of Gases and Vapors

Gases are the simplest atmospheres to generate. They can be metered by flow meters, syringe drives, diffusion tubes, or other techniques into a dilution airstream, allowed to mix, and then introduced into the exposure chamber. A number of flow dilution devices are available. Vapors of either liquid or solid compounds can be formed by heating within a temperature-controlled heating device (care must be taken to prevent chemical decomposition or reaction with air or water at elevated temperatures used to generate vapor). Another technique, depending on physical properties such as boiling point, viscosity, or chemical purity, is to use an infusion pump to meter the liquid test substance onto a heated surface. Other liquid materials may be vaporized in fritted glass bubblers. Frequently, nitrogen is used to vaporize the test substance to minimize chemical reaction or oxidation with air at elevated temperatures. The saturated stream can then be diluted with filtered air or oxygen to raise the oxygen concentration to 19%–21% and to adjust the test substance level to the desired concentration. The application of an automatic proportional-integral-derivative (PID) control algorithm to an inhalation exposure system operating with a concentration monitoring system that samples on a 30 min cycle was shown to produce exposures that accurately achieved and maintained the targeted concentration (Wong 2003).

Special care must be taken when generating vapors from mixtures of test substances with low boiling points. If test atmospheres are generated from the liquid mixture by flash evaporation, the composition of the resulting vapor will be representative of the composition of the liquid mixture. In contrast, if the headspace of the liquid mixture is tapped, the resulting vapor composition in the mixture will reflect the partial pressures of the components with a disproportionate amount of the component with the highest vapor pressure relative to the other components. This is a problem in longer-term inhalation studies, because the composition of the test atmosphere will vary from day to day as the higher vapor pressure components of the mixture are depleted as the mixture is consumed.

Generation of Aerosols

The generation of particulate materials in a uniform manner is considerably more difficult than vapor generation. While two decades ago the focus of inhaled particle dosimetry and toxicology was on micron-sized particles with a characteristic

diameter d of $15 > d > 0.5$ μm, this has changed substantially since currently there is great interest in the potentially hazardous effects associated with the inhalation of ambient ultrafine particles (UFPs) or engineered nanoparticles (ENPs). Several definitions for nanomaterials have been formulated by various national and international bodies including the U.S. FDA (FDA 2007), SCENIHR (2007), ISO (ISO/TS 2008), OECD (2008), Health Canada (Canada 2010), EC Recommendation (EC 2011). Both definitions span the same size range from about 1 to 100 nm with some uncertainties about how to deal with particles or clusters <1 nm and also slightly particles >100 nm. While UFPs—particularly those generated incidentally by human activities such as combustion—are usually a complex mixture of many chemical compounds mostly originating from burning and further modified by chemical reactions according to the thermodynamic condition of the ambient atmosphere, ENPs are specifically designed to offer specific physicochemical properties used for specific functional particle behavior and responses with neighboring materials.

Human ENP toxicology is particularly interested in possible reactions of biological systems, such as organs and tissues as well as body and cellular fluids. Ecotoxicology focuses on responses of ecosystems within aquatic and terrestrial environments. The prominent interest in UFP and ENP relates to changes of the physicochemical properties during shrinkage from micron-sized to nanometer-scaled particles such as quantum physics phenomena (e.g., quantum dots), catalytic and photocatalytic properties (e.g., gold ENP <3 nm or titanium dioxide ENP), ultraviolet (UV)-light absorption (e.g., titanium dioxide, zinc oxide), and the increasing ratio of surface atoms or molecules to internal atoms or molecules within the particle lattice when particle size decreases. This may lead to defects in the outer lattice or may result in unsaturated and hence highly reactive molecules on the high curvature surface of ENP and UFP thereby forming of oxygen and nitrogen radicals, and other highly reactive biomolecules altering homeostasis when compared with submicrometer particles and micron-sized particles. The altered physicochemical properties, together with the increased reactivity of ENP, inspired great hopes for new functional particles and triggered new products and their applications in almost all technological, scientific, and medicinal fields (EC 2005, NCI 2013, EC 2013). At the same time, concerns have been raised that the altered physicochemical properties, together with the increased reactivity of ENP, may also lead to unknown and unexpected biological responses either in human and mammalian bodies or in ecological systems, which may lead to adverse health effects and disturbances of the delicate balance of environmental ecosystems.

Particulate materials may be generated from dry powders or from liquids or by evaporation and subsequent condensation. The generation of aerosols using dry dispersion techniques presents problems that are unique to each dust being studied. In toxicology testing, particle concentration and size distribution must remain constant over long periods of time. The powder being tested must be dispersed into unitary particles of respirable size rather than agglomerates. This requires a means of continuously metering a powder into the aerosol generator at a constant rate, a means of disrupting particle clumps/agglomerates, and a way of suspending the resulting discrete particles into the airstream. Note that disaggregation of particle aggregates is usually not occurring due to chemical bonds within the aggregates. Most materials contain particles of irregular size and shape, which means that monodisperse aerosols rarely are produced and that, in the generating system, the airborne particle size distribution will differ from that in the original powder.

Simple dust metering systems use a gravity feed of loose powder into an airstream, usually assisted by screw-driven conveyors, agitators, or vibrators. Volumetric feeders are useful to deliver specific amounts of powder from a reservoir or hopper into an aerosol generator. The classical Wright dust feed, for example, uses a scraping mechanism to remove a finely ground powder from the surface of a cylinder packed with a test substance. Other metering systems use metal screws or brushes to transport powders at user-selectable rates to the aerosol generator.

Venturi Dispersion of Powders

Aerosol generation involves the dispersion of a powder by supplying sufficient energy, such as a high-velocity airstream, to a relatively small volume of the bulk powder to separate the particles by overcoming their own attraction forces. Hydrophobic materials, such as talc, are more easily dispersed than hydrophilic materials, such as limestone or quartz, because particle agglomeration or clumping is minimal. Thus, dry powders are considerably easier to disperse than humidified ones. The metered powder may be dispersed and agglomerates broken up directly by a turbulent air jet, or the dust-laden airstream can be passed through an impactor or fluidized bed, for example, according to the simple design and easy-to-operate Venturi principle: the flow in the Venturi tube creates suction near the constricted area to feed powders into the device, and the shear flow downstream of the Venturi tube disperses particles into aerosol form. Powders are fed into the Venturi disperser by a screw feeder.

Elutriators or settling chambers have been used to selectively remove large agglomerates and are also useful in dispersion. Clean, dry air can be used to generate aerosols, but it should be noted that extremely dry air (relative humidity less than 50%) can induce strong electrostatic charges on particles favoring agglomeration and reducing their dispersability. As has been discussed, steps must be taken to ensure that the particles generated are respirable for the test species.

Willeke et al. (1974) describe fluidized bed aerosol generators that are capable of a very stable output of particles from 0.5 to 3 μm. This generator uses a fluidized bed of glass or metallic beads (100–200 μm) into which the powdered test substance is added. The mechanism of dispersion involves the agitation of the particles by the beads and their subsequent entrainment into the airstream from both particle impaction, as the beads collide with one another, as well as aerodynamic turbulence. The entire system also acts as

an elutriator, preventing large particles and agglomerates from leaving the system. This means of generation can only be used for dry, nonadhering powders and produces electrically charged aerosols, which need to be neutralized upon leaving the fluidized bed. Compared to some other dust generators, fluidized bed generators do not generally have high particle outputs, limiting their use in acute toxicity testing.

Lee et al. (1983) used a high-pressure air impingement device (microjet) to separate the finer fibrils from a para-aramid fiber matrix. Once separated from the bulk fiber matrix, the smaller fibers pass through a cyclone into the exposure chamber. This system was used to generate fiber mass concentrations as high as 18 mg/m^3 or fiber count concentrations as low as 2.5 fibers/cm^3 for periods ranging from 2 weeks to 2 years. The microjet is a versatile aerosol generator, finding practical applications for both fibrous and nonfibrous materials. By increasing airflow to the secondary high-pressure air jets, the microjet can be adjusted either to disrupt particle agglomerates or to affect some reduction in particle size through trituration in the oval inner chamber. Other examples of the use of this technology for particle dispersal are described by Cheng et al. (1985) and Bernstein et al. (1984). Bernstein et al. (1984) described a brush-feed micronizing jet mill that produces a relatively wide concentration range of respirable particles. Test concentrations from 0.22 to 7.48 mg/L were maintained with particles less than 3 μm. Only at higher aerosol concentrations were these small particle sizes not attainable.

Aerosolization of Carbon Nanotubes

Carbon nanotubes (CNTs) either consisting of only a single layer of carbon atoms in an annular wall (single-walled carbon nanotube [SWCNT]) of the tube or with double, triple, and multiple layers of carbon atoms in concentric annular walls (multi-walled carbon nanotube [MWCNT]) are being produced worldwide in increasing quantities because of great interest in applications resulting from their unique physicochemical properties. Hence, potential respiratory exposures during production and handling lead to an urgent call for inhalation studies to determine their potential toxicity. Baron et al. (2008) described a design for a generation system producing respirable aerosols at several mg/m³ for a 1-week mouse exposure. The starting material used in their experiments was as-produced powder from the high-pressure carbon monoxide method that was sieved to number 6 mesh (<2.3 mm). An acoustic feeder system was developed that handled the SWCNT powder without causing compaction of the material. The feed rate was adjustable, allowing output concentrations as high as 25 mg/m^3. The powder particles were reduced in size using a mill that produced high shear forces, tearing the agglomerates apart. The resulting aerosol was size-separated using a settling chamber and two cyclones to produce a respirable aerosol. The mass output efficiency of the entire system for producing a respirable aerosol from bulk material was estimated to be about 10%. This exposure system is now being used at the National Institute for Occupational Safety and Health (NIOSH) lab; a first comparison versus oropharyngeal aspiration showed increased inflammatory response in the mouse model as a result of the more equally dispersed deposition of inhalable SWCNT agglomerates versus large agglomerates in the aspirated SWCNT suspension (Shvedova et al. 2008).

There is an increasing need to reach the peripheral lung with dry powder medications as well as with collected ambient aerosols in environmental research projects. In a novel aerosol generator to create short-duration, high-concentration exposures, a fixed volume of compressed air was used to create a short burst of a highly concentrated aerosol in a 300 mL holding chamber. Collected diesel soot was deagglomerated to a fine aerosol with a mass median aerodynamic diameter (MMAD) of 0.55 μm. A fine powder such as 3 μm silica particles was completely deagglomerated to an aerosol with an MMAD of 3.5 μm. The aerosol system is particularly useful for peripheral lung delivery of collected ambient aerosols or dry powder pharmaceuticals following a minimal effort in the formulation of the powder (Gerde et al. 2004).

Given the interest in the relationships between ambient aerosols and morbidity/mortality, researchers are attempting to study collected ambient particle samples in animals. The Harvard Ambient Particle Concentrator (HAPC) is designed to deliver concentrated ambient fine particles (<2.5 μm aerodynamic diameter) for conducting animal and human exposure studies. The HAPC consists of the following components: (a) a size-selective inlet (a high-volume conventional inertial impactor with a 2.5 μm cutpoint) and (b) a series of three virtual impactors (stages I, II, and III) with 0.15 μm cutpoints. Like conventional inertial impactors, virtual impactors separate particles from the surrounding air by particulate inertia. Particles larger than the cutpoint of the impactor possess enough momentum to cross the air streamlines into the collection nozzle; as a result, a small fraction of the total flow passes into the collection nozzle, which contains the concentrated particles (larger than the cutpoint) suspended in air. The three successive virtual impactors produce an enrichment of the aerosol mass concentration of fine ambient particles by a factor of about 30 (Sioutas et al. 1995).

Another such high-volume, ambient air particle concentrator focusing on UFPs (<100 nm thermodynamic diameter) has been described by Gupta et al. (2004). The concentrator is similar to the previously mentioned HAPC but induces particle growth due to water vapor condensation prior to the second set of virtual impactors (for concentrating) and consists of several units, including a size-selective inlet, a condensational growth unit, two virtual impactors (concentrators), a thermal size restoration device, an air cooler, and a size-selective outlet. This system was evaluated using single-component artificial aerosols with a variety of physiocochemical properties as well as ambient air. All UFPs grew and were concentrated by about the same enrichment factor of 10–20, regardless of their composition and surface properties.

Aerosol Generation by Nebulization

Atomization of solutions can be achieved by mechanical methods (i.e., nebulization) or by applying an electrostatic potential between the solution and a counter electrode (i.e., electrohydrodynamic atomization [EHDA]). One way of generating aerosol particles is by atomizing liquid solutions of a specified chemical composition. Atomizers can be categorized depending on the forces applied to break up the liquid into small airborne droplets (Hinds 1999). The most appropriate methods are pneumatic, ultrasonic, and electrospray atomization because they produce relatively small primary droplets (1–10 μm in diameter).

In pneumatic atomizers, pressurized air is introduced via an orifice in such a way that the expanding airstream moves perpendicularly to the end of a tube connected to the liquid reservoir. Due to the Bernoulli effect, the low pressure created at the tube end draws the liquid from the reservoir into the airstream. The high forces occurring at the air–liquid interface (ALI) cause the solution to break up into small liquid droplets that become airborne and are carried away by the airflow. The spray stream is then directed onto an impactor plate where the larger droplets are deposited and are either directed back to the liquid reservoir or break up into smaller droplets and exit the atomizer in the outlet stream.

Ultrasonic atomization is another way of breaking up a solution to micron-sized droplets by ultrasonically vibrating its ALI (Wood and Loomis 1927). The mechanical energy applied from a piezoelectric crystal to the system agitates the surface of the solution, thereby creating capillary waves that break up into micron-sized droplets (Faraday 1831, Kelvin 1871, Rayleigh 1883). A particle-free airstream is passed over the solution to take away the generated airborne particles. The diameter of the primary droplets produced is a function of the frequency of vibration and the physical properties of the solution, that is, surface tension and density (Biskos et al. 2008).

EHDA, or electrospraying, is a method for producing very fine monodisperse droplets from a liquid under the influence of electrical forces. By controlling the liquid flow rate and the electrostatic potential between the liquid and the counter electrode, droplets within a narrow size range, with mean diameters from nanometers up to several micrometers, can be generated. Besides generating monodisperse droplets, electrosprays are also distinguished by their self-dispersing nature due to coulombic repulsion, the possibility of trajectory control of the produced charged droplets, and the reduced risk of nozzle clogging due to the large size of the orifice compared to the size of the droplets (Zeleny 1914, Grace and Marijnissen 1994, Biskos et al. 2008).

Spray Pyrolysis for the Generation of Submicron and Nanosized Aerosols

As recently reviewed by Biskos et al. (2008), in spray pyrolysis, the atomized particles are heated in a furnace (e.g., Messing et al. [1993]), a flame (e.g., Madler et al. [2002]), or a laser beam (e.g., Cauchetier et al. [1994]). The high temperatures cause rapid evaporation of the solvent of the droplets and the initiation of interparticle reactions that lead to the final product. The physical (size, morphology, and density) and chemical properties of the particles generated by spray pyrolysis depend on the composition of the liquid precursors, the atomization method, and the operating conditions of the apparatus.

Flame spray pyrolysis can be performed using aqueous solvents for the delivery of metal and/or metalloid oxide precursors while obtaining desirably high flame temperatures for the synthesis of uniform submicron inorganic metal oxide particles. A multiple liquid channel nozzle can be used to deliver liquid for the formation of the aerosol that is combusted in the flame. One or both channels can deliver liquid with metal/metalloid precursors and/or organic fuels. Recently, a novel system for generation of engineered nanomaterials (ENMs) suitable for in situ toxicological characterization within biological matrices was developed. This Versatile Engineered Nanomaterial Generation System (VENGES) is based on industry-relevant, flame spray pyrolysis aerosol reactors that can scaleably produce ENMs with controlled primary and aggregate particle size, crystallinity, and morphology. ENMs are produced continuously in the gas phase, allowing their continuous transfer to inhalation chambers, without altering their state of agglomeration. The ability of the VENGES system to generate families of ENMs of pure and selected mixtures of iron oxide, silica, and nanosilver with controlled physicochemical properties was demonstrated recently (Sotiriou et al. 2012).

Gas-to-Particle Synthesis

Gas-to-particle synthesis can be achieved by using furnace, flame, plasma, and laser reactors, glowing wires, and spark discharges, as reviewed by Biskos et al. (2008). Material evaporation followed by subsequent nucleation and condensation in an inert gas is a widely used approach for generating aerosol particles of uniform chemical composition. The great advantage of particle synthesis from the gas phase is the high purity and the high production rates (Pratsinis and Mastrangelo 1989). In addition, when the cooling of the gas–vapor system is well controlled, the morphology and size of the particles can be precisely adjusted.

Various energy sources can be used to evaporate materials for particle synthesis in the gas phase. Furnace reactors, glowing wires, and spark discharges use electrical energy to heat and vaporize the desired materials. Flame reactors utilize the heat from combustion to oxidize the vapors, which then form clusters and nanoparticles in the cooler regions of the reactor. Plasma and laser reactors utilize the high energy of an ionized gas (plasma), whereas laser reactors employ the high energy and precision of a laser beam. Details of the various methodologies are discussed by Biskos et al. (2008). Particle synthesis from the gas phase is most appropriate for generating single-component particles. One of the great advantages of gas-phase routes for particle synthesis is that small high-purity particles within a very narrow size range can be generated in great quantities.

The process of spark discharge is initiated by gas breakdown and formation of a conducting plasma channel. The rapid discharge consists of a current associated with a high temperature (typically 2000 K), as discussed by Biskos et al. (2008). Briefly, the electrode material is evaporated in the vicinity of the spark. This is followed by rapid cooling, initially governed by adiabatic expansion and radiation. Below the evaporation temperature, cooling is dominated by thermal conduction. The cooling period at temperatures below the boiling point is relatively small, thereby leading to the formation of high concentrations of very small particles. Spark generators typically consist of a chamber of 10–100 cm^3 in volume, in which two opposing cylindrical electrode rods are mounted at an adjustable distance. The electrodes are connected to a high-voltage power supply and in parallel to a capacitor. The power supply delivers a constant current, periodically recharging the capacitor after discharge has occurred at the breakdown voltage. The spark frequency can typically be adjusted up to 1 kHz. The mean particle size can be controlled via the energy per spark, which is in turn determined by the capacitance and the distance between the electrodes. The particle mass produced per unit time is proportional to the spark frequency. Separated, unagglomerated particles a few nanometers in size can be obtained if the inert gas flow through the generator is high enough with respect to the spark repetition frequency. The nanoparticulate mass produced is typically a few g/kWh. Different electrode materials lead to different mean primary particle sizes and mass production rates. Thermal conductivity, evaporation enthalpy, and the boiling point also influence these parameters.

Recently, the methodology of spark discharge aerosol production was extended to the generation of radiolabeled iridium or titanium dioxide (TiO_2) or gold nanoparticle aerosols using previously neutron- or proton-irradiated electrodes of either iridium, titanium, or gold. A schematic drawing is presented in Figure 28.9. It shows a ventilation apparatus holding four anesthetized rats individually in four plethysmograph chambers. The rats are intubated to connect to the aerosol freshly produced by the spark discharge aerosol generator; in the latter, two iridium electrodes are mounted, which had been previously neutron irradiated in a nuclear reactor to form the ^{192}Ir radioisotope. The freshly generated nanoparticle aerosol with a median diameter of 20 nm (geometric standard deviation [GSD], 1.6) was led into an inhalation apparatus for immediate inhalation of rodents in order to study lung retention and nanoparticle clearance and translocation into the circulation leading to retention in secondary organs and tissues (Kreyling et al. 2002, 2009, Gibson et al. 2011, Möller et al. 2013).

Dilution and Delivery Systems

Once a suitable atmosphere has been generated, it must be delivered to the exposure chambers at an appropriate concentration. Dilution is effected by mixing the test atmosphere with conditioned, filtered air before its introduction to the exposure chamber. It is important that the delivery system be fabricated with materials that minimize wall losses, either through absorptive or reactive processes, and designed to minimize physical losses through aerosol deposition within ductwork. The former situation may be avoided by using nonreactive materials and the latter by minimizing the number of bends and maintaining laminar flow in the ductwork. In general, the delivery system should be nonreactive with tubing as wide, short, and straight as practical to minimize test material losses and pressure drop and in order to minimize the residence time of the aerosol. It is especially important to use electrically conductive materials in the choice of tubing materials. Substantial aerosol deposition can occur in areas of high electrostatic charge, leading to excessive and variable aerosol losses along transfer lines. A broad selection of mechanical and electrical valves and flow measurement devices is available to measure and control the flow of test material and dilution air.

Exposure Chambers

There are a number of options when using inhalation exposure chambers either for human subjects or experimental animals such as rodents or large animals: whole-body exposure chambers, nose-only or head-only exposure chambers, or whole-body plethysmographs for controlled breathing. The selection of a suitable exposure chamber depends on the exposure mode (e.g., whole-body or nose-only exposure or whole-body plethysmographs for controlled breathing), reactivity of the test material, available resources (supply of conditioned air and test material), number of animals to be exposed, and efficiency in delivering test material to the animals. Apart from the obvious difference in size, the design objectives for nose-only or whole-body exposure chambers are similar. Chambers should be constructed of nonreactive materials such as stainless steel, glass, or plastic. Although stainless steel is durable and nonreactive toward many materials, it is comparatively expensive. In contrast, glass or plastic chambers are more readily fabricated, are less expensive, and permit ready observation of animals. However, glass or plastic exposure chambers are electrically nonconductive. This may allow charge differences to accumulate within the chamber and cause test aerosol losses through electrostatic attraction. This also can contribute to unacceptable spatial and temporal variations in chamber aerosol concentrations. Normally, chambers are operated under dynamic exposure conditions (i.e., a continuous supply of air is flowing through the chamber) with a slight negative pressure within the chamber to prevent leakage of test material into the exposure room.

Whole-Body Exposure

In a whole-body exposure chamber, the subject is immersed in the atmosphere contained in the chamber, simulating environmental or workplace exposures. Whole-body exposure chambers come in a wide variety of sizes, from very small chambers that hold one animal to very large, room-sized chambers for humans. Large whole-body chambers are most commonly used for long-duration exposure studies and for large numbers of test subjects. The large chambers

are designed to house the test subjects during exposure and nonexposure periods. These large chambers are operated on a dynamic flow basis where there is a continuous flow of air through the chamber. In order to achieve a homogeneous distribution of the aerosol, great care is required to maintain a homogeneous and uniform displacement flow either horizontally or vertically from the inlet to the outlet of the chamber. A design of such a chamber for human exposure was described by Eduard et al. (2008). For dogs, a whole-body chamber for long-term exposure was described by Karg et al. (1992). Many of the rodent exposure chambers go back to the fundamental design of the Rochester chambers by Leach et al. (1959). Inside a whole-body chamber, animals may be housed individually or in groups. Recently, the design and operation criteria were critically reviewed by Wong (2007). Group-housed animals may huddle leading to the potential that an individual may inhale less of the test compound due to the filtration or reaction with surrounding animals' fur. Also, an individual might inhale air that has been exhaled and cleaned of the test compound by surrounding animals. Both of these possibilities could result in varying uptake of the compound among animals. Also, during preening, animals ingest material that has deposited on the fur. Despite those potential limitations, whole-body exposure chambers for inhalation of test aerosols and gases represent the gold standard of inhalation exposure since their application resembles physiological breathing and the behavior of the animals is not changed by restraint.

Nose Only and Head Only

The test subject is confined so that only the head or nose is exposed to the test atmosphere. A continuous flow of air is supplied to the system (Figure 28.7). Particularly in earlier designs, the test subjects inhale from the plenum containing the test atmosphere and exhale back into the same plenum (Smith et al. 1981). In this type of system, the downstream test subjects may inhale air that was exhaled from the upstream test subjects. If the airflow is too low, downstream test subjects may get a lower dose, or the dose to each test subject may be more variable (Cannon et al. 1983). This potential problem has been addressed by a system design in which the test atmosphere flows into an inlet manifold that directs the flow toward the nose or head of each test subject. The exhaled air is then carried along with the excess airflow into an exhaust system (Figure 28.8). Thus, all the test subjects are exposed to the same atmosphere (Prasad et al. 1988, Pauluhn 1994).

Smaller animals such as rodents are held in tubes (Phalen 1997). The tube is attached to the chamber so that a hole or extension from the inlet manifold directs the atmosphere flow toward the animal's nose. An adjustable back restraint is used to prevent the animal from backing out. A restraint that is open to the atmosphere can allow heat and humidity to escape. However, the test atmosphere can leak around the animal as discussed by Wong (2007). Leaks may be prevented by using a restraint system that seals the tube, though heat and moisture buildup in the tube is a concern (Phalen 1997). A sealed restraint system is desirable if the test compound is particularly toxic or hazardous. Animals inside the restraint tubes do not have access to food or water. While loading the animals in the tubes, care must be taken to position them correctly. Animals, particularly the younger or smaller ones, may attempt to turn around inside the tubes with the risk of suffocation. The airflow through the nose-only chamber may be reduced to minimize the amount of test compound used. However, if the flow through each port approaches the minute ventilation rate of the animal, the flow may be insufficient to clear the exhaled atmosphere away from the animal.

Inhalation/Ventilation of Intubated Animals

Aerosol inhalation by a ventilated and intubated animal is an invasive exposure methodology compared to whole-body or nose-only exposure. The anesthetized animal is

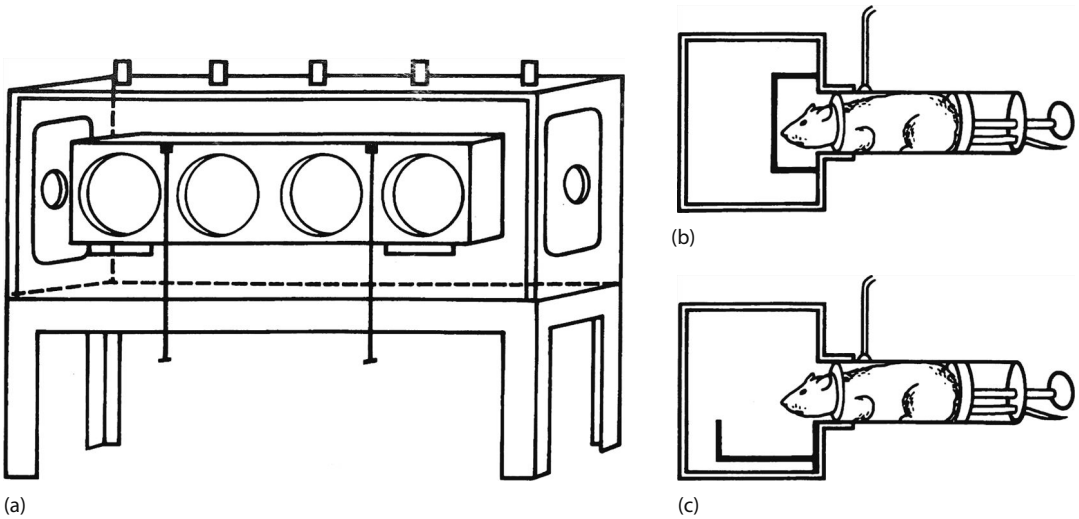

FIGURE 28.7 Airlock exposure chamber for instantaneous exposures. (a) Front view. (b) End view, atmosphere preequilibrated while rats breathe fresh air. (c) Airlock dropped for instantaneous exposure.

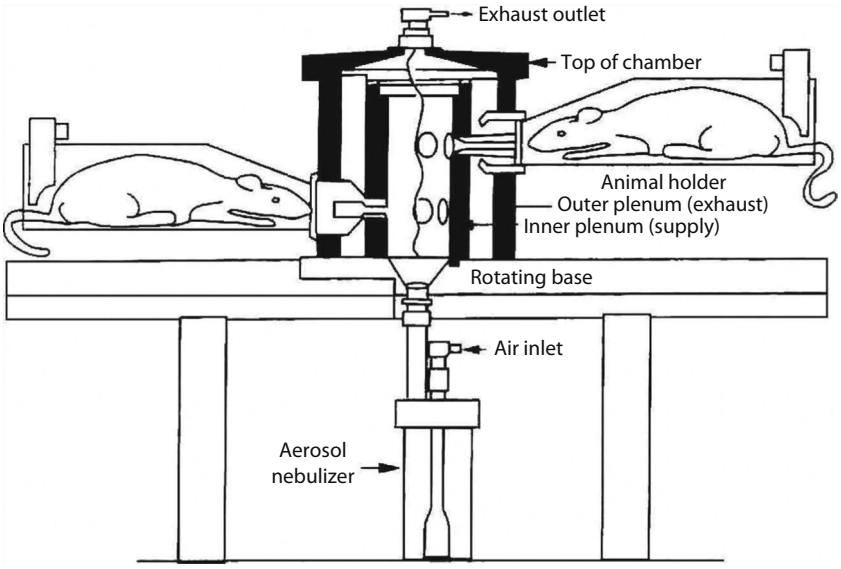

FIGURE 28.8 Exposure chamber and rodent holder designed for nose-only exposures to aerosols and vapors.

intubated and connected to a computer-controlled ventilator unit. Ventilation of the intubated animal, however, allows for higher-precision measurement of the inhaled aerosol volume during controlled breathing and of the aerosol fraction being deposited. In addition, this system allows for bypassing the extrathoracic airways and the upper part of the trachea due to the endotracheal tube being placed and usually sealed against the outside such that the aerosol delivery to the lungs can be enhanced leading to higher particle deposition probabilities. Furthermore, the particle deposition can be further optimized by certain selection of the ventilation parameters (e.g., deep and slowly breathing). Another advantage is the avoidance of any fur contamination during exposure representing a major shortcoming of whole-body exposure. Note that rodents are obligatory nose breathers that filter inhaled particles of sizes larger than 3 μm (2.5 μm) aerodynamic diameter in the case of rats (mice, respectively). Hence, inhalation exposures of aerosol particles larger than these sizes will not reach the thoracic airways and alveoli of rodents under normal breathing; however, aerosol inhalation via an endotracheal tube is an option for such exposures.

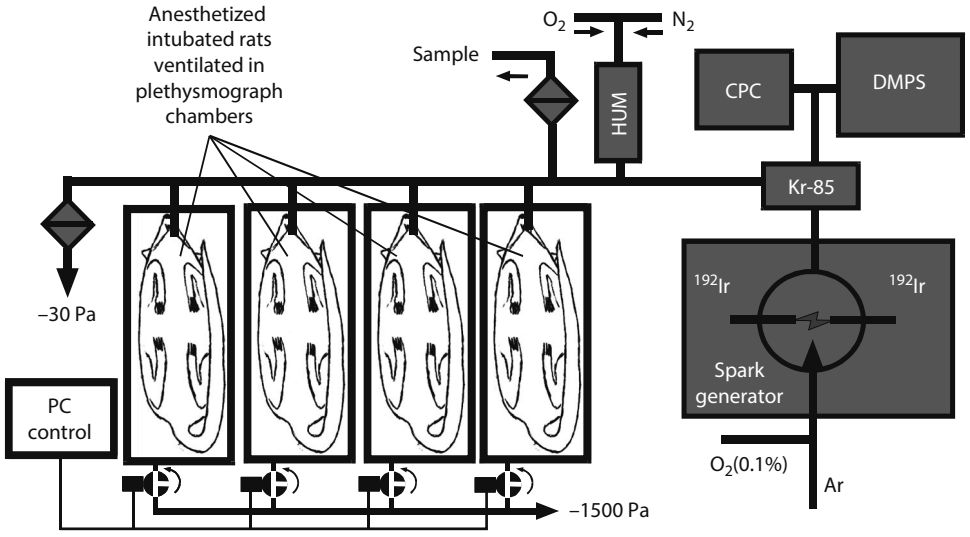

FIGURE 28.9 Schematic drawing of the ventilation apparatus and the spark discharge nanoparticle aerosol generator: Four anesthetized rats individually placed in plethysmograph chambers are intubated to connect to the aerosol. Rats are ventilated by alternately applying and releasing low pressure. The aerosol is freshly produced by the spark discharge aerosol generator in an argon atmosphere. For breathing, this aerosol is air-conditioned and supplied with oxygen and nitrogen. In the spark discharge generator, two iridium electrodes are mounted, which had been previously neutron irradiated in a nuclear reactor to form the ^{192}Ir radioisotope at a selected radioactivity. Size distribution and concentration of the aerosol are continuously monitored.

Two ventilation methods can be used: aerosol exposure via positive-pressure ventilation or via negative-pressure ventilation. In the first case, the anesthetized animal is connected via the sealed endotracheal tube to a piston-type servo ventilator controlled by a computer. When the alveolar CO_2 is low enough, the anesthetized animal does not breathe spontaneously but follows the external breathing pattern triggered by the piston-type ventilator. This system allows ventilation using physiological breathing patterns, which can individually be adjusted to the size and the behavior of the animal. This was demonstrated for dogs (Meyer and Slama 1983, Schulz et al. 1992). A similar system was scaled down and developed by the latter group for rodents to perform lung function tests, achieving such high sensitivity that distinction between the lung functions of two strains of mice was possible (Schulz et al. 2002).

A similar system called intratracheal inhalation was described earlier (Oberdorster et al. 1997, Osier et al. 1997). It consists of a closed system, allowing for the filtration and removal of potentially hazardous or radioactive particles prior to exhaust, thus making decontamination procedures significantly simpler and faster than those for standard inhalation systems. The main advantage is the rather precise estimate of the inhaled aerosol volume when the breathing flow is monitored, which is possible because the number of breaths during the study is set by the ventilation parameters. Knowing the aerosol concentration and the deposition probability or measuring particle deposition additionally, for example, by labeling the aerosol particles, the deposited fraction can be determined precisely.

In the second case, ventilation by negative-pressure ventilation, the intubated and anesthetized animal is located in an airtight plethysmograph chamber, and its lungs are connected via the endotracheal tube tightly sealed in the trachea through the chamber wall to the aerosol line with the bypassing aerosol flow. By applying a negative differential pressure of 1.5 kPa (a reasonable range is 1–2.5 kPa) to the plethysmograph chamber, the thorax expands and the animal inhales; releasing the low pressure to the ambient level, the animal exhales to its functional residual capacity (FRC). When the alveolar CO_2 is low enough the anesthetized animal does not breathe spontaneously but follows the external breathing pattern triggered by the pressure in the plethysmograph chamber (Kreyling et al. 2002, Semmler-Behnke et al. 2012). Since the entire aerosol system was maintained at a slightly lower pressure of 20–30 Pa compared to the lab pressure, the use of radioactively labeled, freshly generated nanoparticles became possible, warranting radiation protection of the operating personal. Various aerosolized materials (iridium, elemental carbon, titanium dioxide, gold, and silver) with a median diameter of 20 nm were applied for biokinetics studies (Kreyling et al. 2009, 2011, Möller et al. 2013).

A transoral/intratracheal inhalation method has been reported previously (Drew et al. 1987). In this system, anesthetized rats were intubated intratracheally and exposed to an aerosol of fibers. Unlike the previously described system, the animals were allowed to breathe spontaneously. Anesthetized rats tend to breathe more shallowly, and ventilation is less which would be expected to decrease deep lung deposition. In trained dogs, permanent tracheostomy can be used to deliver common aerosols for inhalation studies in alert, awake animals (Drazen et al. 1982, Godleski et al. 2000).

Inhalation Exposure of Aerosol Material of Limited Availability

In most animal inhalation systems, the aerosol is freshly generated and flows by such that the inhaled fraction of the aerosol is usually below 0.1% of the generated aerosol. When the material to be aerosolized is limited in its mass, such systems can no longer be used. This may be the case for hazardous materials such as radioactively labeled particles or other chemically toxic materials or for extremely expensive materials such as drugs. In this case, a bag-in-box exposure system may enhance the ratio of inhaled over generated aerosol particles up to 1%–5%. Basically, a flexible bag inside a box is filled with the freshly generated aerosol; thereby, it replaces the air between the bag and the box. Subsequently, the animals start breathing the aerosol from the bag, while air enters the space between the box and the bag replacing the inhaled aerosol volume inside the bag. This procedure allows inhalation of an aerosol of rather constant concentration until the bag is emptied. The procedure can be repeated by filling the bag with freshly generated aerosol (Bailey et al. 1985, Kreyling et al. 1999). Care is required to determine aerosol particle losses in the bag due to settling and diffusion; the inside surface needs be of electrically conducting surface in order to avoid deposition of charged particles.

Atmosphere Analysis: Measuring Size and Concentration

In many cases, analysis of the test atmospheres is the most challenging part of conducting inhalation studies. The investigator must not only sample the chamber for proper environmental conditions (temperature, relative humidity, oxygen content) but must also select, validate, and conduct analyses for the test substance(s) in terms of particle size (if a solid/liquid aerosol), concentration, and solvent concentration (if present in a mixture); the problem magnifies when testing materials are not stable in air or in the presence of moisture and multiple component substances are tested. All of these issues must be addressed and resolved to be considered a well-conducted study. This section attempts to identify some of the available analytical approaches and methods that may be useful.

Analysis of test atmospheres begins with the sampling system. An appropriately designed sampling system is central to accurate analysis of test substance concentrations in the exposure chamber. First of all, the sampler probe should be located in the immediate proximity of the breathing zone of the animals, since regional distribution differences within the chamber skew the actual concentrations inhaled by the animals. The sampling system should be designed to transmit a representative air sample from the animal's breathing zone

to the sensor or collection medium without significant losses. It is not necessary that the collection efficiency be 100%, but if sample losses cannot be avoided, at least the collection efficiency of the sampling system should be measured with the test substance and experimental conditions to be used. In addition, care is required when the aerosol is likely to dynamically change due to, for example, coagulation, growth, or deposition in the test line. Above all, the investigator should strive for a constant collection efficiency. For aerosols, the sampling system should be as straight and short as possible and designed to minimize impaction sites (i.e., those locations with bends, reducers, or turns) as well as diffusional losses of UFPs and ENPs. Rarely are aerosols monodisperse and, since most particle entrapment mechanisms are size dependent, the collection characteristics of a given sampler will change with aerodynamic or thermodynamic particle size and upon sampler airflow. Aerosol collection efficiency will also change in response to sampler particle loading. A filter will be more efficient and trap finer particles as dust collects on the surface, but efficiency will gradually decrease as the pressure drop across the filter increases, reducing airflow. In contrast, the efficiency of an electrostatic precipitator will drop as a resistive layer of particles accumulates on the collection electrode.

Sampling errors generally reflect the contribution of many small errors in the system rather than any single large source of error. The items that need to be carefully considered and evaluated in any such system include sampling train leakage and losses, variations in flow rate and sample volumes, sampler aerosol or vapor collection efficiency, sample stability in the collection media, extraction efficiency from the sampling substrate, and analytical background or interferences introduced by the sampling substrate. Additionally, the air sampling rate should be known with a high degree of precision, and this can be performed with previously calibrated rotameters, gas meters, critical orifices, displacement monitors (dry or wet test meters), or electronic mass flow sensors. Much of this technology is described in classical texts on industrial hygiene.

For gases or vapors, sampling of the test atmosphere may be either instantaneous (i.e., grab sampling) or continuous in nature. If grab sampling is conducted, samples should be taken with sufficient frequency to identify fluctuations in concentration. Samples may be collected in evacuated glass or metal containers, inflatable flexible polymer bags, or by gastight syringes. Alternatively, gas or vapor samples may be taken from remote locations by directing the sample through nonreactive sample lines by using a vacuum pump and introducing aliquots of the sample stream directly into the analytical instrument. Continuous samples can be taken in this manner by pumping (or drawing) a constant stream of gas directly through a dedicated detector or by having the analytical device continuously cycle through sample streams from multiple exposure chambers.

Gases and vapors offer the least difficulty in sampling as they follow the laws of diffusion, mix freely with the general atmosphere, and equilibrate rapidly. Sampling typically involves removal of the substance from air by scrubbing through a solvent or reagent, adsorption to a collection surface, or collection in some type of container (e.g., an impermeable, nonreactive gas bag).

An extractive sampling system for gases, vapors, and aerosols includes sample lines from the breathing zone, a scrubbing device, an airflow or volume meter to determine sample volume, and a vacuum pump. Commonly, solvent-filled impingers are used for extractive sampling. Impingers consist of a sampling tube extending through a reservoir of collecting media; the end of the tube at the bottom of the reservoir may be either open, narrowed, or fritted; the latter two modifications provide comparatively higher collection efficiency. The increased collection efficiency is due to the smaller bubbles produced by the narrow or fritted impinger tips, which allows more complete diffusion of vapor from the bubbles into the surrounding solvent. The solvent used in impingers can quickly evaporate, and, therefore, sampling cannot be conducted indefinitely.

Solid adsorbent sampling devices are used for vapors and some gases. Solid adsorbent samplers consist of a small tube (about 100 mm long × 6 mm diameter) containing a sorbent, typically charcoal, which serves as the collection medium, and a vacuum source to draw a known rate of air over the sorbent. Charcoal is an effective sorbent for many compounds since its surface structure is microporous, thereby providing a high surface area for chemical adsorption. Importantly, charcoal possesses not only a large number of pores, but the pores exist in a range of dimensions to allow molecules of different sizes to enter the pores. Thus, charcoal affords nonspecificity and can trap a wide variety of organic compounds. Other trapping agents include polymers, which can be engineered to trap certain chemicals, silica gel for inorganic substances, or molecular sieves. Once trapped, however, the sorbent must also allow the vapor/gas to be desorbed with high efficiency into a solvent for subsequent quantitation. Carbon disulfide is broadly used as a desorption solvent for charcoal tubes since it has good solvent properties and a low background with the flame ionization detector generally used in analysis. Sampling is done at relatively low airflows to allow time for chemical adsorption yet must be of brief duration to not exceed the adsorbent capacity of the sorbent. While relatively simple and cheap, use of gas sampling tubes in most toxicology studies is uncommon due to the labor involved in sample collection and preparation compared to continuous, direct reading analyzers.

Gas sampling using containment systems is also relatively uncommon in toxicology studies. They serve as temporary storage vessels to allow transport of gas or vapor samples from the exposure system to the analytical device. Examples include evacuated glass or stainless steel containers or Tedlar® or Mylar® plastic bags. While some substances are stable in such containers, there are numerous logistical and practical limitations for their routine use in inhalation toxicology studies. Gas sampling bags are physically cumbersome (their bulk depends upon the sample volume needed), require a logistical commitment to have a sufficient quantity of sample vessels available for the duration of testing and vessel transport to the analytical laboratory, require

demonstration of chemical inertness and storage stability of the substance between the interval of sample collection and analysis, need to be decontaminated if vessels are reused for other substances, and may confound results from undetected leaks or sample losses during shipment.

Instruments for gas or vapor component identification and quantitation have brief response times (seconds or minutes) and are used after air sampling. Sensors in these instruments typically utilize either absorbance of infrared or UV radiation, flame ionization or photoionization, electron capture, or chemiluminescence detection.

As with gas and vapor sampling, instantaneous (grab) or continuous (integrated) sampling techniques may also be used to collect particulate matter. Instantaneous sampling involves removing a small volume of the atmosphere and separating the particle phase by either filtration or impacting the aerosol against a solid substrate on which the deposited particles are later characterized (counted and sized and/or subjected to chemical analysis). For continuous sampling, a constant stream of the test atmosphere is directed to the analytical instrument. Analytical techniques that rely on physical forces such as gravity, impaction, electrophoresis, thermophoresis, electrical mobility, inertia, or diffusion techniques are used for particle collection; collected particles are typically measured using mass or optical properties. Yet due to the increasing interest in UFPs and ENPs, other metrics such as number concentration and the corresponding size distribution and/or particle surface metrics are required in addition to mass concentrations and according size distribution determinations. An overview of the common instrumentation useful for determining particle mass and size for use in inhalation studies is listed in Table 28.3.

Grab sampling of aerosols usually involves either impactors or filters. Fluid-filled impingers (as used for gases and vapors) have been used for aerosols, but as collection efficiency is variable, they are not commonly used. Instead, grab sampling for aerosols generally involves the use of filters for determining aerosol mass concentration in the chamber. For nonhydroscopic aerosols, the accuracy of chamber aerosol concentrations is limited by the sensitivity of the volume measuring device as the weight of collected aerosol can be determined with great precision using modern analytical scales. Hydroscopic aerosols pick up water vapor from the air and consequently can change weight during the brief interval needed for filter weighing. To more accurately measure the weight of hydroscopic aerosols, standardized weighing techniques are needed such as desiccating (especially glass or cellulose acetate fiber filters) or by equilibrating filters in a constant humidity chamber prior to weighing.

The choice of filter media available is broad and includes glass fiber and various polymer membranes (such as cellulose

TABLE 28.3
Features of Some Aerosol Monitoring Instruments

Instrument	Aerosol Size (μm)	Response Time	Measured Parameter	Factors Affecting Response	Advantages	Disadvantages
Photometer	0.3–15	Continuous	Total light scattering	Density, size distribution, refractive index	Continuous readout	Response changes with dust type
β-Attenuation monitor	1–15	1–30 min	Absorption of β-radiation	Atomic number	Direct mass measurement	Low sensitivity
Optical particle counter	0.3–15	0.1–10 min	Light scattering, size, and count	Density, refractive index	Indication of size, high sensitivity	Low resolution and accuracy
Piezobalance	0.02–10	0.5–2 min	Mass	Particle size	Direct mass measurement	Sensor cleaning
Piezobalance cascade impactor	0.05–25	1–60 min	Mass	Particle size	Direct mass measurement, size, distribution	Sensor cleaning, internal losses
Condensation nucleus counter	0.01–1	0.5–30 s	Particle count	Particle count	Small particle sensitivity	Alcohol emission
Diffusional mobility particle size	0.003–1	<1–5 min	Size based on electrical mobility	Electrical charge	Real-time display of UFP size	Measures only fine particles
Fibrous aerosol monitor	Optically visible fibers	1–1000 min	Light scattering size of fibers	Fiber length, size	Specific for fibers	Nonfibrous interferences
Aerodynamic particle sizer	0.8–15	2–10 min	Aerodynamic size	Density	Direct measure of aerodynamic diameter	Coincidence and density effects
Tapered element oscillating microbalance	0.002–15	0.01–30 min	Mass	Absorbed water	Direct mass measurement	Frequent filter replacement

acetate, polycarbonate, polyvinyl chloride, polyvinylidene fluoride, or Teflon®). Membrane filters are perforated with holes of defined size. Unlike fiber filters that trap particles within the filter matrix, membrane filters collect particles on the surface of the membrane. The choice of filter media is dictated by the need for high collection efficiency for particles of the size of interest, chemical inertness (to allow good recovery of the test substance for subsequent chemical analysis), and minimal pressure drop across the filter (to allow high air sampling rates). Pressure drop is especially important for membrane filters since smaller holes create a higher pressure drop, limiting airflow through the filter. To some degree, smaller-size holes in the filter membrane ensure a higher sample collection efficiency, but even larger-pore membrane filters collect many particles smaller than the pore size due to deposition by interception and/or diffusion. Membrane filters are widely used when analyzing the morphology of mineral dusts by either optical or electron microscopy.

In addition to determining aerosol chamber concentrations via measurement of collected mass on filters, the filters may be extracted and analyzed to determine test substance content. This is particularly valuable for mixed aerosol atmospheres where the content of each component must be evaluated, but this will require a specific analytical method for each component of interest. Clearly, in cases where test substances are to be extracted from the filter medium, the filter itself must be chemically unreactive with the test substance and should allow rapid and quantitative desorption of test substances for chemical analysis. Filters made from superfine glass fibers with diameters below 1 μm are available for collecting virtually all suspended particles, have high particle loading levels, and have low airflow resistance. While glass fiber filters interfere negligibly with most subsequent chemical analyses, it should be noted that glass surfaces have imbedded hydroxyl groups that may bind metals or react with some substances. Regardless of composition, filter spiking and recovery studies should be evaluated before use to determine whether the particular filter substrate will interfere with analysis.

Complementary to aerosol mass monitoring by filtration, real-time aerosol monitors can be used to provide analytical data for concentration adjustments. Light-based particle monitoring systems rely on light scattering through either refraction, reflection, or diffraction, all of which will vary with the particle's optical size. The theory and explanation behind light-scattering devices is well described by others (Van de Hulst 1957, Kerker 1969, Bohren and Huffman 1998). While light-scattering techniques for measuring aerosol concentrations provide instantaneous output and have found general acceptance for chamber monitoring, it should be noted that instrument response is a function of aerosol size, shape, color, concentration, and chemical composition. Thus, light-scattering aerosol monitors need to be calibrated against other analytical methods with the specific aerosol of interest to allow quantitative use; even then, they are subject to coincidence errors and are useful only at relatively low aerosol concentrations. These particle monitors do, however, provide immediate display of changes in concentrations and are useful to detect deviations in aerosol generator output or chamber airflow dynamics.

For particle sizing, cascade impactors are frequently used. Impactors are flow-through devices that withdraw aerosol from the test atmosphere. The impactor contains a series of impingement stages, each stage with progressively smaller nozzle dimensions. Since airflow through the impactor is constant, each stage induces progressively increasing airstream velocities coupled with sequentially reduced impaction distances to effect a progressive separation of smaller and smaller particles as aerosol progresses through the unit. Particles deposited on each stage can be weighed and/or examined microscopically. The aerodynamic median size of an aerosol may be determined with the cascade impactor by calculating the percentage of aerosol by weight on each stage using weight, radioactivity, or chemical analysis to determine the amount of material deposited on each stage. This process is shown in Figure 28.10. The same caveats with respect to selection and the use of filter media and filter weighing techniques apply to cascade impactors. A major liability when operating cascade impactors is the potential for overloading impactor stages with excessive particle mass. This may lead to the erroneous conclusion that aerodynamic sizes are smaller than in reality due to particles bouncing off of the target stage and subsequent capture on lower stages, indicating finer particle size.

Advances in electronics permit bypassing manual weighing of individual impactor stages and allows direct, nearly instantaneous readout of aerosol size. An example of a single-particle aerodynamic particle sizer is the TSI aerodynamic particle sizer. This device displays aerodynamic diameters by measuring the particle velocity in a laser light-scattering sensing zone. Particles of different sizes are accelerated to different speeds when directed through a nozzle. The airstream is directed through dual-focus laser beams, one downstream of the other. The system's circuitry measures the speed of the particle in an accelerating flow field, represented by the time taken to traverse the distance between the two lasers, and converts each time-of-flight measurement into an aerodynamic diameter. This device provides high-resolution, real-time aerodynamic measurements of particles between 0.5 and 20 μm, but can only process particles at a concentration of about a few thousand particles/cm^3; otherwise, coincidence errors occur; higher concentrations require dilution before measurement. Unlike the TSI unit, the piezobalance cascade impactor, known as the quartz crystal microbalance (QCM) by California Systems, measures mass concentrations (and aerodynamic diameters) directly. The QCM is a self-contained unit with a 6–10-stage cascade impactor that uses a quartz sensing crystal in lieu of a filter on each stage. The crystal has an inherent oscillating frequency that changes in proportion to the mass of aerosol deposited on the crystal. This allows very small amounts of mass to be detected and thus is ideal for very low (such as ambient aerosol) concentrations; size analysis of high concentrations can also be measured by very short sampling durations to avoid

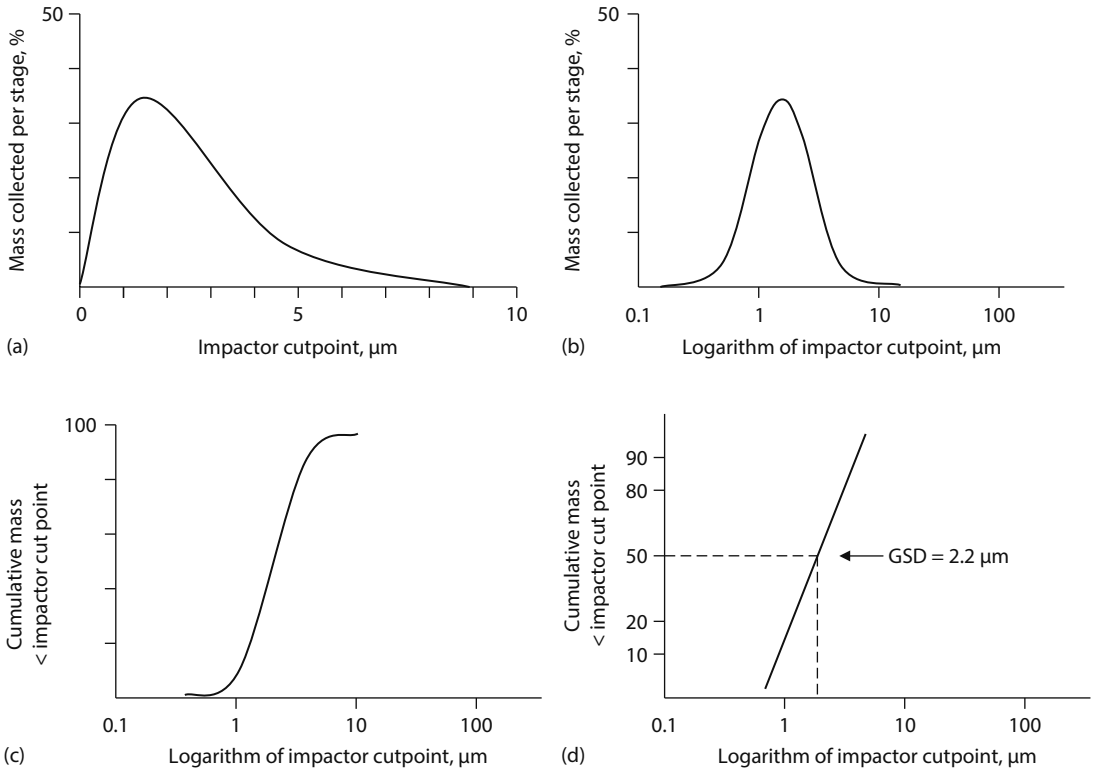

FIGURE 28.10 (a) Cascade impactor data from Table 23.3 plotted on arithmetic axes. (b) Size distribution data from (a), replotted using logarithmic scale for impactor cutpoint. GSD is 2.2 µm.

stage overloading. Based on the same measurement principle as the QCM, the tapered element oscillating microbalance (TEOM) has been widely used for aerosol mass measurements as described in Baron and Willeke (2001). The instrument provides continuous and remote measurements of high sensitivity and can produce high-time-resolution data. The original TEOM has a recommended temperature setting of 50°C. There is evidence that semivolatile components of aerosols are lost from the TEOM measurements at this temperature. The most likely explanation is that semivolatile organic compounds, nitrates, and water are lost from the aerosols during sampling. In newer TEOM models, the operating temperature has been lowered to 30°C to reduce losses of the semivolatile components. New modifications have been made to dry the aerosol particles before measurement to reduce the effect of ambient relative humidity.

A different type of instrument for continuous mass measurements, the β-meter, has also been commercialized. It operates on the principle of β-ray attenuation by a layer of aerosol on a filter substrate. The β-ray source is usually ^{14}C or ^{85}Kr decay and the attenuation can be calibrated with a known mass. Sampling can be done with individual filters or filter tapes, and the β-ray that passes through the filter is continually monitored. Comparison with gravimetric methods usually produces reasonable agreement. Filter or filter tapes can be used for subsequent chemical analysis.

Particle number concentration is a useful adjunct to the determination of number size distributions, providing a direct measure of the integral over the size range of ambient aerosols. Particle number is a relatively easily measured variable that can be used to evaluate aerosol dynamics models that predict aerosol particle number size distributions. Condensation nuclei can be detected after the condensation of water or other condensable vapor (often an alcohol such as butanol) from a supersaturated atmosphere onto the particle. The supersaturation in condensation particle counters (CPCs) is typically quite large, around 150%, allowing detection of particles as small as a few nanometers in diameter. Optical methods are usually used to detect the resulting droplets including photometric observation of light scattered by a collective of droplets in the optical sensing volume. However, the most satisfactory method is individual counting of particles condensed in a continuous flow, as employed in the family of CPCs that have developed from the design of Bricard et al. (1976). This procedure is employed in most modern commercial CPCs. It has the advantage of giving a direct determination of particle number concentrations up to about 10^5 cm^3. Most modern CPCs utilize continuous flow with condensation of an alcohol (typically butan-1-ol) to achieve supersaturation and employ single-particle counting, although photometric detection is used in some. Flow rates, lower detection diameter, and upper concentration ranges vary between counters; the particular counter used needs to be selected to suit the application.

While the uncontrolled increase of size in the CPC during vapor condensation makes it impossible to size classify

the particle, the differential mobility particle sizer (DMPS; Liu and Pui 1974, Knutson and Whitby 1975) and the scanning mobility particle sizer (SMPS; Wang and Flagan 1990) are basically the same type of instrument with only different electronic control mechanisms. They consist of a differential mobility analyzer (DMA), a CPC, and some electronic controlling devices, everything controlled by a personal computer. The DMA enables selecting only a very narrow size fraction of particles that then enters the CPC. The CPC counts the number of particles as usual, and since the size is already determined, information of both concentration and size is obtained. By changing the setting of the DMA, scanning over the whole particle size interval (3 nm to 1 μm) is possible.

The aerosol time-of-flight mass spectrometry (ATOFMS) offers real-time measurement capabilities for characterizing aerosol particles by the aerodynamic size and chemical composition of individual aerosol particles sampled directly into the instrument (Noble and Prather 1996). Such measurements are made in situ by combining a unique dual-laser aerodynamic particle sizing system to size and track individual particles through the instrument and laser desorption/ionization time-of-flight mass spectrometry to obtain correlated single-particle composition data. The size and chemical composition of 50–100 particles/min can be measured (up to 600/min at high particle concentrations).

Recently, a small transmission electron microscopy (TEM) sampler was designed to collect UFPs on grids used for TEM. The sampler is based on electrostatic deposition (Fierz et al. 2007). Particles are collected directly on TEM grids and can be analyzed in the TEM without any further treatment. The sampler consists of three functional units: an aerosol charger, a deposition zone, and an aerosol electrometer. The aerosol is drawn through the sampler at a flow rate of 0.5 L/min with an integrated pump. The charger is a unipolar diffusion charger. In the charging zone, the particles acquire a positive charge. Once charged, the aerosol enters the sampling region through a metallic inlet pipe. The TEM grid is mounted opposite to the aerosol inlet of the sampling region on a conducting rod. Finally, the electrometer can be used to measure the charge of the collected particles on the TEM grid and thereby allowing an estimate of the number of deposited UFPs.

Recently, a new method to classify aerosol particles according to their mass-to-charge ratio was introduced. This method works by balancing the electrostatic and centrifugal forces that act on particles introduced into a thin annular space formed between rotating cylindrical electrodes. Particles having a mass-to-charge ratio lying in a certain narrow range are taken out continuously as an aerosol suspension. This technique involves the use of a DMA (Liu and Pui 1974, Knutson and Whitby 1975) to select particles of a given mobility size and an aerosol particle mass (APM) analyzer (Ehara et al. 1996) to measure the mass of those particles. The APM classifies particles according to mass, regardless of particle density or shape. By multiplying the number concentration downstream of the DMA by the particle mass, it is possible to determine the mass concentration size dependently at a given DMA classifying voltage. The total mass concentration is obtained by integrating across the measured mass size distribution. Because measurements are made on particles suspended in the air, this technique avoids sampling artifacts associated with volatilization or adsorption that occur with filter or impactor sampling. This system also allows the measurement of particle density (McMurry et al. 2002).

Exhaust/Scrubbing Systems

Exhaust systems are included in chamber design not only to assist in the flow of air through the exposure chambers but also to minimize discharge of test material into the environment. Federal, state, and local regulations on air emissions can be stringent in requiring that adequate abatement systems must be incorporated. Depending on the physical properties of the test material, liquid or solid absorbents (e.g., water for water-soluble solvents and activated charcoal for low-level organics) may be employed to remove gases or vapors, whereas high-efficiency particulate air (HEPA) filtering material may be appropriate for aerosols. Since liquid or solid absorbents become saturated with test material, they must be monitored with sufficient frequency to ensure that the adsorbent capacity has not been exceeded. In contrast, particle filters generally become more efficient as particle loading increases, but because airflow may be reduced concurrently when filters become loaded, the exposure chamber aerosol concentration may inadvertently increase. Thermal oxidation or incineration are other means of treating chamber effluent and can be applied to scrubbing combustible test material.

Exposure Modes: In Vivo, Instillation, and In Vitro

A variety of exposure modes have been used to evaluate the effect of substances following inhalation. The whole-body exposure mode is encountered frequently and allows the exposed test species to move freely in the atmosphere containing the test substance. Whole-body inhalation exposures will result in a portion of the substance being inhaled and deposited regardless of physical form by grooming. Gases or vapors can dissolve in the mucus fluid lining the respiratory tract and, via the mucociliary escalator, reach the pharynx, where they are swallowed. Droplets or solid particles also reach the gastrointestinal tract via this mechanism. Further, contributions to total absorbed dose can occur by dermal absorption of the test substance. The normal grooming and preening activities of rodents both during and after inhalation exposures can deliver the substance to the gastrointestinal tract. For example, rats were exposed to respirable zinc chromate dust either in conventional wire mesh cages or nose only in fiberglass tubes (so that the only exposure was through the external nares). The caged rats excreted 8.4 times as much fecal and 5.5 times as much urinary chromium as rats in the tubes, indicating that a significant amount of dust could be ingested or absorbed following whole-body exposure (Langard and Nordhagen 1980).

Dermal absorption may contribute to the total body burden from whole-body vapor exposures. The skin is a partial or incomplete barrier to inward or outward migration of most vapors. Because the surface area of the skin is large, a small flux of vapor across the entire skin surface can result in absorption of sufficient amounts of vapor through the skin to cause adverse health effects. McDougal et al. (1985) described a whole-body chamber in which rats were fitted with face masks and received positive-pressure, charcoal-filtered fresh air while being exposed to vapors of either dibromomethane (DBM) or bromochloromethane (BCM) (volatile organic chemicals for which their major metabolites could be easily measured in blood). In rats exposed to the vapor by inhalation for 4 h, the percent absorption through the skin for DBM was 5.8%, and for BCM was 4.2%. These uptakes were independent of inhalation exposure concentration. Determination of the relative rates of absorption of vapor through the skin and the respiratory tract can be determined by comparing dermal absorption in rats without inhalation contact and inhalation by the usual methods. When inhalation is the route of exposure, the rate-limiting process in absorption of substances with large blood–air partition coefficients, such as bromomethane, is the rate at which the vapor is transferred to the blood by alveolar ventilation (Andersen 1981). The rate-limiting process of absorption for dermal exposure is passage through the stratum cornea, which can be represented by the permeability constant. Blood concentration measurements allow the input of both vapor inhalation and dermal vapor absorption integration when relating total delivered dose to biologic effects (McDougal et al. 1986).

Because nose-only systems limit exposure of the test substances to the respiratory tract and not the entire body, the amount of test material needed is considerably reduced. This feature facilitates testing highly toxic and/or limited-availability test substances. In addition, nose-only exposure units simplify test substance containment and subsequent cleanup and allow the chamber concentrations to be more easily and readily altered. Disadvantages of this system may include loss of material to the fur of the head, difficulty in obtaining a proper seal at the neck without impairing circulation, the possibility of restraint and handling induced stress of the animals, and the relatively limited number of animals that can be tested simultaneously. All of the previously mentioned disadvantages can be dealt with in a manner that makes this type of testing useful in safety evaluation programs. To ensure uniformity of exposure conditions on an animal-to-animal basis, a relatively large airflow is needed. For larger animals such as the dog and monkey, helmet exposures can be conducted. Pressure fluctuations in these systems may be great, and records of breathing patterns during exposure may be needed to accurately measure the exposure doses. In addition, the fitting at the neck must be comfortable and easy to adjust. Designs including both inflatable collars and thin rubber membranes have been used successfully.

A typical nose-only exposure unit employs an animal exposure cylinder, generally constructed from rigid plastic (or glass). This tube is connected to an enclosure or exposure chamber that allows introduction and evacuation of test atmospheres and contains sampling probes to determine test concentrations, particle size distributions, temperature, and humidity. Rodent holders are usually fabricated of plastic (polymethylmethacrylate, polycarbonate), aluminum, or stainless steel cylinders to conform to the general shape of the animals and are fitted with conical headpieces projecting into the plenum of the exposure chamber. Some nose-only systems minimize rebreathing of test atmospheres by attempting to have a constant flow of fresh test atmosphere directed onto the face of the animal while having a local exhaust near the nose, as shown previously in Figure 28.8. The animal holder needs to be of various sizes to accommodate rodents of differing sizes to minimize stress, provide careful support to minimize discomfort to the animal, and adequately ventilated to minimize heat retention within the tubes.

Both physical restraint and inadequate temperature control within the chamber can subject the test animals to additional stress. This seems to be especially true for inhalation developmental and/or reproductive studies. Pathological effects on the male reproductive system, independent of the inhaled test substance, have been reported in restrained male rats where inadequate temperature control occurred, leading to excessive body temperature (Brock et al. 1996). Inhalation developmental toxicity studies conducted with restrained pregnant rodents have produced slight increases in maternal toxicity and either slight (Miller and Chernoff 1995) or no (Tyl et al. 1994) increases in fetal anomalies when dams were restrained during the period of organogenesis. To minimize confinement-induced stress in inhalation developmental toxicity studies in mice, Dorman et al. (1996) utilized a rat restrainer tube to expose an unrestrained pregnant mouse, making essentially a whole-body exposure chamber for individual mice. Adaptation to the stress induced in rats and mice in nose-only inhalation tubes was examined. In naïve animals during the first hour of restraint, heart rate increased by 58 beats/min (BPM) (18.6%) in rats and by 174 BPM (32.3%) in mice, as compared to cage controls. Temperature increased by 2°C in mice and was unchanged in rats, compared to cage controls. Heart rate and temperature values remained within normal physiologic values during restraint. In rats, the response to restraint in nose-only holders was the same after 4 days regardless of whether the duration of restraint was increased gradually to 4 h/day or kept constant at 4 h/day. In mice, the group that was gradually adapted had a statistically significantly higher heart rate and temperature after 4 days than the fixed-duration adapted group. Rats and mice restrained for 4 h/day every day showed a gradual decrease in heart rate and temperature over time. Full adaptation to restraint required 14 days of fixed-duration daily restraint (Narciso et al. 2003).

Overall, the selection of the nose-only exposure mode can affect the outcome of some inhalation toxicity studies and represents a decision that investigators should properly control for in experimental design. Nonetheless, high-capacity nose-only exposure systems, such as those described by Cannon et al. (1983), have been used for various acute and subchronic

inhalation studies. A thorough description of the components used in this nose-only inhalation system, with details on automated collection methods for airflow regulation and test atmosphere analysis, was presented by Pauluhn (1994).

Using a directed-flow nose-only exposure system at flow rates close to the minute ventilation of the animal, it was possible to maintain desired concentrations. At an airflow rate of 2.5 times the animal's minute ventilation, the concentration of test substance in inhaled air was reduced less than 10% (Moss et al. 2006).

Design considerations of head-only units are identical to those of nose-only units. Mask designs represent a unique kind of nose-only exposure and usually are limited to relatively large animals. Masks for dogs (Bair et al. 1969), monkeys (Greenberg et al. 1977), ponies (Mauderly 1974), donkeys (Albert et al. 1974), chickens (Battista et al. 1973), and rats (Stavert et al. 1991) have been used successfully.

The use of intratracheal instillation as an alternative to exposure of animals by inhalation deserves some comment. Conditions exist in which the pulmonary effects of a substance cannot be easily evaluated by inhalation. Although for not entirely valid reasons such as space, time, and/or economics there may be decisions not to use inhalation as the route of test material exposure, but rather to use intratracheal instillation techniques to get the material directly into the respiratory tract. The reason for choosing intratracheal instillation over inhalation can also rest on lack of sufficient quantities of test material or on safety issues (extreme toxicity, flammability, explosivity). Using this method, the actual dose delivered to the lung of the experimental animal can be directly and precisely measured. This technique is inexpensive in that very small amounts of substance are needed (while expensive chambers, generating apparatus, and support personnel are avoided). Also, because the technique is contained and uses relatively little material, exposure hazards to laboratory workers are greatly reduced compared to that of an inhalation study. Finally, materials that are not readily respirable in rodents can be introduced to the lungs with this technique; notably, long fibers that can be inhaled by man but not by rodents can be tested via this route. The problem that limits the usefulness of intratracheal instillation as an exposure technique relative to inhalation is that the dose to the respiratory tissues can be variable and highly artificial and does not accurately reflect the lung distribution of a substance following inhalation exposure. Additionally, intratracheal instillation techniques focus on the lower respiratory tract and, as such, cannot evaluate responses that would occur in the nasopharyngeal region by inhalation exposure.

Intratracheal instillation involves a suspension of particles in a carrier liquid that is injected directly into the lumen of the trachea. By gravity, the fluid and particles flow into the areas of the lungs that cannot be entirely controlled. The carrier liquid is then rapidly absorbed into the pulmonary circulation, leaving the particles on the internal surfaces of the lung. This technique permits the introduction of a wide range of doses and substances to the lung in a short period of time. In larger animals, localized exposures to specific areas or lobes of the lung are possible, often allowing the contralateral lung to serve as a control (for nonsystemically acting agents). This technique was first applied by Kimura (1923), using rabbits and guinea pigs to look at the response to various coal tars. Early works have described in detail the methodologies found to be useful in the mouse (Nettesheim and Hammons 1971, Kouri et al. 1976), in the rat (Blair 1974), and in the hamster (Saffiotti et al. 1968, Brain et al. 1976). The procedures used in these studies are quite similar, with the main difference being the maximal amount of total liquid that can be used to deliver the test substance to the lung without harming the animal.

In small rodents, intratracheal instillation is accomplished by inserting a catheter or needle transorally through the mouth and epiglottis into the tracheal lumen. In larger species (including human), a fiber-optic bronchoscope can be used to more precisely visualize the instillation site. Because the animal must not move during the procedure, the choice of anesthetic is important, with short-acting materials that suppress reflexes for a minimal period of time being preferred. Physiologic saline is the vehicle most frequently used to suspend or solubilize the test substance, although even this may evoke a mild transient inflammatory response. Surfactants can be used to improve the suspension properties for dusts, but the surfactant effect(s) on the lungs needs to be evaluated. In addition, dosage volumes need to be adjusted for the body weight of the animal.

Although intratracheal instillation enables administration of large amounts and nonrespirable sizes of particulate matter that would otherwise not be able to gain access to the lung, more localized deposition of particle results. Indeed, the major obstacle for routine use of intratracheal instillation as a replacement for inhalation bioassays lies in the fact that the patterns of particle distribution in the lung following instillation are uneven and are unlike those resulting from inhalation. Particle deposition by inhalation is focal, that is, inhaled particles deposit at selected sites in the lung depending upon their size and breathing pattern. Brain et al. (1976) showed that intratracheal instillation of particles produced nonuniform deposition patterns, largely dependent on gravity acting on the instilled fluid. These investigators studied the distribution of particles labeled with ^{99}Tc in both rats and hamsters following either intratracheal instillation or aerosol inhalation. Particle distribution patterns in the lung following inhalation were distributed evenly within a given lobe; among lung lobes, most of the dust deposited in the apical lobes (Brody and Roe 1983). Pritchard et al. (1985) found that variability in the deposition of cerium oxide particles in rats within a specific lobe was considerably greater following instillation than inhalation, with little penetration of instilled particles to the peripheral lung. Similarly, greater peripheral lung loading was seen following inhalation of ferric oxide particles than following instillation (Dorries and Valberg 1992). In contrast, the distribution of both short and long glass fibers in rats was reportedly similar using either inhalation or

instillation (Henderson et al. 1995). More recently, uneven and patchy distribution was confirmed after intratracheal instillation of suspensions containing either submicrometer titanium dioxide (TiO_2) particles or nanosized primary TiO_2 particles when compared to intratracheal inhalation (Osier et al. 1997). An important issue of intratracheal instillation is the optimized timing of the instillation coordinated with the inspiration of the animal, for example, during expiration, the instilled volume may be expired completely.

Recently, intratracheal aspiration as a derivative of intratracheal instillation was introduced in which a droplet of particle suspension was placed onto the glottis while the nose of the animal was closed. When opening the nostrils, the droplet was accelerated and partially dispersed into the trachea during a high flow, gasp-like breath of the animal. Aspiration was compared to inhalation and intratracheal instillation using ^{99m}Tc radiolabeled nanosized sulfur colloids followed by gamma camera imaging using a pinhole collimator (Foster et al. 2001). The authors observed higher particle doses and higher 24 h retention in the lungs after instillation and aspiration compared to inhalation. Only after inhalation was the particle distribution in the lungs rather homogeneous. Yet they showed that the aspirated suspension volume critically determines the deposited dose and retention. In addition, cytometric analysis of the bronchoalveolar lavage fluid showed increased numbers of eosinophil and neutrophil granulocytes suggesting an inflammatory response of the peripheral lungs to contaminants on the glottis, which were flushed with the droplet during the high airflow inspiration. Similarly, a higher delivered dose was reported for SWCNTs, but a less even and patchy distribution was observed when compared to inhalation of aerosolized small agglomerates of SWCNT (Shvedova et al. 2008). While the results seem to be promising in mice, we found highly variable deposits of radiolabeled nanoparticles on the thoracic airway epithelium. Mucociliary cleared particle fractions varied from 15% to as much as 80%, as determined by gamma camera imaging during the next 24 h, although emphasis was made to perform the aspiration procedure as standardized as possible. Hence, this highly variable dose to the airways results in an inverse but also highly variable dose to the lung periphery, which hampers the advantage of aspiration in rats considerably.

Another aerosol delivery method utilizes a pressurized air jet to nebulize particle suspension directly through a tiny nozzle within the trachea. Yet air velocities required to disperse the liquid volume led to immediate impaction of the dispersed droplets right behind the nozzle. A standardized method was developed using 2 μm monodisperse.[111] In radiolabeled polystyrene particles, which were dispersed through a nozzle at the end of a bronchoscope placed two-thirds down into the trachea of beagle dogs (Kreyling and Wohland 2007). In all cases without any intrasubject and intersubject variabilities, the deposited particle bolus at the carina and first main bronchus contained more than 95% of the administered particles. Since the main canine bronchus is 10 mm in diameter, the quantitative droplet deposition adjacent to the nozzle within rodent tracheas of less than 2 mm diameter is also close to 100%. Yet the deposited liquid volume may flow down into the lungs when the animal is in an upright position. Finally, some companies make devices similar to those described above. For example, Penn-Century makes a microsprayer that delivers liquid aerosols from the tip of a tube inserted into the airways, as well as a dry powder insufflator, which can be used for nonliquid aerosols.

In summary, pulmonary effects of test substances, for reasons of space, time, and economics, along with nonavailability of sufficient quantities and/or sample tissues, cannot always be tested following inhalation exposures. Uses of intratracheal administration involve methodology that is simple and uses relatively little material so that risk to laboratories is much reduced (from an inhalation study). One can deliver relatively large amounts of material to the lung in a short period of time and with less variability than by inhalation.

Against these advantages, however, is the primary fact that amounts and sizes of particulate that would otherwise not be able to gain access to the lung can be delivered. This requires recognition when designing intratracheal instillation studies as they may lead to doses that can only be inhaled during prolonged time periods of days, weeks, and months. In addition, the dose rate of intratracheally instilled particles is almost high and can never compare to inhaled dose rates, which are several orders of magnitude lower. Furthermore, the patterns of particle distribution in the lung following instillation are uneven. The nonuniformity is partially random but represents systematic and reproducible regional differences. Another difference is that the instillation technique bypasses the upper respiratory tract. Problems can result from altering dosing rates and the use of differing suspending agents. Frequently, an optimal strategy is to do preliminary experiments by direct delivery to the lungs and then having explored clearance rates and biological responses, use this information to design an appropriate inhalation study.

Chamber Selection and Operation

Most inhalation experiments utilize dynamic exposure conditions. That is, the test atmosphere, comprising test substance diluted with fresh air, is continually replenished. Thus, the test atmosphere flows through the exposure chamber and is then exhausted. Once the generation apparatus is turned on, the concentration in the chamber rises to a theoretical equilibrium value, which is the ratio of the flow of the substance to the total flow in the chamber. The equation describing the concentration time curve is

$$C_t = \frac{f}{F\left[1 - e^{-(F/V)t}\right]} \tag{28.1}$$

where

C_t is the concentration after t minutes
f is the flow of substance
F is the total flow through the chamber
V is the chamber volume

Usually, this equation is converted to an expression that defines the time required to attain a given percentage of the equilibrium concentration ultimately attained:

$$t_x = K \times \frac{V}{F} \tag{28.2}$$

where

t_x is the time required to attain $x\%$ of the equilibrium concentration

K is a constant whose value depends on x

Most frequently, the concentration–time relationship is described by t_{99}, the time needed to attain 99% of the theoretical equilibrium concentration. For determination of t_{99}, $K = 4.605$. At this time point, the concentration in the chamber may be considered constant, assuming no changes in air or test substance supply rates. The concentration–time characteristics of a given chamber are described by the values of V and F, which are more descriptive than the outdated practice of giving air changes per hour (Silver 1946, MacFarland 1981).

Airflow to a chamber can vary from approximately 10 to 60 changes/h. This is understood as the addition and withdrawal of a volume of air equal to the volume of the chamber. Because added air mixes with that already present, a complete change of air has not occurred. The term air change is misleading, and the dynamics of mixing in inhalation chambers has been described by the statistical considerations first put forward by Silver (1946). As already discussed, a more descriptive term for chamber airflow is the t_{99}.

The duration of exposure is defined as the interval from the start of flow of test substance to the point where delivery is discontinued. The exposure is terminated by stopping the flow of substance to the atmosphere generator, which leads to the decline in the chamber concentration on an exponential curve that is the inverse of the rising curve (Figure 28.11). Animals are not removed from the chamber, nor are the chamber doors opened to observe the animals, until at least t_{99} min to allow sufficient time for the chamber contents to be fully eliminated. For longer-term exposures, the rising and falling section of the curves can be neglected, and the exposure profile becomes a square wave form. For short exposures, where exposure duration is less than $13 \times t_{99}$, the system

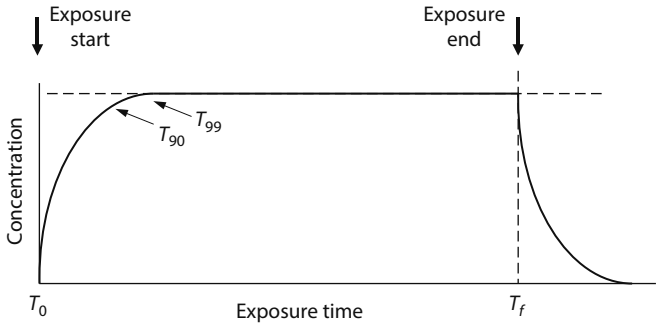

FIGURE 28.11 Concentration and time relationship in a dynamic exposure chamber.

should include an airlock mechanism or some other instant exposure/nonexposure mechanism (MacFarland 1976).

Chambers should be operated at a slight negative pressure (e.g., −20 to 200 Pa) with respect to room pressure to protect personnel against leaks in the system. Chamber pressure should be monitored continually, especially in older units to avoid the possibility of spatial or temporal concentration gradients. The distribution of the test substance within the exposure chamber is determined by taking repeated samples from different areas of the chamber in relation to a reference sampling location, using statistically valid sampling strategies. After homogeneous distribution of test substance within the chamber has been established, the actual concentration should be measured continuously or at least several times during the exposure. For exposures of 4–6 h duration, a common practice is to sample every 0.5 h (or at least hourly), although for regulatory purposes, much less frequent sampling (i.e., 2–4 times per exposure) may be acceptable; the frequency of sampling should be dictated by the temporal stability of the test atmosphere generation and airflow supply systems. Continuous readout monitoring and control instruments are especially useful in long-term studies, because they are capable of preventing concentration excursions when appropriate alarms are integrated into the system. Some type of alarm instrumentation can prevent many weeks or months of effort from being destroyed by sudden elevations in test substance concentration, which could even be lethal.

Inhalation chambers operated in a dynamic mode should have a reasonably uniform distribution of test substance to avoid differential animal exposures. Due to their comparatively higher diffusion rates, it is generally acknowledged that gas and vapor concentrations show less intrachamber variation than aerosols. Aerosols are also subject to size-dependent diffusion, impaction, and sedimentation losses, compounding the difficulty in maintaining uniform chamber concentrations. Furthermore, the uniformity of aerosol concentration may be reduced when animals are housed in the chamber since their body temperatures lead to convection flow, which may cause concentration variations. However, MacFarland (1983) calculated the percentage differences in concentrations between aerosols and gases/vapors and found little difference in the chamber uniformity between aerosols and gases/vapors. Examples from the literature concerning the percent variability from mean concentrations range from 0.7 to 18.0. Because variations exist in all chamber types and airflow control operating systems, the investigator is well advised to carefully characterize the exposure chamber spatial/temporal distribution of test substance under actual generation conditions to prevent concentration-gradient errors from complicating the study.

Control of the relative humidity, but more importantly the internal temperature, of inhalation chambers is crucial to the integrity and interpretation of animal inhalation studies. As already noted, elevated temperatures can alter animal physiology, affect metabolism and ventilation, and increase the rate and type of chemical interactions. Ideally, chamber loading (the total volume of animals in a chamber) should not

exceed 5% of the chamber volume to avoid heat-induced artifacts among test animals (Fraser et al. 1959). Coincidentally, chamber loading also affects the test substance equilibrium concentration in the exposure chamber. Silver (1946) reported, for example, that when the chamber loading exceeded 5%, excessive losses of test substance occurred, presumably by absorption to body surfaces. Temperature should be monitored continuously but at least regularly during the exposure. In some instances, such as when chamber loadings exceed this recommendation, chamber walls or inlet air may be cooled to maintain normal interior temperatures. Heat-balance studies with rats in stainless steel or glass chambers of equal size and using a room air intake of 100 L/min showed that the chamber walls were effective at removing approximately 90% of the animal body heat as compared with the heat loss through the airstream. If conducting studies in chambers with low airflow rates, heat transfer to the surrounding environment can be increased by painting the chambers, by attaching cooling coils to the chamber walls, or by directing air-conditioning ducts directly onto the chamber (Bernstein and Drew 1980). In addition, control of relative humidity is essential for proper heat balance in rodents. Although it is generally recommended that relative humidity should be controlled within relatively narrow limits (e.g., 40%–60%) to minimize adverse effects on feed consumption and behavior on study outcome (Rao 1986), recent work showed that rats tolerated humidity levels of either 3%, 40%, or 80% in repeated-exposure studies without effects on body weights, feed or water consumption, or respiratory tract histopathology (Pauluhn and Mohr 1999).

Administered Dose

The fundamental concept of dose (i.e., the amount of substance taken up by the test subjects) is not excluded from the domain of inhalation toxicology but continues to represent a major effort. Yet due to the difficulty in measuring individual respiratory parameters and the test substance's physical/chemical properties (two primary characteristics that affect the respiratory tract deposition of inhaled materials), the determination of the internalized dose is much more complex by inhalation compared to other exposure routes. Of the total amount of test material inhaled, a variable fraction may actually be deposited, absorbed, and reach target tissues. This absorbed fraction is, in turn, dependent on the local absorptive, metabolic, and clearance processes that may modify the chemical composition and/or its concentration of the inhaled substance along deposition sites in the respiratory tract. Although these processes are not easily determined and have restricted the ability of inhalation toxicologists to provide quantitative measures of inhaled dose, progress in the area of dose determination has evolved in the related areas of biomarkers and mathematical modeling. Increasingly, sophisticated models are being used to estimate toxicant concentrations in the blood and organs by treating the uptake, distribution, metabolism, and excretion of toxicants as a series of independent processes occurring at experimentally determined rates (Crapo et al. 1989).

The administered dose in inhalation studies is most often characterized in terms of the exposure conditions, that is, the exposure concentration and duration according to certain conventions. For example, "rats were exposed to x ppm (or x' mg/m^3) of substance y for 6 hours/day, 5 days/week for 13 weeks." For gases and vapors, concentration may be expressed on a volume basis (i.e., mole *x*/total moles, parts per million [ppm], or parts per billion [ppb]) or on a weight basis (milligrams per liter [mg/L] or milligrams per cubic meter [mg/m^3]). For solid or liquid aerosols, concentrations generally are expressed on a weight basis (milligrams per liter [mg/L]) or, for fibrous materials or nanosized UFP or ENP, on a number basis (number of fibers or particles per cubic centimeter [#/cm^3]). Furthermore, for fibrous aerosols, consideration should be given to expressing concentration on both a respirable mass (mg/m^3) and a particle count (fibers/cm^3) basis; with all UFP or ENP aerosols or some low-density fibers, the number count may be extremely high but the mass concentration may be very low.

A fundamental interrelationship exists for many inhaled substances between exposure concentration and time. Haber (1924), for example, determined that the response of an animal to a gas could be related to the product of the concentration and the exposure time. This relationship, known as Haber's law, states that the product of the concentration (C) and exposure time (T) required to produce a specific physiologic or toxicologic effect is equal to a constant, $C \times T = K$. The specific effect can be something other than death, but death is still a commonly applied end point. Haber's law has been used to predict response for exposure conditions that have not been described experimentally, for example, predicting the expected l h LC50 for a chemical substance where only 4 h data exist. There are short but finite time periods during which some end point may never be attained (i.e., death may not occur at practically attainable concentrations in short [e.g., 0.1, 1, or 10 min] time periods). At the other extreme, some exposure levels exist where a substance does not produce measurably adverse effects despite continuous, prolonged exposures. For these reasons, Haber's law does not apply to all substances but generally is applicable when extrapolated to $C \times T$ values that differ by a factor of about 3–4 for a given $C \times T$ product. Rinehart and Hatch (1964) and Kelly et al. (1981) have shown, for example, that Haber's law applies for phosgene gas and titanium tetrachloride aerosol when evaluated for respiratory rate and lethality end points, respectively. Gelzleichter et al. (1992) also showed that Haber's law applied for nitrogen dioxide or ozone in rats exposed for 3 days over a fourfold range of exposure concentrations. However, if rats were exposed to mixtures of ozone and nitrogen dioxide, lung damage was found to be related to the peak concentration rather than the cumulative dose of the gases: this observation was related to the synergistic, adverse effects of the mixture of these two gases. A quantitative assessment of the temporal and concentration relationship for lethality with several irritant and systematically active substances was evaluated by ten Berge et al. (1986). The authors reported that for the substances evaluated, the $C \times T$

relationship does not always represent the response data over the exposure periods reported. They reported that $C^n \times T$, where the exponent n may vary from 0.8 to 3.5, is often a better predictor of mortality. However, work by Pauluhn et al. (1996), which explains $C \times T$ relationships from acute inhalation testing for product classification purposes suggests that 4 h exposure data provide essentially the same projected acute lethality value as would 1 h testing; where only 4 h data were available, a default value of 4 should be used for conversion of 4 h LC50 values to 1 h LC50 values, independent of the physical state of the test substance.

With sensory irritation as the end point, varying the exposure concentration has a proportionately greater effect than does changing exposure duration. Thus, with the exception of calcium oxide, the other four test substances (chlorine, ammonia, formaldehyde, and 1-octane) did not follow Haber's law (Shusterman et al. 2006).

The internalized dose is related to the atmospheric concentration of the test substance, the duration of exposure, the individual's respiratory volume and frequency, and the deposition efficiency within the individual. These parameters are related according to the following general equation:

$$D = E_d V_m C T \tag{28.3}$$

where

D is the deposited dose (mg)
E_d is the deposition efficiency for the substance within the respiratory tract
V_m is the minute volume (L/min)
C is the concentration of the test substance (mg/L)
T is the time of exposure (min)

The use of this equation presupposes that the previously mentioned parameters are well characterized for the species and test substance under investigation and a given set of experimental conditions. In practice, such data are not generally available, especially for gases or vapors and other methods of dose determination have been used. For a series of vapors, the internalized dose has been determined by measuring the net decrease in test substance concentration in the exhaled air compared to the concentration in the inhaled air (Stott and McKenna 1984); similar methodology has been used to measure disposition of ultrafine aerosols in the human respiratory tract. In a system designed to validate a rat-based physiologically based pharmacokinetic (PBPK) model of nasal extraction and metabolism of vinyl acetate (a water-soluble, reactive vapor), Hinderliter et al. (2005) exposed human volunteers to radiolabeled vinyl acetate via nasal inhalation. Measurements of vinyl acetate and its metabolite, acetaldehyde, concentrations in nasal airways compared favorably with the model predictions providing support for human risk assessments conducted for workplace exposures.

Alternative methods to estimate the deposited dose have included chemical assays for the total amount of test substance or its metabolite in excreta, a useful technique for radioactively labeled materials. Measurement of metabolite levels and DNA or protein adducts in biologic fluids or tissues represents another means of assessing substance exposure and internalized dose (Lucier et al. 1989, Dahl et al. 1991, Bond et al. 1992). An advantage of measuring DNA adducts in evaluating dose–response relationships is the comparatively higher sensitivity associated with the measurement of such biomarkers. In contrast to the comparatively high exposure concentrations employed in cancer bioassay studies, changes in the amount of metabolite DNA adducts may be measured at much lower exposure concentrations compared to those associated with changes in tumor incidences. This method provides a better estimation of the shape of the dose–response curve at low concentrations, provided information is available to address the stability, extraction efficiency, and accuracy of the methods used to measure DNA adducts. For dose estimates of radiation-induced health effects, the International Commission for Radiological Protection (ICRP) provided a large compendium on the human respiratory tract model considering particle deposition of inhaled aerosols, subsequent biokinetics of radionuclides, and finally their effects in the organ of intake as well as target organs in the body (ICRP 1994).

The need for quantifying the internalized dose, particularly as it relates to human risk assessment, has encouraged research in the area of pharmacokinetic (PK) modeling (Andersen 1987). The use of PK or biokinetic modeling is finding wide acceptance among risk assessors and regulatory agencies for predicting the dose of a toxicant to a given tissue across species under various exposure conditions. This approach describes the kinetic relationships between physiologic factors (such as organ and body weights, respiratory rate, and blood flow), biochemical factors (such as substrate affinity for an enzyme and reaction velocity), and physicochemical factors (such as the extent of substance partitioning into air, blood, or tissue) on the disposition of that substance within the body. PK and biokinetic modeling is based on a thorough understanding of these processes in an experimental animal and then extrapolating these parameters, with appropriate validation in experimental animals, to predict target tissue doses and toxic effects in humans. Validated PK models, using accepted physiological values, may then be useful in predicting expected tissue levels of a substance (and thus organ toxicity) under various exposure regimens. Indeed, PK models have been developed to describe the expected tissue doses of substances in rodents or humans for vapors such as butadiene (Himmelstein et al. 1997), benzene (Roy and Georgopoulos 1998), halogenated hydrocarbons (Vinegar et al. 1998), butoxyethanol (Lee et al. 1998), as well as particulate matter such as powdered fire suppressants (Kimmell et al. 1998) or diesel soot, titanium dioxide (Stober et al. 1990), quartz dust (Stober 1999), formaldehyde (Kimbell 1994), vinyl acetate (Plowchalk et al. 1997), carbon tetrachloride (el-Masri et al. 1996), and radionuclides contained in aerosol particles (ICRP 1994). When PK modeling is employed, due caution must be exercised with respect to the applicability of the animal model and experimental techniques used to human values in order for the data to be useful in human health risk assessment.

In Vitro Toxicity Test Methods

The focus of toxicology has shifted somewhat, since the mid-1980s, from whole-animal toxicity tests to alternative in vitro toxicity methods as a result of reducing and even banning the use of experimental animals (Silbergeld 1998, Gad 2000, Bakand et al. 2005, European commission 2013). In vitro toxicology describes a field of study that applies to technology using isolated organs, tissues, and cell culture to study the toxic effects of substances (Hayes and Markovic 1999). The development of in vitro toxicity test methods has been influenced by a variety of socioeconomic factors.

The ethical/technical bases for continued use of animals in research balance a reduction in the number of experimental animals, refinement of test protocols to minimize suffering, and replacement of current animal tests with appropriate in vitro tests opposite to the need for valid, toxicological data (Verheugen 2006). The necessity of determination of the potential toxic effects of a large number of substances and formulations has sparked the need for rapid, sensitive, and specific test methods. At present, in vitro methods cover a broad range of techniques and models, and a standardized battery of in vitro tests can be used for assessing acute local and systemic toxicity as long as they are validated.

A practical strategy for incorporating the concepts of in vitro approaches for inhalation toxicity testing has been proposed by ECVAM (EURL ECVAM 2013). This strategy uses existing literature, evaluating the physicochemical characteristics of test substances, and predicting potential toxic effects based on structure–activity relationships (SARs). Physicochemical characteristics of substances, such as molecular structure, solubility, vapor pressure, pH sensitivity, electrophilicity, and chemical reactivity, are important properties that may provide critical information for hazard identification and toxicity prediction (Gad 2000, Faustman and Omenn 2001).

In vitro exposure techniques include direct exposure to the test substance itself, exposure to collected air samples containing the substance(s) of interest, submerged exposure conditions, intermittent exposure (gases only), or continuous direct exposure (gases).

In vitro screening tests may identify cellular responses allowing estimation of test substance toxic potency. Based on the obtained result, in vitro tests may be followed by a second phase using isolated cells specific to the target organs, for example, nasal olfactory cells, fibroblasts, or mesothelial cells (Lambre et al. 1996). Freshly isolated cells maintained in suitable culture media that can mimic biotransformation activities and cellular functions comparable to the in vivo environment are preferred to long-term cultures or cell lines that may differentiate, lose their organ-specific functions, and lack the enzyme systems required for biotransformation (Barile 1994, Lambre et al. 1996).

The effects of air contaminants have been studied using several in vitro exposure techniques. Most techniques have involved studies of isolated particulate substances added to culture medium (Nadeau et al. 1995, Becker et al. 2002). Although this exposure condition may be adequate for soluble test materials, this may not simulate in vivo exposure conditions of dose and dose rate from airborne aerosols. Moreover, such techniques may often ignore the effects of particle size, which is crucial for in vivo toxicity testing. Some in vitro research has investigated the effects of suspended and extracted particles from atmospheric aerosols (Hamers et al. 2000, Glowala et al. 2002) or cigarette smoke condensate (McKarns et al. 2000, Putnam et al. 2002).

The toxic effects of sulfuric acid aerosols on human airway epithelial cells (Chen et al. 1993) and the effects of ozone on cultures of primate bronchial epithelial cells (Jabbour et al. 1998) or human bronchial cells (Mogel et al. 1998) have been studied using cells grown on collagen-coated membranes. Toxic effects of individual airborne substances such as ozone and nitrogen dioxide, and complex mixtures such as diesel motor exhaust (Knebel et al. 2002) and cigarette smoke (Aufderheide et al. 2003), were studied using cultured human lung cells on porous membranes permeable to culture media. A direct exposure technique at the air–liquid interface offers a reproducible contact between chemically and physically unmodified airborne contaminants and target cells, and technically may reflect more closely inhalation exposure in vivo (Knebel et al. 2002, Paur 2011, Aufderheide et al. 2003). In fact, when studying the effects of deposited aerosol particles on the epithelia of the respiratory tract submersed cell test systems, those are limited as the cells may have undergone functional changes under submersion and, in addition, the submersed particles may have undergone substantial physicochemical changes in the cell media such that results obtained from submersed exposure systems may no longer be valid and comparable to the in vivo exposure as discussed recently (Paur et al. 2011). Hence, test systems utilizing an air–liquid interface of epithelial cells can be exposed under more physiological conditions and results are likely to provide better information.

An important principle of toxicology is that all materials are toxic, if exposure occurs in sufficient quantities (Timbrell 1998). Most commonly, this principle is quoted as phrased by Paracelsus (CH 1493–1541): "All things are poison and nothing is without poison, only the dose permits something not to be poisonous." This fundamental toxicology principle implies that substances with a low hazard generally pose a low risk. If, however, there is a high enough exposure of these low hazard substances, then even these substances can be harmful, or even fatal. And, of course, the opposite can also occur: high hazard but relative low exposure also results in a low risk.

A very important aspect is the identification of the most relevant dose metric for particle toxicity (Schmid et al. 2009, Grass et al. 2010). While the common dose metric for micron-sized particles is their mass, it becomes much more challenging in the cases of UFP or ENP. Hence, it is quite obvious that a single-dose parameter (e.g., number, mass, or surface area) is not likely to adequately describe the toxic effects of any type of nanoparticle. While particle mass is likely to be a reasonable dose metric for completely soluble or biodegradable nanoparticles, (partially) inert or nonbiodegradable nanoparticles reside for an extended period of time in the tissue as

particulate matter interacting with the biological environment via the surface–tissue interface. This is reflected in the mounting evidence that surface area, and not mass or number, best predicts the toxic response of numerous types of nanoparticles (Oberdorster et al. 2007, Stoeger et al. 2007, Donaldson et al. 2008, Stoeger et al. 2009). However, it is important to note that while surface area may be a very relevant contributor to the dosimetry for insoluble, nonbiodegradable particles, there are also other important properties for predicting the toxicity of nanoparticles; for example, frustrated phagocytosis is encountered for rigid, nonsoluble fibers larger than about 10 μm (e.g., asbestos and CNTs) in the lungs (Poland et al. 2008). A more detailed discussion of the effect of the physicochemical properties of nanoparticles on the dose definition has recently been presented by Grass et al. (2010).

The key point for nanotoxicologists is that for submerged in vitro cell exposure systems with standard media heights of one or more millimeters above the cell layer, the theoretical transport rates by diffusion, sedimentation, and thermal convection are sufficiently different between particles of different sizes and different densities in different test cavities and between materials with different agglomeration states, that large differences in the amount of particles reaching the cells in a given time period (cellular dose) are likely, and that there is no simple relationship between particle characteristics and the amount of particles reaching the cells. That is, the exposure–dose relationship is complex. For example, despite concluding that nominal media concentrations (NMCs) were an appropriate metric of dose in vitro, Lison et al. (2008) showed no clear relationship between NMC and cellular dose for 35 nm amorphous silica. More important, perhaps, is the fact that measures of exposure (media concentrations) may misrepresent dose to the cell by many orders of magnitude when viewed across particle size (Limbach et al. 2005, Teeguarden et al. 2007). This can clearly be established based on principles of particle motion in liquids that have been well understood for more than 100 years (Einstein 1905, Dusenberry 2009). In fact, based on theoretical work on the diffusion and sedimentation of particles in fluids by Mason and Weaver (1924), Hinderliter and coworkers (2010) developed an in vitro sedimentation, diffusion, and dosimetry model (ISDD) for nanoparticle transport in cell culture media. While this model had to make estimates on the gravitational density of the nanoparticles that may agglomerate or absorb proteins onto their surfaces, Cohen et al. (2013) developed a rather simple method to measure the apparent density of the tested nanoparticles in the culture medium which improved the prediction of nanoparticle transport in the culture medium considerably. Based on this model, Figure 28.12 shows the transport time (min) of solid, non-agglomerated gold nanospheres for a 1 mm distance.

Surprisingly, this fact has received little attention in the literature, where the focus seems to be predominantly on the suitability of assays, cell types, and methods of characterization (Doak et al. 2009, Donaldson 2009, Kroll et al. 2009, Marquis et al. 2009, Park et al. 2009, Stone et al. 2009).

As a result, for in vitro studies, a clear distinction should be made between exposure and dose metrics for nanomaterials. NMCs (μg/mL, SA/mL, #/mL) and their derivatives most commonly used in in vitro studies are *not* measures of dose; they are measures of exposure and do not accurately reflect the amount of material coming in contact with the cells. Processes such as diffusion, sedimentation, and perhaps convection, all of which are dependent on the size, shape, and density of the nanoparticles, influence the relationship between the nanoparticles in solution above cells and nanoparticles reaching the cells (Limbach et al. 2005, Teeguarden et al. 2007), the latter being a measure of nanoparticle dose. The general comfort in using these exposure metrics, rather than

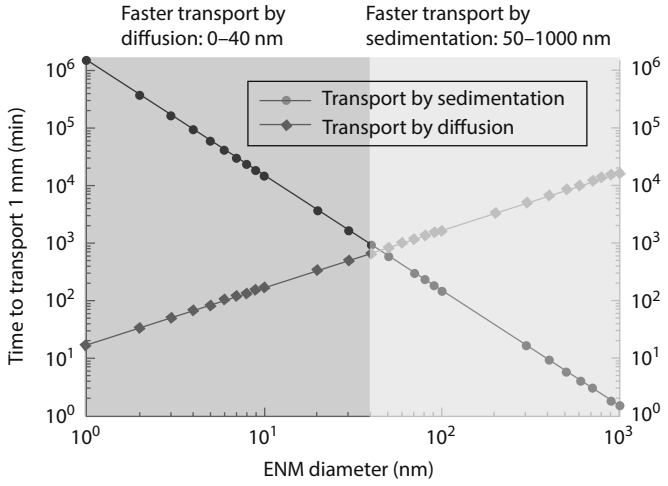

FIGURE 28.12 Impact of particle diameter on the transport in in vitro cell culture systems. The theoretical time to transport non-agglomerating gold nanospheres of known density over a distance of 1mm is plotted against particle diameter, demonstrating a clear size-dependency of diffusion and sedimentation. Nanoparticles ≤40 nm in diameter are primarily driven by diffusion, while nanoparticles >40 nm are primarily driven by sedimentation. (From Cohen, J. and Demokritou, P., Towards accurate and relevant dosimetry for in-vitro nanotoxicology, in *Nanoparticles in the Lung*, Tsuda, A. and Gehr, P. eds., in press.)

dose metrics, is misplaced because there is no justifiable expectation that in vitro exposure and dose metrics consistently have a direct relationship.

In this regard, it is instructive to consider dose levels in terms of nanoparticles per cell. For a number concentration of $3 \times 10^4/cm^3$ in ambient air, whereof almost 100% (80%–90%) can be considered nanoparticles (mobility diameter smaller than 100 nm [Kreyling et al. 2003]), about 2.3×10^{11} nanoparticles are deposited onto the alveolar epithelium per day. Assuming that the alveolar epithelium consists of 2×10^{10} epithelial type I cells, 3×10^{10} epithelial type II cells, and 6×10^9 alveolar macrophages (Stone et al. 1992), about 10 nanoparticles per cell will be deposited daily presuming a uniform deposition density per alveolar surface area (which is not unrealistic since nanoparticles deposit due to their diffusional properties). This rather low value needs to be kept in mind when considering doses of tens of μg per one million incubated cells, which is several orders of magnitude higher than a realistic daily dose of inhaled and deposited nanoparticles.

Air–Liquid Interface of Cell Culture Systems

Early versions of modern ALI cell culture techniques were introduced in the 1970s (Voisin et al. 1975, 1977a,b). As schematically shown in Figure 28.12, the essential aspects for in vitro exposure devices mimicking realistic inhalation exposure conditions as found in the lung are (1) complex pulmonary cell systems, which can be cultivated for at least several hours at the ALI, (2) direct contact between the cultivated cells and the inhalable substances without interfering medium, (3) uniform exposure of the entire cell layer, (4) temperature and humidity conditioning of the air to maintain cell integrity ($T \sim 37°C$; $RH > 85\%$), and (5) precise control of the pollutant levels (Rasmussen 1984, Aufderheide 2005, 2008) for accurate dosimetry.

A variety of such ALI cell exposure systems have been described in the literature (Massey et al. 1998, Aufderheide and Mohr 1999, 2000, Fukano et al. 2004, Aufderheide 2005, Bitterle et al. 2006, Mulhopt et al. 2008, BeruBe et al. 2009). While most of them rely on diffusion and/or gravitational settling as deposition mechanisms, some exposure systems have been introduced utilizing electrostatic deposition for bipolarly or unipolarly charged particles (Savi et al. 2008, Stevens et al. 2008).

The majority of studies are performed with monocultures; however, recent publications have shown that cocultures using a combination of different cell types have an influence on the observed cellular response (Lehmann et al. 2009). Recently, a triple cell coculture in vitro model of the human airway wall was developed to study the cellular interplay and the response of epithelial cells, human blood monocyte–derived macrophages, and dendritic cells to particles (Rothen-Rutishauser et al. 2005, 2008, Blank et al. 2007, Rothen-Rutishauser 2007). In this model, monolayers of two different epithelial cell lines, A549 (Lieber et al. 1976) and 16HBE14o epithelia (Forbes 2000), were grown on a microporous membrane in a two-chamber system. After isolation and differentiation of human blood–derived monocytes into macrophages and dendritic cells (see also paragraph *primary cell cultures*), they were added at the apical and basal sides of the epithelium, respectively. After the triple cell coculture was established, cell densities of macrophages and dendritic cells within the culture were quantified using the specific surface markers CD14 and CD86 for the labeling of macrophages and dendritic cells, respectively, and the quantitative occurrence of macrophages and dendritic cells resembled very closely the in vivo situation (Blank et al. 2007). After its thorough evaluation, this model was exposed to particles (either airborne or suspended in medium) of different materials (polystyrene, titanium dioxide, gold) and of different sizes (≤1μm) (Blank et al. 2007, Rothen-Rutishauser 2007, Rothen-Rutishauser et al. 2007, 2008, Brandenberger et al. 2010). Translocation and cellular localization of particles were studied, as well as the effects of particles on cellular interplay and signaling. Recent results showed that dendritic cells and macrophages collaborate as sentinels against fine polystyrene particles (1 μm in diameter) by building a transepithelial interdigitating network of cell processes (Blank et al. 2007). The translocation of nanoparticles into the different cell types, however, is different compared to their larger particle counterparts (Rothen-Rutishauser et al. 2007).

In that respect, the use of air–liquid exposure systems has the great advantage that such overdosing of cells of the respiratory epithelia is impossible since the nanoparticle deposition follows the same rules of aerosol physics as nanoparticle deposition in the alveolar region during normal breathing.

Regardless of the techniques employed, before in vitro methods can be formally used in lieu of traditional inhalation testing protocols for use in hazard classification, labeling, or risk assessment, validation efforts must be initiated to ensure the approaches, results, and conclusions reached from such techniques are applicable to and consistent with the objectives of international testing guidelines.

DEPOSITION, CLEARANCE, AND RETENTION OF INHALED SUBSTANCES

Gases and Vapors

Gases and vapors share a common physical property of interest to the inhalation toxicologist; both can be present in the gas phase under ambient testing conditions. Gases, by definition, exist in the gaseous state at standard temperature and pressure, while vapors represent the gas-phase components from substances that are solid or liquid at standard temperature and pressure. As the temperature increases, the amount of gas-phase components (represented by its vapor pressure) from a liquid will increase. Thus, liquids with higher vapor pressure will have a greater amount (concentration) of molecules in the gas phase relative to those with lower vapor pressure. For the inhalation toxicologist, liquid- or solid-phase test substances present a special challenge since test atmospheres may exist in both gas and solid/liquid forms, necessitating consideration of their different depositional, clearance, analytical, and biological response characteristics.

Inhaled gases and vapors can be absorbed throughout the respiratory tract to produce either local injury or systemic toxicity. Absorption depends largely on the physiochemical characteristics (e.g., concentration, water solubility, partition coefficient) of the inhaled substance and physiologic characteristics of the respiratory tract (e.g., airflow, respiratory rate, tissue perfusion, local metabolism).

The net driving force for absorption of inhaled gases or vapors is diffusion, the net movement of molecules down a concentration gradient, from regions of high molecule concentrations to low concentration. Substance absorption into tissues continues until the vapor concentrations in the air space and tissue are the same. At this point, the system is at equilibrium and no further transport of substance occurs. However, substance absorption into tissues can continue if the absorbed vapor is removed by transport into the bloodstream, metabolism to a different chemical or reaction with tissue macromolecules. These processes serve to lower the substance concentrations in the tissue so that further diffusion into the tissue may again proceed. Conversely, once the vapor concentration is higher in tissue than the inspired air, the net diffusive force is external, that is, from tissue to air. Passive diffusion is the mode by which carbon dioxide, a byproduct of aerobic metabolism, is conducted from the tissue, to the bloodstream, to the alveolar air space and ultimately removed in the expired breath.

Inhaled gases or vapors may be absorbed directly within the nasal cavity. While this spares the lung from direct exposure, the nose is consequently exposed to high, potentially injurious concentrations of inhaled substances. Vapors may be either physically absorbed within nasal tissues, a reversible process driven in part by the relative solubility of the vapor in air or tissue, or irreversibly bound to tissue components. Vapors highly soluble in aqueous solutions, such as the mucus covering the epithelial surface of the upper respiratory tract, generally tend to be absorbed within these regions. Highly water-soluble substances, such as acetone, methanol, hydrogen fluoride, and propylene glycol monomethylether, are essentially completely absorbed in the nose (Morris and Smith 1982, Stott and McKenna 1984, Morris and Cavanagh 1986). In contrast, gases or vapors with low water solubility, such as nitrogen dioxide or methylene chloride, are not well absorbed in the upper respiratory tract but are absorbed deeper in the respiratory tract (Chang et al. 1986, Morris 1990). These generalizations oversimplify nasal absorption of vapors, but improvements in regional airflow and physiologic parameter measurement can allow deposition to be extrapolated from animal to human results. Physiochemical and physiological parameters (diffusivity, tissue–air partition coefficient, chemical reactivity, metabolism) have been incorporated into computational fluid dynamic models of the rodent and human nose to predict species-dependent nasal deposition of vapor (Frederick et al. 2001); the results suggest that good agreement between rats and humans was attained with either one- or multi-tissue compartment models. Additional determinants of vapor absorption are the upper respiratory tract vascular blood flow and tissue metabolism or binding (Stott and McKenna 1984, Morris 1990). Irreversible binding to nasal tissues may occur if the inhaled vapor is reactive or is metabolized within nasal epithelium, with subsequent formation of covalent bonds with tissue macromolecules. Such reactivity reduces the substance concentration in tissues and facilitates further diffusion and absorption.

Vapors with low chemical reactivity and water solubility generally bypass the nasal cavity and are conducted into the conductive airways. Limited absorption occurs in the conducting airways, and since gas exchange does not occur here, the conducting airways represent a respiratory dead space amounting to approximately 30% of the resting tidal volume (i.e., about 150 mL in humans). Beyond the conducting airways, inhaled substances enter the alveolar (gas exchange) region and diffuse across very thin epithelial and endothelial membranes (typically 0.1 μm thick) into the tissue or blood.

Aerosols

Deposition is the process that determines the fraction of the inspired particles that is caught in the respiratory tract and thus fails to exit with expired air. Deposited dose equals the amount of material inhaled multiplied by the fraction of material that deposits. All particles that touch a surface are assumed to deposit at the site of initial contact. Distinct physical mechanisms operate on inspired particles to move them across streamlines of air and toward the surface of the respiratory tract; these are gravitational sedimentation, inertia, Brownian diffusion, and electrostatic forces. Which mechanisms contribute to the deposition of a specific particle depends on the particle's aerodynamic and physicochemical characteristics, the subject's breathing pattern, the geometry of the respiratory tract, and the flow and mixing pattern of the aerosol. For most aerosols, the first three mechanisms are most important. Detailed treatments on particle deposition are available (Lippmann 1977, Brain and Valberg 1979, Heyder et al. 1980, Raabe 1982, Agnew 1984, Stuart 1984, Stahlhofen et al. 1989, Gerrity 1990), as are comprehensive treatises on the physics of aerosol behavior (Davies 1966, Friedlander 1977, Hinds 1982, Reist 1984, Hesketh 1986, Fuchs 1989, Willeke 1993).

Aerodynamic equivalent diameter: The transport and deposition of a particle larger than 1 μm in the respiratory system are largely determined by aerodynamic characteristics: particle size, density, and shape plus gas velocity (Heyder 1982). A sphere of 3 μm diameter with a density of 4 g/cm^3 behaves aerodynamically the same as a 6 μm sphere with a density of 1 g/cm^3. Such particles may be compared by their aerodynamic equivalent diameter (d_{ae}). The aerodynamic equivalent diameter is the diameter of the unit-density (1 g/cm^3) sphere that has the same gravitational settling velocity in air as the particle in question. Aerodynamic diameter is proportional to $d_p\rho^{1/2}$, where d_p is the geometric particle diameter and ρ is the particle density.

Particle size and size distribution: As mentioned earlier, a major factor governing the effectiveness of deposition mechanisms is the size of the inspired particles. The importance

TABLE 28.4
Total and Regional Deposition Fraction of Stable Unit-Density Spheres in the Human Respiratory Tract during Oral Breathing from FRC at Two Flow Rates (Q) and Tidal Volumes (V)

[a] The airway and acinar region designations are based on fast- and slow-clearing compartments, respectively.

of particle size is seen in Table 28.4, which lists the total and regional deposition fractions as a function of particle size in three healthy subjects. Regional deposition fraction is the fraction of the total inhaled mass that deposits in a defined region. For deposition studies, the typical respiratory tract regions are the oropharynx, nose, larynx, central airways, peripheral airways, and acini. Depending on particle size, total deposition fraction is similarly sensitive (Heyder et al. 1986). As discussed later, proper selection of particle size is one way to target particles to a desired lung region.

In Table 28.4, one can compare the particle size corresponding to the highest deposition fraction for each lung compartment. It can be seen how, during oral breathing, the larynx and airways act as sequential upstream filters for the acini. The larynx, which collects particles by impaction, consistently removes more particles from the airways. The laryngeal deposition fraction maximum is at a d_{ae} greater than 15 μm, since impaction efficiency increases with increasing d_{ae}. For the airways, which collect particles by impaction and sedimentation, the deposition maximum is at a d_{ae} of 7–8 μm. Larger particles are removed upstream in the larynx, while smaller particles have lower impaction and sedimentation efficiencies. For the acini, which collect particles by sedimentation and diffusion, there are actually two maxima. One maximum occurs at a d_{ae} of 3–4 μm. Again, larger particles are removed upstream in the larynx and airways, while smaller particles have lower sedimentation efficiencies. The other maximum occurs at d_{ae} less than 0.006 μm, since diffusional displacement increases with decreasing particle size. A deposition fraction minimum exists at a d_{ae} of 0.4 μm, the particle size with the lowest combined settling and diffusional displacements (see Table 28.5).

Our ability to estimate deposition fraction on the basis of particle size is confounded by the fact that most aerosols are polydisperse. Figure 28.13 shows typical size distributions for polydisperse particles produced by different mechanisms. Diu and Yu (1983) found that increasing polydispersity increases the deposition fraction for aerosols with diameters between 0.04 and 2 μm and decreases the deposition fraction for aerosols with diameters outside this range. Thus, the overall effect of increasing polydispersity is to decrease the dependency of deposition fraction on particle size.

Hygroscopicity and evaporation: Many types of particles undergo size changes with time. Water droplets shrink through evaporation, while hygroscopic droplets, such as NaCl particles, may undergo hygroscopic growth, especially as the relative humidity nears 100% (Cinkotai 1971, Ferron 1977, Ferron et al. 1988a). Since the relative humidity in the lungs beyond the upper airways is 99.5% (Ferron et al. 1988a), hygroscopicity can substantially affect particle size and deposition fraction.

Fibers

A special type of aerosol, and one of particular significance to human health, is fibers, which are particles with an elongated shape. Because of the association of naturally occurring (e.g., asbestos and erionite) and man-made synthetic fibers with the development of pulmonary fibrosis and carcinogenesis in humans (IPCS 1986), interest in the hazards of inhaled fibers is heightened. Major differences in the nature and persistence of lung injury have been identified based on the fiber composition, fiber durability (a factor determining biologic persistence in the lung), fiber size (another factor governing fiber penetration and reactivity into the lung), and fiber exposure concentration.

For the purposes of describing the physical dimensions of fibers of toxicological concern, general characteristics of fibers relating size with respiratory tract toxicity have emerged from both animal and occupational exposure studies. From the animal studies, a variety of fiber types and dimensions have been instilled or injected into the pleura or abdominal cavities (Stanton and Wrench 1972, Wagner et al. 1973, Davis 1974, Pott 1978). Although these methods of fiber introduction into the body are not representative of normal exposure pathways both in terms of the rate and location of fiber deposition and quantitative aspects of the cellular response, this early research provided fundamental insights into the physical bases for the biological reactivity of fibers. Based on this work, a general relationship between the fiber dimension and lung response emerged. Notably, Stanton and Wrench found that intrapleural sarcomas were likely, especially if the implanted fibers were >8 μm in length and <1.5 μm diameter (Stanton and Wrench 1972). In contrast, nonfibrous preparations of these same materials evoked a much less severe pulmonary response (Wright and Kuschner 1977). Walton has suggested that asbestos fibers with sizes of >5–10 μm in length and diameters of <1.5–2 μm with an aspect ratio (i.e., length-to-width ratio) of >5 are most hazardous (Walton 1982). A considerable body of evidence has accumulated supporting the hypothesis that especially long and thin fibers present the greatest health hazard. Recognizing that there aren't necessarily clear distinctions between fiber dimension

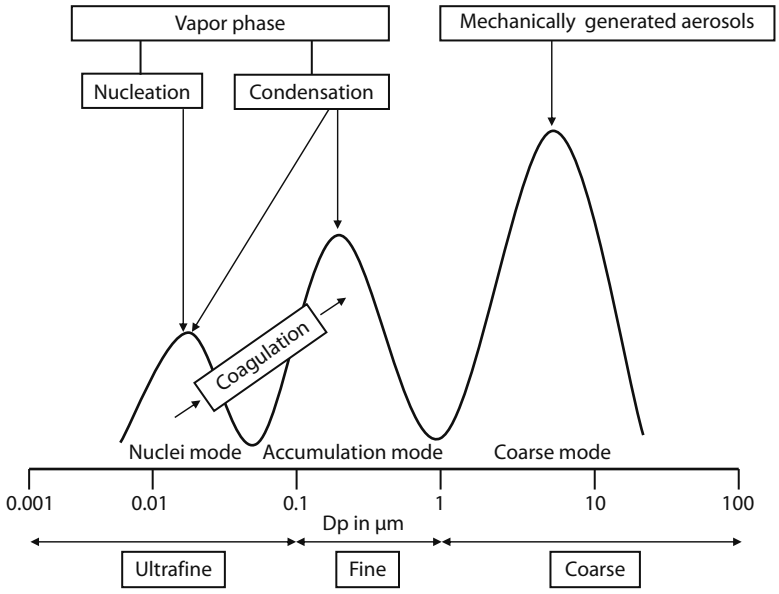

FIGURE 28.13 Particle size regimes and aerosol formation mechanisms. (Adapted from Whitby, 1978; Whitby et al., 1976.)

and pathogenicity, the U.S. Environmental Protection Agency (EPA) has defined a fiber as a particle with a length of >5 μm with an aspect ratio of at least 3 (EPA 1986). In recognition of the higher hazard of the smaller-diameter fibers, the World Health Organization has also stipulated a diameter of <3 μm (WHO 1985) in their fiber definition.

Fiber diameter, length, and shape all influence lung fiber deposition and thus potential tissue injury. Fiber diameter is recognized as the most important factor in determining fiber respirability; the thinner the fiber, the more respirable and penetrating it becomes for the lung. The probability of fiber impaction and sedimentation in the respiratory tract is governed by the aerodynamic diameters of the fibers, which are approximately three times their physical diameter (Timbrell 1965, Stober et al. 1970). Thus, a fiber with a physical diameter of about 3.5 μm will behave aerodynamically as a spherical particle of about 10 μm diameter, a size considered the upper limit of alveolar deposition. Fibers that are very thin are more likely to reach alveoli than larger-diameter fibers. In humans, the upper limit for aerosol deposition in the lung is considered around 10 μm in diameter, so that fibers with actual diameters exceeding about 3 μm are considered to be nonrespirable; conversely, fibers with diameters under 3 μm but that are very long (50–100 μm) are highly respirable. Timbrell and Skidmore (1970) showed that finite limits exist for fiber respirability so that fibers with lengths exceeding about 200 μm and diameters greater than about 3 μm would not penetrate the airways to deposit in distal alveoli to a significant amount. Empirical observations of fiber deposition are supported by modeled predictions of alveolar deposition in rats and humans (Dai and Yu 1998). In their studies, they found that alveolar deposition curves were similar in both species but maximal at an aerodynamic diameter of 2–3 μm in rats (15% alveolar deposition) and ~4 μm (about 30% alveolar deposition) in humans. Essentially no alveolar deposition would occur in humans at ~10 μm aerodynamic diameter, while for rats, it would be ~5 μm. As the fiber aspect ratio increased, the deposition maxima occurred at smaller aerodynamic diameters in both species and the extent of alveolar fiber deposition decreased. Lastly, fiber shape is another determinant of deposition. Timbrell and Skidmore (1970) found that long, straight fibers tended to align their long axis in the direction of airflow, facilitating penetration into the lung. Fibers with any curvature, bends, or twists can twist and rotate in the airstream, increasing the fiber's aerodynamic diameter and therefore reducing its respirability and deposition.

Fiber-containing test atmospheres generated for inhalation toxicity studies require assessment of both fibrous and nonfibrous components to fully characterize the test atmosphere. Large amounts of respirable nonfibrous dust may exacerbate the lung response by taxing the ability of alveolar macrophages to remove inhaled particles. To document exposure conditions, it is essential to minimally characterize fiber composition (including surface modifying agents, such as binding agents), nonfibrous and fibrous length and width distributions, and air sampling data describing fiber concentration (typically by count, i.e., fibers/cm^3); supplemental measurements can include morphology and aerodynamic particle size and mass. Fiber-sizing techniques involve fiber sample collection on an appropriate filter media and counting fiber numbers and/or length/width dimensions by using light electron microscopy, scanning electron microscopy, or transmission electron microscopy.

There are three general fiber categories based on their origin. These include naturally occurring fibers, man-made synthetic mineral fibers, and synthetic organic fibers (Figure 28.13). The most well-known and studied naturally occurring class of mineral fibers is asbestos, which is grouped into serpentine (e.g., chrysotile, a hydrated magnesium silicate) and amphibole asbestos (e.g., amosite, crocidolite, and tremolite, which are hydrated metal silicates). The surface morphology of the two is very distinct; while chrysotile is a curly fiber comprised of parallel fibrillar subunits, amosite fibers have a straight, rodlike structure. These are important distinctions that relate to the durability and pathogenicity of these fibers in the lung. Amphibole asbestos has less water solubility than chrysotile, and chrysotile is more likely to fragment axially, releasing long thin fibrils, which are more reactive, while amphiboles are more likely to fragment longitudinally, releasing shorter fiber fragments. Of the man-made mineral fibers, fibrous glass is perhaps the most studied. Unlike the naturally occurring mineral fibers, fibrous glass is amorphous and does not possess a crystalline structure. Glass fibers are produced by drawing molten glass through a small orifice producing very-small-diameter fibers, typically 3–10 μm in diameter but some as fine as 1 μm. The synthetic organic fibers are useful due to their high tensile strength and chemical or flame resistance. Para-aramid fibers, for example, have been used as asbestos replacement, in automotive and aerospace applications and, more visibly, in ballistic armor. The para-aramid fibers exist as either a continuous filament or as pulped material. As-produced, para-aramid fibers are too thick to be deposited in alveoli, but fiber processing operations can physically break interfibril bonds, literally peeling away respirable-sized, curly fibrils (Lee et al. 1988).

Fibers possess broad differences in biological reactivity in lung tissue that can be related to three general properties: fiber dimension, fiber durability (or biopersistence), and fiber dose.

The physical dimensions of fibers determine how and where fibers will deposit (just as with other aerosols, the deposition site will impact bioavailability of the fiber due to site-dependent processes responsible for facilitating fiber clearance). An early clue to the importance of fiber length in the pathogenicity of inhaled fibers was the observation by Stanton and Wrench (1972) that fibers, regardless of composition, longer than about 8 μm were more potent in the development of pulmonary mesothelial tumors than shorter fibers. For fibers to have any significant lung deposition, fiber diameters must be less than about 3 μm, so the fibers most likely to be pathogenic will have diameters less than ~1–2 μm. Similarly, there is an upper boundary on length, as fibers with lengths >~200 μm do not readily penetrate to peripheral alveoli in humans. Besides the ability of very fine diameter, high aspect ratio fibers to penetrate deeply into the respiratory

tract, long fiber pathogenicity may relate to whether alveolar macrophages are capable of phagocytizing the fibers. Once fibers are longer than about 10–20 μm, they can no longer be readily engulfed and affected by intracellular hydrolysases. The longer fibers are thus less likely to be cleared by macrophages, thereby enhancing fiber retention, interaction with lung epithelium, and translocation to the pleura. Collectively, the results from various in vivo and in vitro studies of fiber toxicity indicate that long thin fibers (i.e., fiber lengths longer than 20 μm and fiber diameters less than 1 μm) are the most pathogenic in causing lung tumors (Miller et al. 1999).

Fiber durability is another critical determinant of ultimate fiber toxicity since fibers that resist dissolution or degradation (i.e., are biopersistent) in the lung or other organs of the body increase the likelihood for adverse effects. Fiber properties that impart chemical or mechanical resistance to fiber disintegration or fragmentation in the lung will prolong fiber presence in tissue. This property of fibers to disintegrate in tissues was first noted when natural and man-made fibers of different compositions were found to have different toxicological properties and lung retention characteristics (Morgan et al. 1982, Johnson et al. 1984, Morgan 1992). Investigators found lower burdens of some fibers in exposed lungs than expected based on the fiber exposure concentrations, and in general, this correlated with a less severe spectrum of pulmonary pathologic effects (Hesterberg et al. 1998). Indeed, a sizeable body of data has accumulated showing that the biological effects of inhaled fibers were not so much dependent on their composition but rather to their durability and resistance to disintegration in the lung (Lippmann 1990). Studies show that biopersistence of fibers longer than 20 μm are good predictors of pathological responses following inhalation (Hesterberg et al. 1998, Bernstein et al. 2001).

There are two general pathways by which fiber degradation may proceed. In the first, the fiber dissolves and is completely solubilized within the lung milieu. In the second, the physical dimensions of the fiber (either diameter or length) may be altered by the action of lung fluids on the fiber surface. If solubilization alters the mechanical integrity of the fiber such that the fiber breaks along its longitudinal axis, both the dimensions and number of subsequent fibers change. If a fiber breaks transversely, an additional fiber or particle is produced (depending upon the dimensions of the resulting fragments), and the overall length of the fiber is reduced; this can result in facilitated clearance, especially if the fiber fragments are now of a size that may be readily engulfed and removed from the lung by macrophages. Conversely, some fiber types are especially prone to mechanical disruption, releasing more fibers. Chrysotile asbestos deposited in the lung, for example, may split longitudinally, releasing numerous fine fibrils and increasing the lung fiber burden, as demonstrated by Bellmann et al. (1986). Similarly, para-aramid fibers can be disrupted transversely at fibril defect sites by enzymatic attack to release shorter fibers (Kelly et al. 1993, Warheit et al. 2006). Dissolution processes that affect fiber length are more likely to reduce potential adverse lung effects by allowing phagocytosis of fiber fragments and alveolar clearance. The various factors influencing fiber durability have been reviewed by Searl (1994), and experimental methods for the evaluation of fiber solubility in vitro and in vivo have been reviewed by Hesterberg et al. (1996, 1998).

Experimental demonstration of fiber degradation in vivo has been reported by measuring dimensions of fibers recovered from the lungs of animals. Techniques vary, but common lung digestion methods utilize either thermal or microwave ashing techniques, chemical digestion with strong alkali, or oxidizing agents (Kelly et al. 1985, Warheit et al. 1991) followed by standard fiber size/count techniques. It is imperative to determine the effects of the lung digestion method on the fibers alone to ensure that artifactual reductions in fiber size or number do not occur. This consideration may be bypassed with in situ observations of fiber dimensions by using histological techniques and scanning electron microscopy/TEM (Brody et al. 1981).

Particle Size and Mass Distributions

To estimate total and regional lung doses, it is necessary to characterize the aerosol in terms of the particle size distribution and the mass concentration. Particle size is a prime factor governing the fraction of inhaled particles that penetrates past the oropharynx and enters the lungs and the particle fraction that deposits in each lung region. The mass concentration is proportional to the actual amount of particles that deposits in each region. Size distributions can be described in terms of particle number, surface area, or mass; most dose estimates use mass. Particle mass distributions are often characterized by two values: the MMAD ($d_{ae,mm}$) and the GSD (σ_g) (Heyder 1991). The $d_{ae,mm}$ denotes the particle size at which half of the total aerosol mass is contained in larger particles and half in smaller particles. Since the $d_{ae,mm}$ is expressed as an aerodynamic diameter, it describes how the overall aerosol behaves in the respired air and can be used to estimate where and by what processes particles deposit in the respiratory tract. Another frequently encountered particle size parameter is the mass median diameter (d_{mm} or MMD), which is the same as the $d_{ae,mm}$ except that the particle size is expressed in terms of the particle's actual density (Figure 28.15).

The σ_g denotes the spread of particle sizes. Most aerosols have particle sizes that are distributed lognormally; that is, on a plot of frequency distribution versus log particle diameter, the distribution looks Gaussian. An aerosol with all identically sized particles has a σ_g of 1.0. An aerosol with a $\sigma_g \leq 1.22$ is considered monodisperse (Fuchs and Sutugin 1981): to a first approximation, all the particles behave aerodynamically alike. An aerosol with a $\sigma_g > 1.22$ is polydisperse: there are appreciable differences in aerodynamic behavior among the particles. Most therapeutic aerosols are polydisperse. An aerosol with a $d_{ae,mm}$ of 2 μm and a σ_g of 2 has ±1 GSD or 68% of its mass contained between particles of 1 and 4 μm. An important implication of a lognormal distribution is that most of the aerosol mass is contained in the large particles, since mass is proportional to the cube of diameter. Where these large particles deposit in the respiratory tract governs where much of the dose deposits.

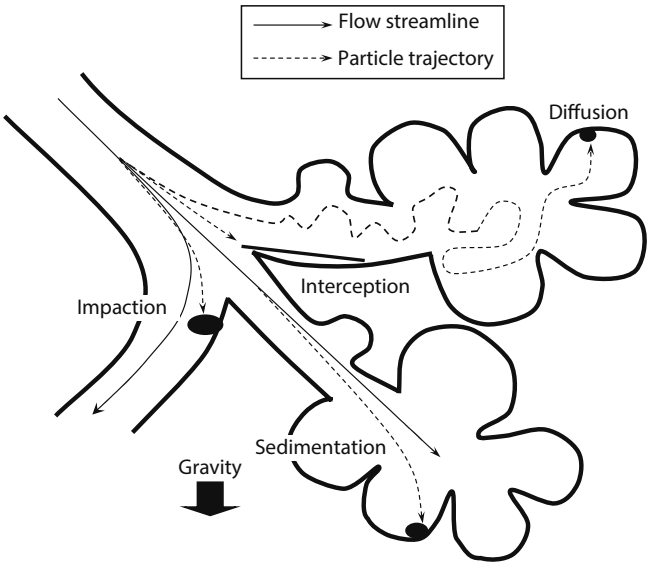

FIGURE 28.14 Mechanisms of particle deposition.

Aerosol Deposition Mechanisms

The major mechanisms of particle deposition are shown in Figure 28.14.

Gravitational Settling

Gravity accelerates falling bodies downward, and a particle reaches its terminal settling velocity when the gravitational force equals the opposing viscous resistive forces of the air. Particles small enough to enter the lungs reach their terminal settling velocity in less than 0.1 ms. Particles deposit when they have enough time to settle onto airway walls or alveolar surfaces. Thus, the probability that a particle deposits by gravitational settling increases with increasing $d_{ae}2t$, where t is the residence time in the respiratory tract (Heyder 1982). Breath holding enhances deposition by sedimentation. Sedimentation is important for particles larger than about 0.1 μm that enter the peripheral airways and alveoli, where airflow rates are slow, residence times are long, and distances to lung surfaces are short (Heyder et al. 1986).

Inertial Impaction

Inertia is the tendency of a moving particle to resist changes in speed and direction. It is related to momentum, the product of the particle's mass and velocity. High air velocities and abrupt changes in airflow direction occur in the nose and oropharynx and at central airway bifurcations. Inertia causes a particle entering bends at these sites to continue in its original direction instead of following the curvature of the airflow. If the particle has sufficient mass and velocity, it crosses airflow streamlines and impacts on the airway wall. The probability that a particle deposits by inertial impaction increases with increasing product of $d_{ae^2}Q$, where Q is the respired flow rate (Lippmann and Albert 1969, Heyder 1982). Impaction probably also increases with increasing angle of airstream deflection. Inertial impaction is an important deposition mechanism for particles with a a_{ee} larger than 2 μm (Heyder 1982) and may occur during both inspiration and expiration in the extrathoracic airways (oropharynx, nasopharynx, and larynx) and central airways. In obstructed airways, the enhanced linear velocities at narrowed sites may cause smaller particles to deposit by impaction as well.

Diffusion

Aerosol particles also undergo Brownian diffusion, a random motion in three dimensions caused by their collisions with gas molecules; this motion can lead to contact and deposition on respiratory surfaces. Diffusion is significant for particles with diameters less than 1 μm, so that their size is similar to the mean free path of gas molecules. Unlike inertial or gravitational displacement, diffusion is independent of airflow rate and particle density; however, it is affected by particle shape and size (Heyder and Scheuch 1983). For diffusing particles that measure 0.4 μm and smaller, size can be expressed in terms of the thermodynamic equivalent diameter (d_{te}), the diameter of a sphere that has the same average diffusional velocity in air as the actual particle (Heyder 1991). The probability that a particle deposits by diffusion increases with decreasing particle size and decreasing values of $(t/d_{te})^{1/2}$ (Heyder 1982); thus, deposition is dependent on the square root of residence time. Diffusion, like sedimentation, is usually most important in the peripheral airways and alveoli (Heyder et al. 1986) but can also occur in the nose and mouth (Gradon and Yu 1989).

As particle size decreases, inertia and sedimentation become less important, but diffusion increases in importance. For example, a particle with a d_{ae} of 2 μm moves by diffusion (Brownian displacement) only about 9 μm in 1 s; it settles by gravity about 125 μm in the same period. However, as particle size drops to 0.2 μm, the diffusional displacement increases to 37 μm, whereas gravitational displacement decreases to only 2.1 μm. Table 28.5 shows a comparison of settling and diffusion displacements for a range of particle sizes. Generally, gravity and inertia dominate the transport and deposition of particles larger than 1.0 μm in diameter, and diffusion dominates the transport of particles smaller than 0.1 μm. For particles between 0.1 and 1.0 μm, sedimentation and diffusion are both important (Heyder and Scheuch 1983, Heyder 1991) (Table 28.5).

Electrostatic Attraction

Electrical forces may cause charged particles to deposit in the respiratory tract. The surfaces of the respiratory tract are uncharged but electrically conducting. When an electrically charged particle approaches the lung surface, the particle induces on that surface an image charge of the opposite polarity that attracts the particle. This attraction may cause the particle to deposit, and thus the deposition of charged particles relative to that of neutral particles is increased. Experimental (Melandri et al. 1983) and theoretical (Yu 1985) studies show that electrostatic attraction may be an important deposition mechanism in the lung periphery for particles (especially fibers) that are charged above a certain threshold and have a diameter of 0.1–1.0 μm (Vincent 1985).

Melandri et al. (1983) established that the probability of electrostatic deposition is proportional to $(q^2/d)^{1/3}$, where q is the electrical charge on the particle. For charged 1 μm particles, deposition is increased over that of uncharged particles once there are about 40 charges on the particle; for 0.3 μm particles, only 10 charges are needed.

Interception and Other Forces

Deposition can also occur in the lungs when particles have dimensions that are significant relative to those of the air spaces. As particles move into smaller and smaller air spaces, some may reach a point where the distance to a surface from the center of a particle is less than the particle size. The resulting contact is called interception. Interception is particularly important for the deposition of fibers (Timbrell 1965, Harris and Fraser 1976). Other forces acting to affect deposition, such as acoustic forces, magnetic forces, or thermal forces, are normally not significant in the respiratory tract.

The physical mechanisms responsible for deposition have already been discussed. The effectiveness of these mechanisms depends on various factors such as particle size, breathing pattern, airway geometry, and disease. Many aspects of particle deposition in the respiratory tract have captured the energy and imagination of investigators; these studies are reviewed in many papers and books (Lippmann 1977, Brain and Valberg 1979, Heyder et al. 1982, 1986, Raabe 1982, Agnew 1984, Stuart 1984, Stahlhofen et al. 1989, Gerrity 1990, Vincent 1990). Other excellent sources of information on deposition are published works from the International Symposia on Inhaled Particles (Davies 1961, 1967, Stuart 1971, Wright 1977, Dodgson 1985, Dodgson et al. 1988). Some major influences on the fraction of the inspired particles that deposit within the respiratory tract and the anatomical distribution of retained particles are now discussed (Figure 28.15).

Effectiveness of Deposition Mechanisms

Anatomy of the Respiratory Tract

The configuration of the lungs and airways is important because the efficiency of deposition depends in part on the diameters of the airways, their angles of branching, and the average distances of particles to lung surfaces in the acini. Along with the volumetric flow rate, airway anatomy specifies the local linear velocity of the airstream and thus determines whether the flow is laminar or turbulent. For example, at the laryngeal aperture, an air jet is formed that creates turbulent and unstable airflows that enhance particle impaction in the trachea (Lippmann and Altshuler 1976, Chan et al. 1980). There are interspecies and intraspecies differences in lung morphometry (Soong et al. 1979, Schlesinger and McFadden 1981, Nikiforov and Schlesinger 1985); even within the same individual, the dimensions of the respiratory tract change with lung volume, age, and pathological processes. Among normal subjects breathing in the same manner, total deposition fraction has a coefficient of variation as large as 27%. This is largely due to intersubject differences in airway geometry (Heyder et al. 1982, 1988, Yu and Diu 1982, Blanchard et al. 1991). Gender differences in laryngeal and airway geometries may cause women to have greater upper airway deposition by impaction as compared with men (Pritchard et al. 1986, Svartengren et al. 1991). For any person, decreasing lung volume not only increases the deposition fraction but also causes the major site of particle deposition within the airways to shift from the lung periphery to more central airways (Agnew 1984). At low lung volumes, airways have smaller cross-sectional areas and higher linear velocities and thus enhanced deposition by impaction in central airways for a given flow rate. As a person ages, anatomical changes of the respiratory tract also affect deposition fraction (Phalen et al. 1991). Children under 8 years old who are breathing at rest have higher total, head, and tracheobronchial deposition fractions and lower alveolar deposition fraction than adults (Xu and Yu 1986, Yu and Xu 1987, Hofmann et al. 1989, Becquemin et al. 1991b). The higher airway deposition may help explain why some children have a greater response than adults to a given dose of a provocation agent (LeSouef 1992).

Choice of Pathway

Most people breath nasally at rest. As ventilation rate rises above 35–40 L/min, the high-resistance nasal pathway starts to be combined with the low-resistance oral pathway (Saibene

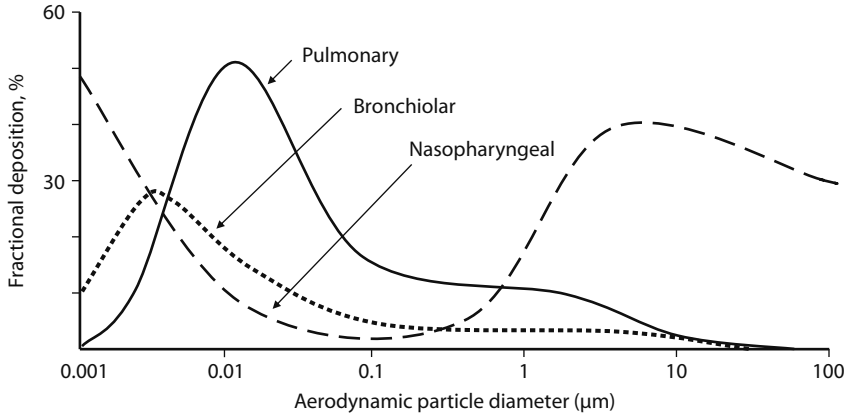

FIGURE 28.15 ICRP model of regional aerosol deposition in humans.

et al. 1978, Niinimaa et al. 1980, Chadha et al. 1987). With continuing increases in ventilation rate, the oral path takes on a greater percentage of the total ventilation, but this percentage varies considerably among subjects, ranging from only 10% to as much as 80% (Niinimaa et al. 1981, Chadha 1987, Wheatley et al. 1991).

A highly significant change in the effective anatomy of the respiratory tract occurs when air is inhaled through the mouth instead of the nose or when the nose is bypassed because of a tracheostomy or an endotracheal tube. The nose has a major role as an upstream filter that prevents inhaled particles from penetrating into the lungs. The smallest total cross-sectional area of the respiratory tract also occurs in the nose. High velocities, sharp curves, nasal hairs, and secondary flows all combine to collect inhaled particles in the nose. Excellent reviews of particle inhalability and deposition in the nose are available (e.g., Hounam and Morgan [1977], Lippmann [1977], Yu et al. [1981], Sato [1988], Stahlhofen et al. [1989], Vincent [1990], Martonen and Zhang [1992]). The inhalability, deposition, and clearance of particles in the head during nasal breathing have been studied by several investigators (e.g., Pattle [1961], Lippmann [1970], Hounam [1971], Heyder and Rudolf [1977], Yu et al. [1981], Heyder et al. [1986], Schiller et al. [1988], Breysse and Swift [1990], Rasmussen et al. [1990], Becquemin et al. [1991a]). Collectively, these reports indicate that the anterior portion of the nose collects particles larger than 1 μm by impaction, with the probability of impaction increasing with increasing $d_{ae^2}Q$, though there is some evidence that impaction probability is better described by $d_{ae^2}p^{2/3}$, where p is the pressure drop across the nose (Hounam 1971, Stahlhofen et al. 1989). Most studies show that particles larger than 10 μm are completely trapped in the nose. The actual fraction of inhaled material trapped in the nose varies considerably among individuals and is more variable than the deposition fraction in the lungs (Rasmussen et al. 1990). These intersubject differences may be due to variations in nasal distensibility and geometry, including the number and shape of nasal hairs.

Besides being an upstream filter, the nose also humidifies the inspired air; it is a more effective humidifier than the mouth because the inhaled air passes by the large surface area of the highly vascular nasal turbinates. Because of this humidification, hygroscopic particles ($d_{ae} > 1$ μm) grow more rapidly when inhaled through the nose than when inhaled through the mouth and thus have enhanced deposition fraction (Ferron et al. 1988b).

The nose is an efficient filter for large particles, but the mouth, because of its simpler geometry, is not. The shift from a higher filtering efficiency during nasal breathing to lower filtering efficiency during oronasal breathing may potentiate asthma attacks during exercise. During exercise, large volumes of air are inhaled by the mouth, so that more and more antigenic particles, such as pollens, penetrate to and deposit in the lungs. This increased exposure of airways increases the risk of allergic responses. With exercise, the amount of particles depositing in the lungs may increase more than predicted by the increased ventilation.

Breathing Pattern: Flow Rate and Lung Volume

When a subject changes breathing pattern, deposition fraction may change profoundly. Minute volume determines the total number of particles entering the lungs. Flow rate affects the probability of particle impaction and the extent of turbulent flow, which enhances particle deposition in the upper airways. The combination of flow rate, tidal volume, breath-holding time, and lung volume affects particle residence time in each lung region and hence the probability of deposition by gravitational and diffusional forces (Heyder 1982). Tidal volume and flow rate also influence the motion of the larynx and affect particle deposition there (Rudolf et al. 1986). Changing lung volume also alters the dimensions of the airways and parenchyma. High levels of ventilation and breath holding represent extremes of breathing patterns; they give rise to markedly different deposition patterns.

Generally, when airflow velocities increase, as during physical exertion or labored respiration consequent to an asthma attack, inertial deposition increases. During slow, relaxed breathing, particle sedimentation and diffusion are the primary deposition processes, and particle collection in the acini increases because of the proximity of lung surfaces there.

Species Differences

Human responses to inhaled gases and particles are often predicted from experiments done in other species, such as rodents or dogs (Brain et al. 1988). In addition to obvious differences in body mass, anatomy, and life-span, differences in metabolism among species are often substantial. For example, the oxygen consumption in rats per kilogram of body weight is 5.5 times greater than that of humans (Badeer 1974). Other differences, such as nocturnal activity or coprophagy, may be important and may influence responses to inhaled toxic agents. Despite these differences, it is often necessary to extrapolate experimental results from animals to humans (Table 28.1).

All aspects of this chapter are influenced by species differences. This includes deposition, clearance, and the magnitude and type of biologic responses. A major difference, which is sometimes not recognized, is that rodents and dogs are obligatory nose breathers, while humans, particularly with increased exercise and ventilation, switch from nose breathing to mouth breathing. This has a profound influence on the concentration of particles and gases reaching airways.

Particle Clearance Mechanisms in Airways and Parenchyma

The lungs' response to particles depends not only on the amount of particles deposited but also on the amount retained over time. Retention is the amount of material present in the lungs at any time and equals deposited mass minus cleared mass. During continuous aerosol exposure, the lungs reach a steady state of retention when the rate of deposition equals the rate of clearance. It is both the amount of particles retained over time within a specific lung region and the physicochemical properties of the retained particles that determine the magnitude of the lungs' response.

As discussed previously, such factors as particle size, hygroscopicity, and breathing pattern affect the site of deposition within the respiratory tract. In turn, where particles deposit in the lungs determines which mechanisms are used to clear them, how fast they are cleared, and the amount retained over time. The implications of particle characteristics for integrated retention are described by Brain and Valberg (1974) on the basis of the model developed by the Task Group on Lung Dynamics (Bates et al. 1966). They show that the total amount and the distribution of retained dose among the nose and pharynx, trachea and bronchi, and pulmonary and lymphatic compartments are dramatically altered by particle size and solubility.

Particles that deposit on the ciliated airways are cleared primarily by the mucociliary escalator. Those particles that penetrate to and deposit in the peripheral, nonciliated areas of the lungs can be cleared by many mechanisms, including phagocytosis by alveolar macrophages, particle dissolution, or movement of free particles or particle-containing cells directly into the interstitium or the lymphatics. Excellent reviews discuss these clearance processes in detail (Lippmann et al. 1980, Raabe 1982, Jones 1984, Lippmann and Schlesinger 1984, Pavia 1984, Stuart 1984, Schlesinger 1985, Cuddihy and Yeh 1988, Oberdorster 1988, Sleigh et al. 1988, Byron and Phillips 1990, King 1990, Lehnert 1990, Vincent 1990).

Mucociliary Transport

Physiology

The ciliated epithelial cells of the airways and nasal passages are covered by a two-layered mucous blanket: a top high-viscosity gel layer and a bottom low-viscosity serous layer. The gel–mucous blanket, along with any less soluble particles that deposit on it, is moved toward the pharynx by the cilia. Also present in this moving mucous carpet are cells and particles that have been transported from the nonciliated alveoli to the ciliated airways. Mucus, cells, and debris coming from the nasal cavities and the lungs meet at the pharynx, mix with salivary secretions, are swallowed, and enter the gastrointestinal tract. In humans, the ciliated epithelium extends from the trachea down to the terminal bronchioles. The particles are removed with half-times of minutes to hours; the rate depends on the speed of the mucous blanket. The speed is faster in the trachea than in the small airways (Serafini et al. 1976) and is affected by factors influencing either the cilia or the amount and quality of mucus. In the airways, there is little time for solubilization of slowly dissolving materials. In contrast, particles deposited in the nonciliated compartments have much longer residence times; there, small differences in solubility can result in significantly different clearance rates.

Ciliary action may be affected by the number of strokes per minute, the amplitude of each stroke, the time course and form of each stroke, the length of the cilia, the ratio of ciliated to nonciliated area, and the susceptibility of the cilia to intrinsic and extrinsic agents that modify their rate and quality of motion. The characteristics of the mucous layer are critically important. The thickness of the mucous layer and its rheological properties may vary widely. In asthmatic subjects, tracheobronchial clearance can be retarded in comparison with normal subjects, possibly because of a combination of ciliary dysfunction and altered mucous rheological properties (Mezey et al. 1978). In the peripheral bronchioles, for example, the gel layer is less evident. Another factor influencing mucociliary clearance in asthmatics is the presence or absence of flow-limiting segments during tidal breathing (O'Riordan et al. 1992). Flow-limiting segments may mechanically disturb the local mucociliary layer, thus slowing clearance (Foster et al. 1988). Asthmatics without flow-limiting segments may have normal or even faster-than-normal mucociliary clearance rates (O'Riordan et al. 1992). Many of the factors that influence mucociliary clearance, and their clinical implications, have been reviewed (Wanner 1977, Camner and Mossberg 1988, Satir and Sleigh 1991).

Measuring Mucociliary Transport

Mucociliary transport has been studied by a variety of techniques, such as monitoring the movement of inert or radiolabeled particles deposited on the tracheal mucus via either a bronchoscope or an inhaled bolus. One can estimate tracheal mucous velocity from the distance the particles move over time, as observed either with movies filmed through the bronchoscope or with a gamma camera (Sackner et al. 1973, Yeates et al. 1975). Bronchoscopic techniques yield higher numbers for tracheal mucous velocity (15–21 mm/min) than do the noninvasive bolus techniques (4.4 mm/min). These values are characteristic only for the trachea and large central airways. Transport in the terminal bronchioles is about 0.1–0.6 mm/min (Morrow et al. 1967).

Many investigators have estimated mucociliary transport from whole-lung clearance curves. These curves are generated by first having a subject inhale a radiolabeled aerosol and then monitoring the amount of radioactivity in the lungs over time (hours to days). Albert and Arnett (1955) first used this method and noted that the clearance curve can be divided into two phases, a fast and a slow phase. The fast phase is complete within 24–48 h and has generally been attributed to tracheobronchial clearance; the slow phase has been attributed to alveolar clearance (Booker et al. 1967, Morrow et al. 1967, Lippmann and Albert 1969). This approach has been used to study clearance in normal and abnormal subjects (Lourenco et al. 1971, Sanchis et al. 1972, Poe et al. 1977, Camner and Philipson 1978, Stahlhofen et al. 1980).

There is now evidence that clearance from the airways may be incomplete in the first 24 h; this may be even more pronounced in patients with lung disease. Gore and Patrick (1982) noted that particles instilled into the trachea can be sequestered in epithelial cells. Geiser et al. (1990) found latex particles trapped in the periciliary sol fluid below the gel–mucous blanket. The particles may have been displaced there by surface tension forces created by surfactant (Schurch et al. 1990, Gehr et al. 1991). Stahlhofen et al. (1986) noted both fast and slow phases of clearance even in humans given a bolus of particles delivered only 45 mL beyond the larynx. Wolff et al. (1989) delivered radiolabeled particles with a bronchoscope to airway generations 6–10 in dogs and found that about 20% of the particles were cleared slowly.

Another approach to measuring mucociliary clearance is to examine the deposition and clearance of particles in central versus peripheral lung regions (Smaldone et al. 1988), which is referred to as the aerosol penetrance or the airways penetration index (Dolovich et al. 1976, Agnew 1991). The appropriate interpretation of such clearance curves bas been noted (Foster 1988, Agnew 1991).

More studies are needed to elucidate the best methodology to model mucociliary clearance and to understand its role and importance in patients with pulmonary disease. Clearly it is also essential to understand the initial deposition pattern of inhaled particles to determine the importance of mucociliary clearance for the disappearance of particles from the lungs.

Nonciliated Regions: Alveolar Macrophages

Particles that deposit in the nonciliated portion of the lungs are cleared mechanically, by dissolution, or by the combined action of these processes. During mechanical clearance, most particles move toward the ciliated region within alveolar macrophages. It is possible that particles also move as a result of a surface tension gradient due to surfactant that extends from the alveoli to the airways (Rensch et al. 1983). Other particles may enter the interstitial tissues, particularly when deposited levels are high (Lehnert 1990). Macrophages are credited with keeping the alveolar surfaces clean and sterile. These cells rest on the continuous epithelial layer of the lung. It is their phagocytic and lytic potentials that provide most of the bactericidal properties of the lungs. Rapid endocytosis prevents particle penetration through the alveolar epithelia and facilitates alveolar–bronchiolar transport. Particle clearance by alveolar macrophages was the focus of international symposium (Morgan 1992). In addition, the biology of lung macrophages has been reviewed (Brain 1985, Herscowitz 1985, Du Bois 1986, Fels and Cohn 1986, Bowden 1987, Sibelle and Reynolds 1990, Reynolds 1991, Valberg and Blanchard 1991), and the various kinds of lung macrophages have been described (Brain 1988). These include alveolar, airway, connective tissue, pleural, and intravascular macrophages.

Particles enter the lung connective tissue by translocation through type I epithelial cells (Adamson and Bowden 1981), though there are some data indicating that alveolar macrophages carry particles into the interstitium as well (Harmsen et al. 1985). Once in the interstitium, most particles are phagocytozed by interstitial macrophages, though some particles may temporarily remain free. Interstitial particles are cleared eventually through either dissolution (Kreyling et al. 1991) or transportation to regional lymph nodes through lymphatic pathways. In tissues, particles are cleared with half-times ranging from a few days to thousands of days, depending on their solubility. In contrast, particles remaining on alveolar surfaces in humans are cleared with biological half-times estimated to be hours to months (Table 28.6).

TABLE 28.6
Particle Clearance

Anatomic Region	Clearance Mechanism	Approximate Clearance Half Time
Nasopharynx	Mucociliary transport	Minutes
Tracheobronchial	Mucociliary transport	Minutes to hours
Alveolar	Macrophages	Days to weeks
Alveolar	Interstitial migration	Months
Alveolar	Dissolution	Hours to months

Measuring Deposition, Clearance, and Retention

A concept essential to inhalation toxicology is the idea of a dose–response curve. Implicit in this concept is quantifying retention (the amount of an aerosol present at any time). It should be remembered that retention is different from deposition (initial attachment of suspended particles to a surface in the respiratory tract). As discussed elsewhere, retention but not deposition is influenced by clearance and translocation. In the next paragraph, we briefly mention strategies to measure retention in animals and humans.

There are obvious advantages to using nondestructive, noninvasive methods for quantifying particle retention. Commonly used technologies include gamma cameras, magnetometry, and PET scans. An advantage is that repeated measurements in the same human or animal is possible. A disadvantage is that there is a lack of spatial resolution, which can be better obtained by killing and dissecting animals. It is then possible to divide the respiratory tract into pieces and analyze the particle content of each piece. In addition to using particles that are radioactive, fluorescent, radio opaque, or magnetic, other particles have a characteristic visual appearance that allows them to be identified in light electron microscopy. Iron oxide and welding fume are good examples.

It is also possible to estimate initial deposited dose based on measurements of the size and concentration of the aerosol, as well as breathing pattern. Numerous models for predicting deposition have been described. Another approach is simply to measure the difference in the aerosol content between inspired and expired gas, that is, it's disappearance as well as ventilation. Then one can determine the total amount of material initially deposited in the respiratory tract. However, no information is obtained regarding the anatomic location.

INHALATION TOXICOLOGY: BIOLOGICAL RESPONSES

Biological Mechanisms of Particle and Gas Injury

There is a growing body of evidence that fine particles are inherently more toxic than larger particles. Proposed hypotheses for fine particle-induced injury include (1) reductions in the integrity of the pulmonary epithelial and/or endothelial barriers, (2) impaired pulmonary host defense mechanisms, (3) release of inflammatory mediators to produce either local or systemic effects, (4) impaired particle clearance with airway hypersecretion of mucus, (5) aggravation of preexisting airway occlusion, and (6) direct or indirect effects on

cardiovascular function (Castranova 1998). While all appear to be involved to varying degrees, particle-mediated inflammation may well be the predominant mechanism for respiratory tract injury and cardiovascular effects.

Inhaled particles can be directly cytotoxic, effecting transudation of serum proteins from alveolar capillaries. This may involve peroxidation of membrane lipids, resulting in defects in membrane integrity, function, and, subsequently, cell death; if injury is sufficiently severe, the airways and alveoli fill with fluid, causing pulmonary edema and ultimately death. The source of these radicals may be membrane-based oxidases (Vallyathan et al. 1992).

Some metal-containing particles, especially those that either contain or can complex the ferric form (Fe^{+3}) of iron, are particularly active in inducing membrane peroxidation through a reduction–oxidation pathway, producing hydroxyl radical ($OH^{\bullet}$) (Ghio et al. 1992b); inclusion of chelators markedly reduces the oxidant-generating capacity of the particles (Ghio et al. 1992a). This pathway may be especially important for nanoscale materials as these particles may have a disproportionately larger number of catalytic sites on the surface relative to larger particles (Tran et al. 2000, Duffin et al. 2002). By a related mechanism, particles, either by themselves (Wilson et al. 2002) or by interaction with pulmonary alveolar macrophages or alveolar type II cells (Kanj et al. 2005), pulmonary epithelium (Shukla et al. 2000), or polymorphonuclear leukocytes (Prahalad et al. 1999), can stimulate generation of reactive oxidant species (ROS) such as hydrogen peroxide (H_2O_2), superoxide anion (O^{2-}), or hydroxyl radical (Gurgueira et al. 2002, Gonzalez-Flecha 2004, Ghelfi et al. 2008, Rhoden et al. 2008). These radicals may cause either direct tissue injury or genetic damage. A variety of metal-containing dusts have been shown to stimulate production of ROS from macrophages (Berg et al. 1993), with iron being among the most active metals (Fubini et al. 1995, Rice et al. 2001), while other metal dusts, such as titanium dioxide, are either inactive or minimally active (Goodglick and Kane 1986, Nyberg and Klockars 1990, Blackford et al. 1994).

Oxidant production, whether caused by fine or UFPs, may also oxidize and deplete glutathione, a cellular antioxidant (Stone et al. 1998). The relative levels of reduced and oxidized glutathione appear to play a pivotal role in determining the lung's inflammatory response to oxidant stresses. Alterations in the redox levels of glutathione can affect the degree of acetylation/deacetylation of histone proteins on DNA and allow transcription to occur (Rahman et al. 2002). Conformational changes in DNA allow access of the nuclear transcription factors (nuclear factor-kappa B [NF-κB]) and the associated activation protein (Galter et al. 1994, Haddad et al. 2000), permitting gene transcription. Studies with SWNT in vitro, for example, show cells undergoing oxidant stress with a decreased ratio of reduced/oxidized glutathione, thereby triggering activation of the AP-1 and NF-κB nuclear transcription factors (Dick et al. 2003, Manna et al. 2005). Gene transcription results in the production of various proinflammatory cytokines, a class of chemical messengers that regulate cellular homeostasis and cell proliferation. Notably, the initiating or proinflammatory cytokines, such as tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1), can induce production of other cytokines that are responsible for the recruitment of inflammatory cells such as neutrophils to sites of particle deposition (Driscoll 1996) with subsequent activation of those recruited cells to produce ROS, providing further toxic insult to airway epithelium integrity.

Noncytotoxic, poorly soluble particles can lead to tissue injury from the prolonged inflammatory response induced by high particle concentrations (either from high exposure levels or inability to remove inhaled particles) in the lung (Morrow et al. 1996). This phenomenon, known as lung overload, can produce similar pathologic lesions in the lung as more cytotoxic dusts such as quartz (Oberdorster 1988), but requires much higher lung burdens than with quartz. Lung overload arises when the normal clearance processes become less and less effective with high particle exposures, leading to accumulation of particles within the lungs (Morrow and Mermelstein 1988). Pathologically, overload appears initially as an increased number of particles in the interstitium in macrophages in air spaces; with time, chronic inflammation may ensue, resulting in alveolar cell hyperplasia, granulomas, fibrosis, and potentially lung tumors (Morrow and Mermelstein 1988). Lung tumors have not been reported if particle clearance and pulmonary inflammation do not occur, suggesting a threshold-related phenomenon for overload-related lung tumors.

The functional decrements in clearance due to dust overloading are apparent if the clearance kinetics is measured; overloaded lungs exhibited a marked increase in particle retention compared to normal lungs. The mechanism for the overload phenomenon is believed to be due directly to a saturation of the capability of alveolar macrophages to ingest particles. The data suggest that alveolar macrophages become overloaded not by the total mass of ingested particles but by the cumulative volume of particles within macrophages. Morrow and Mermelstein (1988) estimated that overload may occur when the average volumetric load of particles exceeds 60 μm^3/macrophage and that macrophage-mediated clearance ceases when the volumetric load exceeds 600 μm^3/macrophage. Once the phagocytic activity of macrophages is reduced by large numbers of particles within alveoli, the mobility of macrophages also diminishes even if the particles are not inherently cytotoxic. The immobilization of alveolar macrophages within the lung results in two detrimental effects: first, subsequent clearance is greatly slowed, and second, the macrophages may continue to elaborate bioactive substances (e.g., proteases, cytokines, growth factors, oxidants, and immunomodulating agents) within the lungs. The overall effect is to increase the likelihood for a prolonged inflammatory response with attendant lung injury and/or tumor development.

The impetus for the overload theory lies, in part, from rodent chronic inhalation bioassays with diesel soot (McClellan et al. 1985, Mauderly et al. 1987), carbon black (Heinrich et al. 1994, Nikula et al. 1995), antimony trioxide (Drew et al. 1986), toner (Muhle et al. 1991), titanium

dioxide (Lee et al. 1985), and talc (Program 1993), particles that previously had been considered benign and do not ordinarily cause pathologic changes if lung clearance processes are not overwhelmed. As a class, these particles have low solubility, low cytotoxicity, and with the exception of diesel soot, are nongenotoxic, although genotoxicity per se is not a rigid requirement for tumor development with these particles (Heinrich et al. 1995). Consistent with all, however, is the observation that high levels of dust exposure were associated with an increasing lung particle burden. At some burden above the capacity of alveolar macrophages to remove particles, lung overload occurs (Warheit et al. 1997).

There are several features of the lung overload phenomenon that impact risk assessment. First, species differences are known in the levels at which overloading and the pathologic sequelae occur, complicating extrapolation of results in test animals to humans. For example, rats have developed lung tumors whereby mice or hamsters, exposed to similar particle concentrations and producing impaired alveolar macrophage clearance, did not (Brightwell et al. 1989, Heinrich et al. 1995). Rats had more severe inflammation after repeated inhalation of carbon black or ultrafine TiO_2 compared to hamsters or mice (Bermudez et al. 2004, Elder et al. 2005). These authors concluded that hamsters had elevated rates of particle clearance relative to the other strains, and while mice and rats experienced lung overload with similar but high TiO_2 lung burdens, mice did not exhibit the progressive fibrosis observed in rats. Elder et al. (2005) also noted that the lung injury and particle burdens with TiO_2 tended to increase as the surface area of the particles increased. Therefore a second consideration is that local tissue dose and subsequent injury from inhaled particles may also be related to particle surface area. While other metrics of exposure concentration may include particle mass, count, volume, or surface area for overload to occur, surface area appears to be the particle characteristic most closely associated with pulmonary inflammation, fibrosis, and lung tumor development (Oberdorster et al. 1994, Castranova 1998, Brown et al. 2001).

By whatever metric, the most important outcome of overload is the persistent inflammation produced by the particles. The consequences of this have an important bearing on the mechanism of tumor development. Marked impairment of particle clearance occurred in rats at 7.1 mg/m^3 or greater with carbon black and was associated with lung injury, chronic inflammation, epithelial hyperplasia, and fibrosis (Driscoll et al. 1996); such changes were not seen in comparably exposed rats at 1.1 mg/m^3, suggesting a threshold phenomenon. In the overloaded rat lung, the investigators reported a significant, dose-dependent increase of HPRT mutations in alveolar epithelial cells at inflammatory concentrations. Inflammatory cell products, including ROS and cytokines, were thought to provide the environment, including induction of cellular mutations and cell proliferation that are necessary for tumor development from oxidant-induced genotoxicity. The observation that particle-elicited rat inflammatory lung cells can be directly mutagenic suggests that there will be an exposure level (or lung burden) below which it does not induce persistent inflammatory changes and therefore mutations should not occur for nongenotoxic particles. However, at inflammatory concentrations, both the inherent genotoxicity of the particle and the resultant genotoxicity ensuing from the particle-elicited proinflammatory milieu may drive tumor development. Overall, the overload theory provides a plausible mechanism into the development of lung tumors from low cytotoxicity, low-solubility nongenotoxic dusts.

Animal Models

The selection of an animal species for an inhalation study is an important one for practical, technical, and ethical reasons. It is apparent that there is no one ideal human surrogate but that each species presents its own advantages and disadvantages. Most commonly, rodents, including the rat, mouse, guinea pig, and hamster (probably in that order), are used. As a consequence of the extensive use of rodents in inhalation toxicology, investigators have generated a large body of information on their responses. Rodents have been used in toxicological tests as models for vapor particle deposition and clearance, mechanisms of toxicant-induced lung and airway injury, and as models for infectivity and immunologic function. Due to their relatively short life-span, the use of rodents represents a reasonable approach for studying chronic toxicity and carcinogenesis. When extrapolating from experimental animal data to humans, factors that need to be considered include the comparative anatomy of the respiratory tract, presence or absence of concurrent diseases or infections, and similarities of the biochemical and physiologic responses in the intended species.

The use of animals in product development and safety assessment needs to continually reflect the welfare and ethical treatment of animals. Intelligent strategies to minimize animal testing by using in vitro or tiered approaches to data collection should be practiced, where possible, recognizing that in vitro tests for inhalation-related end points are only recently being explored; before they can be developed for regulatory acceptance, harmonization and validation activities must occur. In practice, inhalation testing should be conducted at laboratories that possess appropriate facilities and have a trained, competent staff capable of humane animal care and that have institutional review committees to review their testing protocols for compliance with animal welfare policies. All inhalation studies should be scientifically and ethically justified, and every study should be designed to avoid or minimize pain, discomfort, and stress. Care needs to be taken to avoid unnecessary or duplicative testing. Finally, the use of animal enrichment measures, wherever practical, should be encouraged.

In practice, however, selection of the test species is more often based on criteria such as the size and availability of the test animals, the number of animals needed to differentiate chemically induced changes from background or incidental changes, and the expense involved in obtaining and maintaining the requisite number of animals needed for statistical

validity opposite animal use/welfare considerations. Indeed, techniques to reduce the use of animals, without compromising the study, are an important consideration in study design.

In the selection of an appropriate animal species, one must consider the objective of the study, the available toxicological information, the unique functional or structural characteristics, if any, of the species that make it a good (or bad) animal model, what the anticipated response might be that would enable the investigator to most accurately determine the number of animals needed for the duration of the study, and appropriate controls. Historically, the use of small rodents predominates because their size allows testing of larger groups, their relatively short lifetime allows testing over the entire life span (a large body of data already exists on these species), and, finally, the cost of their acquisition and upkeep is relatively low.

The guinea pig has been used in studies of immune function and respiratory sensitization and has been particularly useful in determining the relative potencies of isocyanates (Wong and Alarie 1982, Weyel and Schaffer 1985). The guinea pig's unusually abundant bronchial smooth muscle makes this species a useful model to study airway hyperresponsiveness or bronchoconstriction in asthma models.

The hamster, having a relatively low spontaneous lung tumor rate and resistance to pulmonary infections, has been used in respiratory tract cancer studies. Some investigators feel that the hamster is the best animal model for the study of experimental lung cancer (Saffiotti 1970).

There are several disadvantages in using rodents to predict effects in humans. Because the nasal/pharyngeal anatomy of rodents is unlike that of humans, the amounts and sites of particle deposition may be quite different. Rodents are also obligate nose breathers, with superior nasal filtering efficiency compared to humans. Assessment of pulmonary function in nonanesthetized rodents is difficult, although recent miniaturization of probes and detectors has allowed some success here (Costa 1985). The most serious problems with rodents, especially rats, are those involving spontaneous respiratory infections and their sequelae. Rats appear to be uniquely susceptible to chronic inflammation, pulmonary fibrosis, and cancer from insoluble, noncytotoxic particles by overwhelming lung clearance mechanisms (particle overload). Because rats appear most susceptible to particle overloading, their selection for some types of particle inhalation studies often complicates extrapolation of the results to humans (Oberdorster 1995). In oncogenicity studies, rats appear to be less susceptible to fiber-induced mesothelioma, a malignant tumor of the pleural lung surface. Conversely, hamsters appear to be more susceptible to the development of fiber-induced mesothelioma but less sensitive to induction of lung tumors than rats. Despite these considerations, rats remain the most favored animal model for both short- and long-term inhalation studies.

Inhalation toxicity studies have also been conducted on dogs. The dog is a convenient size for a number of laboratory measurements including evaluation of pulmonary and cardiac function (Godleski et al. 2000, Wellenius et al. 2003, Bartoli et al. 2009a,b). Several natural disease states exist in the dog, making it a good model for evaluating the impact of the substance on conditions such as asthma. The cost and facilities needed to properly care for dogs are a disadvantage relative to rodents. The dog also may be relatively insensitive to certain inhaled gases such as ozone (Stokinger 1957). On the advantage side, extensive use of the dog as an experimental model occurred in studying the effects of radioactive materials following inhalation. There is a wealth of information concerning long-term inhalation of radionuclides.

Because the nasal anatomy of monkeys is similar to humans, monkeys are sometimes used in inhalation experiments. Lung function can be determined. However, considerable cost is involved in obtaining and maintaining monkey colonies, and their lack of general availability is a problem limiting their use. Note that within the species identified as monkey, intraspecies differences do exist. Also, the subgross pulmonary anatomy differs between types of monkeys and humans (McLaughlin et al. 1961).

Other species, such as the ferret, horse, donkey, sheep, cat, rabbit, and pig, have been suggested for use in inhalation studies. Each of these species has been used for special applications, which may take advantage of a particular anatomical feature, chemical sensitivity, or research curiosity. In some instances, the end point of concern drives the animal model chosen. The brown Norway rat has been used as an asthma model in a study design including analysis of cellular infiltrate in the lung, inflammatory factors in bronchoalveolar lavage, immunoglobulin E product in the serum, and changes in delayed-onset respiratory reaction upon inhalation challenges (demonstrated with diphenylmethane diisocyanate [Pauluhn 2005]).

Specific Respiratory Tract Targets for Deleterious Responses and Their Toxicological Assessment

Nose and Nasopharyngeal Region

The nasopharyngeal region plays an important role in the physiological responses to inhaled irritants. There are three basic types of irritants (Alarie 1973): (1) sensory irritants that act on the trigeminal nerve, (2) pulmonary irritants that act on irritant receptors of the airways, and (3) mixed sensory and pulmonary irritants. The initial response to an inhaled irritant may involve an immediate burning or stinging sensation in the eyes, nose, and/or throat. Such stimuli may range from unpleasant to extreme pain and are mediated by interaction of irritants with chemoreceptive nerve endings from the trigeminal nerve in the cornea, nose, tongue, oral cavity, and upper respiratory tract. Once stimulated, these nerve endings can cause systemic responses, resulting not only in a burning sensation of the nose and eyes but also a reflex reduction in respiratory rate. This response occurs once a threshold concentration at the irritant receptor is exceeded and develops immediately or within a few minutes of exposure and is both time- and concentration-dependent. Irritant responses are generally protective in nature, limiting further exposure of

TABLE 28.7
Effects of Inhaled Materials on the Nose

Effect	Examples
Restrict airflow	Temperature changes (cold air), irritants (acids, bases)
Mucociliary flow	Slowing by sulfur dioxide, formaldehyde, methyl amines
Cellular	
Olfactory degeneration	Chloroform, aliphatic esters, methyl bromide
Respiratory/olfactory irritation	Chlorine, sulfur dioxide, formaldehyde
Nasal tumors	Hexamethylphosphoramide, acetaldehyde, formaldehyde, dimethyl sulfate

the offending substance, especially to the lower respiratory tract. Although the effects of sensory irritants per se are not usually life threatening, irritants have the capacity to cause changes in the respiratory tract ranging from minor epithelial injury to fatal lung edema hours or days after exposure.

In our environment, there are many different types of respiratory tract irritants. Chlorine, for example, has been used as a war gas, and an accidental release of methyl isocyanate caused massive human exposures in India. Chemical irritants act on specific targets. Formaldehyde acts primarily on respiratory epithelial cells, chlorine acts on the nasal cilia and bronchial functions, dimethylamine acts on olfactory sensory cells, and cigarette smoke affects the laryngeal epithelium. Furthermore, a number of disease states, including asthma, asphyxiation, chronic bronchitis, emphysema, pulmonary fibrosis, and pneumoconiosis, can be induced or exacerbated by exposure to irritants. Some of the effects of inhaled materials on the nose are shown in Table 28.7.

As a portal of entry, the nasal passages are a target site for a wide range of inhaled substances. For the epithelial mucosa in the nose, squamous tissue is the target of glutaraldehyde toxicity (Gross et al. 1994), transitional epithelial tissue may be damaged by ozone (Morgan 1991), respiratory mucosal tissue by formaldehyde (Morgan et al. 1991), and the olfactory region by β,β-iminodipropionitrile (Genter et al. 1992). The effects produced at these locations may be attributable to the local dose of the substances reaching the site, site-specific tissue susceptibility, or a combination of these factors.

It should be emphasized that recording the lesion distribution is only one step in the process of identifying patterns of nasal toxicity. Because the distribution of lesions results from the interplay of local dose and tissue susceptibility, the relative influence and relevance of such responses to humans are the most important. For example, the airflow-driven local dose of highly reactive water-soluble substances, such as formaldehyde, can dictate the lesion distribution, but airflow is not likely to be a major factor in the lesions produced by less water-soluble substances, such as ozone, chloroform, and methyl bromide (Kimbell et al. 2001).

It has been shown that nasal enzymes acting at localized sites are responsible for the conversion of chemicals, such as dibasic acid esters and hexamethylphosphoramide, to reactive intermediates that cause injury at enzyme-rich cellular locations (Bogdanffy 1990, Dahl and Hadley 1991). The role of local tissue metabolism has important implications in the risk assessment of inhaled materials that cause injury solely in the nose. For example, Bogdanffy and Valentine (2003) described the role of olfactory cell carboxylesterases in the metabolism of vinyl acetate in the development of nasal tumors in rats. Intracellular acidification from the liberation of acetic acid and protons from the metabolism of vinyl acetate and attendant cytotoxicity and regenerative hyperplasia of olfactory epithelium at high doses is thought to be a threshold-related phenomenon in the mode of action for vinyl acetate and perhaps other related esters. For most substances, however, further study is needed to elucidate the dosimetry, susceptibility, and mechanisms of action for inhaled substances on nasal tissue, particularly for use in extrapolating animal data to humans.

Larynx

The laryngeal region, located between the upper respiratory tract and the trachea, is also a potential target tissue of inhaled toxicants, as a variety of substances have produced epithelial injury to this area. The ventral laryngeal epithelium of rats and mice is highly responsive to inhaled materials such as cobalt sulfate (Bucher et al. 1990), tobacco smoke (Sagartz et al. 1992), and a wide variety of industrial chemicals, pharmaceuticals, and aerosol propellants (Gopinath et al. 1987).

Laryngeal lesions commonly involve degeneration of the epithelium with subsequent regeneration, hyperplasia, and squamous metaplasia. In more severe reactions, the larynx may have epithelial ulceration with exudation. Recovery or regression from induced changes is variable and dependent upon the time scale involved and severity of type of initial lesion (Lewis 1991). Specific areas of the rodent laryngeal mucosa appear to be sensitive to inhaled materials. These sites include the epithelium covering the base of the epiglottis, ventral pouches, and the medial surfaces of the vocal processes of the arytenoid cartilage. Therefore, the detection of induced changes requires a consistent, thorough, and detailed histological examination.

Tracheobronchial Airways

The tracheobronchial airways may be the target of a number of inhaled gases, particles, and fibers. Toxicity may be directed at the mucous layer, the mucociliary apparatus of the airway epithelial cells, the epithelial cells, the sensory nerve fibers at the epithelial surface, the basement membrane, or the serous and mucous glands in the lamina propria beneath the epithelium. An example of airway toxicity at all of these levels can be appreciated in animal models of chronic bronchitis using very high levels of sulfur dioxide (250 ppm over several weeks of exposure) first described by Reid in 1963. The chronic bronchitis model in the rat is very similar to the human disease. It includes mucus hypersecretion, mucous plugging of small airways, mucous gland hyperplasia, goblet

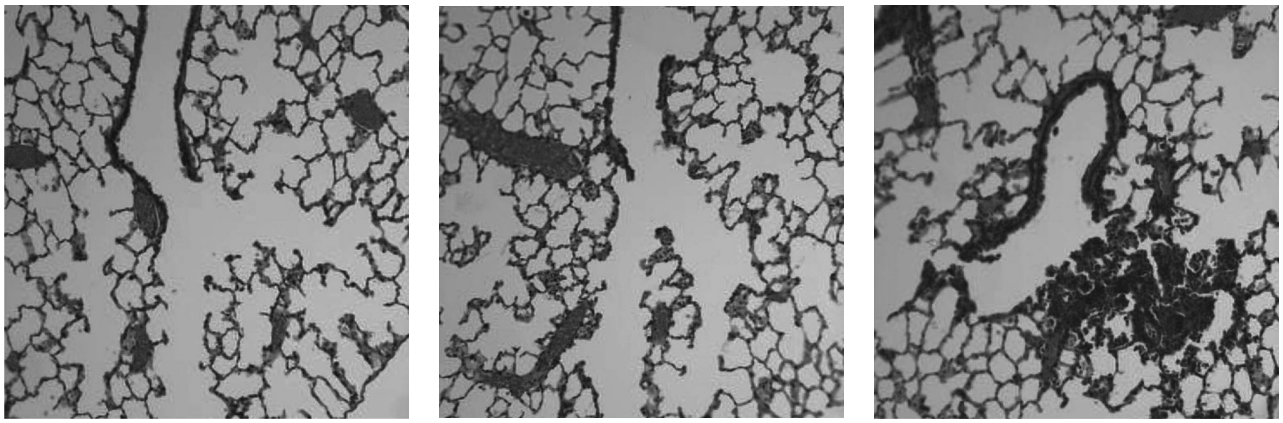

FIGURE 28.16 Bronchoalveolar junction of the rats: Bar at 50 μm in all pictures. (a) Normal rat bronchoalveolar junction. (b) Bronchoalveolar junction of a rat exposed to secondary power plant emissions with minimal inflammation. (c) Bronchoalveolar junction of a rat exposed to vehicular emissions. Note both epithelial proliferation and inflammatory cells in the alveolar.

cell metaplasia (Reid 1963), change in particle deposition patterns (Sweeney et al. 1995), airway hyperresponsiveness (Shore et al. 1995), and significant acute and chronic inflammation (Farone et al. 1995). Early studies with this model showed reversibility of these changes within a few weeks of cessation of SO_2 exposure (Reid 1963). Similar reversibility of changes of chronic bronchitis associated with smoking and its cessation has been described in people.

Pulmonary Region (Bronchioles and Alveoli)

The bronchiolar–alveolar junction is a particularly sensitive site of injury and inflammation with exposure to both particles and fibers. Figure 28.16 shows how this region is altered in rats exposed to either paper or plant or vehicular emissions. The deposition of fibers and particles has been demonstrated at this site as well as the increase in inflammation at this site (Brody and Hill 1981, Brody et al. 1981, Brody and Roe 1983, Saldiva et al. 2002). Demonstration that there is indeed an increase in responding neutrophils at this site often requires morphometric studies of the tissues.

The function of macrophages can be affected by cytotoxic airborne substances, such as asbestos, quartz, and heavy metals. This response is not limited to cytotoxic particles; for example, the instillation of 4 mg of carbon particles (considered a nuisance dust by its relative lack of cytotoxicity) into the lung of a mouse induces an acute macrophage response, with the number of macrophages increasing 10-fold (Bowden and Adamson 1978). A spectrum of responses, resulting in alterations in macrophage numbers, viability, morphology, and changes in the phagocytic capacity, can be produced by chemical insult (Gardner 1984). The effects of inhaled gases and particles on macrophage functions are important because of the function of these cells in homeostasis. Some of the studies of macrophage function describe the injurious effects of gases on macrophage bactericidal activity. In these models, animals first preexposed to ozone had higher mortality if subsequently exposed to pathogenic bacteria, ostensibly by impairing macrophage phagocytosis and lysosomal enzyme activity (Coffin et al. 1968, Goldstein et al. 1978, Gardner 1984).

Patterns of response include acute inflammation with infiltration of neutrophils and acute lung injury. Acute lung injury at the alveolar level includes damage to pulmonary epithelial cells resulting in atelectasis and the eventual formation of hyaline membranes at the level of small airways and alveoli. Hyaline membranes include fibrin, serum proteins, and cell debris from the injury to epithelial cells, alveolar capillary endothelial cells, and interstitial cells. In regeneration of the alveolar epithelium, type 2 epithelial cells, which produce surfactant, serve as the stem cell population that proliferates to cover any areas of denuded basement membrane and injured type 1 epithelial cells. Figure 28.17 illustrates the microscopic appearance of acute lung injury.

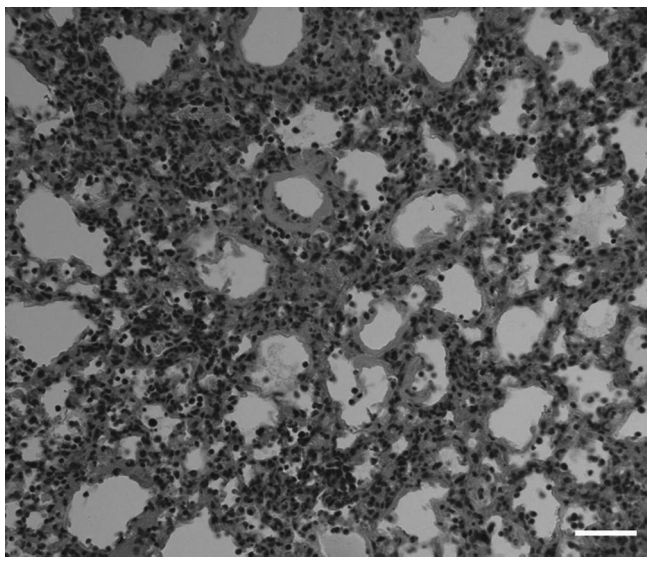

FIGURE 28.17 Acute lung injury in a mouse lung. Hyaline membranes line most alveoli, and the interstitium is thickened with inflammatory cells. Increased numbers of alveolar macrophages are seen in most alveoli. Bar = 50 μm.

Pulmonary Vasculature

The pulmonary vasculature may be the target of injury from ingested or inhaled materials (Batalha et al. 2002). The monocrotaline model of acute lung injury affects the pulmonary vasculature and ultimately results in pulmonary hypertension (White and Rothe 1989, Killingsworth et al. 1997).

Evolving Approaches to the Assessment of Pulmonary Responses

Analytic methods available for assessing the toxicology of materials reaching the respiratory tract are evolving. The continuing increase in the creativity and capabilities of science and engineering have given rise to an ever-growing number of chemicals, particles, and other reagents that have never been experienced by the billions of individuals living on our planet. For new materials, there can be no epidemiological studies in humans. Although considerable information can be learned from lifetime studies in animals, these experimental approaches are expensive and take many years. Thus, there is increasing demand for the development and calibration of high-throughput assays, most of which involve biological measurements in cultured cells. While many reagents can be tested, these assays fail to fully recapitulate the physical and humoral interactions provided by the extracellular matrix, cell–cell interactions, and the diverse cellular components of the actual respiratory tract.

One approach to filling the gap between simple cell assays and intact organisms is by using precision-cut lung slices. Slices can be made from both animal and human lungs, and they function for 7–10 days. This ex vivo approach comes far closer to reality than the cell culture systems in wide use. A recent description of this technique has been published by Rosner et al. (2013). Tice et al. (2013) have reviewed an approach called Tox21, which integrates data from a variety of technologies and multiple endpoints utilizing techniques of systems biology and applying them to toxicology. Geenen et al. (2012) review how systems biology can incorporate multiple sources of information and produce in silico systems where systems biology can explore network-mediated toxicity and make predictions about likely toxic responses as well as predict candidate biomarkers for injury to the respiratory tract.

Finally, as is true for all organizational levels of toxicology from isolated cells to humans, there is increased interest in genomics. We need to identify susceptibility genes and to quantify gene expression elicited by exposures to inhaled chemicals and particles. The emphasis inevitably is on gene–environment interactions. Then, Van Hummelen and Sadaki (2010) review the broad field of toxicogenomics and how it has been used in environmental toxicology. Also see McHale et al. (2010), who give specific examples as to how metals and organic chemicals can be profiled and used to produce risk assessments.

Supporting these approaches to hazard identification and risk quantification are the fields of proteomics, epigenetics or epigenomics, and metabolomics (van Ravenzwaay 2012). The number of genes, proteins, or metabolites is large and "big data" analyses are needed. Interpreting the significance of single cytokines is difficult. It is essential to identify signal-transduction pathways and to provide an integrated story for multiple proteins or metabolites so that we characterize the pathophysiologic story. It is difficult to distinguish cytokines that are an epiphenomenon common to many kinds of injury, such as healing and repair, from cytokines that actually control whether injury leads to progressive and nonreversible damage, such as fibrosis or cancer, or not. We need to go beyond the quantification of individual growth factors, chemokines, and other cytokines that are expressed after exposures to toxins. Instead, we need to delineate the relative intensity and the temporal and spatial relationships among cytokines (Brain 1996). In toto, there is considerable potential in these new approaches. How best to use them will be the subject of future studies.

CONCLUSION

This chapter has discussed the methods and the scientific basis of inhalation toxicology. It describes devices and facilities needed to expose animals to inhaled particles and gases, as well as approaches to estimating or measuring the fraction of the inhaled material that is retained in the respiratory tract. We review the ever-growing repertoire of techniques that can be used to measure the responses elicited by exposures to toxic materials in inspired air. Consequences of exposure to inhaled particles and gases can be studied at many different organizational levels. An understanding of the chemical reactions that take place is important, so are cellular effects and a growing number of in vitro assays. Controlled exposures, such as intratracheal instillation and insufflation, can be valuable, and so can acute and chronic exposures of whole animals. Data from humans are useful, both through experimental clinical studies and observational epidemiologic studies. A challenge is to integrate information from these varied sources.

Inhalation toxicology is of growing importance in the United States and globally. Increases in population and especially energy consumption per capita have increased the number of individuals being exposed to toxic particles and gases, as well as the consequences of those exposures. In poor, rural areas, there continues to be major concerns about indoor air pollution, especially from poorly ventilated sources of heat for warmth and cooking. This is particularly a problem for women and children. Moreover, the massive migration from rural to urban areas has increased the numbers of individuals exposed to significant levels of air pollution from mobile and rural sources. We see more clearly increases in morbidity and mortality, which are attributable to poor air quality.

Toxic exposures persist in a variety of work environments. In the United States, chronic obstructive pulmonary disease increases in importance. Much of the rising incidence in respiratory diseases is attributable to the inhalation of particles and gases in urban and work environments, and especially to the use of tobacco products. Pulmonary diseases are of concern because they are difficult to treat and because they typically manifest themselves only after decades of apparently innocuous exposure. Emphysema and lung cancer are two compelling examples. In their early stages, diagnosis is difficult. In their

end stages, they stand out as diseases that are difficult, sometimes impossible, to treat. This makes primary prevention of toxic exposures critical, and the science of inhalation toxicology in both experimental and observational studies essential.

The study of the toxic effects of inhaled chemicals is usually more challenging compared to dermal or oral routes of exposure due to the high level of technical expertise necessary for the safe generation, control, and characterization of test atmospheres. This chapter provided insights into the toxicological properties of inhaled materials and respiratory tract responses, as well as descriptions of the basic technology needed to properly conduct inhalation exposures. Textbook guidance (such as that provided by this chapter) is valuable, but is no substitute for hands-on experience. Inhalation studies are both art and science.

Despite the introduction of such novel materials as nanoparticles, a foundation in basic inhalation toxicology concepts is necessary to evaluate the hazards that these and all other new materials pose. The mark of a well-conducted inhalation study is clarity. Details of the test atmosphere generation, composition, concentration, and uniformity must be addressed so that the investigator can focus on the significance of the experimental results. Progress creates new materials, new opportunities for exposure, and a deeper understanding of biologic responses. Nevertheless, careful planning and execution of experimental studies will inevitably produce more valuable data.

QUESTIONS

28.1 For animals or humans, how do we relate exposure concentrations of inhaled aerosols to deposited dose? What are the key factors?

28.2 Why are there concerns about the potential consequences of nanomaterials, especially particles smaller than 20 nm and fibrous materials like CNTs?

28.3 Discuss polydisperse aerosols and explain why this distribution of size will be different depending on whether particles are counted, weighed, or characterized by their surface area? For a sphere, how is particle size related to mass and surface area?

28.4 What factors determine where inhaled gases are absorbed? For example, discuss the site of uptake and the site of injury for formaldehyde, sulfur dioxide, ozone, and carbon monoxide.

28.5 What considerations should be given to assess the inhalation hazard of a fibrous material intended to replace asbestos? What properties are associated with increased risk?

28.6 Discuss the relative merits of (1) longitudinal epidemiologic studies in humans exposed to particles, (2) chronic inhalation studies in animals, (3) acute in vivo bioassays in animals, and (4) an increasing array of in vitro tests.

28.7 Imagine marching down the respiratory tract from the mouth to the large airways to the small airways, and finally to the parenchyma. Now describe how geometry and linear velocities will help determine the relative efficiency of different deposition mechanisms. What are the major deposition mechanisms and which will dominate in these different anatomic regions?

28.8 Discuss major ways of generating aerosols for inhalation toxicologic experiments.

29 Detection and Evaluation of Chemically Induced Liver Injury

Gabriel L. Plaa, Michel Charbonneau, and Isabelle Plante

CONTENTS

INTRODUCTION

Liver injury induced by chemicals has been recognized as a toxicological problem for more than 100 years. During the late 1800s, scientists were concerned about the mechanisms involved in the hepatic deposition of lipids following exposure to yellow phosphorus. Also, hepatic lesions produced by arsphenamine, carbon tetrachloride, and chloroform were studied in laboratory animals during the first 40 years of the twentieth century. During the same period, the correlation between hepatic cirrhosis and excessive ethanol consumption was recognized.

Liver injury is not a single entity; the lesion observed depends not only on the chemical agent involved but also on the duration of exposure. After acute exposure, one usually finds lipid accumulation in the hepatocytes, cellular necrosis, or hepatobiliary dysfunction, whereas cirrhotic or neoplastic changes are usually considered to be the result of chronic exposures. Different biochemical alterations may lead to the same endpoint; no single mechanism governs the appearance of hepatocellular degenerative changes or alterations in function. Some forms of liver injury are reversible, whereas others result in a permanently deranged organ. The mortality associated with various forms of liver injury is variable. The incidence of injury can differ among species, and the presence of a dose-dependent relation may not always be apparent.

The marked vulnerability of the liver to chemically induced damage is a function of (1) its anatomical proximity to the blood supply from the digestive tract and high blood flow rate, (2) its ability to concentrate and biotransform foreign chemicals, and (3) its role in the excretion of xenobiotics or their metabolites into the bile. The diverse nature of the functional activity of the liver and its varied response to injury makes the selection of appropriate testing procedures a difficult task.

This chapter discusses the major methods and models that are useful in the detection and evaluation of liver injury in laboratory animals.

CLASSIFICATION OF CHEMICALLY INDUCED LIVER INJURY

The morphological changes observed following hepatic injury produced by chemical and biological agents can be classified according to two parameters: location and type of lesion produced.

Location within the Hepatic Parenchyma

An early system of describing pathological lesions of the liver originated from the concept of the hexagonal lobule introduced by F. Kiernan in 1833 (Figure 29.1). This configuration, the classical manner of presenting the relations between the hepatic cell, its vascular supply, and the biliary system, was considered to represent the functional unit of the liver. The terminal hepatic venule (central vein) is found in the center of the lobule; and the portal space, containing a branch of the portal vein, a hepatic arteriole, and a bile duct, is located at the periphery of the lobule. Based on this

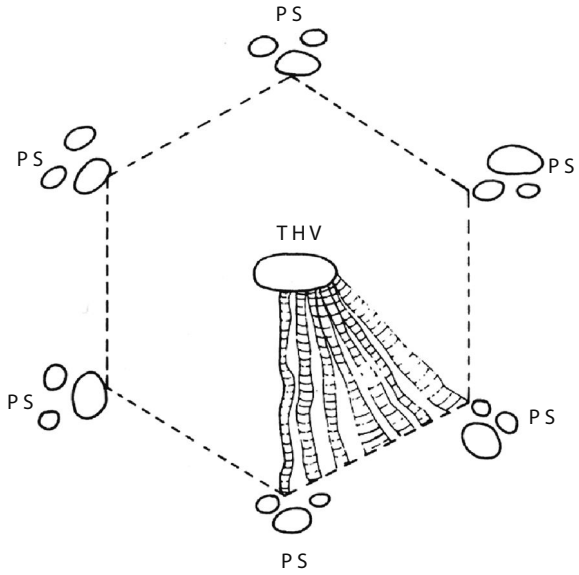

FIGURE 29.1 Schematic representation of the traditional hexagonal lobule. (*PS*) portal space, consisting of a branch of the portal vein, hepatic arteriole, and a bile duct; (*THV*) terminal hepatic venule (central vein). (From Plaa, G.L., *Toxic Responses of the Liver*, M.O. Amdur, C.D. Klaassen, and J. Doull, eds., Pergamon Press, New York, 1991, pp. 334–353. With permission.)

configuration, lesions of the hepatic parenchyma have been classified as centrilobular, midzonal, or periportal.

The hexagonal lobule configuration does not correspond to the functional unit of the liver. The hexagonal lobule is not conspicuous under microscopic examination. Injection of colored gelatin mixtures in the portal vein or hepatic artery shows that terminal afferent vessels supply blood only to sectors of adjacent hepatic lobules. These sectors are situated around terminal portal branches and extend from the terminal hepatic venule of one hexagon to the terminal hepatic venule of an adjacent hexagon. Rappaport defined the parenchymal mass in terms of functional units called the liver acini [397]. A simple liver acinus consists of a small parenchymal mass that is irregular in size and shape and is arranged around an axis consisting of a terminal portal venule, a hepatic arteriole, a bile ductule, lymph vessels, and nerves (Figure 29.2). This acinus lies between two or more terminal hepatic venules with which its vascular and biliary axis interdigitates. There is no physical separation between two liver acini. The hepatic cells of the simple acini are in cellular and sinusoidal contact with the cells of adjacent or overlapping acini. Even with this extensive communication, the hepatic cells of one particular acinus are preferentially supplied by their parent vessels. Three relatively discrete circulatory zones appear within each acinus (Figure 29.2). Hepatocytes in close juxtaposition to the terminal afferent vessel constitute zone 1. These cells are the first to be supplied with fresh blood, rich in oxygen and nutrients. The higher order of zones 2 and 3 is indicative of the greater distance between the cells comprising these zones and the supply of fresh blood.

One of the interesting correlates of the concept of zonal acinar circulation is the growing realization that not all hepatic

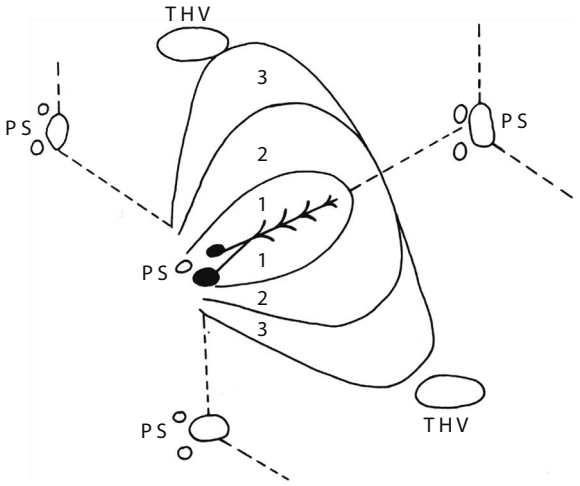

FIGURE 29.2 Schematic representation of a simple hepatic acinus, according to A. M. Rappaport. (*PS*) portal space, consisting of a branch of the portal vein, hepatic arteriole, and a bile duct; (*THV*) terminal hepatic venule (central vein); (1, 2, 3) zones draining off the terminal afferent vessel (in *black*). (From Plaa, G.L., *Toxic Responses of the Liver*, M.O. Amdur, C.D. Klaassen, and J. Doull, eds., Pergamon Press, New York, 1991, pp. 334–353. With permission.)

parenchymal cells within the liver lobule have the same kind of functional specificity. Rappaport's acinar concept has been modulated by others [152,277] to account for differences in enzyme distribution and redox state. Areas of differing metabolic activity exist within the liver [233]. Respiratory enzyme activity is particularly high in the zone closest to the terminal afferent vessel (zone 1) (Figure 29.2), whereas the most distant zone (zone 3) is particularly rich in cytochrome P450-dependent enzyme systems. The perivenous (zone 3) cells are relatively rich in some nicotinamide adenine dinucleotide phosphate (NADPH)-dependent enzymes, and periportal cells (zone 1) are relatively poor [152]. The concept of *metabolic zonation* is based on differences observed between enzyme activities in periportal and perivenous regions [233]. Thurman and Kauffmann [467] reported on the lobular distribution of maximal enzyme activities measured by immunohistochemical or microchemical techniques; these parameters do not always correlate with metabolic flux rates as measured by microfluorometry and miniature O_2 electrodes. Periportal-perivenous gradients are described for cytochrome P450s, sulfatation, glucuronidation, and glutathione-S-transferases [151]. Functional gradients are also reported for hepatobiliary activity [2]. The implications of such findings are not well understood. However, zonal and cellular enzymatic specificity and metabolic heterogeneity may permit the rationalization of differing mechanisms of action in the development of hepatic lesions associated with hepatotoxic agents.

The classical hexagonal descriptions of focal, midzonal, periportal, and centrilobular lesions, although functionally incorrect, are compatible with Rappaport's zonal acinar configuration. Centrilobular necrosis, for example, occurs in cells located in the distal acinar zone (zone 3) (Figure 29.2). When several such zones are affected, a concentric lesion can be visualized. Regeneration is said to occur from cells located in the midzonal region of the hexagonal representation, which corresponds to the acinar zone closest to the terminal afferent vessel (zone 1), a zone shown to be particularly high in cytogenic activity. Therefore, it appears that the acinal circulatory concept of the hepatic lobule does not come into serious conflict with the earlier descriptions of pathologic lesions.

Morphologic Classification

Morphologically, liver injury can manifest itself in different ways [378]. The acute effects can consist of an accumulation of lipids (steatosis) and the appearance of degenerative processes, leading to cell death (necrosis). The necrotic process can affect small groups of isolated parenchymal cells (focal necrosis), groups of cells located in zones (centrilobular, midzonal, or periportal necrosis), or virtually all of the cells within a hepatic lobule (massive necrosis). The accumulation of lipids can also be zonal or more diffuse in nature. Although acute injury may consist in both necrosis and fat accumulation, it is not necessary that both features be present. The cholestatic type of lesion, resulting in diminution or cessation of bile flow with retention of bile salts and bilirubin, is also an important form of liver injury [372,383]; this lesion leads to the appearance of jaundice. A type of massive necrosis that resembles a viral infection [528] is produced by certain chemicals. A number of drugs are also associated with a mixed type of lesion, that is, one that possesses both cholestatic and viral-like hepatic components [528].

Chemically induced liver injury resulting from chronic exposure can produce marked alteration of the entire liver structure with degenerative and proliferative changes observed in the various forms of cirrhosis. Through the years, a number of classification systems have evolved to describe the chemicals involved. The schemes are beyond the scope of this chapter. In brief, however, some are based on morphological changes [378], and others deal with the postulated mechanisms of action or the circumstances of exposure [528]. In the morphological classifications, one finds those chemicals (e.g., carbon tetrachloride [CCl_4], chloroform [$CHCl_3$], phosphorus, tannic acid, ethionine, ethanol) that produce zonal hepatocellular alterations (necrosis, steatosis). Intrahepatic cholestasis is a lesion produced by a number of drugs (e.g., phenothiazine derivatives, antimicrobial agents, anabolic steroids, oral hypoglycemics) and is characterized by biliary dysfunction. In addition, massive hepatocellular necrosis is produced by other drugs (e.g., iproniazid, monoamine oxidase inhibitors, halothane).

Regarding mechanisms of action involved [237,455,528], one finds a variety of possible effects. At least six different sites of action have been described [284], including bleb formation on the cell membrane, transport pumps in the canaliculus, enzyme-drug adduct formation in the endoplasmic reticulum, vesicle movement to the cell surface, apoptotic processes, and inhibition of β-oxidation and/or respiration in mitochondria. Predictability of the appearance of the injury and production of the lesion in laboratory animals

are important considerations. Some forms of drug-induced liver injury in humans are due to hypersensitivity (allergic reactions) or an expression of individual susceptibility (idiosyncratic reactions) [237,455,528]. Reactive metabolites and immunological mechanisms appear as important components in the elucidation of such lesions [351].

From these classifications, one sees that there are a variety of pathological processes involved in what is called, in general terms, *liver injury*. Furthermore, many different substances can cause injury. Although classification schemes assist in conceptualizing what is occurring, it should be understood that with additional knowledge of the events actually involved in the elaboration of the biochemical lesion changes in the classifications certainly occur. Regardless of this fact, the pathological types of injury produced by hepatotoxicants largely determine the biochemical and functional manifestation of injury and thus the battery of toxicological tests needed to detect and evaluate *liver injury*.

Neoplastic changes may be another endpoint of chemical liver injury. Liver cancer is one of the leading cause of cancer worldwide, being responsible for over 500,000 deaths a year [123]. Hepatocellular carcinoma (HCC), the most common type of liver cancer, arises from hepatocytes [473]. Chronic liver diseases are at the origin of the vast majority of HCC, particularly viral hepatitis B and C infections. HCC is a progressive disease, divided in three distinct phases: molecular, preclinical, and clinical [473]. Mutations or changes in gene expression occurring in the molecular phase are thought to provide a growth advantage to differentiated cells by promoting proliferation and inhibiting apoptosis [473]. Decreased cell–cell interactions are commonly observed in chemically induced HCC and can be considered as an early marker of hepatocarcinogenesis [475,476].

MODELS AND METHODS IN HEPATOTOXICITY

Many laboratory procedures have been performed to diagnose and monitor liver diseases in human clinical medicine. The performance characteristics of common tests used in humans were evaluated in 1999 and guidelines were published by the National Academy of Clinical Biochemistry [115]. Over the years, many techniques and procedures used in humans [143] were applied to laboratory animals. Ex vivo and in vitro models were also developed, allowing more mechanistic evaluation of hepatotoxicity of compounds. This chapter gives an overview of some of the common models and established methods used in hepatotoxicology, as well as more recent avenues. Some approaches, such as necrosis or hepatic function, are not discussed, and the reader is referred to good reviews for additional information [227,396].

Models Used in Hepatotoxicity Studies

Hepatotoxicological studies have been carried on virtually all common in vivo models generally used in medical sciences [147]. Other than the usual considerations in choosing an animal model (i.e., cost, caging, number of animals, and strain), it is crucial to consider the interspecies differences in the metabolism of xenobiotics in hepatic studies [530]. Indeed, the same compounds can be biotransformed at different rates and produce diverse metabolites or various amounts of metabolites in a given species [287]. Thus, when using an animal model to study human toxicity, one must choose the model that will reflect the most close human toxicity and/or biotransformation of the compound [147].

In complement to in vivo models, the approaches available to assess hepatotoxic properties of chemical agents encompass different levels of organization such as precision-cut liver slices and isolated livers (ex vivo) and isolated hepatocytes and cell cultures (in vitro). Liver cell organization is not disrupted in these four systems, such that the injuries caused by a chemical result from the overall effects of Phases I and II biotransformation reactions, defense and repair systems, and cellular processes. Zonal architecture of the liver, normal polarity of hepatocytes (biliary and plasmatic poles) and presence of all liver cell types are present only with the liver slice system and the isolated perfused liver. Isolated hepatocytes, however, offer many advantages: (1) they are relatively easy to prepare without sophisticated equipment; (2) a large number of experiments with the liver of one animal, serving as its own control, can be performed; and (3) sampling throughout the experiment is feasible. Selection of a particular approach depends on specific research needs; xenobiotic biotransformation is generally comparable from one system to another as exemplified by similar metabolic profiles for caffeine biotransformation in liver slices, hepatocyte cultures, and microsomes, with a rate of metabolite formation close to that calculated from in vivo caffeine elimination [40]. While in vivo model is required for an integrated evaluation of toxic effects of compounds, ex vivo and in vitro systems offer the possibility of assessing liver injury in the absence of extrahepatic factors, such as the absorption, distribution, and extrahepatic metabolism of the chemical, humoral factors, and toxic effects caused at other sites. For this reason, they are especially valuable for studying specific mechanisms involved in chemically induced liver injury. In the present chapter, however, we focus on the use of these systems to detect and evaluate hepatotoxic properties of chemical agents.

Ex Vivo Models

Isolated Perfused Liver

Studying the entire organ is probably what resembles the in vivo situation the most closely. In this model, the freshly isolated organ remains intact and is nourished with media via the ligation of the hepatic artery [168], thus retaining tissue architecture, hemodynamic parameters, bile production, tissue function, and cell–cell interactions [168,177,178]. On the other hand, perfused isolated livers are expensive and complex, can be maintained for only a few hours, and many animals are required as a particular liver can be used for only one experiment [176]. Technical aspects and applications of the isolated perfused liver system will not be discussed in the present section. For additional reading on the use of the isolated perfused liver as a model for studying drug- and chemical-induced hepatotoxicity, the reader can consult monographs and reviews [25,42,176,458].

Liver Slices

To overcome limitations of the isolated perfused liver model, methods were developed to preserve precision-cut liver slices in culture. Precision-cut liver slice technology was pioneered at the University of Arizona (reviewed by Brendel et al. [54]). Their dynamic organ culture system allows both the upper and lower surfaces of the cultured slice to be exposed to the gas phase during the course of incubation to overcome disintegration of the slice-medium interface in long-term incubation of tissue slices. The liver slice procedure appears to be more efficient for the collection of serial data than the perfused liver preparation. In a discussion of techniques for studying drug metabolism in vitro, Gillette [156] presented the liver slice system in the following terms: "Since the circulation of nutrients and oxygen through the capillaries is lost, the transfer of these substances from the medium to the innermost cells must depend on passive diffusion. It is therefore imperative that the slices be thin because the rate of diffusion is inversely related to the square of the distance the substances must traverse. Even with slices as thin as 0.5 mm, the concentrations of the nutrients and other substrates that are rapidly utilized by cells in the slice may not be identical throughout the slice." In recent years, technological improvements in the preparation of precision-cut rat liver slices have allowed this system to assess liver injury in a reproducible fashion. About 200–250 μm thick liver slices (~8 cell layers) allow multiple experimentations on the liver of a single animal [286,308,332,526]. Recent research showed that slices as thin as 100 μm can also be used successfully [103]. Three different tissue slicers (Krumidieck/Alabama Research and Development Tissue Slicer, Brendel/Vitron Slicer, Leica VT1200 S microtome) have been described [149,363,529]. All slicers appear to readily produce liver slices that are adequate for biotransformation or toxicity studies [391,529]. Produced liver slices can then be cultured in a continuously submerged culture system in which they are floating within the culture medium in plates or flasks that are gently shaken or placed onto a grid in magnetically stirred culture medium [484]. Liver slices can also be placed on inserts in a rolling glass vial or in rocking six-well plates and exposed to the gas phase and the culture medium in dynamic culture systems. In both continuously submerged and dynamic culture systems, tissues are cultured at 37°C in a humidified incubator in the presence of oxygen (5%–20%) and CO_2 (5%). One issue with these two systems is the accumulation of waste products and the depletion of substrates in the medium that is thought to result in decreased metabolic activity and protein expression over time [241,431,486]. Different systems have recently been designed to overcome these limitations that represent promising models for toxicological studies [195,241,431,486].

The slicing buffer medium should be similar in inorganic composition to the culture medium used in liver cultures; HEPES is recommended. Waymouth's medium is recommended as the culture medium, and a viability of 120 h is claimed for liver slices. A roller culture system is claimed to be most effective for the extended viability of precision-cut tissue slices. The parameters for assessing viability of liver slices originally described by the Arizona group include enzyme (lactic dehydrogenase [LDH]) leakage, intracellular potassium content, nonprotein sulfhydril content, lipid peroxidation, protein synthesis, gluconeogenesis, Phase I and II biotransformation, and histological evaluation. Olinga et al. [354] compared different methods (magnetically stirred 24-well, full immersed system; shaker-stirred, 6-well, fully immersed system; rocker platform, 6-well culture plate system; roller incubation vial, partially immersed system) for incubation of liver slices for periods of 1.5–24.5 h. In terms of cell viability, the stirred systems, generally, fared the least, whereas the rocker and roller methods appeared to be superior. In another study [471], where precision-cut liver slices were incubated in either a shaking platform or a roller incubation system for 72 h, the roller system was reported as the better one for preserving histological and functional integrity of the slices.

Behrsing et al. [32] took advantage of refinements in procedure that prevent necrosis at the contact point with the support mesh to demonstrate that rat liver slices can retain their integrity and viability for at least 10 days in culture. Refinements included (1) flushing the liver and slicing the cores in cold University of Wisconsin (UW) solution, (2) loading the slices onto cellulose–ester filters placed on the mesh inside the inserts in a dynamic roller culture system rather than directly in contact with the titanium mesh or Teflon screen, and (3) culturing in a defined medium based on Waymouth's MB 752/1 under a high O_2 content atmosphere. The known hepatobiliary toxicant, geldanamycin, produced biochemical and morphological deficits in both hepatocytes and biliary cells in this model system, consistent with its target in vivo. Subsequent studies showed that in rat liver slices it is possible to detect compound-, concentration-, and cell-specific toxicities in response to geldanamycin and 17-allylaminogeldanamycin [31] and that species-related differences in toxicity seen in vivo are replicated using dog liver slices [5].

Liver slices maintained for short periods of time have been used with success in biochemical and pharmacological research for over 50 years. For hepatotoxicity, Weldon [502] reported in 1965 a clear dose-dependent reduction in the metabolism of L-leucine by liver slices incubated with CCl_4. Smuckler [448] subsequently observed a marked reduction in amino acid incorporation into proteins by liver slices from animals that had received CCl_4, as well as in control slices incubated with CCl_4. Marsh and Bizzi [306] concluded that the rat liver slice was a valid and useful system for the study of the action of drugs on lipid and lipoprotein metabolism. The parameters measured to evaluate liver injury include LDH leakage, decreased protein synthesis, decreased intracellular potassium content and histological alterations. Pig and human liver slices have also been cryopreserved with success and used for subsequent toxicological and metabolic studies [134]. High viability of rat liver slices has been observed when tissues were rapidly frozen after preincubation with 18% Me_2SO or VS_4 (a 7.5 M mixture of Me_2SO, 1,2-propanediol, and formamide with a weight ratio of 21.5:15:2.4) [104]. Fisher et al. [132] observed that three

dichlorobenzene isomers were more toxic to human liver slices when the incubation medium was Krebs–Henseleit buffer compared to Waymouth's medium.

Assessing the relative toxicities of bromobenzene, *o*-bromobenzonitrile, *o*-bromobenzene, *o*-bromoanisole, *o*-bromotoluene, and *o*-bromo-benzomethyltrifluoride, Fisher et al. [133] concluded that results obtained with precision-cut liver slices appear to be more representative of those observed in vivo than do results obtained from isolated hepatocytes. Wormser et al. [512] observed species and age differences in toxicity and reported that the relative toxicities of various chemicals in the liver slice system were similar to those reported in vivo. The hepatotoxic properties of CCl_4 and $CHCl_3$ in precision-cut liver slices suggested that this system is a useful tool for the investigation of site-specific toxicants [16,17]. In rats, bromobenzene produces centrilobular necrosis in vivo, whereas allyl alcohol produces periportal lesions. In liver slices, centrilobular lesions following bromobenzene exposure were observed, but the expected periportal lesion with allyl alcohol was not observed [149,446]. The lack of the expected site-specific response with allyl alcohol is attributed to the absence of circulatory influences in the tissue slice system. Indications of oxidative stress (glutathione (GSH):glutathione disulfide (GSSG) ratio), as a mechanism of action to explain the hepatotoxic properties of atractyloside, was reported in studies using precision-cut liver slices obtained from rats and domestic pigs [350]. The hepatotoxic properties of coumarin, menadione, and allyl alcohol on protein synthesis, potassium content, and mitochondrial dimethylthiazoldiphenyl tetrazolium–formazan production (MTT assay) were assessed in liver slices prepared from different species (rats, guinea pigs, Cynomolgus monkeys, and humans) and incubated for 24 h periods [391]. Menadione toxicity was evident in all four species, while allyl alcohol toxicity was less evident in rats; coumarin concentration-dependent toxicity was evident in guinea pigs and rats, but less effective in monkeys or humans. These interesting species-dependent observations demonstrate the utility of the liver slice technique for evaluating species differences in chemical-induced hepatotoxicity.

The application of the precision-cut slice technique to the biotransformation of xenobiotics in liver, including the coupling of Phases I and II metabolic pathways, has been extensive [3,94,149,300,363,465]. The utility of cultured human liver slices for assessing the effects of chemicals on P450 enzymes has been demonstrated [121]. Liver slices from several species (rats, dogs, guinea pigs, and humans) have been employed with success. Liver slices also were shown to respond to several known different metabolic situations: peroxisome proliferation, hormone-regulated glucose metabolism, unscheduled DNA synthesis, and formation of neoantigens after halothane exposure. Other applications of the technique have been demonstrated. The live-time evaluation of cell toxicity by following production of specific fluorescent dyes in liver slices by confocal microscopy was studied after exposing precision-cut slices to 1,1-dichloroethylene and then examining them microscopically; very few dead cells were observed at 2 h, progressively more were seen after 3–7 h [93]. Apoptosis (detected by DNA fragmentation, amplification of the Bax gene, and histology) in liver slices was assessed after incubating slices in the presence of staurosporine, a protein kinase C inhibitor [81]; features of apoptosis were successfully detected even in the presence of necrosis. Histopathological changes, DNA fragmentation, caspase-3 activation, and release of cytochrome *c* induced by thioacetamide in both rat liver slices and in vivo treated rats indicated that precision-cut liver slices provide a valuable system to study chemical-induced apoptosis [328]. Chemical–DNA adduct formation has been observed in benzo[a]pyrene-exposed rat liver slices [194]. Precision-cut liver slices from two transgenic mouse strains, one of which couples the promoting region of CYP 1A1 to ß-galactosidase, and another that couples two forward and two backward 12-otetradecanoyl phorbol-13-acetate [12] repeat elements (TRE) to luciferase (termed AP-1/luciferase), showed promotional effects in the presence of β-napthoflavone and TPA, respectively, indicating that precision-cut liver slices from transgenic mice offer a novel in vitro method for toxicity evaluation, while maintaining normal cell heterogeneity [66]. Precision-cut liver slices from neonatal rats showed fewer morphological alterations and increased viability compared to adult rats and excellent induction of cytochrome P450 isoforms [300]. Finally, precision-cut liver slices have been reported to test specificity and efficiency of gene transfer as well as of viral replication using human tissue [244].

The diverse utility of precision-cut liver slice technique for evaluating liver function and injury is now well established, since its original introduction in 1985 by Smith et al. [447]. Furthermore, it is readily adaptable to the evaluation of human tissue. One advantage the system offers over isolated or cultured hepatocytes is the fact that tissue architecture is preserved, all cell types remain present, and multiple analyses coupled with morphological examination are possible.

In Vitro Models

Isolated Hepatocytes

The liver is constituted of six different cell populations: the hepatocytes, biliary epithelial cells, endothelial cells, Kupffer cells, Ito cells (lipocytes, fat-storing cells), and pit cells. The cells other than the hepatocytes are designated as the nonparenchymal cells. The hepatocytes (or parenchymal cells) constitute 60% of the liver cell population and occupy 80% of the total liver volume. Much of the effort in isolation of liver cells has focused on viable hepatocytes, since they are the main metabolic unit of the liver. Procedures, however, are also available for isolating nonparenchymal cells [140].

The literature on preparation, properties, and application of isolated hepatocytes is abundant, and excellent monographs and reviews have been published [37,180,312,313,458]. The in situ two-step procedure is the most commonly used technique to isolate hepatocytes. It is derived from the pioneering work of Berry and Friend [37], who introduced in situ liver perfusion with digestive enzymes, and from the subsequent work of Seglen [434,435], who enhanced the recovery of isolated viable cells by initially perfusing the liver with a calcium-free

buffer and then placing the digestive enzymes in a calcium-supplemented buffer. In current techniques, buffers containing a chelating agent and collagenase as the digestive enzyme are used for the first and second steps; suspensions exhibiting greater than 90% viability are usually obtained. Nonviable hepatocytes can be separated from viable ones using a dibutyl phthalate separation technique [128].

Hepatocytes are most commonly isolated from rat liver; the two-step procedure, however, has been successfully adapted to other species such as the mouse, rabbit, and guinea pig [312,313]. Specialized techniques are also available for preparing suspensions enriched with periportal or perivenous hepatocytes [38]. Increasing interests in toxicological risk assessment have prompted the development of procedures, such as the biopsy perfusion methods [4], to isolate hepatocytes from human liver samples. Successful approaches have also been achieved to optimize cryopreservation procedures for human hepatocytes [77,281,298].

Isolated hepatocytes have been extensively employed for studies on chemical (including drugs) biotransformation and toxicity. Over the years, the bulk of the reports published on chemical metabolism in isolated hepatocytes have defined the capabilities and limits of this system. There is no doubt that isolated cells have proved valuable for investigating biotransformation [37,38,182]. The activity of Phases I or II metabolizing enzymes in viable cells is maintained for a few hours [180]. However, in standard metabolic/toxicological studies, the incubation period of the cells with the chemical is relatively short (<3 h), such that the losses in activity do not generally invalidate the experiments. The substrate metabolic rates are often similar or slightly slower in isolated hepatocytes than in corresponding 9000 g supernatant or microsomes [180]. The parameters measured to evaluate liver injury include LDH leakage, decreased protein synthesis, decreased intracellular potassium content, and histological alterations.

Cytotoxicity of chemicals in freshly isolated hepatocyte suspensions is a valuable tool when screening xenobiotics for hepatotoxic properties. As with the in vivo tests, the major cytotoxicity parameters studied are based on the structural integrity of the cell membrane. The uptake of normally non-permeable dyes, such as trypan blue and neutral red, is one of the most common tests; the percentage of nonviable colored cells requires a cell counting analysis under a light microscope. Leakage into the medium (separated from the cells) of the cytosolic enzyme LDH is a biochemical test that is as frequently common as the dye exclusion assay. The former, however, is more convenient to perform than the dye assay, and it also offers the advantage of summing up the release of all damaged cells, including disintegrated hepatocytes. For some chemicals, decreases in intracellular concentrations of LDH have been reported at dosages in which LDH leakage into the medium could not be detected [303]. Measurement of intracellular potassium, sodium, or calcium content is a more sensitive marker of cell membrane integrity. Fariss et al. [128] observed a decrease in potassium level 3 h prior to LDH leakage in cells treated with adriamycin in combination with 1,3-bis(2-chloroethyl)-1-nitrosourea or ethyl methanesulfonate. Indices of cellular metabolic competence are also sensitive markers; modifications of glycogen deposits and protein synthesis have been shown to detect early changes in isolated cells treated with chlorpromazine, promethazine, bromobenzene, acetaminophen, and isoniazid [160]. Frazier [139] reported that cellular potassium concentration was the most sensitive toxicity index, with inhibition of protein synthesis second, and trypan blue staining least, to evaluate cadmium, copper, and zinc toxicity. Finally, morphological changes in isolated cells can be assessed by electron microscopy.

The isolation procedure inevitably introduces changes and renders cells more susceptible to the effect of chemicals compared to the intact liver. When studying the hepatotoxic properties of organic solvents, care should be given to the selection of concentrations used, since these agents are thought to exert direct solvent effects [37]. In addition, it is preferable to use equilibration techniques in stoppered flasks to study volatile chemicals with low water solubility.

Studies have shown that known in vivo hepatotoxicants tested in isolated cell suspensions are cytotoxic in vitro. Individual chemicals such as acetaminophen, ethanol, methotrexate, fentanyl, bromobenzene, and chlorinated aliphatic compounds [182,479,494], as well as mixtures like CCl_4/$CHCl_3$ [349] and combinations of trichloroethylene, tetrachloroethylene, and 1,1,1-trichloroethane [451] are hepatotoxicants in vivo and in vitro. There are also examples of species and strain differences observed in vivo that also occur in vitro [326,511]. Differences between in vivo and in vitro hepatotoxic potency, however, were observed in several occasions. Dimethylnitrosamide and thioacetamide are not as potent in the isolated cell system as expected from their in vivo hepatotoxicity [453]. Rankings of relative toxicity for different haloalkanes or bile salts in isolated hepatocytes differ from those observed in vivo [98,169,451]. Finally, the ability of isolated cell suspensions to accurately detect the hepatotoxic properties for chemicals with unknown in vivo effects remains to be fully demonstrated, in particular for chemicals found to be weak or moderate hepatotoxicants.

Cholestatic responses per se cannot be seen in isolated hepatocytes. It is possible, however, to evaluate chemical interference with processes involved in the transport of endogenous substances into and out of hepatocytes. Such approaches have been successful for thioacetamides and cyclosporin A [55,273]. Hepatocyte couplets (two adjacent hepatocytes surrounding a lumen or vacuole) represent the primary bile secretory unit and are thought to be the equivalent of the bile canaliculus [49]. Secretory polarity is retained in hepatocyte couplets and methods that permit the isolation of these couplets, as well as their utility for assessing canalicular function, have been perfected. The functional aspects include (1) the excretion of fluid, organic anions and cations, lipids, and proteins; (2) the regulation of cellular and canalicular pH; (3) transcytosis and protein transport; (4) cytoskeletal function and canalicular contractility; (5) signal transduction, calcium signaling, and paracellular permeability; and (6) electrophysiological events [49]. The effects of cholestatic agents on tight junctional permeability in isolated

rat hepatocyte couplets have been assessed by monitoring the retention of a fluorescent bile acid analogue (cholyl-lysyl-fluoresein) or the penetration of horseradish peroxidase [417]. Incubation of couplets in the presence of taurolithocholic acid, cyclosporin A, estradiol 17β-glucuronide, menadione, or *t*-butyl hydroperoxide (substances known to affect hepatobiliary function in vivo) resulted in a quantifiable dose-dependent decrease in canalicular retention.

Hepatocyte Cultures

Hepatocyte cell cultures represent an extension of the isolated hepatocyte assay that permits longer test periods by attaching cells to a matrix placed in a periodically refreshed medium to keep them viable. Hepatocytes can be cultured in monolayers, in *sandwich* between two layers of collagen or in speroids, the two latest allowing induces the formation of distinct apical and lateral membrane domains, and enhanced hepatic functions. The comprehensive review prepared by Grisham [175] in 1979 is one indicator of the long-standing popularity of hepatic cell cultures to detect and evaluate the mechanisms of actions of toxic chemicals. Also, Berry et al. [37] reviewed the subject in their excellent monograph on the use of isolated hepatocytes for in vitro studies, while technical aspects of culturing hepatocytes are presented in other monographs [102,179,312]. Factors such as matrix used for cell attachment, culture medium, addition of hormones, oxygen tension, cell density, and the presence of other cell types determine enzyme and gene expression and affect cell viability in monolayer cultures of hepatocytes [312].

Biochemical parameters used to measure liver injury in isolated cells also apply to hepatocyte cultures. CCl_4-induced biochemical changes in cultured hepatocytes followed nearly the same continuum as observed in vivo, although the progression was much more rapid in vitro [297]; leakage of alanine aminotransferase (ALT) was increased and G6Pase activity was decreased in intact liver and cultured cells, whereas 5′-nucleotidase activity was unaffected in either preparation. In hepatocyte cultures incubated with tetracycline or norethindrone, Anuforo et al. [7] found that the leakage of arginosuccinate lyase (ALT), and LDH into the medium was more pronounced than that of alkaline phosphatase (AP) and aspartate aminotransferase (AST). Chao et al. [71] reported that intracellular LDH content is a better indicator of the number of viable hepatocytes in contrast to LDH released into the medium.

Cultures of viable hepatocytes can be maintained for several days. Xenobiotic biotransformation enzyme activities decrease, however, after 1 or 2 days in culture [180,313,444]. For this reason, assessment of cytotoxicity in hepatocyte cultures is routinely performed during the first 2 days of culturing. Hepatocytes cultured in hormone-supplemented, serum-free medium maintain, however, high biotransformation enzyme activities for several days [110,183,313]. Long-term cultures of functional hepatocytes can be achieved by coculturing hepatocytes with another rat liver cell type and represent a promising tool to investigate chronic liver toxicity [183]. Human hepatocytes, particularly when mixed with rat liver epithelial cells, may provide a valuable tool for predicting hepatotoxicity of new drugs in humans [181]. Finally, there is evidence for the reconstruction of functionally intact biliary polarity in hepatocytes in culture, indicating the possible utility of this system for studies on intrahepatic cholestasis [151].

Toxicity studies involving cultured hepatocytes usually assess three types of effects: cytotoxicity, genotoxicity, and enzyme induction [288]. For cytotoxicity, one can follow morphology, dye permeation (trypan blue), as well as release of cytoplasmic enzymes (ALT, AST, LDH). Promutagen activation and induction of unscheduled DNA synthesis can be used to assess genotoxicity. Finally, enzyme induction effects can be discerned by following peroxisomal induction or cytochrome P450 induction. Cultured hepatocytes are considered useful for the study of peroxisome proliferation, since the cells can be used for screening new chemicals, for evaluating the sequence of events involved in their mechanism of action, and for assessing the potential for producing such effects in humans [136].

Methods Used in Hepatotoxicity Studies

Traditional approaches used for evaluation of experimental hepatic injuries in laboratory animals can be divided into six main categories: (1) serum enzyme tests, (2) histological analysis of the liver injury, (3) hepatic excretory tests, (4) alterations in mitochondrial functions, (5) lipid peroxidation and oxidative stress analysis, and (6) formation of binding metabolites. This chapter covers major tests that have proved useful to detect hepatic dysfunction or injury over the years. While additional biochemical, metabolomic, genomic, and proteomic approaches are also employed to define the different mechanisms involved, they will not be covered in this chapter. The reader is referred to reviews and monographies for further information [30,253,487].

Serum Enzyme Techniques

Determination of the activity of hepatic enzymes released into the blood by the damaged liver is still one of the most useful tools in the study of hepatotoxicity. The application of serum enzyme methodology to the detection of liver injury was introduced during the 1930s and 1940s with the demonstration of abnormal serum activities of AP [414] and cholinesterase (ChE) [53]. However, the discovery during the 1950s that the activity of several serum aminotransferases was increased by tissue destruction represents the true advent of the serum enzyme methods. Subsequently, a number of other enzymes were identified in blood, several of which demonstrate abnormal activity in the presence of liver injury.

Zimmerman [528] identified four major categories of serum enzymes based on their specificity for and sensitivity to different types of liver injury. The first group contains enzymes such as AP, 5′-nucleotidase (5′-NT), and γ-glutamyltranspeptidase (γ-GT). Elevated serum activities of these enzymes appear to reflect cholestatic injury more effectively than necrogenic injury. In contrast, the second group of enzymes includes those that are more sensitive to cytotoxic hepatic injury. This group has been further subdivided into

(1) enzymes that are somewhat nonspecific and can reflect injury to extrahepatic tissue, for example, AST, LDH, malic dehydrogenase (MDH), and aldolase (ALD); (2) enzymes found mainly in the liver, for example, ALT, isocitrate dehydrogenase (ICDH), and glutamate dehydrogenase (GDH); and (3) enzymes that are almost exclusively located in the liver, for example, ornithine carbamyl transferase (OCT), sorbitol dehydrogenase (SDH), LDH, guanase, and fructose-1-phosphate ALD. Assay of the more hepatospecific subgroup of enzymes may be particularly useful when studying agents with unknown hepatotoxic potential. Although elevated serum activity of the aminotransferases may reflect injury to extrahepatic organs such as the heart, skeletal muscle, or kidney, elevated activities of OCT and SDH are reliable reflections of hepatic injury. The third and fourth serum enzyme categories contain, respectively, enzymes that are relatively insensitive to hepatic injury but are elevated with extrahepatic diseases, for example, creatine phosphokinase (CPK), and enzymes that demonstrate a depressed serum activity in liver disease, for example, ChE.

Aminotransferases, Ornithine Carbamyl Transferase, and Sorbitol Dehydrogenase

The selection of a battery of enzymes for evaluating the hepatotoxic potential of an unknown chemical in laboratory animals is complicated by the varying sensitivity of the enzymes to different types of lesion. In an early series of experiments, Molander et al. [325] found that the measurement of serum AST provided a more sensitive index of hepatocellular injury in rats treated with CCl_4 than did the measurement of either ChE or AP. A number of experimentally induced necrotic states are also detectable by an elevation in the serum activity of ALT, a liver cytoplasmic enzyme. Balazs et al. [23] assessed serum ALT as a liver test in rats after treatment with ethionine, CCl_4, thioacetamide, dimethylnitrosamine, or allyl alcohol. Serum ALT elevation occurred following the acute administration of all of these agents, but with ethionine the elevation was not pronounced. This finding is understandable in that ethionine does not produce extensive centrilobular necrosis but usually results in fatty infiltration.

Other investigators also found that ALT is an insensitive measure of hepatic steatosis [9,154]. On the other hand, those agents that are associated with severe necrotic lesions produce pronounced elevation of serum ALT. Balazs et al. [22,23] found that when the gross pathological changes or the severity of the histopathology were compared to the elevation in ALT, there was a good correlation between the elevation in serum activity and the severity of the lesion. Others showed [381] that there was an excellent correlation between the severity of quantified histologic damage produced by $CHCl_3$ and the elevation in serum ALT activity in rats. Therefore, it seems with ALT that not only is it possible to detect the presence of liver injury, but under some circumstances, the severity of the lesion can be estimated by the elevation in serum enzyme activity. In chemical interaction studies, in which the severity of the hepatic lesion of interest may be enhanced or diminished because of the presence of a second or third chemical [381], measurement of serum ALT activity is a useful investigative tool.

Aminotransferase activity in different tissues varies and distinct species differences occur [513]. In most instances, AST activity is greater than ALT. High AST activity occurs in skeletal muscle, diaphragm, heart muscle, and liver tissue. ALT is not as widely distributed; in humans, the greatest activity is found in the liver. Cornelius [87] studied the hepatic distribution of ALT in various animals and found that a relation exists between body size and the amount of hepatic ALT: generally speaking, the smaller the animal is within the weight range studied, the greater the hepatic ALT activity [88]. Low activity of ALT was found in horses, cattle, and pigs, and, when these species were subjected to CCl_4 intoxication, significant elevation of serum ALT occurred only in the dog. On the other hand, when serum AST activity was used for measuring hepatotoxicity, all species exhibited an increase in serum enzyme activity after CCl_4. In the rat, both serum AST and ALT activities are markedly elevated after experimental injury; either enzyme could probably be used for detecting injury in this species. Hemolysis, however, has a marked effect on serum AST in the rat, whereas its effect is practically negligible in the case of serum ALT [376]. This fact should be kept in mind when one is using rats for assessing liver function. In addition, since the hepatic specificity of ALT is greater than AST, measurement of serum ALT activity, rather than AST, might be preferable for determining the status of the liver.

OCT is found predominantly in the mitochondrial fraction of liver cells [96,403,404] and normally occurs only in minute amounts in serum. The mucosa of the small intestine contains a small amount, 1%–2% that of the liver, and tissue such as brain and kidney contains only trace amounts [405–407]. OCT serum activity is markedly elevated in both acute and chronic liver disease in humans [331,407]. With experimentally induced hepatotoxicity, Reichard [404] found that serum activity of OCT increased considerably more than those of the aminotransferases but followed a similar temporal phase. Serum OCT activity is a useful monitor of liver injury in rats treated with various hepatotoxicants [96,113,114,265]. Indeed, Drotman [113] described a dose-dependent relation between the amount of CCl_4 administered to rats and serum OCT activity. In addition, a sixfold increase in OCT activity was found at a CCl_4 dose that did not produce distinctive liver damage upon light microscopic examination of the tissue, suggesting that OCT may be as sensitive an index of liver injury as histopathological examination [114]. The correlation between elevation in serum OCT activity and quantified histological changes following $CHCl_3$ administration is good [381].

SDH, a cytoplasmic enzyme, is also relatively specific for liver [10,96], and an increase in the serum activity of this enzyme is a relatively sensitive index of hepatocellular damage. In an elegant series of experiments, Korsrud et al. [264] determined the serum activity of nine hepatic enzymes in CCl_4-poisoned rats in an attempt to identify those enzymes that would respond quantitatively to varying CCl_4 doses and would indicate minimal liver damage. They placed the

enzymes in three groups based on the lowest dose of CCl_4 required to elevate serum activity and concluded that SDH was the most sensitive enzymic index of liver injury. A group of four enzymes (ICDH, fructose-1,6-aldolase [F-1,6-ALD], ALT, and AST) were less sensitive to CCl_4 than SDH but were more responsive to liver injury than were alcohol dehydrogenase (ADH), 6-phosphodigluconase (6-PDG), LDH, and MDH. However, histological alterations were observed at CCl_4 doses that did not elevate serum enzyme activity. Subsequently, Korsrud et al. [265] studied thioacetamide and dimethylnitrosamine. As before, serum SDH was the most sensitive enzymic index of liver necrosis.

SDH, however, was not a preferentially sensitive index of liver injury in diethanolamine-treated rats. Six enzymes (SDH, ICDH, F-1,6-ALD, ALT, AST, and MDH) were equally responsive to diethanolamine hepatotoxicity, whereas a higher dose of this compound was required to elevate the serum activity of OCT, GDH, and LDH. Based on these observations, Korsrud et al. [265] suggested that SDH was the best enzymic index of liver injury when minimal damage or minimal changes are being assessed. However, histological changes characteristic of each hepatotoxicant were noted at doses that did not result in an elevation of serum activity. Thus, the serum enzyme assays were less sensitive than histopathological examination for detecting liver damage. Later work by Travlos et al. [472] compared the relative sensitivities of SDH, ALT, and histopathology as indices of liver injury in rats. When increases in both enzymes occurred simultaneously, terminal histopathological changes were very highly predictable (75%–100%). They concluded that clinical chemistry evaluations could be useful for detecting potential treatment effects throughout a study, although histopathological evaluation can only be performed on termination.

Serum ALT activity is probably the most frequently used enzymic parameter to assess hepatic injury in laboratory animals. Because of the high sensitivity of OCT and SDH, however, it appears reasonable that one of these two enzymes could be used in conjunction with ALT when examining the hepatotoxic potential of an unknown chemical. In this manner, the battery of tests might better reflect the range of sensitivity encompassed by light microscopy. When the effects of several hepatotoxicants on plasma ALT and GDH values were compared in rats, the latter enzyme was reported to be a more effective marker than ALT, based on plasma elevations following injury, persistence following injury, and sensitivity [348]. Also, plasma ICDH/ALT ratios appear useful for differentiating mild-to-moderate degrees of centrilobular hepatic necrosis from periportal necrosis in rats [249].

Analytical determination of aminotransferase activity is mainly achieved by two techniques. For AST, one measures the conversion of aspartic acid and α-ketoglutaric acid to glutamic acid and oxaloacetic acid; for ALT, one measures the conversion of alanine and α-ketoglutaric acid to glutamic acid and pyruvic acid. With the ultraviolet method of analysis, the enzyme processes are coupled with ones in which nicotinamide adenine dinucleotide (NAD) is converted from its reduced form (NADH) to the oxidized form (NAD). The course of the reaction is followed by the decrease in absorbance at 340 nm produced by the oxidation of NADH. The colorimetric procedure involves the reaction of the product (oxaloacetic or pyruvic acid) with dinitrophenylhydrazine to form a colored hydrazone. This product can be determined by its absorbance in the visible range. The principal advantages of the colorimetric method are that an ultraviolet spectrophotometer is not required and temperature control of the enzymic reaction is more easily attained. Many kits are available commercially.

Similarly, as OCT catalyzes the transfer of the carbamyl group from carbamyl phosphate to ornithine, which results in the formation of citrulline, OCT activity may be measured directly by following the appearance of citrulline. Citrulline is determined colorimetrically with diacetyl monoxime after destruction of serum urea with urease [67,68,489]. Alternatively, OCT activity can be monitored indirectly by arsenolysis, in which the enzyme catalyzes the reverse reaction of citrulline to ammonia, carbon dioxide, and ornithine. OCT activity is then determined by the production of $^{14}CO_2$ from (^{14}C-ureido)-L-citrulline [113,265,408] or by the production of ammonia. The formation of ammonia can be analyzed by conversion to indophenol [262] or by a microdiffusion procedure in a Conway cell [403].

Enzymes Useful for Detecting Obstructive Disorders

Most of the preceding discussion concerns the use of serum enzymes to detect necrotic or degenerative processes following the administration of toxicants. In general, these enzymes are not as useful for detecting those types of hepatic alteration that are associated with diminution or cessation of bile flow. The degree of change in serum enzyme activities that one can obtain by the induction of experimental hepatotoxicity in mice is demonstrated in Table 29.1. Three hepatotoxic procedures were employed in this study [376]. One group of animals received α-naphthylisothiocyanate (ANIT), another received CCl_4, and the third group had their bile ducts ligated. Serum enzyme activities (ALT and AP) were determined 24 h later. For comparative purposes, sulfobromophthalein (BSP) retention and serum bilirubin concentrations were also measured in these animals. It is evident (Table 29.1) that a necrotizing agent such as CCl_4 produces sufficient parenchymal injury to cause a large increase in serum ALT activity, whereas those experimental procedures that markedly impair biliary excretion (ANIT treatment, bile duct ligation) causes only a mild increase in ALT activity. The reciprocal relation is obtained when serum AP activity is assessed; obstruction of biliary flow (bile duct ligation) markedly increases serum AP activity, whereas the necrotizing challenge (CCl4) produces only a mild elevation.

Alkaline phosphatase is the prototype of those enzymes (Zimmerman's group 1) that reflect pathological reductions in biliary flow. In the rat, this enzyme is found in the liver and the intestine. Alkaline phosphatase exerts a role in the downregulation of the secretory activities of the intrahepatic biliary epithelium [4]. After bile duct ligation, the activity in the liver increases due to de novo synthesis of the membranous form of the enzyme [433]. The use of this enzyme

TABLE 29.1
Effect of Various Hepatotoxic Procedures on Four Liver Function Tests in Mice[a]

Hepatotoxic Procedure[b]	BSP Retention (mg/dL)	Alkaline Phosphatase (Units)	Bilirubin Concentration (mg/dL)	ALT Activity (Units/mL)
Control (no treatment)	0.3 ± 0.3	3.0 ± 0.5	0.2 ± 0.1	25 ± 5
ANIT (150 mg/kg p.o.)	45.0 ± 23	5.6 ± 2.6	1.1 ± 0.4	282 ± 126
CCl_4 (1 mL/kg p.o.)	13.0 ± 7	5.3 ± 1.3	0.4 ± 0.2	8510 ± 1930
Bile duct ligation	26.0 ± 3	19.0 ± 10	3.8 ± 0.8	655 ± 132

[a] Values are expressed as mean ± SE; each group contained 10 mice.

[b] Hepatotoxic procedure was performed 24 h before assessing function.

in chemically induced liver dysfunction has been fairly extensively investigated. In the dog, the enzyme is useful for detecting biliary dysfunction. In the cat, however, ligation of the common bile duct results in only a slight increase in serum AP activity. The normal level of serum AP in the rat is exceptionally high, independent of growth, and unusually susceptible to variations in diet [184]. Increases in serum AP activity were not remarkable in a comparative study of clinical chemistry and liver histopathology performed in a subchronic study in rats, whereas increases in serum total bile acid concentration were [472]. Thus, serum AP activity may not be useful for detecting cholestatic changes in the rat.

In addition to AP, other enzymes, for example, 5′N, γ-GT, and leucine aminopeptidase (LAP), may be of use in assessing obstructive liver injury. The serum activity of these enzymes, which are localized in the membranes of hepatocytes and bile duct cells, is increased during extrahepatic cholestasis in humans [28,507]. Kryszewski et al. [271] found a significant elevation in serum activity of AP, 5′N, and γ-GT 12 h after bile duct ligation in the rat; AP and 5′N peaked at 24 h and then gradually decreased, and γ-GT peaked at 48 h and remained elevated even 192 h after bile duct ligation. Fujii [143] found serum AP and γ-GT useful indicators of cholestasis in dogs. Thus, changes in the serum activities of these enzymes are useful for detecting toxicant-induced cholestatic changes in laboratory animals. A simplified electrophoretic method was developed to separate and quantify multiple forms of human serum 5′N [362]; three isoforms were identified in normal subjects and hepatobiliary dysfunction resulted in the increased activity of only one form of serum 5′-nucleotidase. To the best of our knowledge, comparable studies have not been performed in animals.

Of interest is the observation of Moritz and Snodgrass [96] that acute obstruction of the bile duct in the rat produced a rapid rise in the serum activity of SDH and OCT. From 1 to 24 h following bile duct ligation, the activities of these two enzymes increased in serum to levels approximating those found after a single dose of CCl_4, even though the histological degree of hepatic necrosis was substantially less with obstruction than with CCl_4 poisoning. This finding confirmed and extended the observation of Hallberg et al. [188] that bile duct obstruction in dogs resulted in increased serum OCT activity. These observations, if confirmed in other models of experimentally induced obstructive disorders, suggest that OCT and SDH could serve to identify hepatic alterations associated with a diminution or cessation of bile flow.

Lactate Dehydrogenase Isoenzymes

In addition to serum enzyme activities, serum isoenzyme patterns have been utilized for the detection of organ damage in humans and laboratory animals [89,90,174,508]. Isoenzymes are enzymatically active proteins that catalyze the same reactions and occur in the same species but differ in their physicochemical properties. The isoenzymes of LDH are used as diagnostic agents in clinical medicine [90] and in some instances have been evaluated for use in experimentally induced organ damage in laboratory animals. Cornish et al. [90] utilized LDH isoenzymes to detect specific organ damage in rats; they found that the serum isoenzyme patterns resulting from liver or kidney damage differed markedly and concluded that these differences could be utilized to distinguish the damaged organ. Liver damage resulted primarily in an increase in serum LDH-5 isoenzyme activity, whereas the activity of the LDH-1 and LDH-2 isoenzymes was elevated in rats with kidney injury. Grice et al. [174] treated rats with CCl_4, mercuric chloride, thioacetamide, or diethanolamine at doses that would produce either minimal or pronounced tissue damage. Although AST activity was a more sensitive indicator of organ damage than LDH, it did not provide isoenzyme patterns that could identify the specific target organ. In contrast, LDH isoenzyme patterns were capable of identifying the specific target organ; the LDH-5 bands indicative of liver injury were increased in rats poisoned with CCl_4, diethanolamine, and thioacetamide, whereas mercuric chloride, a potent nephrotoxicant, increased the activity of LDH-1 and LDH-2. Morphologic damage generally occurred at dosage levels considerably below those producing detectable serum enzyme alterations. Thus, these authors concluded that serum enzyme activities and isoenzyme patterns are an important supplement to, but not a substitute for, histopathological examination of tissues.

Histological Evaluation

Analysis of the hepatotoxic potential of a chemical agent is incomplete without a histological description of the lesion produced. Quantification of the degree of injury observed

by light microscopy can be achieved using the method of Chalkley [69] essentially as described by Mitchell et al. [320]. One ocular of a microscope is fitted with a micrometer eyepiece containing a grid on which 16 points of reference are chosen. A section of suitably stained liver tissue is selected from each animal and examined at 400× magnification. In a study of acetaminophen hepatotoxicity in mice, Mitchell et al. [320] found that a single section of liver could be considered to be representative of the entire organ. Each section is evaluated by scanning a series of 25 microscopic fields chosen at random. In each field, the tissue element immediately underneath each of the 16 points of reference is termed a *hit*; thus, 16 hits are examined per field. A total of 400 hits are examined in each section. The hits are categorized as (1) normal parenchymal hepatocyte, (2) degenerated parenchymal hepatocyte, (3) necrotic parenchymal hepatocyte, and (4) other cellular structure [201]. Hits on each of the first three categories are recorded and expressed as a percentage of the total number of hepatocytes examined in that section. Accumulation of the data from three to five animals in each treatment group provides a base of sufficient size for statistical analysis. This type of quantitative histological analysis was useful for determining the relative ability of various solvents to potentiate $CHCl_3$-induced hepatotoxicity (Table 29.2). In this study [201], rats were pretreated with an equimolar dose of *n*-hexane (H), acetone (A), 2,5-hexanedione (2,5-HD), or methyl *n*-butyl ketone (MBK); 18 h later the rats received a small challenging dose of $CHCl_3$, calculated to produce minimal signs of liver injury. Hepatic damage was assessed 24 h after $CHCl_3$ administration. Although each of the solvents was capable of potentiating the hepatotoxic effects of $CHCl_3$, it is clear (Table 29.2) that a marked difference exists in the severity of the potentiation produced. Normal hepatocytes accounted for approximately 88%, 75%, 52%, and 45% of the total of $CHCl_3$-challenged rats pretreated with H, A, 2,5-HD, or MBK, respectively. Degenerated hepatocytes accounted for approximately 6% of the total in rats receiving the combination of H and $CHCl_3$ and rose to approximately 18% in rats treated with MBK + $CHCl_3$. The percentage of necrotic hepatocytes was greatest in rats treated with MBK + $CHCl_3$ (37%) and decreased in the following order: 2,5-HD + $CHCl_3$ (35%), A + $CHCl_3$ (15%), and H + $CHCl_3$ (6%). These results indicate that this method for quantifying histological alterations provides an index of toxicity sensitive enough to discern the varying potentiating capacities of the four solvents tested. It is also noteworthy that the use of histological criteria to rank these solvents in order of increasing potentiating ability (H < A < 2,5-HD ≈ MBK) provided results similar to those obtained via determination of serum ALT (Table 29.2) and serum OCT activity [201]. Furthermore, the quantitative histological analysis provided a greater degree of discrimination between the solvents tested than did determination of total plasma bilirubin content (Table 29.2). In general, this procedure for quantifying histological abnormalities correlates well with other indices of liver injury [381]. An example of correlations between histopathological alterations and changes in functional indices of liver injury is given in Table 29.3. The severity of the hepatic lesion, expressed as the percentage of degenerated hepatocytes, the percentage of necrotic hepatocytes, or the percentage of abnormal hepatocytes (necrotic plus degenerated) is compared to alterations in ALT and OCT or to the plasma content of bilirubin. Regardless of the parameters assessed, a linear correlation was observed between the extent of the lesion as quantified by light microscopy and the severity of the biochemical alteration. Marked differences, however, were observed in the strength of correlation between the different combinations of parameters examined. In general, elevations in the serum activity of ALT were most strongly correlated with the histopathological alterations. The correlations between the severity of the lesion and alterations in relative liver weight, however, were not strong.

Minor modifications of this method have been used. Mitchell et al. [320] used an eyepiece containing eight points of reference and examined 50 random microscopic fields to collect 400 hits. It appears that the arrangement and number of reference points examined per field are of little consequence so long as a sufficient number of hits are collected

TABLE 29.2
Histologic Evaluation of the Effects of Pretreatment with Various Agents on $CHCl_3$-Induced Hepatotoxicity in Male Rats[a]

Treatment	Normal Hepatocytes (%)	Degenerated Hepatocytes (%)	Necrotic Hepatocytes (%)	ALT Activity (units/mL)	Total Bilirubin (mg/dL)
$CHCl_3$	99.7 ± 0.1	0.3 ± 0.1	0	37 ± 3	0.18 ± 0.01
n-Hexane + $CHCl_3$	97.9 ± 2.3	5.8 ± 0.9	6.3 ± 2.2	347 ± 100	0.24 ± 0.01
Acetone + $CHCl_3$	76.2 ± 4.7	9.2 ± 2.1	14.6 ± 3.0	1177 ± 534	0.26 ± 0.02
2,5-Hexanedione + $CHCl_3$	51.9 ± 5.0	13.5 ± 2.6	34.7 ± 3.1	2228 ± 477	0.82 ± 0.32
Methyl *n*-butyl ketone + $CHCl_3$	45.2 ± 2.0	17.5 ± 2.0	27.2 ± 1.8	4910 ± 631	1.35 ± 0.17

[a] Relative liver weight = liver wt./body wt. × 100.

for analysis. In one study [200], 30 points of reference per field and 50 fields were examined for a total of 1500 hits/section. However, H. Miyajima (unpublished observations) found no statistical difference between the results obtained by examining 1500 versus 400 hits per section. Thus, for routine usage, it appears that collection of 400 hits per section is satisfactory.

The quantitative method described above does not allow one to visualize the lobular distribution relative to the zonal configuration of the hepatic lobule. Iijima et al. [216] devised a semiquantitative morphologic method that permits such visualization. To evaluate the morphologic patterns, 10 hexagonal lobules are chosen randomly for each liver section. The distance of the injured area from the hepatocytes adjacent the terminal hepatic venule (THV; central vein) to the portal area is measured in one fixed direction per lobule using a micrometer ocular disc (5 mm divided into 100 parts). This distance is measured at a magnification of 100×. The sections are then examined at a magnification of 400× to classify the cellular changes observed. The damage is classified using six categories: (1) necrosis, (2) ballooning of hepatocytes, (3) swelling of hepatocytes, (4) inflammatory cell infiltration, (5) presence of lipid droplets, and (6) normal hepatocytes. The results are expressed in absolute mean distances (micrometers) from the THV. The mean distance for each category observed in a treatment group is calculated for four to six animals (total of 40–60 hexagonal lobules). The graphic representation of such an analysis is depicted in Figure 29.3, in which the lesions produced by two dosages of CCl_4 (0.1 and 1.0 mL/kg, i.p.) were monitored over a 120 h period [72]. It is evident that the severity of the lesion and recovery were dose dependent. The major advantage of this semiquantitative morphologic procedure is that it permits the investigator to prepare a graphic representation of what is visualized after examination of many microscopic sections. It can be particularly useful for the preparation of toxicological reports.

Electron microscopy is also of value in toxicological studies, as it permits a correlation between the ultrastructural and functional changes induced by foreign chemicals. Grice [173] delineated several of the advantages and disadvantages encountered in the application of electron microscopic techniques to the study of chemically induced liver injury. In general, electron microscopy provides a much earlier demonstration of hepatocyte injury and is of value for detecting minimal and often reversible pathologic changes that may be evident before they are detectable by light microscopy. The ability to detect subtle ultrastructural defects early in the course of poisoning often permits identification of the initial site of the lesion and thus can provide clues to possible biochemical mechanisms involved in the pathogenesis of liver injury. In addition, the power of these techniques can be enhanced through a quantitative, morphometric analysis of chemical effects [47,106]. Serious restrictions involving proper fixation techniques, sampling procedures, and the

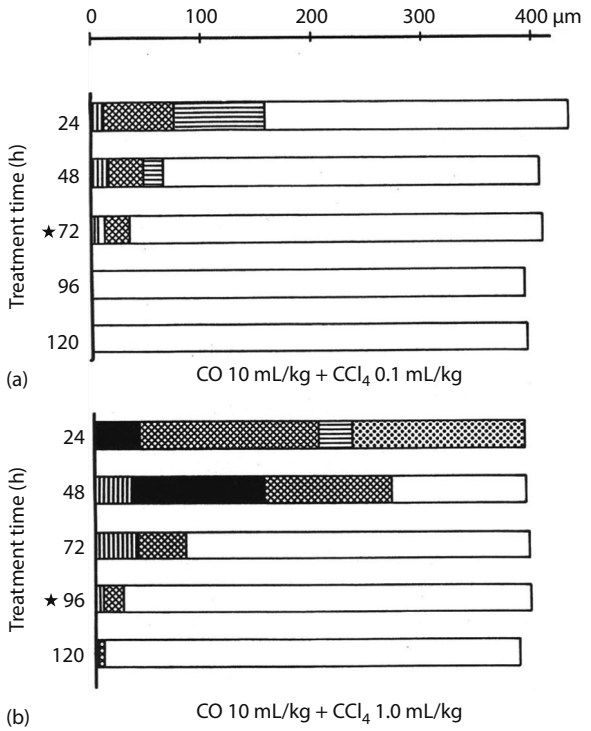

FIGURE 29.3 Lobular morphologic patterns of 0.1 mL/kg (a) or 1.0 mL/kg (b) of CCl_4-induced liver injury for a 120 h posttreatment period, according to the technique of Iijima et al. [216]. The left side (0 μm) of the figure corresponds to the centrilobular region, whereas the right side (400 μm) corresponds to the periportal space of the hepatic lobule. (From Charbonneau, M. et al., *Toxicology*, 35, 95, 1985. With permission.)

complexity of sample preparation, however, argue against the routine use of electron microscopy in the initial evaluation of the hepatotoxic potential of a new chemical. Rather, this technique is probably of greatest use for confirming a suspected alteration or defining a pathologic event [173].

Hepatic Excretory Function

Chemicals entering the systemic circulation may be excreted by the liver unchanged or after modification within the hepatocyte. Compounds that undergo biliary excretion have been divided arbitrarily into three classes [395] based on the bile/plasma concentration ratios obtained during their excretion [251]. Examples of class A substances include sodium, potassium, and chloride ions as well as glucose; these compounds have a bile/plasma ratio of about 1.0. Class B substances, for example, bile salts, bilirubin, BSP, and many xenobiotics, achieve a bile/plasma ratio of more than 1.0, usually between 10 and 1000. Among class C substances, which have a bile/plasma ratio of less than 1.0, are macromolecules such as inulin, phospholipids, mucoproteins, and albumin.

Transport systems in the sinusoidal and canalicular membranes of hepatocytes have been characterized [228,250,367,452]: sodium-taurocholate cotransporting polypeptide (NTCP), organic anion transporting polypeptides (OATPs), organic cation transporters, organic anion transporters (OATs), the ATP-dependent transporters multidrug resistance P-glycoproteins (MRP1, MRP2, MRP3, and MRP6), bile salt export pump (BSEP), and multidrug resistance–associated proteins (MDR1, MDR2, and MDR3). NTCP is associated with the sinusoidal sodium-dependent uptake of conjugated bile salts, while OATP is a multispecific carrier for sodium-independent uptake of bile salts, organic anions, and other amphipathic organic solutes. Several MRP efflux pumps are present in the basolateral membrane. They are said to function as reverse transporters [228] and may reduce intracellular concentrations (monovalent glucuronides and glutathione S-conjugates) when secretion via the canalicular route is impaired. Canalicular transport systems are important for the biliary excretion of bile salts (BSEP), bilirubin glucuronide (MRP2), nonbile salt organic anions (MRP2), glutathione (MRP2), and phospholipids (MDR2 and MDR3). Microsomal enzyme inducers can increase bile flow and biliary excretion of glutathione-derived sulfhydryls by affecting Mrp2 in rats [231]; they also induce the Mrp family in mice [302] via distinct transcription factors. Hereditary defects of intrahepatic transporters have been described (progressive familial intrahepatic cholestasis, Dubin–Johnson syndrome, Wilson's disease) [299,367]. Perturbations associated with extrahepatic or chemical-induced cholestasis [91,92,153,228,452,471] are known, although the mechanisms involved and causality are still unclear. Mrp2 and Bsep can be affected by taurolithocholate-, troglitazone-, or estradiol glucuronide-induced acute decreases in bile flow in rats [91,92,146,153,445], while Mdr2 does not appear to be involved in the bile flow deficiency following manganese–bilirubin combined treatment in mice [409]. Differential expression of hepatic transporter genes has been demonstrated in mice [503] following treatment with the hepatotoxicants acetaminophen and CCl_4.

Sulfobromophthalein Retention

The most common class B chemical used for the detection of liver injury is BSP. In 1925, this anionic phthalein dye was used in clinical medicine by S. Rosenthal and E. White after preliminary tests with other phthalein dyes proved less satisfactory [420]. Since its introduction, this substance has been used extensively for the assessment of liver function in humans and laboratory animals. After intravenous injection, BSP is present in the cardiovascular compartment. Its disappearance from the circulatory system depends on its uptake by the liver. The use of BSP to assess liver function is based on the observation that dye removal from blood is delayed by hepatic dysfunction. Commonly, BSP concentration in plasma is determined at a specific time after a standard dose of dye (per unit of body weight) is administered intravenously. Selection of the optimal dose of BSP is essential for correct interpretation of functional impairment.

The removal of BSP from the plasma is dependent on the simultaneous operation of a number of hepatic processes, for example, active transport across the plasma membrane into a storage compartment, metabolic transformation, and ATP-dependent transport across the canalicular membrane [521].

The most critical step in this process is thought to be the transfer of BSP from liver to bile. Most important in terms of selecting an optimal BSP dose is that its biliary excretion can be saturated and a transport maximum (Tm) exists; the clearance of BSP by laboratory animals is dose dependent [247]. Usually one observes that small doses are rapidly removed from the circulation; this rate of removal continues as one increases the dose, until a dosage level of BSP is reached where the rate of disappearance becomes longer. For example, with the isolated perfused rat liver [382], 5, 10, and 20 mg of BSP are cleared at the same exponential rate; the capacity of the liver to extract BSP from the perfusate, however, becomes saturated when 30 or 40 mg is injected. With the latter dose, the rate of disappearance becomes zero order, which indicates that the maximal capacity of the transport system is reached. This same type of phenomenon occurs in mice in vivo [118].

A marked species difference exists in the ability of the rat, rabbit, and dog to remove BSP from the plasma; this difference can be readily discerned by administering varying BSP doses to these laboratory animals (Figure 29.4). Both the rat and the rabbit have a remarkable ability to clear BSP from the plasma, whereas the dog has a relatively poor capacity [247]. If the overall BSP Tm for biliary excretion is measured, large differences are observed [247]. The significance of these findings is that the optimal dose of BSP for measuring liver function depends on the species employed. The dose should be one that is relatively close to the one that indicates BSP clearance capacity is being exceeded.

Determination of the BSP Tm has been used as an index of hepatic function in humans. Wheeler et al. [506] devised a procedure that can be employed in conscious dogs. With this technique, one infuses BSP at three different rates and measures the serum concentration at varying times. From the data, one can calculate the Tm and the relative storage capacity (S) for BSP. In addition, methods have been devised for making similar measurements in rabbit and rat [246]. The use of these techniques has not been widespread in laboratory animals. They are useful for assessing excretory capacity, however, and are employed in mechanistic studies to determine specific functional lesions involved in the reduction of BSP clearance. For example, defects in (1) transfer of BSP from plasma to liver, (2) storage of BSP within the hepatocyte, (3) conjugation of BSP with glutathione, or (4) transfer of BSP from the liver cell into the bile could participate in the CCl_4-induced depression of BSP clearance.

When these possibilities were evaluated, it appeared that the major effect of CCl_4 was to decrease the transfer of BSP from the hepatocyte to the bile [248,394]. Klaassen and Plaa [248] found that 24 h after a single intraperitoneal dose of CCl_4 both the BSP Tm and hepatic BSP conjugating activity were depressed; no change in hepatic BSP storage was detected. Because CCl_4 reduced plasma disappearance and the Tm of phenol-3,6-dibromophthalein disulfonate (DBSP), a nonmetabolized analog of BSP, and depressed excretion of both BSP and DBSP under submaximal conditions, it was concluded that the excretory parameter was probably the prime event altered by CCl_4. Subsequently, Priestly and Plaa [394] demonstrated that impaired BSP excretion, bile flow rate, relative hepatic storage, and BSP retention were observed as early as 3 h after CCl_4 administration. Impaired BSP conjugation, however, was not unequivocally demonstrated until 12 h after CCl_4. Thus, although impairment of both conjugation and excretion contributes to BSP retention, the effect on excretion appears to be more important.

Although BSP was introduced in 1925, it was not until 1950 that it was realized that this dye is excreted in a conjugated form into the bile [51,52]. Up to that time, it was assumed that this material did not undergo biotransformation prior to its excretion. BSP is conjugated with glutathione in humans, rats, and dogs. A number of other conjugates, including BSP-cysteinylglycine and BSP-cysteine, are also formed, presumably by cleavage of glutamic acid and glycine from the glutathione moiety. BSP conjugation, catalyzed by a glutathione S-transferase, is a cytoplasmic process. Under certain conditions, the impairment of

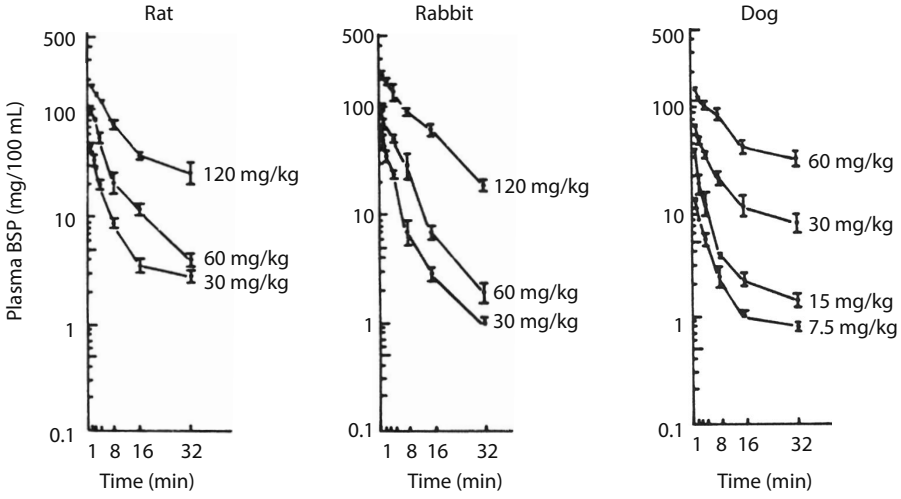

FIGURE 29.4 Plasma disappearance curves for BSP administered in varying doses in the rat, rabbit, and dog. (From Klaassen, C.D. and Plaa, G.L., *Am. J. Physiol.*, 213, 1322, 1967. With permission.)

BSP conjugation with hepatic glutathione can lead to depression of BSP excretion in the bile without impairment of general excretory function [50,84,392,393].

Although BSP is a useful and sensitive test of liver function, a variety of events can cause BSP retention. Diffuse and severe hepatocellular damages are associated with an increase in dye retention [189]. Liver injury of the cholestatic type, however, usually decreases biliary excretion to a greater extent than does parenchymal cell injury [515]. For example, using ANIT, Becker and Plaa [29] showed that the amount of BSP retained following such treatment is much greater than that observed after the necrotic effects of CCl_4. In this instance, ANIT affects BSP retention by decreasing the biliary excretion of BSP [380]. In rabbits, treatment with anabolic steroids can result in BSP retention owing to a decrease in excretory capacity [285]. In contrast, bunamiodyl [sodium 3-(3-butyramide-2,4,6-triiodophenyl)-2-ethylacrylate] seems to diminish uptake of BSP by the hepatocyte [39]. Finally, decreased hepatic blood flow can also cause BSP retention [118].

Indocyanine Green Retention

Several other compounds have been introduced into clinical medicine for the purpose of measuring liver function by the dye-clearance principle. The rose bengal test appeared in 1931 [108], and a third useful dye, indocyanine green (ICG), was introduced in 1959. ICG was originally used to measure cardiac output by the indicator-dilution technique. It was subsequently found in the dog, however, that 97% of the administered dose was eventually recovered from the bile in an unaltered form [505]. No dye was found in the urine. ICG has about the same spectrum of sensitivity and specificity as BSP, but it has a number of properties that make it more desirable to employ under certain circumstances. Cherrick et al. [76] found the following: (1) ICG is rapidly and completely bound to plasma protein, of which albumin is the principal carrier; (2) the dye is excreted in bile in an unconjugated form; (3) there seems to be no extrahepatic mechanism for removing the material; (4) ICG is nonirritating when inadvertently introduced subcutaneously, and it produces no untoward reactions upon single or repeated intravenous injections; and (5) the plasma disappearance of ICG is similar to that of BSP.

In laboratory animals, ICG is usually employed to supplement BSP tests. In the dog, Hunton et al. [214] found that (1) the plasma disappearance rate of ICG is exponential for at least 15 min and usually for 30–60 min; (2) the amount removed per minute seems to be inversely related to the dose administered; (3) the maximal rate of excretion of ICG into the bile is about 0.4 mg/min/kg; and (4) substances such as bilirubin, rose bengal, and BSP interfere with ICG excretion. Klaassen and Plaa [250] found that over a 32 min period, the rate of disappearance of ICG was exponential in the rat, rabbit, and dog (Table 29.4). The rabbit exhibited a greater capacity to remove ICG from plasma than did the rat, and the dog had the lowest capacity. It appears that the optimal dosage for ICG clearance in the dog is about 1.5–2.0 mg/kg; in the rat, approximately 16 mg/kg; and in the rabbit, 25–30 mg/kg.

TABLE 29.4
ICG Plasma Disappearance Rates in Rats, Rabbits, and Dogs

ICG Dose (mg/kg)	$T_{1/2}$ (min)	K (% Removed/min)
Rat		
4	2.5	28
8	4.0	17
16	6.5	11
32	8.5	8
64	18.0	4
Rabbit		
8	1.5	46
16	3.5	20
32	7.0	10
Dog		
1	7.0	10
2	17.0	4
4	30.0	2

Biliary excretory maximum and hepatic storage values for ICG could not be determined [250], as infusion rates sufficient to produce a biliary excretory Tm produced a marked decrease in bile flow. Decreased bile flow was observed in all three species but was most pronounced in the rat and least in the dog. Rapid administration of ICG, as used in plasma clearance experiments, does not produce marked alterations in bile flow. Other investigators [193] reported maximal biliary excretion rates for rats given ICG that were comparable to the peak excretion rates obtained by Klaassen and Plaa [250]. In Mdr2-deficient mice, the biliary excretion of ICG was reduced by 90%, while the excretion of total glutathione was decreased by 65%, relative to wild mice [213].

The major advantage of ICG in the detection and evaluation of hepatic function is that the material is not biotransformed prior to excretion. In addition, ICG is directly determined in plasma, without chemical treatment. In practice, it simply involves diluting an aliquot of plasma (0.1–1.0 mL) with water and determining the absorbance at 805 nm, the wavelength for peak ICG absorption. ICG, however, is unstable in aqueous solutions, which can be prevented by mixing ICG directly with serum or with an albumin solution. The dye is unstable when mixed with heparin solutions containing bisulfite [82], indicating that preservatives of the same type may also have an effect on ICG.

Other Anionic Chemicals

Although rose bengal was introduced before ICG, it has not been extensively employed in laboratory animals; in humans, the dye is used to diagnose hepatic disorder, especially in children. Rose bengal, like ICG, has the advantage that it is apparently not biotransformed before excretion into the bile [245,272]. It is available commercially in a radioactive form, and, therefore, its concentration can be quantified in small blood samples. Its uptake in isolated hepatocytes is similar

to that of BSP [521]. Klaassen [245] examined the pharmacokinetics of rose bengal in four species (rat, rabbit, dog, guinea pig) and found that, with the exception of biotransformation, the dye appears to be handled by the liver in a manner similar to BSP; it is a class B anion that is actively excreted into the bile. A marked species variation in the rate of biliary excretion of rose bengal exists [245]. The rat and rabbit excrete rose bengal into the bile at comparable rates, whereas the guinea pig is much more efficient and the dog much less efficient. Like BSP, the removal of rose bengal from the blood is altered by changes in hepatic excretory function [245,317,462], and Klaassen [245] indicated that the dye could be used as a measure of hepatic excretory function in laboratory animals. Because it is not biotransformed, alterations in its clearance would reflect primarily changes in its uptake into the liver or its excretion into the bile.

Other agents exist for monitoring hepatic excretory function. Mehendale and coworkers [314,316] used phenolphthalein glucuronide (PG), imipramine (IMP), and the polar metabolites of imipramine (PMIMP) as model compounds to characterize the hepatobiliary dysfunction produced by mirex. This pesticide did not suppress hepatic uptake and metabolism of IMP but inhibited the movement of PMIMP from the hepatocyte to bile; it also inhibited the biliary excretion of PG, a model anionic substrate that does not undergo biotransformation. These model substrates allowed the investigators to localize the site of mirex-induced dysfunction. In another report, they suggested that PG may be a more sensitive model compound than BSP for detection of hepatobiliary dysfunction. CCl_4 at 100/μL/kg depressed biliary excretion of PG in rats [95]; hepatobiliary dysfunction was undetectable with BSP at this dosage of CCl_4 [52,248]. The plasma disappearance and biliary excretion kinetics of PG in the rat have been described [314]. The biliary excretion of phenolphthalein sulfate is reported to be markedly delayed in Mrp2-deficient rats, suggesting that this substance is handled by Mrp2 [461].

The effects of some known potential cholestatic agents were investigated in vitro using taurocholate in regular and collagen-sandwich-cultured human hepatocytes [267]. Cyclosporin A, bosentan, glyburide, erythromycin estolate, and troleandomycin all inhibited bile acid efflux. Glyburide administered to rats resulted in elevated serum total bile acids in rats. These preliminary findings are quite encouraging and warrant more extensive studies.

Endogenous Cholephiles

At least one endogenous substance, bilirubin, has been used to evaluate chemically induced hepatic injury. Normally, bilirubin is excreted into the bile. Elevation of serum bilirubin concentration accompanies sufficiently severe parenchymal injury, but it is a relatively insensitive measure of chemically induced hepatic injury. The degree of change in serum bilirubin that one obtains with experimental hepatotoxicity in mice is summarized in Table 29.1. CCl_4, although producing sufficient parenchymal injury to cause a large increase in serum ALT activity, does not affect bilirubin concentrations greatly. On the other hand, bile duct occlusion does elevate serum bilirubin considerably. ANIT also elevates serum bilirubin but not to the extent that biliary occlusion does. The BSP retention values indicate that those experimental procedures that markedly impair biliary excretion also affect BSP retention, whereas CCl_4 causes a lesser degree of retention. However, if one assumes that BSP retention and bilirubin concentrations measure relatively the same type of liver function, it is evident that the changes occurring with BSP are considerably greater than those occurring with bilirubin. A likely explanation is that the measurement of endogenous concentrations of bilirubin may not assess the total capacity of the liver to clear bilirubin, as does a load of BSP selected to be a near-capacity dose for the particular species of animal employed. Indeed, if one does administer exogenous amounts of bilirubin and follows its plasma disappearance, as with BSP, the sensitivity of the bilirubin clearance procedure can be increased. Nevertheless, BSP clearance is simpler and more sensitive than bilirubin and is therefore preferred for the measurement of hepatocellular injury.

Bile acids, a second group of endogenous chemicals that are normally excreted into bile, have been used to assess some hepatotoxicants. Unlike serum bilirubin retention, elevation of serum bile acid concentrations, presumably because of decreased biliary secretion, appears to be a highly responsive index of hepatobiliary dysfunction [18,137]. At least following $CHCl_3$ and CCl_4 treatments in rats, elevation of serum bile acids occurred at dosages that exerted no effect on serum enzyme activity or bilirubin concentration [18]. Furthermore, elevations of individual serum bile acids occurred at dosages of CCl_4 that produced no consistent histological change. Neghab and Stacey [340] recently demonstrated that toluene, a nonhalogenated aromatic hydrocarbon, also results in increases in serum bile acids in rats in a dose-dependent manner; the elevations occur in the absence of other abnormal liver enzyme findings. Xylene also results in toluene-like interference of hepatocellular uptake of bile acids in isolated hepatocytes [340]. While these findings are consistent with toluene and xylene actions on hepatocellular bile acid transport, they are not necessarily indicative of liver injury. The specificity of serum bile acid elevations and the role of such events in the evaluation of hepatotoxicity are yet to be determined.

Biliary Secretory Function

Techniques designed to assess bile secretory function are also available; these methods, however, lend themselves more to specific research problems than to overall toxicological assessment. Fujimoto [144] reviewed older methods that can be applied in vivo. The so-called bile acid-dependent and bile acid-independent fractions of total bile flow [24,48,251] have been studied extensively in several species; secretin-sensitive bile flow is thought to be small in the rat but more important in rabbit and dog.

Fujimoto [144] developed a number of new techniques, in which marker substances are injected retrogradely into the biliary tree to assess the permeability characteristics of the biliary system. ANIT, which produces intrahepatic cholestasis in rats, and bile duct ligation increase the distended

capacity of the biliary tree, whereas another cholestatic agent, taurolithocholate, decreases the distended capacity; CCl_4 seems to exert no effect [142,356,371].

The retrograde technique has been modified to become the *segmented retrograde intrabiliary injection* (SRII) procedure [355]. With the use of radioactive marker substances of varying molecular weights (D-glucose, mannitol, sucrose, inulin, or dextran), one can assess the *membrane* characteristics of the biliary tree (canalicular and tight-junction complexes). This procedure was used to study the hepatobiliary dysfunction produced by Amanita phalloides [142], taurolithocholate [144], colchicine [21], S,S,S-tributylphosphorotrithioate [21], manganese and manganese–bilirubin combinations [15], and sequential treatments with ketones and chloroform [199]. These studies have been useful for discerning the site and possible mechanisms of action involved in their hepatobiliary effects.

Determination of Biliary Function

Sulfobromophthalein Clearance The BSP test dose is first injected intravenously. After 30 min, a suitable amount of blood is withdrawn and plasma is prepared by centrifugation. Aliquots of plasma are placed into tubes containing alkalinized or acidified saline. The BSP plasma content is determined by the difference between the absorbance in alkalinized and acidified saline. The BSP dose administered depends upon the species of animal being employed. It should be one that normal animals can readily clear in a 30 min collection period. Thus, the amount of BSP retained at 30 min should be about 1% of the dose administered. For the dog, rat, rabbit, and mouse, these dosages are about 15, 75, 50, and 100 mg/kg, respectively [247,376].

Biliary Sulfobromophthalein Transport Maximum The procedure can be performed in anesthetized rats or rabbits [246]. With the rat, the bile duct is cannulated as well as the femoral vein; the rectal temperature is maintained at 37°C to prevent hypothermic alterations in Tm [413]. The BSP solution is infused (2.5 mg BSP/kg/min) at a rate of 0.03 mL/min for 60 min, and bile is collected at 15 min intervals. The amount of BSP excreted (min^{-1} kg^{-1}) is calculated; the maximum value attained is the Tm. In the Sprague-Dawley rat, the BSP Tm is about 1.0 mg/kg/min.

SRII Method The procedure can be performed in anesthetized rats [144], and the rectal temperature should be maintained at 37°C to prevent hypothermic alterations in bile flow [413]. The bile duct is cannulated with PE-20 tubing just distal to the bifurcation of the biliary tree; this tubing is attached to a longer length of PE-20 tubing capable of containing a calibrated (40 mL) amount of solution. An exact amount of radioactive marker substance (D-glucose, sucrose, mannitol, inulin, or dextran) is infused into the bile duct and washed through with saline. Bile flow is then reestablished and bile drops collected serially. The bile flow rate is calculated by determining the time required to form each drop; the content of each drop is determined by liquid scintillation spectrometry, and the recovery expressed as a percentage of total marker recovered. The volume of the distended biliary tree can also be evaluated by the SRII method [144,371].

Mitochondrial Function

Mitochondrial function was one of the first biochemical processes investigated in chemical-induced hepatotoxicity, and many studies were performed to establish its role in various experimental models [528]. With carbon tetrachloride, unfortunately, it fell in disrepute as a possible initiating event, because the temporal appearance of the biochemical lesions in this organelle seemed to follow, rather than precede, histological changes [379]. More recent studies with acetaminophen [237] and 1,1-dichloroethylene (DCE) [307] have demonstrated the importance of mitochondrial dysfunction in liver injury. With DCE, dose-dependent and time-dependent mitochondrial parameters (oxygen consumption, state 3/state 4 oxygen consumption ratio, ADP phosphorylation per oxygen consumed) in isolated liver fractions obtained from treated mice showed that state 3 (ADP-stimulated) respiration rates for glutamate (complex I)- and succinate (complex II)-supported respiration were decreased 20 and 90 min, respectively, after treatment, whereas state 4 (resting) respiration was unaffected. Serum ALT was significantly elevated at 2 h, and centrilobular necrosis was observed 24 h after treatment. Thus, with DCE, mitochondrial dysfunction was one of the early events observed in the progression of the lesion.

Mitochondria play a vital cellular role in fat oxidation and energy production [370]; the β-oxidation and tricarboxylic acid cycles are key elements; cytochrome *c* oxidase and ATP synthase are critical enzymes. Microvesicular steatosis results from acute impairment of fatty acid oxidation. This lesion has been observed in humans and in laboratory animals following exposure to valproic acid, pirprofen, tetracyclines, and amiodarone [237,528]. Several dideoxynucleosides and the experimental agent, fialuridine, have resulted in inhibition of mtDNA replication in humans with mitochondrial cytopathy [370]. The treatment of rats with the cholestatic agent ANIT for 16 weeks resulted in impaired mitochondrial bioenergetics [361].

Mitochondria are the main source of reactive oxygen species (ROS), which, in turn, can lead to oxidative damage of mtDNA and cell death. ROS are important cytotoxic and signaling mediators in inflammatory liver diseases [225]. Ethanol exposure can promote oxidative stress by increasing ROS formation and decreasing cellular defense mechanisms [206]. Oxidative stress also appears involved in acetaminophen hepatotoxicity [226]. The mitochondrial permeability transition (MPT) pore, located in the inner membrane, allows cell survival when closed, but leads to cell death when open [370]. If all mitochondria have open pores, ATP synthesis is decreased; ATP depletion and necrosis occur. If only some pores are open, unaffected organelles still synthesize ATP, whereas the open ones cease to form ATP, release cytochrome *c*, thus activating caspases, which leads to apoptosis. Overall, the importance of mitochondria in the development of hepatic dysfunction seems well established. Pessayre et al. have even

suggested [370] that the possible action of new pharmaceutical agents on mitochondria should be evaluated before marketing.

Lipid Peroxidation and Oxidative Stress

It is generally accepted that the toxicity of CCl_4 depends on the cleavage of a carbon–chlorine bond to generate a trichlormethyl free radical ($\bullet CCl_3$); this free radical reacts rapidly with oxygen to form a trichlormethyl peroxy radical ($\bullet CCl_3O_2$), which may contribute to the toxicity [499]. The work of a number of investigators [85,379,401,499] demonstrates that (1) the cleavage occurs in the endoplasmic reticulum and is mediated by the cytochrome P450 mixed function oxidase (MFO) system, (2) the product of the cleavage can bind irreversibly to hepatic proteins and lipids, and (3) the CCl_4-derived free radical(s) can initiate a process of autocatalytic lipid peroxidation by attacking the methylene bridges of unsaturated fatty acid side chains of microsomal lipids.

The peroxidative process initiated by the $\bullet CCl_3$ radical is thought to result in early morphologic alteration of the endoplasmic reticulum, loss of activity of the cytochrome P450 xenobiotic metabolizing system, loss of G6P activity, loss of protein synthesis, loss of the capacity of the liver to form and excrete very low density fraction of the lipoproteins (VLDL), and eventually, through as yet unidentified pathways, to cell death [85,379,401,499]. Alterations in these parameters have been used to monitor the course and extent of CCl_4-induced hepatic damage, and furthermore, have been applied to the evaluation of other hepatotoxicants.

Normal cellular metabolism can result in the production of reactive oxygen species (superoxide, hydrogen peroxide, singlet oxygen, and hydroxyl radical) and all cells contain defense systems to prevent or limit damage. Glutathione is the major component of this system, but μ-tocopherol and ascorbic acid play important roles [290]. The imbalance between prooxidants and antioxidants is known as oxidative stress [402].

Three groups of agents have been described to characterize the toxicants associated with the induction of lipid peroxidation or oxidative stress in liver cells [85,402]. One group consists of agents biotransformed to reactive free radicals that promote membrane lipid peroxidation directly; CCl_4 and $CBrCl_3$ are examples of this group. A second group consists of chemicals that are biotransformed to electrophilic intermediates, which then conjugate with glutathione and result in glutathione depletion; bromobenzene and acetaminophen are examples. The third group consists of substances that are converted to nonalkylating intermediates and generate reactive oxygen species by redox cycling; diquat and menadione serve as examples.

It is now established that nonparenchymal cells can be involved in oxidative stress responses leading to hepatotoxicity [279]. Reactive oxygen intermediates are generated by macrophages, endothelial cells, and stellate cells (Ito cells), but under physiologic conditions, cellular antioxidants normally present prevent the intermediates from producing cytotoxicity. Enhanced formation of oxygen intermediates was demonstrated with CCl_4, galactosamine, and 1,2-dichlorobenzene. With the latter agent, recent evidence indicates that Kupffer–cell–derived oxygen species are largely responsible for the lipid peroxidation [207], while with ANIT, neutrophils appear to be involved [261].

Several procedures for the detection and quantification of lipid peroxidation in tissue samples or whole animals have been developed [384,401]. The reaction of malonaldehyde (MDH), a degradation product of peroxidized lipids, with thiobarbituric acid (TBA) to produce a TBA–MDH chromophore has been taken as an index of lipid peroxidation and is the most widely used method for detecting lipid peroxidation in vitro. Because MDH is rapidly metabolized in whole animals [384] and in whole liver homogenates [400], the failure to detect TBA-reacting material is not an indication of the absence of lipid peroxidation.

The determination of conjugated dienes in lipid extracts of hepatic subcellular fractions is a second approach for detecting lipid peroxidation [401]. The ultraviolet difference spectra of peroxidized lipids show an absorption maximum at 233 nm with a secondary absorption maximum between 260 and 280 nm due to the presence of ketone dienes. The appearance of conjugated dienes after treatment in vivo with toxicants is an unmistakable indication that lipid peroxidation has taken place.

Several other methods for the measurement of lipid peroxidation have been described. For example, the iodometric procedure of Bunyan et al. [57] has been employed. A variety of molecules that occur commonly in tissue may react with MDH and yield characteristic fluorescent chromophores [79]. MDH undergoes decomposition, and the decomposition products may also lead to fluorescent products when they react with proteins [438]. Measurement of these fluorescent products seems to offer a workable way for detecting lipid peroxidation in biological systems and tissues [401]. A second approach is the measurement of hydrocarbon gases. These gases appear early in the course of autoxidation of edible fats [138,209]. Two gases, ethane and pentane, are useful for measuring the peroxidative process in vitro and in vivo. Ethane is the predominant gas produced during autoxidation of linolenic acid [289], and pentane is the major gaseous hydrocarbon arising during thermal decomposition [124,125] and iron-catalyzed decomposition of linoleic and arachidonic acid hydroperoxides [116]. Riely et al. [411] initiated the use of ethane analysis in biological systems. They observed that ethane production was a characteristic of spontaneously peroxidizing mouse tissue (liver and brain) and was found in mice injected with CCl_4. In addition, they found that CCl_4-induced ethane evolution in vivo was potentiated by prior administration of phenobarbital and diminished by α-tocopherol, an antioxidant. Several other groups of investigators used ethane production to monitor the course of lipid peroxidation in vivo [58,187,266,292]. Dillard et al. [111] suggested that pentane expiration was a more sensitive index of lipid peroxidation than ethane in rats fed a vitamin E–deficient diet containing a high content of linoleic acid. Pentane production has also achieved considerable use as an index of the lipoperoxidative process [293,423,424]. A method has been devised for monitoring lipid peroxidation in humans by quantifying the excretion

of ethane and pentane in exhaled breath during a 2 h period [495]. Although the measurement of hydrocarbon gas production is an alternate procedure for the determination of lipid peroxidation, this technique cannot identify the tissue or subcellular organelle from which these substances arise. In addition, precautions must be taken to prevent or estimate the evolution of hydrocarbon gases by microorganisms in the gastrointestinal tract when in vivo studies are undertaken.

Prostaglandin F2–like compounds (F2-isoprostanes) are produced by peroxidation of arachidonic acid in phospholipids and released into the circulation [85,436]. The presence of lipid peroxidation in rats exposed to halothane has been demonstrated by the quantification of F2-isoprostane in plasma and liver [13]. The measurement of F2-isoprostanes in vivo is said to represent a promising method for detection of lipid peroxidation because of its reliability and sensitivity [14,85], but its utility in various forms of chemical-induced lipid peroxidation remains to be investigated.

Formation and Binding of Reactive Metabolites

Although the concept of lipid peroxidation is one of the truly important concepts of experimental pathology and toxicology, it does not appear to serve as a universal mechanism of liver injury. A number of drugs and chemicals, for example, acetaminophen [156,321], furosemide [173,321], 1,1-dichloroethylene [224,310,311], trichloroethylene [3], bromobenzene [157,410], and dimethylnitrosamine [157], produce hepatic damage but do not appear to promote lipid peroxidation. Rather, these agents are converted to highly reactive, electrophilic metabolites by the hepatic MFO system. Following formation, the metabolites, which are considered to be the ultimate toxicants, can interact with hepatic constituents (e.g., protein, lipid, RNA, DNA) to form alkylated or arylated derivatives. Even with CCl_4, the effects on lipids and lipoprotein metabolism (leading to steatosis) appear likely due to covalent binding [499]. Various investigators postulate that the binding of reactive metabolites to hepatic macromolecules can initiate cellular damage through processes as yet unidentified. This can result in intrinsic or idiosyncratic liver injury.

A detailed discussion of the formation and detoxification of reactive metabolites and their interaction with hepatic constituents is beyond the scope of this chapter, and the reader is referred to several excellent reviews [157,158,319,321,443]. However, the experimental work carried out to unravel the mechanisms by which several toxicants produce liver injury has led to some important observations that need to be discussed. One is that hepatotoxicity need not be correlated with the pharmacokinetics of the parent substance or even its major metabolites, but may be correlated with the formation of quantitatively minor, highly reactive intermediates. Assuming that a relation exists between the severity of the lesion and the amount of covalently bound metabolite, the covalent binding of the metabolite can be used as an index of its formation. Indeed, this parameter might well be the most reliable estimate of the availability of the metabolite for production of damage at the target site, as most of the metabolite may undergo decomposition or further metabolism before it can be isolated in body fluids or urine [319]. Thus, one widely used maneuver to assess the contribution of formation and binding of metabolites in chemically induced hepatotoxicity is to determine if radiolabeled chemicals administered to animals over a wide dosage range are covalently bound to macromolecular constituents in tissues that subsequently become necrotic [319].

A second concept is that a threshold tissue concentration of the metabolite must be attained before liver injury is elicited; if it is not attained, injury does not occur. Endogenous substances, such as glutathione, play an essential role in protecting hepatocytes from injury by chemically reactive metabolites. The mechanism that establishes a dose threshold, however, may vary from compound to compound. Finally, other enzymic pathways, for example, glutathione-*S*-transferase and epoxide hydrolase, also play a role in protecting the hepatocyte by catalyzing the further degradation of the toxic reactive intermediates.

The studies mentioned earlier have provided relatively straightforward biochemical strategies for uncovering the possible existence of potentially toxic chemically reactive metabolites in new compounds [319]. In general, a dose–response study employing the radiolabeled compound over a wide dosage range is perhaps the single most important facet of the overall study in that it can provide information relating to a dose threshold for toxicity, possible mechanisms for the threshold response (e.g., glutathione depletion), and the degree of covalent binding of metabolites to target organs or constituents with the target organ. This latter information, in conjunction with dose–response studies documenting the dosages required to produce necrosis (or other endpoint), provides strong presumptive evidence favoring toxicity mediated by a reactive metabolite. Subsequent efforts should include the use of inducers (e.g., phenobarbital, 3-methylcholanthrene) and inhibitors (e.g., SKF-525A, $CoCl_2$, piperonyl butoxide) of the MFO system. Enhancement of in vivo or in vitro covalent binding of the radiolabeled compound, as well as toxicity by an inducing agent, can provide support for the contention that a reactive metabolite mediates toxicity. A similar conclusion can be drawn if an inhibitor of the MFO system depresses covalent binding and toxicity. However, the observation that inhibitors increase the response or that inducers decrease the response does not preclude the possibility that the toxicant exerts its effect through the formation of chemically reactive metabolite [319]. For example, an inducing agent may stimulate the activity of a detoxifying pathway to a greater extent that a toxifying pathway. In addition, manipulation of the concentration of hepatoprotective substances, such as glutathione (e.g., depression of hepatic GSH concentration by diethylmaleate administration), can alter covalent binding or toxicity of a compound and support the likelihood that the toxic effects are mediated by a metabolite. Correlation of the data from several of these studies with a pharmacokinetic analysis can delineate the participation of a chemically reactive metabolite in the production of toxicity. For a more detailed discussion of these concepts, the reader is referred to the reviews cited earlier.

LIVER STEATOSIS

In addition to producing elevations in serum enzyme activities and altering hepatocyte transport processes, chemical hepatotoxicants can produce changes in structural and functional hepatic constituents that have been found useful for detecting and quantifying the degree of liver injury produced, as well as elucidating the mechanism(s) involved in producing the lesions. A number of agents that produce liver injury also cause the accumulation of abnormal amounts of fat, predominantly triglycerides, in the parenchymal cells. In general, triglyceride accumulation can be thought of as resulting from an imbalance between the rate of synthesis and the rate of release of triglyceride by the parenchymal cells into the system circulation. Nonesterified fatty acids (NEFAs) removed from the circulation or synthesized endogenously are processed through two major pathways in the liver: (1) mitochondrial β-oxidation for production of metabolic energy; and (2) incorporation into complex lipids, especially triglycerides, phospholipids, cholesteryl esters, and glycolipids. Once synthesized, the complex lipids may be used for production of cellular membranes (structural lipids) or be continuously secreted from the liver into the blood. The latter pathway appears to be of greatest interest in the triglyceride accumulation observed in steatosis.

Blockage of the secretion of hepatic triglyceride into the plasma is the basic mechanism underlying the fatty liver induced in the rat by CCl_4, ethionine, phosphorus, puromycin, or tetracycline, by feeding a choline-deficient diet, or by feeding orotic acid [210,296]. When hepatic triglyceride is released into the plasma, it is not released as such but as a lipoprotein. The VLDL is the major transport vehicle for endogenously synthesized triglyceride; there is some evidence indicating that CCl_4 and ethionine cause a fall in the level of circulating lipoprotein, principally VLDL. The composition of VLDL by weight is 8%–10% protein and 90%–92% lipid. Of the lipids, triglyceride is the most abundant component (56%); the average content of phospholipid is 19%–21% and cholesterol 17% [223].

Elevated triglyceride could result because of an increase in the rate of synthesis of this substance. There is evidence that the rate of synthesis is directly proportional to the concentration of the substrates present (NEFAs and glycerophosphate), and therefore it is theoretically possible that increased hepatic triglyceride synthesis could occur because of increased NEFAs or increased glycerophosphate. Increased NEFAs could result from decreased oxidation, increased synthesis, or increased mobilization from peripheral stores. In the case of ethanol-induced fatty liver, impaired mitochondrial oxidation of NEFAs appears to be the primary abnormality seen in humans [210] due to a shift in redox potential (increased NADH/NAD ratio). It may be accompanied, however, by other abnormalities [221]. There is little evidence to support the idea that fatty acid synthesis is involved in the development of fatty liver.

In humans, two types of steatosis, macrovacuolar and microvacuolar, have been characterized as hepatic lesions. With macrovacuolar steatosis, the hepatocyte contains a single, large, vacuole of fat and the nucleus is displaced to the periphery of the cell. In microvacuolar steatosis, the lipid exists in the hepatocyte as numerous small lipid vesicles and the nucleus remains in the center of the cell. Impaired mitochondrial ß-oxidation of NEFAs has received more attention as a possible explanation for the presence of microvacuolar steatosis [141]. Among the drugs reported to be associated with such a lesion, one finds salicylates, hypoglycin, valproic acid, amineptine, 2-arylpropionic acids, tetracyclines, zidovudine, and fialuridine.

Determination of hepatic fat content remains a reliable technique for demonstrating alterations by agents that produce steatosis with little or no necrosis (ethionine, phosphorus, tetracycline) and that are poorly reflected by serum enzyme measurement [528]. Alterations in hepatic triglyceride content have also been used as one of a battery of tests to determine the relative hepatotoxic potential of various halogenated hydrocarbons in rats [249] and to determine the ability of various alcohols to potentiate the hepatotoxic actions of CCl_4 [470] (Table 29.5).

TABLE 29.5
Effect of Alcohol Pretreatment on CCl_4-Induced Hepatotoxicity in Rats[a]

Treatment	ALT Activity (units/mL)	Triglycerides (mg/g Liver)	G6Pase activity (mg Pi/g Liver/20 min)
Ethanol (5.0 mL/kg)	50	8	6.7
Isopropanol (2.5 mL/kg)	50	6	6.2
CCl_4 (0.1 mL/kg)	100	9	6.0
CCl_4 (1.0 mL/kg)	500	17	3.8
Isopropanol + CCl_4 (0.1 mL/kg)	2250[b]	22[b]	2.8[b]
Ethanol + CCl_4 (0.1 mL/kg)	500[b]	13[b]	4.8[b]

Source: Data obtained from Traiger, G.J. and Plaa, G.L., *Toxicol. Appl. Pharmacol.*, 20, 105, 1971.

[a] The alcohol was given orally 18 h before intraperitoneal CCl_4 administration. Liver function was assessed 24 h after CCl_4 in 10 rats.

[b] Significantly different from the group given alcohol alone; $p < 0.05$.

LIVER FIBROSIS

Fibrosis, the accumulation of collagen, represents a key phenomenon in chronic liver disease [416]. Septal fibrosis is the principal feature of experimentally induced liver cirrhosis. CCl_4 and ethanol have been the toxicants most frequently used to induce liver fibrosis and cirrhosis. In the rat, twice weekly administrations of CCl_4 for 7–12 weeks have been shown to produce cirrhosis [63,73,197]. Ito cells (also called lipocytes, fat-storing cells, or stellate cells) acquire characteristics of myofibroblasts [415] and play an important role in the formation of collagen in liver fibrosis [459]. Ito cells isolated from fibrotic livers have significant increases in mRNA levels of type I, III, and IV procollagen compared to normal cells [501]. Serum concentration of the aminoterminal propeptide of procolagen type III (PIIIP) can be used as a fibrogenic marker for the period progressing to cirrhosis, but its use in cirrhosis seems to be limited by factors other than liver fibrogenesis [197].

High concentrations of the amino acid 4-hydroxy-L-proline are found only in collagen. Determination of hepatic hydroxyproline content represents a valuable marker to evaluate total collagen content and thus fibrosis in liver tissue [416]. The hepatic levels of hydroxyproline are well correlated with the degree of liver fibrosis measured histologically [73,197,239,353]. Figure 29.5 illustrates the effect of repeated CCl_4 gavage on hepatic hydroxyproline concentrations in corn oil– and acetone-pretreated rats; after 10 weeks of treatment, acetone + CCl_4-treated animals showed a fully developed cirrhosis, whereas a much less severe lesion was observed in corn oil + CCl_4-treated rats (37% ± 2% and 16% ± 3% of the liver occupied by fibrous connective tissue, respectively). Finally, the serum activity of immunoreactive prolyl hydroxylase, the enzyme responsible for proline hydroxylation, is elevated in rats with fibrotic livers, but Okuno et al. [353] suggested that these elevations should be carefully evaluated when being used as a parameter to estimate the activity of fibrogenesis in the liver.

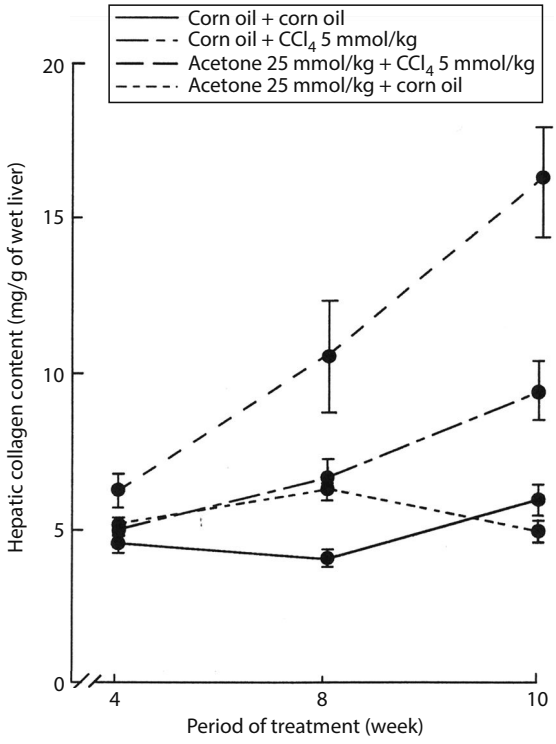

FIGURE 29.5 Temporal progression of hepatic collagen content in rats treated with corn oil or acetone twice weekly (Tuesday and Thursday) and challenged with corn oil or CCl_4 18 h later. Values represent the mean ± SE determined in eight rats. (Data obtained from Plante, I. et al., *Carcinogenesis*, 23(7), 1243, 2002.)

Analytical Determination of Hepatic Triglyceride, Hepatic Malonaldehyde, and Hepatic Collagen Contents

Hepatic Triglycerides

The hepatic triglyceride assay described by Butler et al. [61] is an adaptation of the method of Van Handel and Zilversmit [485], originally developed for the direct determination of serum triglycerides. The procedure consists of five steps: (1) homogenization of liver; (2) adsorption of phospholipids onto zeolite, followed by extraction of triglycerides into chloroform; (3) hydrolysis of triglycerides to fatty acids and glycerol; (4) oxidation of glycerol with $NaIO_4$ to formic acid and formaldehyde; and (5) formation of a colored complex of formaldehyde and chromotropic acid [61]. The procedure is relatively simple and can be used to analyze a large number of tissue samples in a single day.

Hepatic Malonaldehyde

The analysis is based on the reaction of MDA with TBA to produce a fluorescent complex. The method described by Buege and Aust [56] employs fluorescent measurements as put forth by Yagi [516] with the exception that the excitation wavelength is 532 nm. A calibration curve (0.15–2.5 mM) is prepared using 1,1,3,3-tetraethoxypropane (TEP), a chemical releasing MDA under acidic conditions [445]. The sample (1 mL) for analysis (e.g., mitochondrial fraction, cytosol, or homogenate) is prepared to yield a protein concentration of 4–6 mg/mL in phosphate buffer, is mixed with 2 mL of TBA solution, and is incubated at 100°C. After adding butanol and centrifuging, one analyses the organic phase for fluorescent content (532 and 553 nm for excitation and emission, respectively). The MDS content is expressed as pmol MDA/mg protein.

Hepatic Collagen

Liver content of hydroxyproline is measured by the colorimetric method of Edwards and O'Brien [120]. Hydroxyproline is liberated from collagen by acid hydrolysis, oxidized to pyrrole with chloramine-T, then transformed into a red chromogen using a p-dimethyl-aminobenzaldehyde solution, commonly called the Ehrlich reagent. The hydroxyproline is calculated from the absorbance at 500 nm; assuming 12.5% of collagen is constituted of hydroxyproline residues, the total collagen content is derived.

INTERCELLULAR JUNCTIONS IN HEPATOCARCINOGENESIS

The liver is constituted of parenchymal and various types of nonparenchymal cells, which all have to cooperate to perform a plethora of specialized functions. The establishment of cell–cell interactions mediated, in large part, by intercellular junctions is required to coordinate these functions. Cells junctions are specialized regions on the borders of cells that can be classified in three functional groups: occluding junctions (tight junctions), anchoring junctions (adherens junctions and desmosomes), and communicating junctions (gap junctions) (Figure 29.5). Many studies have shown that junctional proteins from the three types of junctions interact, colocalize, and coimmunoprecipitate and that they can regulate the expression or localization of each other in various tissues [109,198,318,500,514]. In hepatocytes, assembly of adherens junctions is needed for the formation of gap junctions [145]. Similarly, gap junctions expression is necessary for the formation and function of tight junctions, and upregulate the expression of tight junctions components [255,258]. Zonula occludens-1 (ZO-1), a tight junction protein, is thought to (1) coordinate the cellular dynamics of various associated junctions and (2) maintain the structural functionality of this multijunctional network [109,155,283]. Cell–cell interactions are required for the regulation of homeostasis and diverse cellular and tissue functions related to cell specialization, growth, and differentiation. In the liver, albumin secretion, ammonia detoxification, glycogenolysis, and bile secretion depend on intercellular junctions [45,192,337,341,343,440–442,454,463,522]. Thus, changes in junctional regulation by environmental contaminants can result in loss of tissue function and have been linked to hepatocarcinogenesis.

HCC, the most common type of liver cancer, arises from hepatocytes [473]. HCC is a progressive disease, divided in three distinct phases: molecular, preclinical, and clinical [473]. During this progression, hepatocytes gradually lost their architecture, polarity, and interactions, adopting a fibroblast-like phenotype, a process referred to as epithelial-to-mesenchymal transition (EMT). During EMT, disassembly of junctional structures is also observed. As a result, many junctional proteins have been associated with HCC progression and are considered as tumor suppressor.

Occluding Junctions and Hepatocarcinogenesis

Tight junctions are complex structures composed of integral membrane and cytoplasmic proteins (Figure 29.6). Integral membrane proteins include occludin, claudins, coxsackieadenovirus receptor (CAR), junctional adhesion molecules (JAMs), and tricellulin [305], each of them forming homodimers with transmembrane protein from adjacent cells. Cytoplasmic components of tight junctions are subdivided into two classes according to either the presence of a postsynaptic density protein-95/disc large protein/zonula occludens-1 (PDZ) domain or their functional properties [309,493]. The latest system distinguishes adaptors or scaffold proteins (e.g., ZO-1, -2, and -3), membrane-associated guanylate kinase–inverted protein (MAGI-1, -2, and -3), regulatory proteins (e.g., Rab13, aPKC, PTEN), and (post)transcriptional regulators (e.g., Symplekin, ZONAB). Tight junctions form highly polarized paracellular barriers that are selectively permeable to ions and small hydrophilic molecules, an essential function for homeostatic maintenance. Claudins and occludin are critical components of tight junction strands as their types and concentrations are thought to determine the ions and size selectivity of the barrier.

Tight junctions are found in two localizations in the liver: between adjacent hepatocytes and between bile duct epithelial cells. They form the blood–biliary barrier that keeps the bile in the bile canaliculi, apart from blood circulation, and allow the maintenance of hepatocytes polarity [260,282]. In human and rodent, claudin-1, -2, -3, -5, -7, -8, -14, occludin, JAM-1, -2, -3, -4, CAR, tricellulin, ZO-1, -2, -3, MAGI1, MUPP1, Cingulin, Symplekin, and 7H6 antigen are detected, with species variations in expression and localization [218,257,493].

HCC generally results from chronic liver diseases, in large part associated with viral hepatitis B and C, or cirrhotic livers [473]. Tight junctions are considered as the *door* for entry of hepatitis viruses, as hepatitis C virus can bind to claudin-1 and occludin, which act as coreceptors to facilitate entry of the virus into hepatocytes [167,282,369,525]. Tight junctions molecules also act as coreceptors for other viruses, such as adenoviruses and coxsackievirus [185]. Thus, on one side, tight junctions can promote liver hepatocarcinogenesis by facilitating viral infections, which render the liver more susceptible to HCC. On the other side, loss of cell interactions

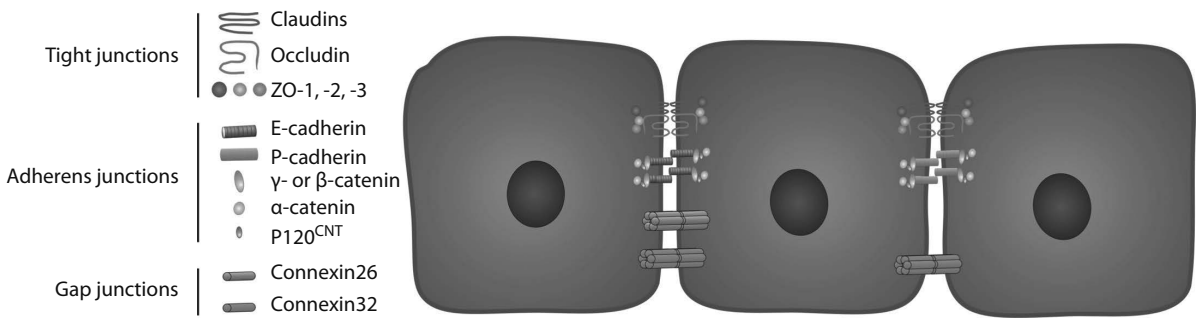

FIGURE 29.6 Schematic representation of tight, adherens, and gap junctions in hepatocytes.

is a hallmark of cancer and EMT, and many tight junctional components are considered as HCC biomarkers. Claudin-1, occludin, and CAR expressions are reduced in human HCC as compared to normal liver tumors [263,358], and downregulation of claudin-1 has been associated with poor survival in patient [203]. Recently, a decreased expression of symplekin in premalignant and malignant liver lesions was observed, suggesting that reduction of tight junction proteins may be an early step in the transformation of a normal hepatocyte [64].

On the other hand, overexpression of claudin-10 is observed in HCC and is thought to be associated with angiogenesis and invasiveness [212]. Introduction of claudin-10 in cultured Hep3B HCC cells, which lack claudin-10 expression, promotes cancer cell survival, motility, and invasiveness [220]. Silencing of the same protein in HLE, an invasive cell line with high level of claudin-10 expression, abolished invasiveness [220]. As a result, it has been suggested that claudin-10 protein could be a useful marker to predict poor prognosis of HCC patients after hepatectomy [212].

Anchoring Junctions

Anchoring junctions include two major groups, adherens junctions and desmosomes. Both are formed by transmembrane proteins, the cadherins, and cytosolic proteins (catenins for adherens junction and Armadillo proteins and plakins for desmosomes) [117,171,488]. Cytosolic components link adherens junctions and desmosomes to the cytoskeletal microfilaments and intermediate filaments, respectively. The role of anchoring junctions is to attach adjacent cells together by dimerization of their cadherins, which is dependent on the presence of Ca^{2+} ions (Figure 29.6).

In human and rodent livers, only stellate cells and hepatocytes form adherens junctions; Kupffer cells express β-catenin without forming junctions. Hepatocyte adherens junctions are formed by E-cadherin and N-cadherin, binding to α-, β-, γ-catenin, and $p120^{CTN}$, while adherens junctions in stellate cells involve N-cadherin and α-, β-catenin, and $p120^{CTN}$ [202,215,327]. As E- and N-cadherin are expressed in hepatocytes, four different cadherin/catenin complexes are present in the liver: E-cadherin/β-catenin/α-catenin/$p120^{CTN}$, E-cadherin/γ-catenin/α-catenin/$p120^{CTN}$, N-cadherin/β-catenin/α-catenin/$p120^{CTN}$, and N-cadherin/γ-catenin/α-catenin/$p120^{CTN}$ [268]. Many desmosomal components were also detected in liver extract, including desmoplakin 1 and 2, desmoglein 1 and 2, and desmocollin 2, which are expressed in hepatocytes [64,196,217,252,359,428,468].

While only few studies focused on desmosomal components in cancer [117], the role played by adherens junctions has been well studied [488]. In many tissues, including liver, E-cadherin is considered as a tumor suppressor [70,229,368]. Moreover, alterations in the expression of adherens junctions α-, β-, and γ-catenin were observed in hepatic tumors [105,215,219,268,324]. Interestingly, Kozyraki and collaborators [268] found a loss of E-cadherin, but not in N-cadherin, in HCC, suggesting that both complexes can have distinct function or stability in the liver. Desmosomes and adherens junctions have been studied in normal, premalignant liver lesions and HCC in a recent study [64]. Expression and localization of anchoring junctions in benign and premalignant lesions were uniform in hepatocytes and did not differ from normal tissue. In contrast, expression of components of desmosomes and adherens junctions was heterogeneous in HCC, ranging from none to very high per cell, and differs also between samples. Similarly, localization of junctional proteins in HCC was either at the plasma membrane, as in normal liver, or cytoplasmic and/or nuclear. Finally, the authors showed that the expression levels of the adherens junctions and desmosomes correlated with the grades of HCC cell differentiation by both immunohistochemical and Western blotting analysis [64].

Communicating Junctions

Communicating junctions, or gap junctions, are formed by a family of transmembrane protein named connexins (Cxs). The family is composed of 20 members in the mouse and 21 members in humans, named according to their predicted molecular weight, with different temporal and spatial expression in different cell and tissue [274]. Within cells, connexins form hexameric hemi-channels, called connexons, which are delivered to the plasma membrane. Once inserted in the plasma membrane, connexons freely diffuse within the cytoplasmic membrane bilayer and are clustered at the edges of specific area, named gap junction plaques [148,280,467]. While the mechanisms are not totally understood, guidance of connexons toward gap junction plaque seems to implicate N- and E-cadherin [232,318,500]. Connexons can then dock with connexons from adjacent cells to form gap-junction channels. Gap junctions allow direct passage of small molecules, such as cAMP, $Ins P_3$, adenosine, ADP and ATP, and second messengers, between cells, a process known as gap junctional intercellular communication (GJIC). Gap junctions are removed from the cell surface by internalization in specialized vesicle named annular junctions or connexosomes [148,375].

In rodent and human livers, Cx43 is expressed in endothelial, Kupffer, and stellate cells, as well as in the Glisson's capsule, Cx40 and Cx37 are expressed in vascular cells, while transcripts of Cx37, Cx31.9, and Cx30.2 were detected in whole liver [33,41,172,347,422,439,510]. Hepatocytes, on the other hand, are loaded with Cx32 and Cx26, as gap junction channels occupy about 3% of their membrane surface [330,450] (Figure 29.6). Cx32 is predominant, representing about 90% of the total hepatic connexins content, and uniformly distributed, while small amount of Cx26 is expressed mainly in the periportal acinar area [65,344,450].

Similar to E-cadherin, connexins are considered as tumor suppressor genes in many tissues [338]; inactivation of connexins genes in normal cells results in increased cancer-like phenotype, and cancer cells adopt a more normal phenotype upon transfection with connexins [97]. As Cx32 is the major hepatic connexin, Cx32-knockout mice are more susceptible

to diethylnitrosamine (DEN)-, radiation-, and chemical-induced liver hepatocarcinogenesis [126,242,243]. Similarly, transgenic rats carrying a dominant-negative mutant of Cx32 under the control of the albumin promoter (Cx32DTg) are more susceptible to DEN-induced hepatocarcinogenesis [208]. Interestingly, hepatic GJIC function decreases with aging, which can also render aged rats more susceptible to hepatocarcinogenesis [334]. Interestingly, Cx43, which is expressed in fetal but not in adult hepatocytes, is re-expressed in damaged hepatocytes [333], in primary culture and in many cell lines derived from normal liver [256,456,509]. However, Cx43 is usually localized in the cytoplasm or in the nucleus, and its reappearance could be considered as part of a dedifferentiation process, whereby hepatocytes gradually adopt a more fetal-like pattern [509]. Consistently, Cx43 is detectable in HCC [360].

Cell Interactions in Toxicological Studies

The liver is the primary site of detoxification, which involves cytochrome P450–mediated xenobiotic biotransformation. Many studies have suggested that cytochrome P450 expression is linked to the presence of Cx32 and E-cadherin; however, the mechanism is not clear [192,343,440–442]. Yet, in all previous studies, exposure to xenobiotic (β-naphthoflavone, phenobarbital, or clofibrate) resulted in a decrease in Cx32 expression and a concomitant induction of cytochrome P450 isoenzymes. Similarly, alcohol-, carbon-, tetrachloride-, and thioacetamide-induced acute hepatic injuries, and chemically induced chronic liver diseases are associated with downregulation of junctional components [43,80,259,322,335,336,426,518].

As cell junctions are critical for proper hepatic functions and in functions related to cell differentiation and proliferation, it has been suggested that they could be used as biomarkers in toxicological screening of chemical and epigenetic carcinogens [493]. In particular, inhibition of GJIC has been reported following exposure to numerous epigenetic carcinogens, whereas genotoxic compounds usually do not affect gap junctions [304,419,474–477,482,519,520]. Although not clear yet, some mechanisms and pathways have been associated with chemically induced downregulation of junctional components, focusing mainly on Cx32 in the liver.

Mechanisms Implicated in Connexin32 Downregulation

GJIC is regulated by both short-term and long-term mechanisms. Long-term regulation is mainly achieved by biosynthesis, trafficking, and turnover of connexins [274] and is more likely to be involved in hepatocarcinogenesis. Connexins half-life is short for transmembrane proteins: less than 2 h in cultured cardiomyocytes and 5 h in hepatocytes for Cx43 and Cx32, respectively [127,276]. As a result, downregulation of connexins transcription shortly results in decreased GJIC, which in the long term can promote carcinogenesis. Epigenetic mechanisms such as histone acetylation, DNA methylation, and micro-RNA-related control have been implicated in connexins regulation [490,492]. Using two cell lines of liver cells, one expressing Cx32 but not Cx43, the other expressing Cx43 but not Cx32, Piechocki and collaborators showed that connexins expressions correlate with their respective promoter methylation status, hypermethylation of the promoter region leading to silencing [373]. In rat HCC induced by a choline-deficient L-amino acid–defined (CDAA) diet, Cx26, and E-cadherin promoters were hypermethylated, resulting in gene silencing, as compared to normal liver tissue [478]. Interestingly, changes in methylation seem to be an early phenomenon even in hepatocarcinogenesis [437], and have been observed in tumors from other tissues [74,75,205,460].

Albeit its promoter has been identified, little is known about transcriptional regulation of Cx32 [19,20,131,342]. The human Cx32 gene is driven by two tissue-specific promoters containing binding sites for transcription factors, including hepatocyte nuclear factor-1 (HNF-1), Sp1, YY1, and NF-1, which role in carcinogenesis remains to be elucidated [254,329,374]. Pathways implicated in the regulation of these transcription factors remain, for the most part, to be identified. Snail, a tumorigenic transcription factor, mediates inhibition of E-cadherin gene expression in HCC [323,457]. In a study looking at mechanisms implicated in female rats susceptibility to hepatic tumor promotion by hexachlorobenzene (HCB) [269,278], Plante and collaborators demonstrated that both Cx26 and Cx32 were decreased in HCB-treated female rats, but not in males, resulting in downregulation of GJIC [385]. They demonstrated that downregulation of Cx32 was induced by the female-specific activation of the integrin-linked-kinase [508] pathway and resulted from decreased binding of transcription factors on the Cx32 promoter [386–388]. The same studies also showed that the activation of ILK pathway concomitantly reduced E-cadherin expression, but through different effectors, identifying for the first time a pathway implicated in the regulation of junctional proteins from two different types of junctions [386,387]. From this study, two important points were made: (1) exposure to environmental pollutants can promote tumorigenesis by inhibiting intercellular junctions, and (2) members of the junctional complexes can concomitantly be regulated by signaling pathways. Together, these data support the premise that cell–cell junctions are important early biomarkers of chemically induced hepatic cancer.

Methods to Evaluate Hepatic Connexins and GJIC

Changes in hepatic connexins expression in cancer or following exposure to chemicals are normally assessed by Western blot analysis, as good antibodies are available for Cx26, Cx32, and Cx43 [385,386,389]. Cellular localization is also critical when evaluating gap junctions since connexins need to be at the cytoplasmic membrane to be able to achieve their function [274,275]. Typically, gap junctions present as punctate structures at the junction of two adjoining cells [155]. Consistently, trafficking defects were associated with diseases and intracellular localization of connexins has been observed in tumors from diverse tissues [235,509]. While plasma membrane localization of connexins is required for

gap junction functions, it is not sufficient as channels can be closed by different mechanisms [301]. Some disease-linked connexin mutants showed proper localization but are not functional [274,432].

Because gap junctions allow the direct passage of ions and small molecules from one cell to the other, methods developed to evaluate GJIC usually involve tagged small molecular size molecules [1]. Transfer of endogenous and biologically relevant compounds can be monitored from loaded donor cells to unlabeled recipient cells using radiolabeled precursors, such as uridine. In this type of assay, GJIC is evaluated by autoradiographic labeling of the cytoplasm of recipient cells [162–164]. Increase in intracellular calcium, which propagate from cell to cell after stimulation, a process known as intercellular calcium waves (ICW), is linked to the presence of functional gap junctions and can be monitored using calcium-sensitive fluorescent dyes as another indicator of functional GJIC [427]. Gap junctional electrical conductance can also be monitored using dual voltage patch clamp technique, which is a very sensitive method, allowing the recording of a single gap junction channel [191,345].

The most commonly used methods, especially in carcinogenesis and toxicological studies, involve small fluorescent dyes transferring from adjacent cells through gap junction channels [1]. Dyes can be introduced into a confluent cell culture in one single cell, or in a restricted number of cells, by micro injection [236], scraping [122,357], or electroporation [398], and GJIC evaluated either by counting the number of receiving cells (or layers of cells) or as incidence of coupling (*yes–no* evaluation). Usually, a combination of two dyes is used: the first one, which is able to pass through gap junctions (i.e., Lucifer Yellow [LY]), is used to evaluate GJIC, and the second one, which cannot pass through gap junctions (i.e., Rhodamine-dextran [RH]), is used to evaluate transfer due to cell damage or other nonjunctional mechanisms. Alternatively, cells can be loaded with lipophilic cell plasma membrane permeable dyes, such as calcein acetoxymethyl ester, which once hydrolized by cytoplasmic esterases becomes fluorescent and membrane impermeable. Fluorescence is then irreversibly photobleached in a cell, or in a small number of cells, and fluorescence recovery after photobleaching (FRAP), coming from the transfer of fluorescent dye from the adjacent cells, is monitored [496]. Cells can also be loaded with a gap junction–permeable dye, such as calcein, and a gap junction–impermeable dye, such as DiI, and either cocultured with unloaded cells (preloading assay [161]) and allowed to form a monolayer, or spread on top of a monolayer of unloaded cells and allowed to adhere to them (parachute assay [527]). GJIC between donor preloaded cells and receiving unloaded cells is measured by fluorescent microscopy. More recently, Dakin and collaborators [100] used tracers that are nonfluorescent (or weakly fluorescent) when key functional groups of fluorophores are masked by photolabile protecting groups (cages), and become fluorescent upon removing of the protecting group by photoactivation (uncaging). The gap junction–permeable tracers can be activated (uncaged) by illumination in a single, or a small group of, preloaded cells (Local Activation of Molecular Fluorescent Probe [LAMP]) and fluorescence followed. This latest technique can also be applied in three-dimensional systems (infrared-LAMP assay [99,523].

These methods have been successfully used to study toxicological effects of compounds on GJIC in hepatocytes in vitro [1,491]. Ex vivo, GJIC can be determined in freshly removed precision-cut liver slices by injection of fluorescent dyes [222,270,418]. A modified version of the scrape loading has also been successfully developed in order to evaluate the effect of carcinogen in vivo [425]. Sai et al. [425] demonstrated a dose-dependent decrease in GJIC in the liver of mice treated with pentachlorophenol, which correlates with the dose dependency of tumor-promoting activity previously observed by the same team [481]. Similarly, Plante and collaborators showed that exposure to HCB, an epigenetic carcinogen, decreases GJIC in female rat liver (Figure 29.7) [385]. Likewise, exposure to cadmium, perfluorooctanoate (PFOA), perfluorooctane sulfonic acid (PFOS), phenobarbital, and HCB all decrease GJIC in vivo [211,230,385,483,498].

Role for Gap Junction Intercellular Communication in Spreading Liver Damage and Immune Responses: The Bystander Effects

In the last few years, increased connexins and GJIC have been shown to be beneficial in cancer treatments through *bystander effects*. Bystander effects refer to biological effects in cells that are not directly targeted by a treatment, such as transmission of damage signals from irradiated to nonirradiated cells that kill an increased number of tumors cells [190]. A promising approach combining the bystander effect and GJIC involves the herpes simplex virus-thymidine kinase (HSV-TK). In this system, cells expressing the TK gene can phosphorylate an antiviral drug, the ganciclovir (GVC), to GVC triphosphate, a nucleotide analog that causes DNA chain termination and apoptosis. This toxic metabolite can then be transferred to cells that do not express the TK gene, presumably through gap junction, and thereby induce apoptosis in TK-negative cells [190,346].

Paradoxically, in recent years, the GJIC-related bystander effects have also been associated with spreading of liver damage and immune response induced by drugs or chemicals. When developing new drugs, hepatotoxicity is a major concern as toxic metabolites can lead to oxidative stress and DNA damage in hepatocytes [339]. It has been suggested that GJIC should decrease to avoid transfer of these toxic metabolites to neighboring cells and thereby reduce liver toxicity [333,364]. Using rats carrying a dominant-negative mutation in the gene coding for Cx32, Naiki-Ito et al. [333] demonstrated that the loss of Cx32 is protective against acetaminophen-induced hepatotoxicity, a drug involved in many cases of drug-induced liver injury. More recently, Patel et al. [364] treated Cx32-knockout mice with acetaminophen or thioacetamide (TAA), a classic hepatotoxin known to cause fulminant hepatic failure, and showed that they had less liver damage and a reduced inflammatory response as compared

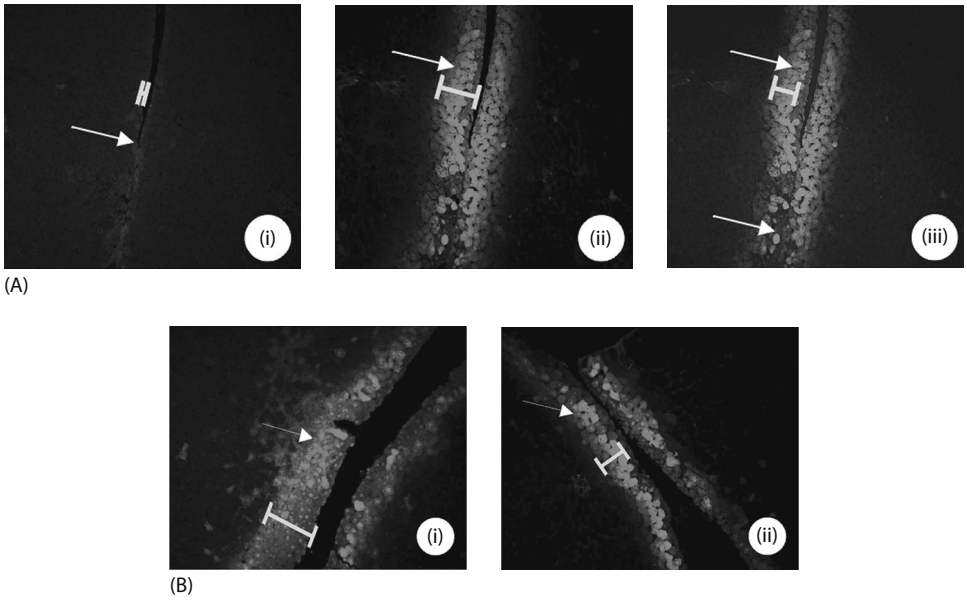

FIGURE 29.7 Effect of hexachlorobenzene (HCB) on gap junctional intercellular communication in female rat liver. Rats were administrated HCB (100 mg/kg) by gavage for 5 consecutive days and samples on day 100 of the experiment. Liver were excised and subjected to incision-loading/dye-transfer analysis. (A) Rhodamine-dextran (RhD) (panels i and iii) was used as a control for damaged cells, while Lucifer-Yellow (LY) was used to measure cell–cell communication (panels ii and iii). Distance of LY migration is indicated by a white lane (A and B). (B) LY migration in a control (panel i) and a HCB-treated female liver (panel ii). (Data obtained from Plante, I. et al., *Carcinogenesis*, 23(7), 1243, 2002.)

to wild-type mice. Moreover, TAA-induced mortality was extensively reduced after exposure to a lethal dose of the drugs. Oxidative stress is a well-known effect of hepatotoxicans; decreased Cx32 and GJIC in knockout mice would prevent transmission of an oxidative stress signal throughout the liver. Interestingly, pretreatment, coadministration, or posttreatment with a Cx32 inhibitor had similar effects in TAA- or acetaminophen-exposed wild-type mice, suggesting that targeting gap junction proteins could be a broad strategy for preventing drug-induced liver injury at all of these stages.

While GJIC-mediated bystander effects have received a lot of attention regarding drug-induced liver injury in the last few years, little is known about such hepatic effects induced by chemicals. Asamoto and collaborators demonstrated that exposure to D-galactosamine or carbon tetrachloride results in milder liver damage in transgenic rats expressing a dominant-negative Cx32 than in their wild-type counterparts [11]. Whether or not other toxicological damages could be amplified by GJIC remains to be determined.

LIVER REPAIR AND RECOVERY

The liver is a remarkable organ in its ability to regulate its growth and gain or loss of optimal mass. The biology of proliferative properties of the organ, the mechanisms initiating regeneration, the relationship between hepatocyte proliferation and apoptosis, and the involvement of nonparenchymal cells (Kupffer cells and stellate cells) have been well described [129,500]. Liver regeneration is a multistep process involving priming and progression. Although various forms of chemical-induced liver injury have been studied extensively in terms of biochemical events for over 50 years [379], interest generally has focused on the early initiating effects leading to the appearance of hepatocellular dysfunction, rather than on the later recovery phase of the lesion. In the rat, organ recovery after acute hepatotoxic insult is largely dose dependent; recovery time is longer when the lesion is more extensive. As the lesion progresses, hepatocellular regeneration appears; it appears within 6 h after administration of a low dose of CCl_4 in the rat, even though the centrilobular necrosis is just becoming evident [294,295]. When the hepatic lesion is enhanced by the introduction of another agent, however, recovery time can be an important consideration for assessing possible mechanisms of action involved in the potentiations [377]. With the combination of CCl_4 and several potentiating agents (*n*-hexane, 2-hexanone, 2,5-hexanedione, isopropanol, and acetone), this relationship was assessed using both biochemical indices (serum ALT and OCT activities) and morphological patterns (quantitative histology) of liver injury; appropriate dose–response curves were established from the percentage of animals affected [72]. Time of recovery was shown to be due to the maximal severity of the lesion, regardless of the potentiation. Although pretreatment with the potentiator resulted in an enhanced hepatotoxic response from a low dose of CCl_4, the dose–response curve for the enhanced response was no different than that produced by a higher, but equitoxic dose of CCl_4 administered alone. These data were interpreted as an indication that the five potentiators did not alter the temporal progression of CCl_4-induced liver injury.

Mehendale and his collaborators have performed an extensive series of experiments to assess the role of tissue repair in potentiated liver injury. The studies originated from the observation that chlordecone-potentiated CCl_4 hepatotoxicity in rats was quantitatively quite remarkable and resulted in enhanced lethality. Two tissue repair responses were observed after exposure to a low dose of CCl_4 [62]; the early phase regeneration (EPR) response (arrested G2 hepatocytes activated to proceed through mitosis) occurs quickly (peaks at about 6 h) and is followed (at about 24 h) by the secondary phase regeneration (SPR) response (hepatocytes mobilized from G0/G1 to proceed through mitosis). During chlordecone potentiation of CCl_4 hepatotoxicity, the EPR phase appears to be eliminated and the SPR phase decreased; thus, the progression of the severe injury is facilitated and leads to lethality. There is evidence that induction of EPR may accelerate SPR. Interestingly enough, large doses of CCl_4 given alone also result in regeneration responses similar to those obtained with chlordecone and a small dose of CCl_4. Experiments performed with colchicine, partial hepatectomy, CCl_4 autoprotection, nutritional factors, and different animal species have provided data consistent with the purported roles attributed to EPR, SPR, and liver injury [62,449].

The role of tissue repair has been assessed with other hepatotoxicants [315,449]. Dose–response studies indicate that thioacetamide when given alone affects hepatic tissue regeneration (measured with ^{3}H-thymidine incorporation into DNA; proliferating nuclear cell antigen) in a manner not unlike that observed with CCl_4. Comparable observations were obtained with o-dichlorobenzene and trichloroethylene, although the dose-dependent relationships were not as evident with these agents. Increased lethality was not observed with isopropanol-potentiated CCl_4 liver injury. Expression of stimulators of promitogenic signaling interleukin-6, inducible nitric oxide synthase, hepatocyte growth factor, transforming growth factor-α, and epidermal growth factor receptor were studied after thioacetamide hepatotoxicity in rats; they were modified by moderate caloric restriction [315]. With a binary mixture of chloroform and allyl alcohol, tissue repair was shown [6] to exert a key role in the final outcome of the liver injury in rats. Mehendale and his collaborators have proposed [291,449] a two-stage model for chemical-induced hepatotoxicity. Stage one would involve initiation and infliction of injury; stage two would lead to recovery or progression to massive injury depending on the effects of the toxicant on cellular regeneration (enhancement would lead to recovery; inhibition would lead to massive injury). They hypothesized that progression of the liver injury might be mediated by cytoplasmic and lysosomal degradative enzymes leaking from dying cells [291]. The experimental results carried out following CCl_4- and acetaminophen-induced hepatotoxicity suggest that calpains may be involved. Although various aspects of the repair–recovery process are still hypothetical or speculative, the concept as such is thought provoking and certainly an important contribution to the understanding of chemical-induced liver injury. It will be interesting to see how it evolves.

APOPTOSIS

Previous sections highlighted the fact that necrosis of hepatocytes is a common type of cell death occurring after chemical exposure. There exists, however, another type of cell death, called apoptosis (from the Greek "apo" meaning "away from" and "ptosis" meaning falling: cells "falling away from" a tissue) [86] that is recognized as an important process in chemically induced effects in the liver and liver disease [421]. In a landmark article, Kerr et al. [240] defined a form of cell death morphologically distinct from necrosis, which they called apoptosis. Apoptotic cells exhibited nuclear and cytoplasmic condensation followed by dissociation of the cell into membrane-bound fragments similarly to the events observed in a phenomenon previously described by embryologists as programmed cell death. For this reason, apoptosis has been inappropriately used as a synonym for programmed cell death. Apoptosis is defined as an active mode of cell death, since it requires RNA and protein syntheses, is controlled by pro- and antiapoptotic genes, and is induced by physiological stimuli in addition to the typical pathological stimuli associated with necrosis [83]. On the other hand, necrosis is considered to be a form of *passive* cell death. Recently, however, necrosis has also emerged as an alternate form of programmed cell death, whose activation might have biological consequences, including the induction of an inflammatory response [119].

Apoptosis is morphologically defined by a progressive condensation of the chromatin to the inner face of the nuclear membrane (DNA hyperchromicity and cresenteric caps), convoluted cell shape (*blebbing/budding*), dilatation of the endoplasmic reticulum, cell shrinkage with consequent loss of membrane contact with neighboring cells, and fragmentation of the cell with formation of membrane-bound acidophilic globules (apoptotic bodies) often containing nuclear material. The latter are frequently found within the cytoplasm of intact cells, indicating they are phagocytized by adjacent cells [101]. In addition, apoptosis is not commonly associated with the inflammatory response that accompanies necrosis [240]. Other morphological criteria specific for necrotic cells are cellular and nuclear swellings, patchy chromatin condensation, swelling of mitochondria, vacuolization in cytoplasm, plasma membrane rupture (*ghost-like* cells), and dissolution of DNA (karyolysis). Histological criteria of cell death, such as pyknosis and karyorrhexis, can be applied to both apoptosis and necrosis at certain stages and hence cannot distinguish between these two modes of cell death [366]. Finally, from the above it is apparent that apoptosis involves only scattered single cells, whereas necrosis affects large areas of liver lobules. In the normal liver, apoptosis is predominant in acinar zone 3 and is thought to subserve the elimination of senescent cells [34].

Apoptosis and mitosis play complementary contrasting roles in tissue homeostasis as the former leads to cell removal and tissue hypoplasia, whereas the latter causes tissue hyperplasia. For example, the induction of altered hepatic foci appears to be related to compensatory cell proliferation

in PCB-77-treated rats, whereas the inhibition of apoptosis appears to be important in PCB-153-treated rats [464]. Because apoptosis plays a critical role in deleting cells from tissues, it is not surprising that failure of apoptosis leads to imbalanced cell proliferation and is now recognized as a phenomenon associated with carcinogenesis. Bursch et al. [59], however, recently suggested that in contrast to rat liver, inhibition of apoptosis in mice appears to be a minor determinant of tumor promotion. Tumor promoters and nongenotoxic carcinogens inhibit active cell death, thereby increasing the accumulation of (pre)neoplastic cells and accelerating the development of cancer [430]. Sustained activation of the aryl hydrocarbon receptor (AhR) is postulated to generate a strong selective pressure in liver treated with 2,3,7,8-tetrachlorodibenzodioxin (TCDD), leading to selection and expansion of clones evading growth arrest and apoptosis [44]. Suppression of apoptosis with TCDD coincided with a marked hyperphosphorylation of p53 mediated by the AhR [429]. Using the inhibition of UV-induced apoptosis in rat hepatocytes in primary culture as an in vitro model for mechanistic studies on the inhibition of apoptosis, Bohnenberger et al. [46] showed that *non-dioxin-like* PCBs are likely to promote liver carcinogenesis via the suppression of apoptosis. Heptachlor strongly inhibited TGF-induced apoptosis and cytochrome *c* release into the cytosol in rat hepatocytes [352]. Peroxisome proliferators, a large and chemically diverse family of nongenotoxic rodent hepatocarcinogens that activate the peroxisome proliferator-activated receptor alpha (PPARα), have been shown to suppress apoptosis induced by both spontaneous and transforming growth factor ß1, the physiological negative regulator of liver growth [412]. Experimental evidence supports a mechanism involving diminished apoptosis in the age-related difference in sensitivity, where PPAR agonists produce a five- to seven-fold higher yield of grossly visible hepatic tumors in old-relative-to-young animals [524].

Examples of Chemically Induced Liver Apoptosis

In addition to being present in various viral, immunological, malignant, or drug-induced human liver diseases, hepatocyte apoptosis in animals can be triggered either in vivo or in vitro by many toxic agents [130]. Histopathologic features of apoptosis are frequently observed in chronic cholestatic disorders as a result of accumulation of toxic bile salts within hepatocytes [366]. Bile salt–induced apoptosis occurs in a concentration-dependent manner at concentrations that are far smaller than those critical for micelle formation and do not cause cell necrosis [365]. Hydrophobic bile salts, such as glycodeoxycholate, glycochenodeoxycholate, or taurochenodeoxycholate, cause apoptosis in isolated hepatocytes [78,366]. The hydrophilic bile acid tauroursodeoxycholic acid significantly reduced glycochenodeoxycholate-induced hepatocyte apoptosis [36]. Death receptor activation is an important endpoint in bile acid–induced apoptosis. Higuchi et al. [204] reported that deoxycholate is more potent than glycodeoxycholate, chenodeoxycholate, and glycochenodeoxycholate to upregulate death receptor 5 (DR5)/tumor necrosis factor–related apoptosis inducing ligand (TRAIL) receptor 2 sensitizing hepatocytes to TRAIL-mediated apoptosis. Glycochenodeoxycholate-induced hepatocyte apoptosis is modulated by caspase cascade activation [497]. Hepatobiliary diseases are characterized by elevated caspase activation and apoptosis, which can be specifically detected in situ by a cleavage site-specific antibody against cytokeratin-18 [26].

Increases in the number as well as changes in the distribution of apoptotic bodies within the liver were observed in ethanol-fed rats and mice [35,165]. When compared with normal livers, the increased apoptosis was more pronounced as the duration of ethanol exposure increased and was reversed by ethanol withdrawal. All the putative mechanisms for alcohol-induced hepatocellular damage (i.e., oxidative stress, toxic acetaldehyde adduct formation, hypoxia, or immunologically mediated destruction) can induce apoptosis, such that it may represent a final common mechanism mediating hepatocellular damage by ethanol [366]. Alcohol increases liver apoptosis predominantly through an intrinsic signaling pathway [107].

Metals cause changes in liver apoptosis. Mice injected with 5–60 μmol/kg i.p. of cadmium showed both a time- and dose-dependent increases in liver apoptosis, which peaked at 9–14 h after cadmium administration, then decreased [186]. The time-course of apoptotic DNA fragmentation index, monitored by quantification of oligonucleosomal DNA fragments, correlated with the results obtained by histopathological analysis and a commercial in situ apoptotic DNA detection kit. An interesting conclusion of this work is that apoptosis is a major mode of elimination of critically damaged cells in acute cadmium hepatotoxicity in the mouse, and it precedes necrosis. Cadmium also causes a biphasic elevation in parenchymal cell apoptosis in the rat [480]; apoptosis of nonparenchymal cells is the basis of the pathogenesis of peliosis hepatitis. An organic metal, tributyltin, which is a highly toxic water contaminant, also induces apoptosis in rainbow trout hepatocytes through a step involving Ca^{2+} efflux from the endoplasmic reticulum or other intracellular pools and by mechanisms involving cysteine proteases, such as calpains, as well as the phosphorylation of apoptotic proteins, such as Bcl-2 homologues [399]. Denizeau et al. [234] reported the involvement of initiator and effector caspases, cleavage of their intracellular substrates and activation of both death receptor and mitochondrial pathways in TBT-induced apoptosis in rat hepatocytes. Long-Evans Cinnamon (LEC) rats, an animal model for inherited copper toxicosis, show liver apoptosis with increasing age [135]. Finally, chronic arsenic administration induces a specific pattern of apoptosis called postmitotic apoptosis [27].

Assessment of Apoptosis

Precision-cut liver slices provide a valuable in vitro system for studying drug-induced liver apoptosis [328]. Using a model of apoptosis-driven regression of rat liver hyperplasia induced by cyproterone acetate, the mean duration of the histological stages of apoptosis was found to be approximately 3 h

[60]. Since apoptosis occurs in isolated single cells and does not stimulate persisting tissue changes, such as inflammation and scarring that characterize necrosis, procedures based on biochemical endpoints, such as DNA cleavage patterns, have been developed as complementary tools for the analysis of cell morphology. Internucleosomal DNA cleavage caused by a Ca^{2+}/Mg^{2+}-dependent endonucleases is a prominent feature of apoptosis [8]. During apoptosis, DNA is cleaved in a non-random manner into 50–300 kilobases, then into 180 base-pair fragments. Several techniques are based on the analysis of DNA fragments. Separation of nuclear DNA from apoptotic cells on agarose gel yields a typical *ladder* appearance of fragments, whereas DNA from necrotic cells produces a smear on electrophoresis. The use of DNA electrophoresis as the sole criterion for apoptosis is not recommended, since DNA ladders can be observed in cells with necrotic-type morphology, and cells with ultrastructural characteristics of apoptosis can fail to produce DNA ladders.

Individual cell electrophoresis can be performed using the so-called *comets* assay [101]; the apoptotic cells appear as *comets* having characteristic *heads*, that represent the remains of the cells containing high molecular weight DNA and *tails*, which represent a fraction of the degraded DNA. Commonly used techniques involve in situ labeling of DNA strand breaks such as the TdT-mediated dUTP-digoxigenin Nick End Labeling (TUNEL) assay; deoxynucleotides can be either fluorochrome- or enzyme (phophatase or peroxidase)-tagged. For a description of this procedure used in the context of liver toxicity assessment, see Habeebu et al. [186]. Wheeldon et al. [504] suggested that further validation is required before in situ end labeling can be used confidently alone, since they observed variation in apoptotic body indices after cyproterone acetate withdrawal between in situ end labeling and hematoxylin and eosin staining techniques. Similarly, Grasl-Kraupp et al. [170] concluded that DNA fragmentation is common to different kinds of rat liver cell death and that its detection in situ should not be considered a specific marker of apoptosis.

Several techniques for measuring apoptosis rely on flow or laser scanning cytometry (for a review, see pp. 49–61 in [101]). Dive et al. [112] proposed a rapid multiparameter flow cytometric assay that discriminates and quantifies viable, apoptotic, and necrotic cells via measurement of forward- and side-light scatter (proportional to cell diameter and internal granularity, respectively) and the DNA-binding fluorophores Hoechst 33342 and propidium. For a comparison of approaches for quantifying hepatocyte apoptosis, see Goldsworthy et al. [166], and for a discussion on the selection of methods and the inappropriate uses of methodology, see pp. 61–69 in Ref. [101]. Annexin V is a 36-kDa protein that binds with high affinity to phosphatidylserine lipids in the cell membrane, a component that goes from the inner membrane leaflet to the outer cell surface in apoptotic cells. Therefore, Annexin V has been shown useful for detecting the earliest stages of apoptosis. Recent advanced positron emission tomography (PET) techniques using either ^{18}F-annexin V [517] or ^{124}I-annexin V [238] have opened the way for in vivo measurement of chemically induced apoptosis in rats.

Modulation of molecular endpoints based on proteins involved in signaling cascades controlling apoptosis can be used to demonstrate chemically induced apoptosis. For example, the caspase (cysteine–aspartyl–proteases) enzymes play a central role in the cell death machinery as indicated in chemically induced apoptosis discussed earlier. They are subdivided into initiator (caspase-2, -8, -9, and -10) and effector (caspase-3, -6, and -7) caspases. Two main pathways are well established in apoptosis, that is, the death receptor pathway and the mitochondrial pathway. The first pathway requires membrane receptors such as Fas, which is involved in a signaling complex activating caspase-8, ensuring activation of caspase-3. The second pathway involves the release of a small apoptogenic molecule, cytochrome *c*, leading to formation of apoptosome, which also leads to caspase-3 activation. The two pathways can be linked through Bid, a pro-apoptotic member of the Bcl-2 family of proteins [234]. At least 15 different Bcl-2 proteins have been identified and can be subdivided into pro- and anti-apoptotic members. Bcl-2, Bcl-xL, Bcl-w, Mcl-1, Bfl-1, Brag-1, and A1 inhibit apoptosis, whereas Bax, Bak, Bcl-xS, Bag, Bid, Bik, Hrk, and Bad promote apoptosis in mammalians [421].

A simple cytological method has been used for evaluating the apoptotic rate of human neutrophils, since these cells are known to spontaneously undergo apoptosis without any stimulation and are recognized as an excellent model for studying this biological process [150]. The assay can be applied to tissue slices, primary cells, cell lines, freshly isolated cells, and can be performed with cells of virtually any origin. Furthermore, observations made using this technique correlate well with the results obtained by conventional Hoechst 3342 and propidium iodide cytofluorimetric analyses [159]. This simple and low-cost histologically based procedure is performed at room temperature. Isolated cells (suspension of approximately 1.5×10^6 cells/mL) are loaded into a cytospin chamber and gently spun with a cytocentrifuge to adhere the cells onto a microscope slide, whereas adhering cells can be directly grown on glass coverslips and tissues slices used. A rapid coloration procedure is performed using the Diff-Quick staining kit (Baxter, Miami, FL) according to the manufacturer's instructions. The slides are rinsed and sealed with warm parafilm or nail varnish; the sealed slides can be kept for several days. Cells are observed with a light microscope at a magnification of 400× or 1000×; nuclei appear as dark purple structures. Apoptotic cells are easily distinguished from normal cells by examining morphological changes: cell shrinkage, nuclear collapse (crescent shape or small dot profiles), dense white inner cell vacuoles, and apoptotic bodies (plasma membrane blebs/buds or granules). It is recommended that a minimum of 100 cells from different fields be counted in two replicate slides. Results are expressed as the percentage of cells in apoptosis (100 × the number of apoptotic cells/the total number of cells). For new applications

using isolated or cultured cells, it is strongly recommended that cell viability be verified by trypan blue exclusion before performing the assay; unlike necrotic cells, apoptotic cells exclude trypan blue.

CONCLUDING REMARKS

It can be seen that although techniques for determination of chemically induced liver injury in laboratory animals are readily available, no single technique is satisfactory for the detection and quantification of all forms of injury. Rather, a battery of procedures consisting of one or more of the biochemical/functional techniques coupled with a histological analysis of the liver is essential for the correct evaluation of the hepatotoxic potential of a chemical agent.

DEDICATION

This chapter is dedicated to the memory of two internationally recognized toxicologists, Gabriel L. Plaa (May 15, 1930 – November 11, 2009) and Michel Charbonneau (April 10, 1959–June 27, 2013).

Gabbie was a hepatotoxicologist who set up the basis for many assays and mechanisms that are still in use these days. Among others, he served as president of the STC, the SOT, as well as the Pharmacological Society of Canada.

Michel's main interests were to understand the risks associated with pollutants exposure on human health and cancer. His scientific achievements were recognized by numerous awards, and by his implication in SOT, as president of STC and director of Réseau de Recherche en Santé Environnementale. Above all, Michel was my first mentor, recently my colleague, and forever my friend and "scientific father." This wonderful person left us too early and will be missed by many.

ACKNOWLEDGMENTS

The authors are thankful to Drs Robert Tardif and Sami Haddad for their critical reading of this chapter.

30 Principles and Methods for Renal Toxicology

Lawrence H. Lash

CONTENTS

INTRODUCTION

This chapter focuses on guiding and underlying principles and methods used to study kidney function and toxicity on levels ranging from the whole animal or humans, to the organ, cellular, subcellular, and all the way down to the level of individual molecules. This broad range reflects the need to have noninvasive means of detecting renal function and toxicity in the clinic as well as to develop more effective therapeutic approaches to treat renal disease and renal injury resulting from exposures to toxic chemicals. The latter requires an understanding of the molecular changes that accompany exposures to toxic chemicals and in various disease states that affect the kidneys. An important theme that underlies much of the chapter is that of biomarkers. Although the concept and use of biomarkers (also called biological markers) to assess renal function or exposure to nephrotoxicants is not new,[1] recent advances in methodology and in our understanding of renal function have identified new biomarkers that can be very useful for identifying chemical exposures or indicating changes in renal function.

To be most effective and useful in the clinic, the biomarker must be something that is readily measured in a noninvasive manner, such as in a blood or urine sample. One can divide biomarkers into three types[1]: biomarkers of exposure, biomarkers of effect, and biomarkers of susceptibility. Biomarkers of exposure (to a drug or chemical contaminant) are typically either the chemical itself, a key stable metabolite, or a product derived from interaction between the chemical and a component in the target cell. An example of the latter might be a protein with a specific adduct or a chemically modified residue. Utility of such markers for therapeutics is questionable because so many drugs have common metabolites or produce similar molecular changes in target cells. Biomarkers of effect are by far the most common and include some measurable cellular, physiologic, or biochemical change. For these to be most useful, they must be tissue- and chemical-specific and highly sensitive. Finally, biomarkers of susceptibility are those that can identify a genetic factor or preexisting disease that alters response to a chemical exposure. The study of pharmacogenetics or pharmacogenomics has greatly increased our understanding of potential variations in the response of the human population. By identifying genetic polymorphisms in processes such as drug metabolism or transport or ligand–receptor binding, for example, one can identify those individuals who are more likely than the majority of the population to experience adverse effects from chemical exposure and at lower doses of the chemical. From this has developed the concept of personalized medicine.

The text is divided into four main sections. The first section reviews some key properties of renal structure and function as they relate to the kidneys as a target organ for chemically induced toxicity. Although much more detailed information on renal structure and function can be found in several texts, books, and book chapters,[2,3] it is important to provide some foundation to address the critical issue of what makes the kidneys particularly susceptible to many forms of injury. The second section considers the various experimental models that can be used to study renal function and toxicity. Key considerations in the use of these models are presented, focusing on advantages and limitations to their use in renal toxicology. The third section considers several selected examples of assays used to quantify renal cellular function. These range from parameters that can be measured in blood or urine, and are thus potentially applicable to clinical use to cellular and subcellular parameters that can be used to help understand mechanism and develop novel therapeutic approaches to treating renal injury. These assays are presented to illustrate examples of both some classic assays as well as newer approaches that can provide insight into cellular metabolism and molecular regulation. The fourth section discusses the topic of human disease and risk assessment, which integrates discussion of experimental models of renal disease and chemically induced nephrotoxicity and that of how animal models are used to make predictions for humans.

It is important to note that this chapter is meant to provide a summary and overview of factors that determine or contribute to nephrotoxicity and the experimental models and assay methods used in studies of renal function and toxicity. Presentation of methods and assays is not in the form of detailed, step-by-step procedures; rather, presentation of the highlights, advantages, and limitations are the major emphases.

RENAL PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY

The kidneys are uniquely sensitive to many toxicants because they receive and filter a large quantity of blood relative to its weight. On average, the two kidneys receive 25% of cardiac output while comprising only about 1% of body weight. Additionally, plasma membranes of renal epithelial cells, especially those of the proximal tubule, possess a myriad of transport proteins. Thus, the combination of renal blood flow and membrane transporters can often lead to a high degree of accumulation and high concentration of chemicals relative to that in plasma within the tubular epithelial cells. The presence of drug metabolism enzymes, which can result in bioactivation of inert or nontoxic chemicals, further contributes to the potential susceptibility of the kidneys to chemically induced injury.

The major function of the kidneys is to excrete waste products while maintaining total body salt, water, and acid–base balance. The kidneys are thus the primary organs responsible for maintaining the constancy of the internal environment. This is accomplished by three mechanisms: (1) glomerular filtration, (2) tubular reabsorption, and (3) tubular secretion. Each mechanism, primarily with a focus on its contribution to renal susceptibility and injury, are discussed later in this chapter. The following subsection will briefly discuss some of the key structural and functional features of the mammalian kidney. A critical point is that the kidneys exemplify

form following function. It is also important how these functions, in a toxicological or pathological context rather than under normal physiological conditions, make the kidneys a unique target organ.

Overall Structural Organization of the Kidneys

The major tissue types in the kidneys are vascular tissue and tubular epithelia. Kidney structure can be considered at multiple levels of organization. At the highest level, the kidney is subdivided into cortex, outer stripe of the outer medulla, inner stripe of the outer medulla, and inner medulla or papilla. Humans and larger mammals have multipapillate kidneys whereas small mammals, such as rat and rabbit, are unipapillate. Each papilla descends into a renal fornix. In multipapillate kidneys, fornices merge to form the renal pelvis, which is an expanded upward extension of the ureter. There is a close association, both physically and functionally, between the renal vasculature and epithelial tissue. The renal artery enters the kidney alongside the ureter, branching to become progressively the interlobular arterioles that lead to the glomerular capillary network. The venous system has subdivisions with similar designations, terminating in the renal vein, which also flows beside the ureter.

At the closed end, the nephron is extended to form the cup-shaped Bowman's capsule. The lumen of the capsule is continuous with the narrow lumen that extends through the renal tubule. Associated with the capsule is the tuft of capillaries that forms the glomerulus inside Bowman's capsule. This structure is responsible for the initial step in urine formation. A filtrate of plasma passes through the single-cell layer of capillary walls, through the basement membrane, and finally through another single-cell layer of epithelium that forms the wall of Bowman's capsule. The filtrate then passes into the lumen of the tubules to begin its passage through the various segments of the nephron, eventually passing into the collecting duct and the renal pelvis. The wall of the renal tubule is one cell layer thick and this epithelium functions to separate the plasma and urinary filtrate in the lumen from the interstitial fluid.

The nephron is considered the functional unit of the mammalian kidney, and consists of a glomerular capillary network surrounded by Bowman's capsule, a proximal tubule (convoluted and pars recta or straight segment), a loop of Henle (thin descending limb, thick ascending limb), a distal tubule (convoluted tubule and collecting tubule), and a collecting duct (Figure 30.1). The nephron is an epithelial tubule that is closed on one end and opens into the renal pelvis and collecting ducts at the other end. Nephrons are divided into three classes, based on the location of their glomerulus: superficial, midcortical, and juxtamedullary. Glomeruli located near the surface of the kidney give rise to superficial nephrons, which generally only descend into the outer medulla. These nephrons are also called short-looped nephrons and lack thin ascending limbs. Glomeruli located deep within the cortex, near the corticomedullary border, give rise to juxtamedullary nephrons. These nephrons are called long-looped nephrons and enter the inner medulla and have thin descending limbs. In general, mammals that produce highly concentrated urine have longer papillae and a higher proportion of long-looped versus short-looped nephrons. Glomeruli located between the superficial and juxtamedullary glomeruli give rise to

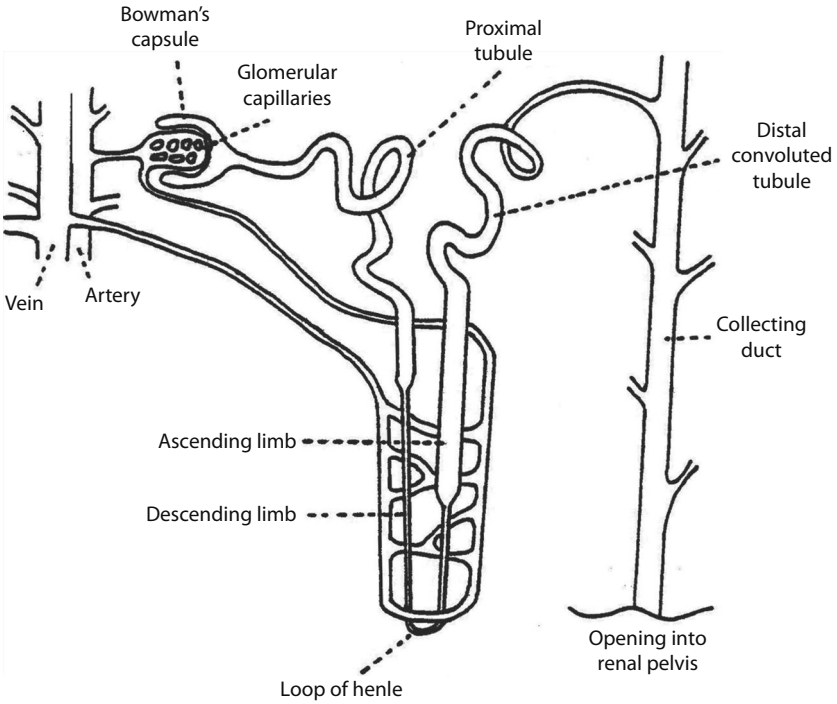

FIGURE 30.1 Diagram of basic nephron structure and the associated renal vasculature.

midcortical nephrons. These may be either long-looped or short-looped, although the deeper glomeruli are more likely to be associated with long-looped nephrons.

Basic nephron structure can also be considered on the basis of localization relative to the vascular or urinary poles. The urinary pole starts at the proximal convoluted tubule in the cortex. The tubule enters the medulla where it forms the loop of Henle. The distal tubule returns to the glomerulus of origin and then enters the cortex where it is somewhat convoluted. The distal tubule then leads into the collecting duct, which goes into the medullary pyramid and then into the papillae. The nephron ends at the junction of the distal tubule and the collecting duct. Several nephrons feed into a single collecting duct. The vascular pole is the juxtaglomerular region, which contains mesangial cells and the returning distal portion of the distal tubule. This region has many closely packed nuclei and is called the macula densa. The afferent arteriole breaks up into 8–10 capillary loops in the glomerulus. On the opposite side of the glomerulus is the urinary pole where the proximal tubule begins.

An important region of the nephron that is critically involved in regulation of renal blood flow and urine formation is the juxtaglomerular apparatus (JGA), which consists of specialized epithelial cells, the macula densa cells, and specialized secretory or granular cells at the vascular pole where the afferent and efferent arterioles enter and leave the glomerulus. The JGA is thus a combination of specialized tubular and vascular (i.e., smooth muscle) cells. A key function of the JGA is secretion of renin, which is involved in the formation of angiotensin and ultimately, in secretion of the mineralocorticoid aldosterone. This process is part of the feedback system that regulates glomerular filtration and renal blood flow.

Glomerular Filtration and Urine Formation

Each kidney receives its blood supply from a single renal artery and renal vein. The renal arteries originate from the aorta and the renal veins drain into the interior vena cava. The urine formed in each kidney is drained via a single ureter into the bladder. The initial stage of urine formation is filtration of plasma and accumulation of the ultrafiltrate in the lumen of Bowman's capsule. The glomerular filtrate contains nearly all the constituents of the blood except for the blood cells and large proteins. Approximately 15%–25% of the water and solutes are removed from the plasma during a single pass through the renal circulation by filtration alone. In humans, the glomerular filtrate is typically produced at a rate of 125 mL/min or about 200 L/day. Consideration of normal fluid intake implies that most of the glomerular filtrate must be reabsorbed into the bloodstream to maintain water balance and prevent dehydration. The critical importance of the kidneys in this function is illustrated in a bar graph comparing major sources of fluid input and output under normal conditions (Figure 30.2). Input of fluid comes from metabolism and the gastrointestinal (GI) tract. Both of these are highly adaptable, although water production from metabolism typically is geared toward energy production rather than volume regulation. Input of water from the GI tract can be modulated by activation of the thirst mechanism in dehydration. The prominence of the kidneys is clearly seen in a comparison of the primary sources of water output: Although the lungs, GI tract, and skin are significant sources, the kidneys provide 68% of the output under basal conditions.

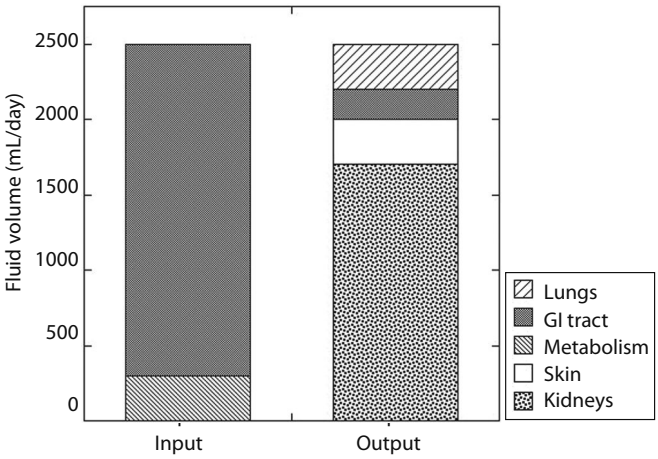

FIGURE 30.2 Summary histogram showing the function of different organ systems in fluid volume homeostasis.

Glomerular filtration refers to the movement of water and solutes across the glomerular membrane to form an ultrafiltrate of plasma in the tubular lumen, and is the first step in urine formation. It depends on two factors: (1) a pressure gradient from the lumen of the capillary to the lumen of Bowman's capsule and (2) the sieve-like properties of the three-layered tissue separating the two compartments. Water and nonprotein solutes (e.g., inorganic anions and cations, intermediary metabolites such as glucose and urea) are found in the filtrate at approximately the same concentrations at which they occur in plasma. The exclusion of most proteins above a threshold molecular weight from the glomerular filtrate is critical for maintenance of the osmotic pressure difference across the glomerular membrane. As described in the following text, appearance of significant amounts of high-molecular-weight proteins in the urine is an obvious indicator of glomerular damage. Thus, filtration occurs because forces moving fluid out of the capillary (i.e., hydrostatic pressure) exceed forces preventing both movement out of the capillary (i.e., oncotic pressure due to plasma proteins) and into Bowman's space (i.e., hydraulic pressure within Bowman's capsule).

The glomerular filtration rate (GFR) is affected by changes in blood pressure, plasma protein concentration, and the ultrafiltration coefficient (K_f). GFR varies directly with blood pressure and inversely with protein concentration in the afferent arteriole. Although GFR is highly dependent on blood flow, renal blood flow is normally independent of systemic blood pressure and is autoregulated (i.e., to be approximately constant) as long as blood pressure is above about 80 mmHg. K_f is not a constant, but varies in response to agents such as angiotensin II, vasopressin, and norepinephrine.

Contraction of the mesangium reduces K_f. Alterations of this coefficient are thought to be important in the progression of glomerular damage but not tubular damage.

The two other processes, besides glomerular filtration, that account for the ability of the kidneys to regulate electrolyte, organic metabolite, and water balance are tubular reabsorption and tubular secretion. Tubular reabsorption refers to the movement of substances from the tubular fluid, through the epithelial cell, back into plasma. In this manner, substances that would otherwise have been excreted in urine are reabsorbed. The functional significance of tubular reabsorption is evident from an evaluation of the renal handling of Na^+ ions and glucose. The kidneys actively reabsorb >99% of the Na^+ ions and glucose that emerge in the tubular fluid after glomerular filtration. Although reabsorption of the filtered NaCl load occurs along all segments of the nephron, the proximal tubules account for approximately 60% of the total reabsorption under normal conditions. The remainder is reabsorbed in the thick ascending limb (~30%), distal convoluted tubule (~7%), and collecting duct (~2%–3%). Depending on the filtered NaCl load, however, these proportions can be greatly modified as Na^+ ion transport in the more distal portions of the nephron and the collecting duct is under hormonal control. Tubular secretion, in contrast, refers to the movement of substances from plasma, through the epithelial cell, into the tubular fluid and ultimately the urine. Tubular secretion is a critical component of how the body handles many drugs and xenobiotics.

The processes described earlier lead to a glomerular filtrate in the proximal tubular lumen that is isosmotic with plasma (i.e., ~300 mOsM). As the filtrate progresses along the nephron, however, there is a countercurrent mechanism that generates an extremely high osmolarity in the medullary interstitium. Thus, the medullary interstitium at the base of the loop of Henle in long-looped nephrons can reach as high as 1200 mOsM. As fluid progresses through the thick ascending limb to the distal and cortical collecting tubules, osmolarity decreases to ~100 mOsM. This behavior is dependent primarily on three factors: (1) active chloride or sodium reabsorption in the ascending limb, (2) the anatomical relationship between the descending and ascending limbs (i.e., both limbs are close together and flow in each is in the opposite direction), and (3) the parallel vascular structure to the nephron structure that forms a countercurrent exchange of blood and prevents solutes from coming out of the descending limb and being washed away.

Nephron Heterogeneity: Physiological, Biochemical, and Toxicological Implications

The mammalian kidney is a complex organ whose basic structural unit, the nephron, is composed of several cell populations, each exhibiting diverse morphological, biochemical, and physiological properties.[4,5] As briefly described earlier, specific properties of each segment are critical to overall kidney function in reabsorption and secretion. As presented in the following text, each segment is both morphologically and biochemically designed to perform specific functions in urine formation and maintenance of electrolyte, fluid, and metabolite homeostasis. Additionally, these features also give each nephron segment a characteristic susceptibility to either chemical toxicants or to pathological states, such as hypoxia or ischemia/reperfusion. As will be briefly described in the following subsections, these susceptibility differences are due in part to the distinctive composition of membrane transporters and enzymes in each segment but also to differences in cellular energetics and oxygenation.

An important feature of all nephron cell types, and is also characteristic of transporting epithelia in general, is that they are polarized cells, meaning that the plasma membrane is physically separated by tight junctions into distinct regions (luminal or brush-border membrane and basolateral membrane). A critical feature of this separation is that each region comprises distinct enzymes, carriers, channels, and other proteins. This separation is essential for functions such as vectorial transport as part of tubular reabsorption and tubular secretion; disturbances in the processing of key membrane proteins have been identified as a response to nephrotoxicants and disease states.

Nephron Cell Types: Structure and Function

The subsections that follow will summarize some key morphological and functional features of several major nephron segments. Additional details and discussion of other nephron segments can be found in any number of texts or book chapters.[2,3] An overview of the major nephron segments, highlighting some of their key morphological features and physiological roles, is presented in Table 30.1.

Proximal Tubules

The first nephron segment to which the tubular filtrate comes in contact after glomerular filtration is the proximal tubule. The proximal tubule is subdivided into three segments, S1, S2, and S3. The first segment (S1) is located within the pars convoluta or proximal convoluted tubule, and is found in the cortex. The S2 segment is localized at the end of the convoluted and beginning of the straight section (pars recta or proximal straight tubule), and the S3 segment is localized entirely within the proximal straight tubule, which is in the outer stripe of the outer medulla.

The epithelial cells of the S1 segment are rather leaky, allowing movement of solutes between cells by a paracellular route. Approximately 60%–70% of the initial tubular filtrate is reabsorbed in the S1 segment. Reabsorption occurs via an array of active and passive transport processes, with water flowing passively down the osmotic gradient. Hence, the tubular fluid remains isosmotic with respect to the plasma in spite of the large reduction in fluid volume to approximately 25% of its original volume. Cells of the S1 segment are tall and have a prominent brush border, extensive infoldings of the basal membrane, and interdigitations of the lateral borders of adjacent cells. The extensive brush border, or microvilli, and the infoldings of the basal membrane illustrate the correlation between form and function, as these structures

TABLE 30.1
Summary of Morphology and Physiology of Selected, Key Nephron Segments from Mammalian Kidney

Nephron Cell Type	Morphology	Physiology
Proximal tubule	Tall and prominent microvilli on luminal membrane (especially S1)	75% of filtered Na^+ removed by active transport
		Passive water and Cl^- reabsorption
	Cuboidal shape	Organic anion secretion (S2, S3)
	Extensive basolateral infoldings	Most glucose, amino acid reabsorption
	Leaky epithelium	Tubular fluid remains isosmotic to plasma
	High density of mitochondria	
Thin descending limb	Squamous epithelium	Extremely high osmotic water permeability
	Little cellular interdigitation (type I)	Aquaporin 1 on luminal and basolateral membranes
	Better developed lateral interdigitations (types II, III)	Low permeability to Na^+
	Deep tight junctions (type I)	Variable permeability to urea (low to moderate)
	Shallow tight junctions (types II, III)	Tubular urine concentration
	Low density of mostly spherical mitochondria	
Thin ascending limb	Flat, moderately interdigitated cells	Water impermeable; no aquaporin
	Shallow tight junctions	Little, if any, active Na^+ transport
	Low density of mostly spherical mitochondria	Highly permeable to NaCl
		Vasopressin-sensitive C1C-K1 Cl^- channel
		Variable permeability to urea (low to moderate)
Thick ascending limb	Extensive interdigitation	CYP-dependent arachidonic acid metabolism
	Shallow tight junctions	Water impermeable; no aquaporin
	Large number of elongated, rod-shaped mitochondria	Na^+–K^+–$2Cl^-$ cotransport
	Cortical cells are thinner and have less mitochondria than medullary cells	Active Na^+ transport
		Active Ca^{2+} and Mg^{2+} transport
		Dilution of hyperosmotic tubular urine
Distal tubule (distal convoluted and connecting tubule)	Distal convoluted tubule (DCT)—appears bright under microscope short deep tight junctions; numerous long mitochondria	High rates of Na^+ reabsorption
		Thiazide-inhibitable Na^+–Cl^- cotransporter
	Cortical collecting tubule (CCT)—appears granular under light microscope wider than DCT	K^+–Cl^- cotransporter
		Ca^{2+} reabsorption
		DCT—water impermeable
		CCT—vasopressin-regulated aquaporin 2 water channel
Cortical collecting duct	Two cell types: principal cells (PC), intercalated cells (IC) (2:1)	IC—abundant carbonic anhydrase
		PC—no carbonic anhydrase
	PC—few cellular organelles including mitochondria sparse, short microprojections on apical membrane	Vasopressin-dependent water permeability
		Low urea permeability
	IC—abundant cytoplasmic vesicles higher mitochondrial content densely packed microvilli on apical membrane	Active and passive transport of Cl^- and K^+ ions
		Acid–base regulation

provide a large surface area for reabsorption. The cells possess a high content of mitochondria near the basal pole, a characteristic feature of Na^+-transporting epithelia. The vast majority of filtered glucose and amino acids are reabsorbed in this segment as well.

Cells of the S2 segment are structurally less complex than those of the S1 segment; S2 cells have a shorter, less dense brush border, less basolateral interdigitation, and a lower content of mitochondria. While the rate of volume reabsorption is thought to decrease in vivo going from S1 to S2 segment, in vitro studies show a similar capacity for the two segments. The results in vivo are, therefore, likely due to the decreased concentration of electrolytes in the S2 tubular fluid due to the large reabsorption that occurred in the S1 segment. Certain carriers, however, are present at higher activities in the S2 segment, such as many of those for organic anions.

The transition between S2 and S3 segments is relatively subtle, and species-dependent differences exist in S3 ultrastructure. For example, S3 cells are shorter and less complex than S2 cells in rabbits whereas S3 cells in rats have a well-developed brush border that is longer than that in other proximal segments. Although glucose reabsorptive capacity is much lower in S3 segments than in either S1 or S2 segment, organic anion and organic cation transport is high in S3. Consistent with this distribution, several enzymes involved in drug metabolism are present at the highest levels among the three proximal tubular segments in the S3 segment.

Thin Descending and Thin Ascending Limbs

Thin descending limbs are present in both short-looped and long-looped nephrons. They are subdivided into three subtypes in most mammalian species, types I, II, and III.

Short-looped nephrons contain only type I cells, which form a squamous epithelium with little cellular interdigitation and deep tight junctions. Long-looped nephrons of rat and hamster, in contrast, contain type II cells in the more proximal portion of the thin limb and type III cells as the thin limb enters the inner medulla. Type II cells contain well-developed lateral interdigitation and shallow tight junctions. A key physiological feature of type I, II, and III thin descending limb cells is their extremely high osmotic water permeability, which is mediated by aquaporin 1 water channels in both luminal and basolateral plasma membranes. Urea and sodium permeability exhibits a good deal of heterogeneity among both the different cell types of thin descending limbs and across species that have been studied, ranging from very high to low.

Thin ascending limbs are only present in long-looped nephrons, and begin slightly before the bend of the loop of Henle in most species. There is an abrupt conversion of cell type to the medullary thick ascending limb as the tubule progresses past the inner–outer medullary border. The thin ascending limb contains flat, moderately interdigitated cells that are connected by shallow tight junctions. Unlike the thin descending limb, cells of the thin ascending limb are water impermeable in all species studied and do not express any aquaporin water channels. Thin ascending limb cells have very low Na^+ pump activity, suggesting little if any active Na^+ transport. In contrast, there is a high passive NaCl permeability, which is thought to involve paracellular flux. Vasopressin-sensitive, transcellular Cl^- transport occurs and is mediated by the ClC-K1 Cl^- channel that is present on both the luminal and basolateral plasma membranes. Cells from both thin descending and thin ascending limbs contain a low density of mostly spherical mitochondria, which is consistent with the low activities of active transport processes.

Thick Ascending Limb

The thick ascending limb is divided into two segments, the medullary thick ascending limb, which is located in the outer medulla, and the cortical thick ascending limb, which is located in the medullary rays within the cortex. The medullary thick ascending limb originates at the inner–outer medullary border, either from the thin ascending limb of long-looped nephrons or from the thin descending limb of short-looped nephrons. The cell type becomes the cortical thick ascending limb at the outer medulla–cortex junction, although the transition between medullary and cortical cell types is not abrupt.

Medullary thick ascending limbs are longer in long-looped as compared with short-looped nephrons. There are extensive interdigitation and shallow tight junctions between adjacent medullary thick ascending limb cells. They contain a large number of elongated, rod-shaped mitochondria and one or two cilia on their luminal surface. Medullary thick ascending limbs are subdivided into two types, based on the smoothness or roughness of their luminal surfaces. Although the transition is fairly subtle from medullary to cortical thick ascending limb, the cortical thick ascending limbs are thinner than those of the medullary thick ascending limb and cells from the cortical region contain a lower density of mitochondria. The cortical thick ascending limb extends past the macula densa, varying in length among species.

Although most of the renal cytochrome P450 (CYP) activity is found in the proximal tubules (predominantly the S3 segment), both medullary and cortical thick ascending limbs contain CYP activity that metabolizes arachidonic acid to several biologically active products, indicating the importance of these nephron segments in regulation of renal hemodynamics. Like the thin ascending limb, both medullary and cortical thick ascending limbs are water impermeable and do not express aquaporin water channels. Unlike the thin ascending limb, medullary and cortical thick ascending limbs have active ion transport processes. Active transporters include the bumetanide-sensitive Na^+–K^+–$2Cl^-$ cotransporter (NKCC2, BSC1) in the luminal plasma membrane, the (Na^++K^+)-stimulated adenosine triphosphatase (ATPase) on the basolateral plasma membrane, and the membrane potential-dependent, divalent cation transporter for Ca^{2+} and Mg^{2+}. These active solute reabsorption processes provide the primary mechanism for dilution of the luminal fluid as it moves up the nephron through the thick ascending limbs.

Distal Tubule

The term "distal tubule" is generally used to refer to the portion of the nephron that lies between the macula densa and the first junction of two tubules, although it is actually composed of several structurally and functionally distinct cell types. The most proximal portion begins just beyond the macula densa and contains cortical thick ascending limb cells. These cells abruptly transition to distal convoluted tubules. The distal convoluted tubules appear bright under light microscopy and are short. The cells contain deep tight junctions, short blunt apical microvilli, deep basolateral invaginations, and numerous long mitochondria oriented perpendicular to the basolateral membrane. The third portion of the distal tubule, the connecting segment or connecting tubule, appears granular under light microscopy and is wider than the distal convoluted tubule. This segment is also sometimes referred to as the granular distal tubule.

Functionally, both the distal convoluted tubule and connecting tubule exhibit high rates of Na^+ reabsorption that are mediated by the thiazide-inhibitable Na^+–Cl^- cotransporter (NCC1, TSC). Potassium is transported by the K^+–Cl^- cotransporter (KCC1) on the luminal plasma membrane and a conductive K^+ channel is expressed in rabbit distal convoluted tubules. Calcium ion reabsorption is also a prominent function of the distal convoluted tubule but occurs at a lower rate than in the cortical thick ascending limb. Finally, the distal convoluted tubule is water impermeable, but the connecting tubule in rat possesses a vasopressin-regulated water channel, aquaporin-2, indicating this segment can be water permeable.

Cortical Collecting Duct

The cortical collecting duct originates at the convergence of two collecting tubules and extends down to the corticomedullary

TABLE 30.2
Substrate Preferences and Predominant Pathways for Energy Metabolism among Nephron Cell Types

Nephron Cell Type	Substrate Preference	Mitochondrial Density	Pathway Preference for ATP Generation
Proximal tubule	Fatty acids, ketone bodies, lactate, glutamine, glutamate, pyruvate, citrate, acetate	High	Oxidative phosphorylation, citric acid cycle, gluconeogenesis
Thick ascending limb (medullary and cortical)	Lactate, glucose, ketone bodies, fatty acids, acetate	Moderate to high	Oxidative phosphorylation and glycolysis
Distal convoluted tubule	Glucose, lactate, β–hydroxybutyrate	High	Glycolysis
Cortical collecting duct	Glucose, lactate, β-hydroxybutyrate, fatty acids	Low	Glycolysis

border. This segment contains two cell types, the principal (or light) cells and the intercalated (or dark) cells, at a ratio of approximately 2:1. In comparison with the intercalated cells, principal cells have fewer cellular organelles, including mitochondria, a less electron-dense cytoplasm, and sparse, short microprojections on their apical membranes in contrast with the abundant cytoplasmic vesicles and more densely packed microvilli on apical membranes of intercalated cells. Another important difference between the two subtypes of cortical collecting duct cells is that carbonic anhydrase is abundant in intercalated cells but is either absent or present at relatively low levels, depending on species, in principal cells. This has functional implications for pH regulation of the urine.

Physiologically, the collecting duct regulates the final composition of the urine. Although the collecting duct has a low capacity for reabsorption, it is important in regulating the reabsorption of water, solutes, electrolytes, bicarbonate, and protons. Water permeability of the cortical collecting duct is almost completely dependent on vasopressin, which stimulates baseline osmotic water permeability by a factor of 10–100 in rats and rabbits. The cortical collecting duct has a low permeability for urea that is unaffected by vasopressin. In the presence of vasopressin, therefore, this property enables the kidneys to increase the concentration of urea within the lumen of the cortical collecting duct. This nephron segment also contains both active and passive transport processes for Cl^- and K^+ ions and plays an important role in acid–base regulation.

Cellular Energetics

Patterns of cellular energy metabolism differ widely among the cell types of the nephron. These patterns are based on a number of factors, including cellular energy (i.e., adinosine triphosphate [ATP]) requirements, mitochondrial density, and oxygenation.[6] The first factor, cellular energy requirements, is largely dependent on active transport capacity. As described earlier, each nephron cell population exhibits markedly different levels of various active transport pathways. Thus, while the proximal tubules contain high activities of active Na^+, organic anion, glucose, and amino acid transport pathways, and have correspondingly high needs for ATP and high densities of mitochondria, thin descending and ascending limb cells have low activities of active transport pathways and correspondingly low needs for ATP and low densities of mitochondria. Thick ascending limb cells, particularly those in the medullary region, have high activities of active Na^+ and divalent cation transport and high densities of mitochondria. Distal tubular cells also have high rates of active Na^+ transport and high amounts of mitochondria.

In terms of substrate utilization, each segment has a characteristic preference for energy needs and exhibits distinct patterns of activity for pathways of carbohydrate utilization and synthesis (Table 30.2). For example, although many segments contain a high density of mitochondria, ATP generation primarily comes from glycolysis in the more distal segments of the nephron. Although fatty acids and ketone bodies can be used by several nephron segments, they are the preferred source of reducing equivalents for ATP generation in the proximal tubules. Because many toxicants target mitochondria as an early step in their mechanism of action, cells such as those in the proximal tubule are particularly susceptible to injury, provided that the chemical is transported into the cell.

An example of two nephron cell populations exhibiting a markedly different susceptibility to inhibition of mitochondrial function and ATP depletion, is illustrated in our studies of the susceptibility of suspensions of freshly isolated proximal tubular and distal tubular cells from the rat to hypoxia or chemically induced ATP depletion.[7,8] In the hypoxia study,[7] cells were incubated under either hyperoxic (95% O_2/5% CO_2), normoxic (21% O_2/74% N_2/5% CO_2), or hypoxic (95% N_2/5% CO_2) conditions to determine the extent of cell death over time. Distal tubular cells were markedly more sensitive to cytotoxicity from O_2 deprivation than those from the proximal tubule; moreover, this difference was not correlated with the extent of ATP depletion, as proximal tubular cells exhibited ~75% ATP depletion yet little or no cytotoxicity. Essentially, similar results were obtained with the chemical model of cellular ATP depletion[8]: Proximal tubular cells exposed to iodoacetate + KCN exhibit little cytotoxicity, but significant ATP depletion, whereas distal tubular cells exhibited a similar degree of ATP depletion but markedly higher release of lactate dehydrogenase (LDH). This suggests that nephron cell populations have differing abilities to withstand marked (>80%) ATP depletion.

Another factor that relates to differences in cellular energetics is in vivo oxygenation. As described earlier and in our hypoxia study,[7] proximal and distal tubular cells respond differently in vitro to O_2 deprivation. In the intact animal or in humans, however, the situation is more complex. On the one

hand, each nephron cell population has different ATP consumption rates and differing mitochondrial densities. Beyond that, however, it is known that an O_2 gradient exists in the kidneys as one goes from cortex to medulla such that the inner medulla has been described as being on the brink of anoxia. Accordingly, the pars recta (S3) segment of the proximal tubule and the medullary thick ascending limb in isolated, perfused rat kidneys are particularly susceptible to injury from hypoxia.[9–13] An additional series of studies from Epstein and colleagues[14–17] correlated the degree of cellular injury from hypoxia or ischemia with either ATP consumption (i.e., cellular work) or the inverse of mitochondrial activity.

Organic Anion and Cation Transport

As indicated earlier, an important component of susceptibility of a specific cell type to chemically induced injury is whether that cell type possesses the capacity to transport and accumulate the chemical. Although there are several classes of transporters involved in renal physiology that are localized in various nephron segments, perhaps the most important for toxicology and experimental therapeutics relating to the kidneys are those for transport of organic anions and cations because most therapeutically used drugs belong to these two classes of molecules. Although these carriers are also distributed in multiple segments of the nephron, they are expressed at the highest levels in the proximal tubules. As shown in Figures 30.3 and 30.4, transport of organic anions and cations, respectively, occurs by multiple carriers and mechanisms. While each carrier certainly has a discrete substrate specificity pattern, there is also considerable overlap between carriers, providing functional redundancy. Most of these carriers are polyspecific, that is, they transport multiple substrates. Several recent reviews have been published on the properties and regulation of these carriers and their importance in renal function.[18–27]

Organic anions, including many Phase II metabolites of xenobiotics such as glucuronide, glutathione (GSH), and sulfate conjugates, are transported across the basolateral and brush-border membranes of renal proximal tubular cells, which constitute the mechanism for their secretion into tubular urine. Uptake of organic anions across the basolateral plasma membranes of renal proximal tubules from the renal plasma and interstitial space occurs primarily by organic anion transporters 1 and 3 (Oat1/Slc22a6 in rodents and OAT1/SLC22A6 in humans; Oat3/Slc22a8 in rodents and OAT3/SLC22A8 in humans) (Figure 30.3). Oat1/OAT1 and Oat3/OAT3 are considered tertiary active transporters, because uptake of organic anions (OA^-) is dependent on the 2-oxoglutarate concentration gradient, which is in turn determined by counter transport with Na^+ ions as mediated by the sodium-dicarboxylate carrier (NaC3/SLC13A3). The Na^+ ion gradient used to drive 2-oxoglutarate transport is achieved by the (Na^++K^+)-stimulated ATPase, a primary active ion transporter. An additional member of the SLC22

BBM, brush-border membrane; BLM, basolateral membrane; MRP, multidrug resistance–associated protein; NaC3, sodium-dicarboxylate 3 cotransporter; OAT, organic anion transporter; OATP, organic anion transporting polypeptide; 2-OG^-, 2-oxoglutarate. The "h" in front of some of the carriers indicates it has only been found in humans? = Unknown what, if anything, is coupled to organic anion efflux.

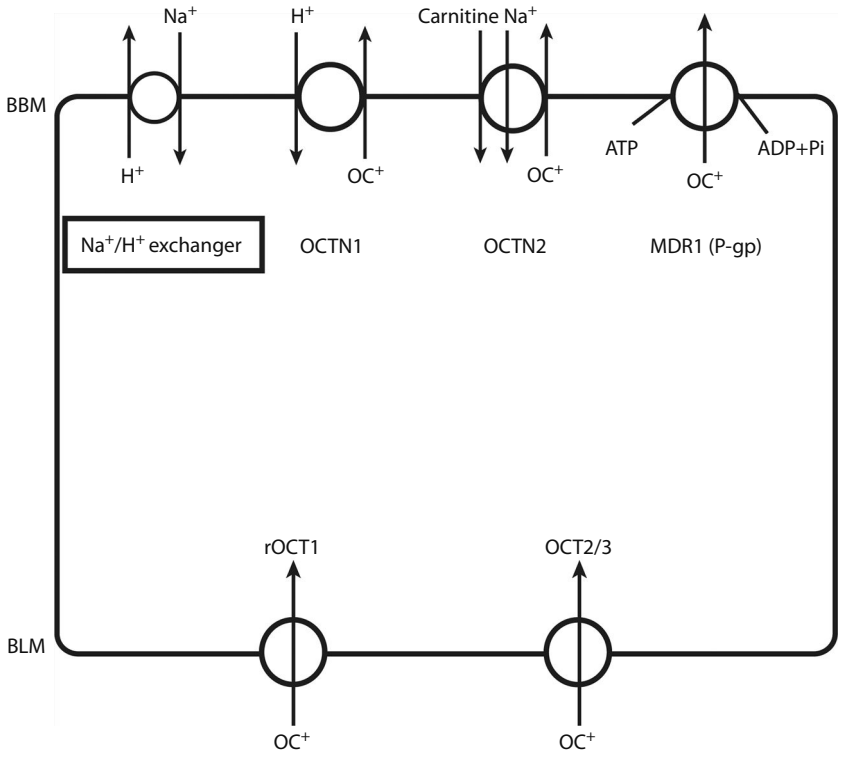

FIGURE 30.4 Scheme for organic cation (OC^+) transport in renal proximal tubule. BBM, brush-border membrane; BLM, basolateral membrane; MRP, multidrug resistance–associated protein; OCT, organic cation transporter. The "r" in front of some of the carriers indicates it has only been found in rats.

transporter family, OAT2, is expressed in basolateral membranes of human kidney proximal tubules; in contrast, Oat2 is expressed primarily in liver and not in kidney of rodent kidney proximal tubules. OAT2 functions as an OA^- uniporter. Finally, OA^- uptake across the basolateral membrane, particularly for Phase II conjugates of xenobiotics, can occur by the multidrug resistance proteins 5 and 6 (Mrp5/6–Abcc5/6 in rodents; MRP5/6–ABCC5/6 in humans), which are primary active transporters using the free energy of ATP hydrolysis to drive uptake of OA^-.

In some respects, less is known about the mechanisms of the exit step by which OA^- are transported across the luminal or brush-border membrane of renal proximal tubules into the tubular lumen (Figure 30.3). The major carriers involved in the efflux step include the organic anion transporting polypeptide-1a1 (Oatp1a1/OATP1A1; Slco1a1 in rats and mice, SLCO1A2 in humans), the rat-specific Oat-k1 and Oat-k2 (Slco1a3), and two MRP isoforms (MRP2/4–ABCC2/4). Oatp1a1/OATP1A1 catalyzes uptake of OA^- in exchange for the tripeptide GSH, which may be the principal carrier responsible for the delivery of intrarenal GSH to the active site of γ-glutamyltransferase (GGT) for its turnover.[28] A member of the SLC22 family, URAT1 (SLC22A12), is expressed exclusively in renal proximal tubules and is responsible for the uptake of urate in exchange for OA^-, thereby maintaining blood levels of uric acid.

Many important drugs are organic cations or weak bases and are secreted into the tubular lumen by an array of organic cation transporters (OCTs) (Figure 30.4). These carriers, which are mostly members of the SLC22 carrier family, include two or three carriers, depending on species, on the basolateral plasma membrane, and three carriers on the brush-border plasma membrane of the renal proximal tubule. On the basolateral membrane, Oct1/OCT1 (Slc22a1/SLC22A1) is only expressed in the kidney in rodents and is mainly expressed in the liver in humans. Oct1/OCT1 transports a variety of organic cations (OC^+), some weak bases, noncharged compounds, and some anions. Oct2/OCT2 and Oct3/OCT3 (SLC22A2/3) exhibit a similar, broad substrate specificity. All three carriers are electrogenic, Na^+-independent, and reversible with respect to direction. Driving force is solely based on the electrochemical gradient of the transported substrate.

On the luminal membrane, two SLC22A family carriers, OCTN1 (SLC22A4) and OCTN2 (SLC22A5), are present and catalyze efflux of organic cations into the tubular lumen. OCTN1 may function as either an OC^+ uniporter or a H^+/OC^+ exchanger, with the H^+ gradient generated by the Na^+/H^+ exchanger. OCTN2, in contrast, may function as either an OC^+ uniporter or a Na^+/carnitine cotransporter. Finally, the multidrug resistance P-glycoprotein (MDR1; P-gp; ABCB1) catalyzes efflux of OC^+ into the lumen and is driven by the hydrolysis of ATP.

In addition to tissue- and species-dependent differences in expression of these various transporters, there exist both sex-dependent differences in expression due to regulation

by estrogens and androgens[29–31] and individual differences based on genetic polymorphisms.[32] OA^- transport in rats is higher in males than in females,[30] and this difference in activity correlates with Oat1 and Oat3 protein expression. Wright and colleagues[29,31] made the interesting finding that while the androgen-stimulatory and estrogen-inhibitory patterns exist in rodents (i.e., rats and mice), no sex-dependent differences in transport activity or Oat expression were observed in rabbits or rabbit proximal tubules. These observations highlight two key points: First, not all animal models are appropriate to reflect sex-dependent differences in OA^- or OC^+ transport that might occur in human kidney; second, the sex-dependent differences indicate that males and females will exhibit pharmacokinetic differences in the handling of many drugs that are organic anions or cations, which could lead to a greater susceptibility to potential drug overdose toxicity due to greater accumulation of drug. Several plasma membrane transporters from human proximal tubular cells have been documented to exhibit genetic polymorphisms,[32] which also indicates that some individuals will exhibit pharmacokinetic differences in drug handling, leading to altered accumulation and differences in susceptibility to potential drug overdose toxicity.

Drug Metabolism

Another key component of the intoxication process for most chemicals involves metabolism, as most chemicals are not toxic in their native form but must be metabolized to exert their effects. Thus, for polar or hydrophilic chemicals, once they are transported into the renal cell by one of the various carriers discussed earlier, they can then be bioactivated by a large array of Phase I and/or Phase II enzymes to yield potentially reactive metabolites. The traditional view of renal function is that the kidneys act as filters to remove toxic waste products from the blood via glomerular filtration or tubular secretion. Whereas the focus of most drug metabolism studies has been the liver, it became apparent that the kidneys have a significant capacity to carry out extensive oxidation, reduction, hydrolysis, and conjugation reactions.[33,34] Enzyme systems similar to those present in the liver and other extrarenal tissues are involved in renal drug metabolism. An important difference between the kidneys and other tissues is that many of the drug metabolism enzyme systems, such as CYPs, glutathione *S*-transferases (GSTs), and others, are differentially distributed among the different nephron cell populations.[4,5,35] Thus, for example, whereas CYPs are exclusively found in the cortex (primarily the proximal tubules), prostaglandin synthetase, which catalyzes co-oxidation of several drugs and xenobiotics, is localized in the medulla.

Knowledge of the nephron cell type localization of drug metabolism enzymes and drug accumulation patterns are critical to understanding nephrotoxicity. A clinically important example of this is for acetaminophen.[34] Whereas the acute nephrotoxicity of acetaminophen is characterized by proximal tubular necrosis and is associated with metabolism by CYP, chronic nephrotoxicity of acetaminophen is characterized by papillary necrosis and interstitial fibrosis and is dependent on oxidation by prostaglandin synthetase in the inner medulla. This difference is largely due to the accumulation of acetaminophen in the cortex under acute exposure conditions and in the inner medulla under chronic exposure conditions. The differential distribution of acetaminophen thereby provides access to different drug metabolism enzymes.

Nonpolar or hydrophobic chemicals may also be bioactivated within the kidneys. Because of their chemical nature, these chemicals generally enter renal cells by passive diffusion rather than by specific membrane carrier proteins. Two related examples of this process are for the halogenated solvents trichloroethylene[36] and perchloroethylene.[37] Each of these related chemicals may be metabolized by either CYPs or GSTs, although trichloroethylene is a far better substrate than perchloroethylene for CYPs. Both chemicals, besides sharing metabolism by multiple enzymatic pathways, also share having multiple target organs. For the renal-specific, toxic effects of tri- and perchloroethylene, metabolism by the GSTs is the relevant pathway. Both chemicals are converted, through a series of metabolic steps, involving both intracellular and plasma membrane-bound enzymes, to the corresponding cysteine *S*-conjugates. These metabolites are then substrates for either the cysteine conjugate β-lyase or the flavin-containing monooxygenase, which convert them to chemically reactive species that are directly associated with alkylation of DNA and protein, oxidative stress, and various signal transduction mechanisms that lead to altered cellular function.[36–38]

In the study of drug metabolism, human tissue is often unavailable and studies are conducted in animal models, most typically using rodents. One then extrapolates the animal data to humans by using physiological parameters of the animal model and humans to account for differences. Further, if information about relevant genetic polymorphisms in drug-metabolizing enzymes or preexisting diseases or health conditions is not available, uncertainty factors are included in such human health risk assessments based on the animal model data. For the kidneys, significant species differences exist between rodents and humans such that drug metabolism data from the former cannot be readily extrapolated to the latter. Examination of renal activities of CYPs provides a clear illustration of this. For example, whereas rodent kidneys, particularly in the proximal tubular segments of the nephron, contain a large array of CYP enzymes that is very similar to that found in the liver,[33,34,39,40] human kidney expresses a much smaller number of CYP enzymes.[41–43] Additionally, the pattern of inducibility of both CYPs and Phase II enzymes such as GSTs or UDP-glucuronosyltransferases in the kidney differs between rodents and humans.[44,45] Enzyme induction is the process by which prior or concurrent exposure to certain chemicals causes the increased expression of specific enzymes. For example, whereas CYP1A1/2, that metabolizes polycyclic aromatic hydrocarbons is expressed at low constitutive levels in rodent kidney, CYP1A1 is highly inducible; in contrast, this CYP enzyme is both not detectable and poorly inducible in human kidney. Another example is CYP4A2/3

in rodent kidney, that is found in the proximal tubules and is inducible by fibrates; the human ortholog CYP4A11 is also expressed in renal proximal tubules but is inducible by ethanol and dexamethasone. The toxicological implication of this is similar to that of genetic polymorphisms in humans, namely that different capacities to metabolize drugs will produce characteristic responses.

Regulation of Renal Function

Glomerular filtration is a primary function of the kidneys and is typically measured by either direct or indirect methods to gauge kidney function. GFR is primarily regulated by three factors: (1) the balance of pressures acting across the capillary wall (glomerular capillary hydraulic pressure and Bowman space oncotic pressure tend to favor filtration whereas glomerular capillary oncotic pressure and Bowman's space hydraulic pressure tend to retard filtration); (2) the rate of plasma flow through the glomeruli; and (3) the permeability and total surface area of the filtering capillaries. Each of these factors is, in turn, regulated by several physiologic factors, including local and systemic hormones. GFR is also regulated by a process called tubuloglomerular feedback, which involves transmission of a stimulus at the macula densa to the arterioles of the same nephron, based on the composition of the tubular fluid flowing past the macula densa. Tubuloglomerular feedback causes glomerular vasoconstriction when Na^+ delivery to the macula densa increases and glomerular vasodilatation when Na^+ delivery is decreased. The extent of the feedback response is also modulated by extracellular fluid volume. Thus, because Na^+ ions are the major solute available for renal excretion and Na^+ ions are the major cationic component of the extracellular fluid, changes in renal Na^+ excretion provide a primary driving force for these regulatory responses.

Renal effector mechanisms that modulate body fluid volume homeostasis include GFR, several peritubular and luminal factors (e.g., peritubular capillary Starling forces, luminal composition, medullary interstitial composition, and transtubular ion gradients), humoral mechanisms (e.g., the renin–angiotensin–aldosterone system, vasopressin, prostaglandins, atrial peptides, and endothelium-derived factors), and renal nerves. The reader is referred to textbooks of renal physiology[2] for more detailed information on these regulatory mechanisms.

Besides control of ionic composition and extracellular fluid volume, the kidneys play a central role in the handling of acids and bases. pH is controlled largely by the HCO_3^-/pCO_2 ratio. While the lungs regulate pCO_2, the kidneys control HCO_3^- concentration. Considering a plasma HCO_3^- concentration of 24 mEq/L and the normally high GFR, the kidneys typically must reabsorb 5000 mEq HCO_3^-/day. This occurs by two processes, the carbonic anhydrase reaction, which is found in most cells but is highest on the brush-border membranes and cytoplasm of proximal tubular cells, and transport across the luminal and basolateral plasma membranes. More than 95% of filtered HCO_3^- is reabsorbed in the proximal tubules, with the remainder being reabsorbed in the loop of Henle. By the time the filtrate reaches the distal tubule or collecting duct, essentially all the HCO_3^- has been reabsorbed.

The pH in plasma and extracellular fluids is thus determined by the following equation:

$$pH = 6.1 + \log\left\{\frac{[HCO_3^-]}{0.03\,pCO_2}\right\}$$

where

$[HCO_3^-]$ is regulated by the kidneys

pCO_2 is determined by the lungs

At the physiological extracellular pH of 7.40, the ratio $[HCO_3^-]/0.03\ pCO_2 = 20$. Normal arterial plasma concentration of HCO_3^- is 24 mM and normal arterial pCO_2 is 40 mmHg. Any primary change in either parameter causes the kidneys and lungs to respond to reattain the normal ratio.

Acid–base balance is also maintained by secretion of ammonia derived from amino acid catabolism. This occurs primarily in the distal nephron, where ammonia is secreted into the lumen and protonated. The protonated form of ammonia, NH_4^+, is impermeable to the luminal membrane and becomes trapped in the lumen and is excreted. During metabolic acidosis, for example, renal ammonia production is increased by induction of amino acid deamination reactions, thereby increasing excretion of H^+ ions. A summary scheme of mechanisms by which kidneys maintain acid–base balance is shown in Figure 30.5. Factors that regulate or influence renal acidification and alkalinization are summarized in Table 30.3. These factors include renal hemodynamics, filtered load of ions, systemic acid–base conditions, and hormones, among others.

As discussed earlier, organic anion and cation transport is an important step in the regulation of the volume, electrolyte, and acid–base homeostatic functions mediated by the kidneys, which influences susceptibility to toxicants. Modulation of organic anion secretion, which in turn influences Na^+ and fluid balance, is under hormonal control, with the subsequent receptor-mediated responses being signaled by protein kinases or other second messengers.[18,27,46] Protein kinase C activation reduces OA^- uptake mediated by OAT1 and OAT3, reduces OA^- efflux by MRP2, and reduces OA^- transport by OATP1A1. There are several potential biochemical and molecular mechanisms involved in this downregulation. For OAT1, for example, regulation has been shown to occur by the modulation of: (1) gene transcription, (2) mRNA stability, (3) mRNA translation, (4) phosphorylation of the carrier protein, (5) internalization of membrane transporters, (6) recruitment of preformed transporters into the membrane, or (7) by allosteric control by regulatory proteins. Additionally, the function of OA^- transport may be indirectly modulated by regulation of $(Na^+ + K^+)$-stimulated ATPase activity.

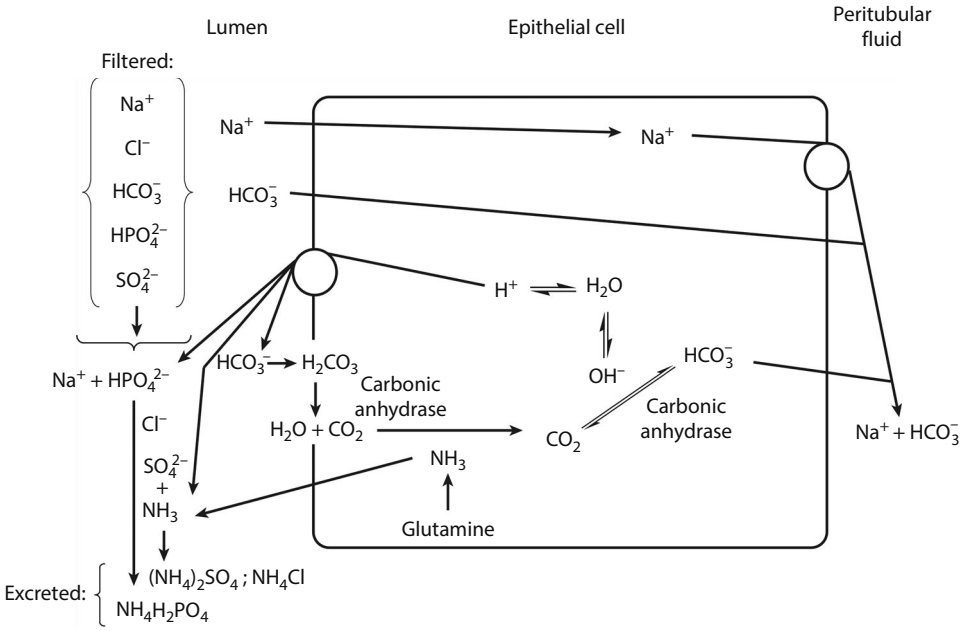

FIGURE 30.5 Summary scheme of how renal epithelium regulates acid–base balance.

TABLE 30.3
Factors Influencing or Regulating Renal Acid–Base Balance

Proximal Nephron	Distal Nephron
Filtered load: GFR, ultrafiltrate [HCO_3^-]	Aldosterone
Peritubular [HCO_3^-] and pH	Luminal buffering capacity
pCO_2	Systemic pH, pCO_2
Angiotensinaz II	Na^+ delivery and transport (cortical collecting tubule)
Extracellular volume	K^+ homeostasis
NaCl reabsorption	Anion transport
K^+ homeostasis	Parathyroid hormone, Ca^{2+} homeostasis
Parathyroid hormone, Ca^{2+} homeostasis	
Adrenergic nerve activity	

Besides protein kinase C, other protein kinases have been either shown or suggested to possibly regulate OA^- transport, including protein kinase A (inhibition or no effect), mitogen-activated protein kinase/extracellular regulated kinase (MEK; inhibition), tyrosine kinase (inhibition or no effect), phosphatidylinositol 3-kinase (PI3K; inhibition), and calcium/calmodulin-dependent protein kinase II (inhibition). Hormones or hormone-like compounds acting through these various kinases and other second messengers such as cAMP, either inhibit (e.g., phenylephrine, dopamine, parathyroid hormone, bradykinin, endothelin, estradiol) or stimulate (e.g., catecholamines, epidermal growth factor, thyroid hormone, testosterone, dexamethasone) OA^- transport and/or secretion. As discussed earlier, OA^- secretion is faster in males than in females, illustrating the influence of estrogen/androgen balance.

EXPERIMENTAL MODELS FOR ASSESSING RENAL FUNCTION AND TOXICITY

General Considerations for Choosing a Model

A large variety of experimental models can be used to assess renal function and toxicity. Each model has its advantages and limitations. The choice of experimental model is often dictated by the questions being asked and the extent of knowledge of the process under investigation. Factors to be taken into consideration include the potential involvement of extrarenal processes and hormones in the renal response, knowledge of the nephron cell type localization of any effects being studied, and the molecular mechanisms mediating the renal response. Some models are limited by an inability to distinguish nephron cell type localization or by the lack of functional expression of certain biochemical processes. The various experimental models that can be used to study renal physiology and toxicological responses are summarized in Table 30.4, and each is discussed in more detail in the following text. The reader is also referred to two reviews on this subject.[47,48]

To gain a full understanding of how a chemical may cause nephrotoxicity, more than one experimental model is usually necessary, both to enable different types of questions to be addressed and to validate certain approaches (e.g., in vivo model to validate an in vitro model). An example of a situation in which the use of only one approach and experimental model could lead to incorrect conclusions can be found in studies on the cytotoxicity of inorganic mercury salts.[49,50] In these studies, Lash and colleagues found that inorganic mercury was a more potent cytotoxicant in suspensions of freshly isolated rat renal distal tubular cells than in rat renal proximal tubular cells. In vivo, however, the proximal tubule

TABLE 30.4
Summary of Selected Experimental Models Used to Study Renal Physiology and Toxicity

Model System	Uses/Advantages	Limitations
Clinical measurements and whole animals	Assess integrated physiological responses and regulatory mechanisms Measure noninvasive markers of renal function Applicable to humans	Minimal control of experimental exposure conditions Limited ability to distinguish nephron cell type involved Limited ability to distinguish biochemical/molecular mechanisms
Isolated perfused kidney	Intact tissue structure Distinguish intrarenal from extrarenal effects	Short-term viability (≤2 h) Interanimal variability Incomplete definition of conditions Expensive
Micropuncture and microperfusion	Determine tubular site of action Quantitate transport processes in single nephrons	Sophisticated technology Subject to technical errors and misinterpretation of results
Renal slices	Intact tissue structure Ease of preparation Drug screening Measurement of drug metabolism	Short-term viability (≤2 h) Often limited access to luminal membrane Poor oxygenation Multiple nephron cell types present
Isolated perfused tubules	Determine tubular site of action Quantitate transport processes in specific nephron segments	Short-term viability (≤2 h) Sophisticated technology
Isolated tubules/tubular fragments	Intact tubular structure Precise definition of conditions Ease of preparation Several test samples with paired controls	Short-term viability (≤4 h) Often limited access to luminal membrane Some mixture of cell types
Freshly isolated renal cells	Bidirectional exposure Ease of preparation Several test samples with paired controls Cells from specific nephron segments Drug screening	Short-term viability (≤4 h) Loss of plasma membrane polarization
Primary renal cell cultures	Similar to in vivo kidney Longer-term viability Maintenance of polarity	Difficult to maintain Dedifferentiation Limited lifetime relative to cell lines
Renal cell culture lines	Precise definition of incubation conditions Immortalized Reproducible Easy to subculture Transfect with cDNAs	Dedifferentiation Often of ill-defined origin

is the primary nephron segment target for inorganic mercury and little cellular injury is seen in the distal nephron, except at very high doses.[51] The primary reason for the in vivo nephron-segment selectivity for mercury is that the proximal tubules are the first epithelial cells to be exposed to filtered or renal plasma mercury and possess sufficient membrane transporters and membrane and intracellular target molecules to bind and accumulate virtually all the mercury to which it is exposed. From the in vitro studies, therefore, one might erroneously conclude that it was the distal tubules and not the proximal tubules that were the primary target for mercury.

Whole Animal and Clinical Assessments: Markers of Renal Function and Toxicity in Blood and Urine

Studies of renal function in whole animals or in humans typically involve measurement of parameters in blood or urine.[52] These types of studies permit the collection of large amounts of data, but are often limited by the ability to define biochemical or molecular mechanisms of injury. In vivo studies are often necessary or are one necessary component to establish target organ specificity, involvement of extrarenal processes in nephrotoxicity, or when more invasive procedures are not feasible, such as with humans in the clinic. In experimental animals, however, in vivo studies have the advantage of allowing for the isolation of tissue for morphological analysis following chemical exposure or drug administration.

Urinalysis

Quantitative urine collection is used to more precisely determine treatment-related changes in renal excretory function and to define renal clearances (see next section). To enable quantitative and complete urine collection in animals, they are often housed in metabolism cages. A metabolism cage consists of an animal chamber mounted above an excrement collection system, which usually consists of a funnel and a

TABLE 30.5
Parameters Often Determined in a Typical Urinalysis

Parameter	Purpose or Use of Measurement
Urine osmolarity or specific gravity	Overall fluid homeostasis
Urinary pH	Acid–base balance
Urinary volume	Overall fluid homeostasis
Urinary electrolyte and solute concentrations: Na^+, K^+, Cl^-, urea	Extracellular fluid balance
Creatinine excretion	Indicator of glomerular filtration
Glucose excretion	Proximal tubule function
Aminoaciduria	Proximal tubule function
Proteinuria:	
Low-molecular-weight proteinuria (β_2-microglobulin, α_1-microglobin, retinol-binding protein), Kim-1	Proximal tubule function
Albuminuria	Glomerular damage
Enzymuria:	Specific enzymes derive from specific nephron segments
GSH *S*-transferase-alpha (GSTα/GSTA; proximal tubule)	
GSH *S*-transferase-pi (GSTπ/GSTP; distal tubule)	
N-Acetyl-β-glucosaminidase (NAG; papillary collecting duct, proximal tubule > distal tubule)	
γ-Glutamyltransferase (GGT; proximal tubule)	
Tamm-Horsfall glycoprotein (thick ascending limb)	
Lactate dehydrogenase (LDH; distal tubule > proximal tubule)	

urine/feces separator. Both urine and feces are collected for metabolism and metabolic balance studies. For assessment of renal function, urinalysis is performed. Major parameters determined in typical urinalysis are listed in Table 30.5.

The various parameters provide indications of the function of the kidneys in maintenance of fluid, pH, electrolyte, and solute balance. Additionally, the appearance of specific components in the urine at concentrations outside of the physiological range can provide information about the function of specific nephron segments. This application of urinalysis is particularly applicable in the clinical setting, where the search for biomarkers that can be early and sensitive indicators of exposure to toxic chemicals is a significant emphasis in research and was the subject of a National Research Council/National Academy of Sciences publication back in 1995.[1] Since that time, extensive work has been conducted to identify novel, more renal-specific, and sensitive biomarkers that can provide early indications of exposure to nephrotoxic chemicals prior to the onset of irreversible injury. Biomarkers can be divided into three categories: biomarkers of susceptibility, biomarkers of exposure, and biomarkers of effect. A marker of susceptibility is an indicator of an organism's inherent or acquired sensitivity to toxicity from exposure to a specific xenobiotic. Some general factors that serve as markers of susceptibility include age, gender, and environmental exposures. Genetic polymorphisms may also render an individual more susceptible to the nephrotoxic effects of a given chemical. In terms of a urinary biomarker, for example, one may administer a test chemical that is metabolized by a specific enzyme that is known to exhibit genetic polymorphisms and then quantify metabolite levels in urine. Because determinants of susceptibility are multifactorial, validation of a marker of susceptibility must be carefully performed.

A marker of exposure is a chemical or a metabolite of the chemical or a product of an interaction between the chemical and some target molecule. One typically measures markers of exposure as concentrations of chemicals or its metabolites in blood, urine, or other body fluid or tissue. Difficulties in the use of such markers include that many drugs and other chemicals have the same or similar metabolites, making identification of the causative agent uncertain. Exposures to large doses of toxic chemicals may alter their rate of metabolism and/or excretion, thereby making a correlation between measured levels of the chemical or metabolite and the actual exposure difficult to obtain. Moreover, without taking susceptibility into account, a marker of exposure in one individual may have markedly different functional implications than that in another individual.

As suggested by its name, a marker of effect should indicate the influence of a chemical exposure on some biological process. Markers of adverse effect can be indicators of altered biochemical processes in a target organ or cellular signals of tissue toxicity. The effects that occur may only be indirect in that they may only indicate a potential for toxicity but by themselves cannot be construed to directly produce toxicity. Examples of this type of marker are protein or DNA adducts. As discussed earlier in the section on whole animal and clinical assessments, parameters such as blood urea nitrogen (BUN) and serum creatinine (SCr) and urinary proteinuria can be indicators of renal injury. Their disadvantages, however, include a lack of sensitivity and an inability to indicate information about site or mechanism of action. As noted earlier, BUN and SCr do not become significantly elevated until renal toxicity occurs to a significant extent. Hence, an ideal biomarker of effect would be one that is highly sensitive, is measurable prior to a significant degree of renal toxicity has occurred, persists throughout the time course of the alterations in renal function, is specific to the kidneys, correlates in amount with the degree of injury, and is specific to a nephron cell type or specifically indicates a mechanism of action. Ideal markers should also be stable in urine over a long enough period of time and at a wide enough range of urinary pH values, and if they are enzymes, they should not be readily inactivated in the urine. Some of the more sensitive and specific markers are shown in the bottom row of Table 30.5; examples include the urinary secretion of enzymes that are derived from various nephron segments.

The ultimate goal of using biomarkers of effect for nephrotoxicity is to have an easily measured, sensitive, and stable indicator of renal injury at its very early stages so that measures to counter the nephrotoxicity can be instituted prior to a significant decrease in renal function or to the advent of irreversible renal cell death.

The traditional markers of renal function, BUN and SCr, although considered the gold standards for assessment of kidney injury, are not particularly sensitive.[53–56] Rather, a number of other urinary biomarkers have recently been validated in both humans and experimental animals with regard to both sensitivity and specificity, including kidney injury molecule-1 (Kim-1), cystatin C, clusterin, and lipocalin-2.[55,57]

Clearance Methods

Methods to assess renal clearance are fundamental to whole animal studies and have wide clinical applicability as well. These procedures involve the measurement of blood or plasma (P_x in mg/mL) and urine (U_x in mg/mL) concentrations of a substance. Urine flow rate (V in mL/min) is also taken into account. Depending on the test substance used, either glomerular or tubular function can be assessed. Combining these parameters, gives the classical clearance equation:

$$C_x = \frac{U_x V}{P_x}$$

The clearance, C, represents the quantity of blood or plasma cleared of the substance per unit time and has units of volume per unit time (usually mL/t).

The most common substances monitored for determination of renal clearance are inulin or creatinine. Inulin is the preferred indicator of GFR, as it is a fructose polysaccharide (M_r = 5200 Da) that is freely filtered and then is neither reabsorbed nor secreted. Hence, all of the inulin that appears in the urine arises from plasma via glomerular filtration. Inulin is considered the *gold standard* of exogenously administered markers for GFR. Its scarcity and high cost, however, have made its use less favored in the clinical setting. Inulin is readily measured in plasma or urine by a colorimetric assay, although glucose is also measured; separate measurement of glucose is needed for correction to obtain the inulin concentration.

Creatinine is also used to monitor GFR, and has the advantage of not requiring infusion of an exogenous substance. This makes creatinine useful for monitoring of GFR over a protracted period of time in the same individual. Because creatinine undergoes some reabsorption, however, measurement of its clearance tends to underestimate that of inulin by 10% or more, depending on species. Creatinine (M_r = 113) is a metabolic product of creatine and phosphocreatine, which are both found almost exclusively in muscle. Creatinine production is proportional to muscle mass and varies little from day to day, although it can be affected by diet. Thus, because of its convenience and low cost, creatinine is the most widely used indirect measure of GFR. Correct interpretation of data in a clinical setting, however, can be problematic.

One can also measure renal plasma flow if a test substance is used that undergoes both filtration and active tubular secretion. *p*-Aminohippurate (PAH) is often used for that purpose because it is freely filtered by glomeruli and undergoes active secretion by several OATs. PAH extraction by the kidneys can vary from about 70% to 90%, depending on species, due to heterogeneity of the distribution of OATs and blood flow, thereby causing incomplete extraction. Renal blood flow is converted from RPF by dividing RPF by the plasma fraction of whole blood, as estimated from the hematocrit (Hct), according to:

$$RBF = \frac{RPF}{(1 - Hct)}$$

Clearance ratio relative to a marker substance (usually inulin) can be calculated and used to determine whether a test substance is reabsorbed or secreted. Thus, if a substance has a C value less than that of inulin, this indicates reabsorption. Glucose is a good example of a highly reabsorbed substance whose C value is always less than that of inulin. C_{PAH}, in contrast, is usually greater than C_{inulin}, indicating secretion.

Another method for measurement of GFR is to determine plasma clearance of an intravenous bolus injection of an indicator radionuclide-labeled marker. Renal clearance is measured as the plasma clearance, or the amount of indicator injected divided by the integrated area under the plasma concentration curve; models to estimate plasma clearance assume that the volume of distribution and renal excretion are constant over time. Two indicators that have been used and validated are ^{125}I-iothalamate and ^{51}Cr-labeled ethylenediaminetetraacetic acid (EDTA). The basic procedure involves injection of radiolabeled marker into arterial blood and sampling of venous blood. After correcting for noninstantaneous equilibration between arterial and venous circulations, plasma levels are measured and clearance is calculated from the slope and intercept of a line plotted on a logarithmic scale, using the following formula:

$$C = V_o \frac{(\ln(2))}{t_{1/2}}$$

where

V_o is the volume of distribution

$t_{1/2}$ is the half-time for decay of marker levels in plasma

An additional parameter to indicate GFR that is popularly used in whole animal toxicity screening studies is measurement of BUN. As filtration slows, BUN rises and is generally paralleled by levels of SCr. Thus, in the absence of changes in protein intake or metabolism, BUN or SCr are useful indicators of GFR. An important point to realize is that although BUN may be the most commonly used measurement for

glomerular filtration, substantial loss of renal function (on the order of at least 50%) must occur before BUN rises above normal levels. BUN, like SCr, as discussed earlier, is thus not a very sensitive indicator of renal injury and thus does not have much preventive value.

Experimental Models

Isolated Perfused Kidney

As compared with in vivo studies in whole animals, the isolated perfused kidney shares the advantage of being a model that maintains intact renal structure. It also possesses the advantage of enabling separation of extrarenal from intrarenal factors that may be part of the mechanism of action. The methods used in animal preparation and kidney isolation and perfusion have been described in several reviews[58,59] and will only be highlighted briefly here.

Being at the highest level of structural organization for in vitro kidney models, it is not surprising that the isolated perfused kidney preparation has been in use for nearly 150 years. The basic isolated perfused kidney preparation consists of the whole kidney isolated from the systemic vasculature and usually removed from the animal, and perfused through the renal artery with a synthetic plasma- or blood-like medium. Oxygenated perfusate is delivered into the renal vasculature with an adjustable pump so that a constant, mean arterial pressure can be achieved and maintained during the course of experiments. Urine is collected through a cannula placed in the ureter. Several variations of the basic method have been implemented, depending on the purpose of the experiment. For example, various in-line monitoring devices have been included to measure perfusate temperature, pH, and oxygen content. The perfusate leaving the renal vein can either be recirculated or collected in a reservoir to achieve single-pass perfusion. The single-pass method has the advantage of ensuring a constant arterial perfusate composition, as it is not modified by renal metabolism or excretion, but has the disadvantage of being expensive because it consumes large amounts of perfusate, particularly if the perfusate contains physiologic colloids such as albumin. Although isolated perfused kidney preparations have been described for several species, including the dog, rabbit, guinea pig, pig, and toad, the most common species used in recent years has been the rat.

As summarized in Table 30.4, advantages of the isolated perfused kidney preparation are that it retains kidney structure, so is particularly well suited for studies requiring intact renal morphology. It is the only in vitro preparation in which glomerular filtration and tubular functions are both retained in manners similar to the in vivo kidney. Control over many of the aspects of the perfusate composition is possible, including concentrations of dissolved and gaseous metabolites and electrolytes, colloids, oxygen carriers, drugs and their metabolites, and other chemicals added to modify function. This type of control enables establishment of reproducible exposures to chemicals or drugs under investigation. Also, because the isolated tissue is being used, higher concentrations of test chemicals are possible to achieve than could be used or tolerated in vivo.

Some of the limitations with the isolated perfused kidney model are those that are inherent with any in vitro model. For example, once the tissue is removed from the animal, function (e.g., GFR and tubular function) decline progressively over the course of experimentation. Hence, the model can only be useful for a limited period of time, which is generally on the order of 2 h. Because of this time limitation, studies are naturally restricted to acute effects as responses that occur over longer periods of time, such as changes in gene expression or enzyme induction, require longer exposure and/or study times. As explained by Diamond,[59] the isolated perfused kidney exhibits several functional abnormalities that must be considered when evaluating results. These abnormalities include relatively high perfusion rates and low filtration fractions as compared with the in vivo kidney, loss of urinary concentrating ability, and glomerular proteinuria. Various structural abnormalities have also been observed in tubules of isolated perfused kidneys, including cellular necrosis of the medullary thick ascending limb and the S3 segments of the proximal tubule. The latter is particularly significant for drug metabolism and nephrotoxicity studies because the S3 segment of the proximal tubule is the site of a large proportion of the metabolism and toxic effects of exogenous compounds. Finally, other limitations exist in the ability of studies with the isolated perfused kidney to discriminate mechanisms of action and localization of processes in specific nephron cell types.

Micropuncture and Microperfusion Techniques

In vivo microperfusion and micropuncture are two techniques that are used to study the function of individual nephron segments in the intact kidney.[60] For example, these methods can be used to directly determine the tubular handling of drugs and nephrotoxicants, characterize the function of specific carrier proteins, or determine the effect of toxicant administration on tubular function. A particular application of micropuncture is to determine the in vivo concentration and profile of luminal fluid along the nephron. Microperfusion, on the other hand, is a valuable approach because a drug or other chemical of interest can be applied directly to the tubule in the luminal perfusate and the effect on tubular function determined.

Although micropuncture and microperfusion are performed in several mammalian species, the rat is the most common experimental animal that is used. Moreover, specific strains of rats are often used in preference to others for particular purposes; for example, the Munich–Wistar rat is often used in studies of glomerular function because glomeruli are visible and accessible at the surface of the kidneys. Other strains, such as the spontaneously hypertensive or Brattleboro rat, are used to study nephron function under specific pathophysiologic conditions. Rats of 200–250 g body weight are usually used for micropuncture of superficial cortical nephron segments whereas young rats weighing less

than 150 g are used for micropuncture of collecting ducts, loops of Henle, or vasa recta because they are more readily accessible at this stage of development. Micropuncture or microperfusion is most often performed on the left kidney because of its accessibility and longer vascular pedicle as compared with the right kidney.

Once the kidney is isolated and placed in a holder, superficial nephron segments can be visualized with a stereomicroscope. The majority of the tubules visible on the surface are proximal convoluted (S1) tubules. As noted earlier, superficial glomeruli are visible in kidneys of strains such as the Munich–Wistar rat. Peritubular capillaries are visible as thin red lines between and around the tubules. A few distal tubular segments are also visible on the surface of the rat kidney and can be distinguished from proximal tubules by their thinner epithelial walls and smaller lumina. Typically, approximately 60% of the length of proximal tubules from dog or rat is accessible to micropuncture. Besides visual identification, proximal and distal tubules can also be distinguished by use of dyes such as lissamine green. After intravenous infusion of a small bolus of the dye, a distinct time course for appearance in the tubules is used to enable the identification of specific tubular segments. Because of natriuretic effects and an increase in single nephron GFR caused by lissamine green, micropuncture or microperfusion experiments should begin only after the dye has completely disappeared from the kidney and the effects of the dye on renal function have reverted to normal, which typically takes approximately 30 min.

Micropuncture has been instrumental in demonstrating tubular reabsorption and secretion of a large variety of endogenous and exogenous chemicals. It has the advantage that the tubule is studied in the intact, functioning kidney, and can be studied as a physiologically stable preparation for several hours. One is limited, however, to using certain species. Because the method requires surgery, anesthesia is required, which necessitates consideration of potential effects of anesthesia on tubule function. This concern can be taken into account by the use of paired control and experimental conditions in the same anesthetized animal. Another concern is that because of internephron heterogeneity, sampling from a single nephron may not be representative of all nephrons. Microperfusion is useful in determining and discriminating between luminal and peritubular actions of a drug or nephrotoxicant in the in vivo kidney, with the chemical being added specifically to either the tubular perfusion fluid or the systemic circulation to study luminal or peritubular action, respectively. Another advantage of microperfusion is the ability to distinguish net reabsorption from secretion, although other models can accomplish that as well (see following text). Both micropuncture and microperfusion involve surgical procedures and careful placement of micropipets. Thus, significant skill is required to conduct such microprocedures.

Renal Slices

Renal slices have been a useful tool for many years to study renal physiology and biochemistry. Organic anion transport, for example, has been extensively studied with this technique. Most studies using renal slices have used slices from the cortex, in part because of the predominance of the proximal tubules in renal transport and toxic responses, and because of its ready accessibility. The simplest method to prepare renal slices is freehand, using a razor blade and a glass microscope slide as a slicing guide.[61] Slices need to be uniform in thickness and be taken only from the section of kidney desired. To address the issue of uniformity of slice thickness and the attainment of slices that are as thin as possible, several automated tissue slicers have been developed. The first slicer developed to prepare the so-called *precision-cut tissue slices* was the Krumdieck slicer.[62] The slicer is filled with an oxygenated, physiological buffer solution to preserve function and operates on the principle that a core of tissue is fed into an oscillating blade that is drawn across the core to make a slice. The slice is then swept away into a collection chamber. Slice thickness is adjustable, with optimum thickness considered to be around 250 μm.[63] The diameter of the core is preset and typically ranges from 4 to 8 mm. The Brendel–Vitron slicer was developed more recently[64] and differs from the Krumdieck slicer in having a simpler design that is possibly more rugged and *user friendly*.[63]

Once prepared, slices are typically incubated in a Dubnoff metabolic shaking bath, that permits control over temperature, shaking rate, and gas environment. Many assays are carried out in a bicarbonate-based buffer system, such as Krebs–Ringer, thus necessitating an atmosphere containing CO_2 (typically 95% O_2, 5% CO_2). There is some concern over oxygenation of the tissue slice and nephron heterogeneity. Improvement in procedures, however, has made poor tissue slice oxygenation less of a problem. Incubations are typically done as for short-term cell cultures, using a serum free, 1:1 mixture of Dulbecco's Modified Eagle's Medium (DMEM) and Ham's F-12. Medium is gassed with 95% O_2, 5% CO_2, and pH is adjusted to 7.4. Other media, such as Waymouth's culture medium or a Krebs-HEPES buffer, have also been used.

A variety of assays of renal function and toxicity have been used with renal slices. In most cases, parameters are normalized to slice weight rather than other parameters, such as cell number or protein, as this is the most convenient and appropriate factor to use. If the tissue slice becomes edematous or dehydrated, then tissue weight will be an inappropriate normalizing factor. Inasmuch as loss of protein may occur in nephrotoxicity, slice DNA content is recommended to use to normalize assays.[63] Tissue slice K^+ content is a good indicator of cell viability, as it reflects (Na^++K^+)-stimulated ATPase activity and membrane integrity. Losses in K^+ content are indicators of toxicity. As with other in vitro models, intracellular enzyme leakage (e.g., lactic dehydrogenase) is used as an indicator of membrane disruption and necrosis. Both cellular ATP content and respiration (O_2 consumption) are useful to assess energetic status of the tissue slice. Protein synthesis activity, as measured by incorporation of ^{3}H–L-leucine, is also used to assess functional competence. Because active transport of organic anions and cations is a

primary, energy-dependent function of proximal tubular cells, measurements of medium:slice ratios of transported substrates are often used as a measure of tubular viability.

Advantages of the renal slice technique include its versatility, correspondence with in vivo tissue, the general ease of preparation, its relative low cost, and the ease with which incubation conditions can be manipulated. Limitations to the use of renal slices exist, however, including the possibility of collapsed lumens, poor oxygenation, particularly if slices are too thick, the presence of some damaged tubules, which is more problematic if slices are too thin, and the presence of multiple nephron cell types, thus making it difficult to ascribe observed effects to specific cell populations.

Isolated Perfused Tubules

The techniques of isolating and perfusing individual nephron segments in vitro have been widely used in transport physiology studies since their development in the 1960s. Although nephron segments can be and have been obtained from many species, tubules are the easiest to dissect from the rabbit kidney without the use of digestive enzymes. Detailed procedures for the harvesting of renal tissue, dissection and identification of nephron segments, and the design of perfusion and collection pipettes are described by Zalups and Barfuss.[65] S1, S2, and S3 segments of the proximal tubule, cortical collecting ducts, and medullary and cortical ascending thick limbs of Henle's loop have all been isolated from rabbit kidney, and studied for their transport function and viability after exposure to various xenobiotics.

In most studies, perfusing and bathing solutions are simple electrolyte solutions supplemented with D-glucose and glutamine or glutamate, with pH adjusted to 7.4. When it is desirable to more closely mimic the in vivo state, isolated segments of the nephron can be perfused with an ultrafiltrate of rabbit plasma, made by passing the plasma through a 50 kDa cutoff filter. Thus, a great deal of control over the fluid environment can be achieved with this method. Another application of this model is to determine the transepithelial transport of solutes, including nephrotoxicants. Thus, depending on whether substrate is placed in the perfusate or bathing medium, lumen-to-bath or bath-to-lumen fluxes can be determined. Limitations in the application of this model for renal toxicology include the requirement for sophisticated and expensive equipment, the difficulty in preparing the nephron segments, the rather poor ability to isolate and perfuse nephron segments from species other than the rabbit, and a relatively limited life span for the model once nephron segments are isolated.

Isolated Tubular Fragments and Cells: Freshly Isolated and Primary Culture

Tubular segments derived from specific nephron cell populations can be isolated by microdissection. These preparations maintain their normal tubular architecture, function, and polarity. Because the isolation method is rather tedious and yield of tubules is typically low, other procedures, most notably treatment with collagenase, were developed. For example, perfusion of renal cortical tissue with buffers containing chelators such as EDTA and collagenase have been used to prepare tubule fragments from rats and rabbit. One problem was that these preparations comprised tubules from multiple nephron segments. Hence, procedures, such as density-gradient centrifugation in Percoll or Ficoll or electrophoresis were then applied to obtain enriched preparations of tubules from either proximal tubule or distal tubule.[66–72] Although less commonly used than proximal tubular suspensions as an experimental model, tubule fragments from the medullary thick ascending limb have also been used.[73–77]

In general, procedures for the isolation of proximal tubules involve either enzymatic digestion and separation or mechanical separation.[78] In the enzymatic methods, cortical tissue can be digested either by perfusion with a collagenase-containing, balanced salt buffer or medium or can be dissected, minced, and incubated with the collagenase-containing buffer. Either of these methods provides a high yield of highly enriched proximal tubules that are largely S1- and S2-derived. Tubules can then be used for either short-term studies of metabolism, transport, and toxicity, or can serve as seed material for primary culture.[79–82] Variations of culture and incubation conditions to increase oxygenation have also been used to improve the ability of rabbit proximal tubule primary cultures to maintain differentiated function.[83] Contamination with glomeruli can be minimized by including iron oxide in the initial perfusate, which collects in glomeruli and can be removed with magnets.

Individual epithelial cells, rather than tubule fragments, can also be isolated and used as either fresh suspensions for acute studies or as seed material for primary culture.[47] Isolation of single cells generally requires somewhat more vigorous enzymatic treatment than for nephron segments. As with methods to isolate tubules, once isolated, suspensions of cells require a secondary enrichment step to obtain highly enriched cells derived from a specific nephron segment. Hence, procedures such as Percoll density-gradient centrifugation[83,84] can be applied to enhance purity of a mixed cortical cell population (see following text).

The decision to use either tubule segments or single cells as a model depends on several factors. Firstly, the ease with which either tubule fragments or single cells can be prepared varies with species, so that the choice of model is partly dictated by the species of interest. As noted earlier, tubule fragments are readily isolated from rabbit kidneys. Although tubule fragments can also be isolated from rat, it is easiest to obtain single cells.[85] Isolation procedures have also been adapted to prepare suspensions of proximal tubular cells from human kidneys.[41,42,86] This is a significant advance because the use of cells derived from human kidneys eliminates the uncertainty involved in extrapolation of data from experimental animals to humans for risk assessment purposes. A second consideration is experimental design. One major difference between tubule fragments and isolated cells is that epithelial polarity is lost in the latter. Thus, all membrane surfaces have equal access to substrates in the

suspending medium. Additionally, collapse of the lumen in tubule fragments may occur, thus limiting access of substrate to the brush-border membrane.

Although single cells in suspension can be isolated from nephron cell types derived from multiple regions of the kidney, most studies have been performed with cells derived from the renal cortex and outer stripe of the outer medulla.[47,48,84,85] The basic procedure involves perfusion of the kidneys through the aorta below the renal arteries, first with a Ca^{2+}-free Hank's buffer containing EGTA and then with a Hank's buffer containing Ca^{2+} added back and collagenase. Because the inner medulla is poorly perfused, it can be removed intact with forceps, thus yielding a preparation that is predominantly of proximal tubular origin but also containing other cell types from the cortex and outer stripe of the outer medulla. Glomeruli, tubular fragments, and multicellular aggregates are removed by filtration through polypropylene mesh. The suspension of isolated renal cortical cells can then serve as a starting material for additional purification or enrichment steps to prepare multiple epithelial cell populations.[47,48,84]

Advantages of the single cell preparation include the high degree of homogeneity of the biological material, the equal access of all membrane surfaces to chemicals in the suspending medium (if membrane polarity is not important for the process being studied), that there are adequate amounts of material from a single animal to permit paired control and treated samples, and control of incubation conditions (e.g., temperature, pH, osmolarity, buffer and medium composition), thereby eliminating some of the uncertainty for mechanistic studies. Limitations of the procedure include potential damage to the cells during the isolation procedure, the limited life span of the cell suspensions (≤4 h), and the loss of membrane polarity (if membrane polarity is important for the process being studied). Although potential damage can occur just by the collagenase perfusion step, any damage is typically modest and the versatility of the procedure allows paired controls and treated samples to be used for incubation, thereby helping to ensure that observed responses are due to treatments and not to cell isolation artifacts. Moreover, cell viability is routinely checked upon completion of the cell isolation by both trypan blue exclusion and LDH leakage assays. In the first case, cells are mixed with trypan blue in saline and are viewed under a light microscope on a hemacytometer. Only those cells whose plasma membranes are damaged will take up the dye and stain blue; trypan blue is thus referred to as a vital dye. Cells are thus counted for the proportion of staining, which is typically 5% to at most 15% after isolation. Similarly, for the LDH leakage assay, cells are mixed with pyruvate and NADH; oxidation of NADH is measured by the decrease in absorbance at 340 nm and only those cells whose plasma membranes are damaged will either leak out LDH or allow NADH to enter and be oxidized. After recording the decrease in A_{340} for 2 min, the detergent Triton X-100 is added to fully solubilize the membranes, thereby providing complete access of the cellular LDH to the added NADH; A_{340} is recorded for another 2 min. Comparison of the slopes representing the rate of NADH oxidation (decrease in A_{340}) gives a measure of cellular viability. Typically, the slope of the two rates for control cells is between 0.05 and 0.15, indicating the presence of a high proportion of cells with intact cellular membranes and thus high viability. If measurements of trypan blue exclusion or LDH leakage fall outside of these typical ranges, the cells are not used for further studies.

As with the tubule fragments, specific nephron cell types in the cortical cell preparation can be enriched by a variety of methods. Although microdissection methods provide material of extremely high purity, the procedure is not particularly useful for most typical biochemical or toxicological studies, particularly those with cells from the rat or mouse, because of low yield of material. Additionally, such methods are fairly tedious and time consuming. The limited time frame for which the isolated cells are viable necessitates that they be used in studies as soon as possible after their isolation. Electrophoretic separation methods also suffer from the same limitations. Hence, any procedure used to obtain enriched populations of renal epithelial cells must satisfy four primary criteria[47]: (1) the procedure must be relatively rapid, (2) any material used in the separation process must be biologically inert, (3) final yield must be high enough to enable performance of a sufficient number of paired control and test incubations, and (4) purity must be high enough to enable unambiguous conclusions regarding the nephron cell type of origin.

Differences in cell density are one common means to separate different cell populations from one another. Although methods relying on cell density differences provide enrichment rather than absolute purification (because cell density is generally not a discrete property, but exhibits a range of values for a given cell population), many of the procedures readily satisfy the four criteria noted earlier. Procedures for application of density-gradient centrifugation with Percoll to separate proximal tubular and distal tubular cells from cortical cell suspensions from the rat are described in detail elsewhere.[47,84] Percoll is a liquid consisting of microscopic, carbohydrate-coated beads that spontaneously forms a continuous density gradient when placed in a centrifugal field. Colored, density marker beads are commercially available to calibrate the density gradients. Once distinct cell populations are obtained, marker enzymes are used to confirm identity and to assess the degree of enrichment. Markers include parathyroid hormone-sensitive adenylate cyclase, alkaline phosphatase, GGT, and glucose-6-phosphatase for proximal tubules and hexokinase and renal kallikrein for distal tubules.

A limitation with the use of suspensions of either tubule fragments or single cells is their short life span. To accommodate experiments that study processes that occur on longer time frames than the few hours that are possible with the freshly isolated tubules or cells and yet retain the use of a model that comprises material derived directly from the in vivo biological material, many investigators have established primary cultures of renal epithelial cells. The proximal tubule from rat, rabbit, or mouse has been the most common biological source for primary cell culture,[47,79–83,87–96] although investigators have also developed culture methods for thick ascending limb and distal tubular cells.[76,92,97] Although tissue from rodents is more

TABLE 30.6
Composition of Medium Used in Primary Culture of Proximal Tubular Cells from Rat or Human Kidney

Basal medium: DMEM/Ham's F12 (1:1)
HEPES (15 mM, pH 7.4)
$NaHCO_3$ (20 mM)
Antibiotics (only through Day 3): penicillin192 IU/mL), streptomycin sulfate (200 μg/mL),
Amphotericin B (2.5 μg/mL)
Bovine insulin (5 μg/mL)
Human transferrin (5 μg/mL)
Sodium selenite (30 nM)
Hydrocortisone (100 ng/mL)
Epidermal growth factor (100 ng/mL)
3,3′,5-Triiodo-DL-thyronine (T_3) (7.5 pg/mL)

readily obtained, investigators have applied essentially identical methods to grow primary cultures of human proximal tubular cells.[42,86,98–102] Regardless of their species of origin, primary cultures of proximal tubular cells are generally grown in a serum-free, hormonally defined medium, one version of which is shown in Table 30.6. Serum is omitted because it encourages or enables growth of fibroblasts, which comprise a very minor contaminant of the cell preparation but can readily overtake the culture and prevent growth of the proximal tubular epithelial cells. The disadvantage is that the cells do grow more slowly in the absence of serum. Importantly, the cell culture maintains their differentiated properties in the serum-free, hormonally defined medium.

A photomicrograph showing human proximal tubular cells grown in monolayer culture and exposed to either control conditions or to the nephrotoxicant *S*-(1,2-dichlorovinyl)-L-cysteine (DCVC) illustrates the morphology of primary cell cultures under both physiological and toxicological conditions (Figure 30.6). Control cells exhibit normal epithelial morphology, with a prominent nucleus and a generally cuboidal shape with close cell-to-cell contacts. In contrast, cells incubated with increasing concentrations of DCVC exhibit an increased number of intracellular vesicles and many cells with elongated shape, indicating cellular injury. At the highest dose of DCVC used (i.e., 500 μM), abnormal cellular shape is observed with numerous intracellular vesicles and vacuoles. We have shown that human proximal tubular cells incubated with a relatively low dose of DCVC (≤100 μM) for

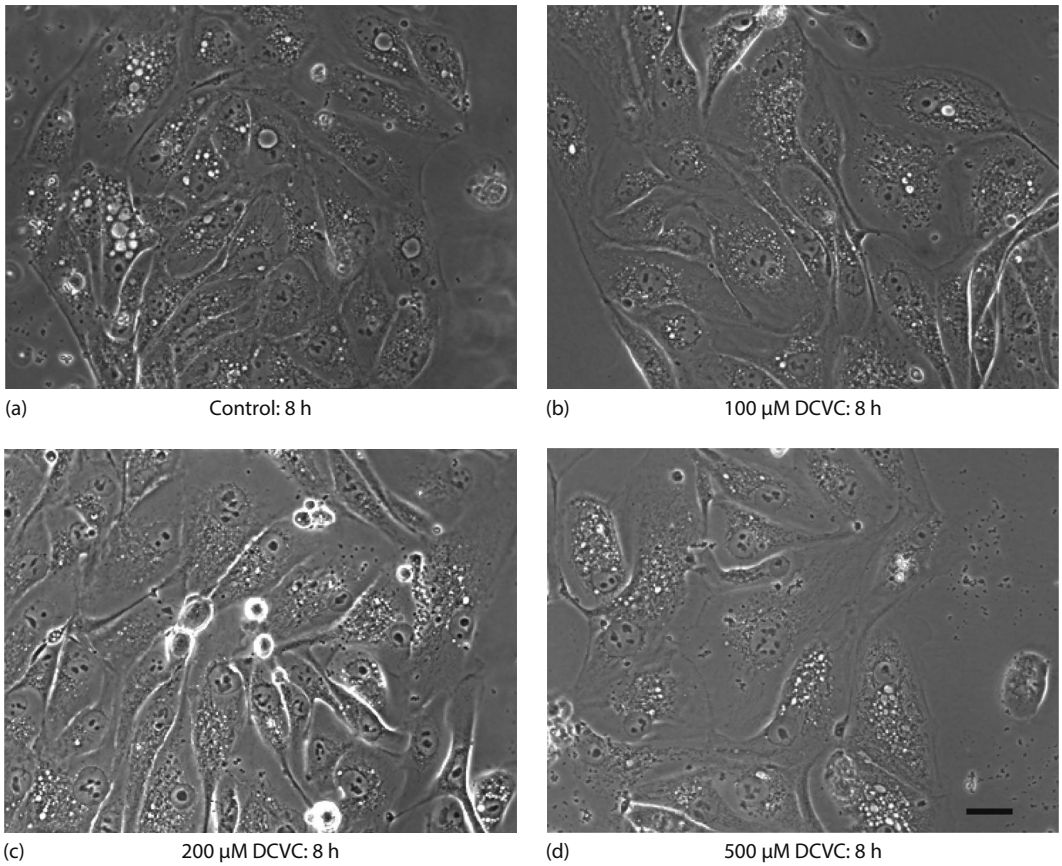

FIGURE 30.6 Photomicrographs of confluent primary cultures of hPT cells treated for 8 h with DCVC. hPT cells were cultured for 5 days in supplemented, serum-free, hormonally defined DMEM:F12 medium on 35 mm polystyrene dishes coated with vitrogen until they were confluent. Cells were then incubated for the indicated times up to 48 h (results for 8 h are shown) with either medium (= Control) (a) or 100 μM (b), 200 μM (c), or 500 μM DCVC (d). At the indicated times, photomicrographs were taken at 100× magnification on a Carl–Zeiss Confocal Laser Microscope. Bar = 5 μm.

a relatively short time period (≤8 h) undergo both apoptosis and enhanced proliferation whereas cells incubated with a higher dose of DCVC (≥100 μM) for a longer period of time (≥24 h) exhibit primarily necrosis.[103,104]

The use of primary cell cultures has many advantages. Inasmuch as cells grow in monolayers, plasma membrane polarity is maintained. Depending on the growth surface used, processes such as transepithelial transport can be studied. Many studies use renal cells grown on collagen-coated, plastic tissue culture flasks or dishes; cells will grow with their luminal membrane face up. Thus, although membrane polarity is maintained, components in media only have direct access to the luminal membrane. This problem has been solved by the use of semipermeable filters that are raised over the culture dish surface, thereby creating both luminal and basolateral compartments to enable media components to come in contact with both membrane surfaces. The only disadvantage of using such filters is that they are usually somewhat opaque, thus making it impossible to view the cells on the filter surface on a microscope. Another advantage is that the primary cultures are relatively simple to prepare. Because these cells remain viable in primary culture for up to 7 days (or longer if passaged), there are a large variety of assays and tests that can be done with them, including all the assays one can perform with the freshly isolated tubules or cells (e.g., acute cellular necrosis as determined by trypan blue exclusion or LDH leakage, metabolism, transport, cellular oxygen consumption, levels of key intracellular metabolites, e.g., ATP, glutathione), as well as assessments of apoptosis, repair and proliferation, gene expression, DNA damage, etc. Hence, the primary cell culture model is extremely versatile and, if cultured properly, should reflect very well the normal, in vivo biochemistry and physiology of the proximal tubule.[32,42,43]

If not passaged, primary cultures remain viable only until they become confluent, which is typically within 7 days. Hence, if longer-term studies are required, a different experimental model must be chosen, as will be discussed in the following section. In some cases, primary cell cultures can be passaged, thereby extending their usable lifetime to as much as several weeks.[99] In spite of the use of serum-free, hormonally defined media, such passaged cells often exhibit altered phenotypes with respect to drug metabolism, cellular energetics, and membrane transport properties.[42] This loss of differentiated function makes them a questionable model for use in assessing cell type–specific toxicity, but they may be useful for study of specific processes whose expression and/or function are retained.

Renal Cell Culture Lines

In contrast with primary cell cultures, cell lines are cells that have been transferred at least once to another culture surface (i.e., subcultured) and, more often, have been transferred multiple times. In some instances, cellular genetics have been altered so that the cells become immortalized and can thus be passaged indefinitely. Such immortalized cells are referred to as continuous cell lines. The process by which cells can be immortalized can be spontaneous or can be induced by various agents (e.g., mutagenic chemicals, radiation, viruses). Some continuous renal cell lines that have been used for studying renal cell function and toxicology are listed in Table 30.7.

TABLE 30.7
Selected Immortalized, Continuous Renal Cell Lines

Cell Line	Species	Presumed Cell Type of Origin
SGE_1	Wistar rat	Glomerulus
NRK-52E	Norway rat	Proximal tubule
$LLC\text{-}PK_1$	Hampshire pig	Proximal tubule
OK	American opossum	Proximal tubule
MCT	Mouse	Proximal tubule
JTC-12	Cynomolgus monkey	Proximal tubule
HK-2	Human	Proximal tubule
GRB-MAL	Rabbit	Medullary thick ascending limb
M-m TAL-lc	Mouse	Medullary thick ascending limb
MDCK	Cocker spaniel	Distal tubule and collecting duct
A6	African clawed toad	Distal tubule and collecting duct

The development of immortalized cell lines of epithelial cells generally requires transfection of short-term cultures with plasmid or viral DNA containing an immortalizing gene (e.g., an oncogene). Taub[105] has reviewed in detail procedures for obtaining such continuous cultures. Others[106,107] have also successfully developed immortalized cell lines from proximal tubular and distal tubular primary cell cultures using the SV40 virus as a transforming agent. The need to use an immortalizing agent is necessitated by the generally poor ability of primary cultures to undergo and survive multiple subculturing. Most of the short-term cultures have a limited doubling potential and undergo senescence and eventually die. It is unclear whether the limited doubling potential of normal cells is an inherent property or is due to imperfections in the tissue culture environment. For example, primary cultures of human proximal tubular cells can be subcultured up to five or six times, but it is important that cell density is not decreased by more than 50% in each passage or cells will not grow.[42,99]

There are several advantages and uses for continuous epithelial cell lines in renal toxicology studies. For example, examination of processes that occur over relatively long time periods can be studied in these cultures whereas the life span of primary cell cultures is insufficient for such studies. Other advantages are that these cell lines are relatively easy to use and produce highly reproducible results, without much of the difficulties inherent in the use of primary cultures. That said, however, the mere fact that the cell lines are immortalized indicates that they have undergone genotypic and phenotypic changes that make them different from the cell types from which they were derived. Hence, it is critical to validate that the processes under study are expressed and regulated properly. Even when the process under investigation is expressed in the cell line, other processes that are normally found in the in vivo cell type or in the kidney as a whole may not be expressed or not be regulated in the same manner. This

makes interpretations of physiological significance difficult and highlights a point made at the beginning of this chapter that multiple experimental models are needed to fully understand the processes of physiological, pathological, or toxicological importance. Nonetheless, immortalized cell lines have been invaluable for numerous studies of renal function and will continue to provide significant insight as long as the constraints and limitations to their use are kept in mind.

ASSAYS OF RENAL CELLULAR FUNCTION

Urinary Enzymes and Other Proteins

Measurements of urinary enzymes and other proteins were discussed earlier in the context of clinical and whole animal assessments of renal function and toxicity. In this section, the focus is on the measurement of renal enzymes and other proteins that can be used as specific biomarkers of renal function or toxicant exposure. This section will focus on biomarkers of effect that can be used to provide specific, mechanistic insight into pathological or chemically induced renal injury.

A recently discovered marker for renal injury that has been described in a series of studies by Bonventre and colleagues[55,57,108–110] is Kim-1. Kim-1 is a type 1 transmembrane protein that is not detected in normal kidney tissue but is expressed at very high levels in dedifferentiated proximal tubular epithelial cells of human and rodent kidneys after either ischemic or chemically induced injury. It appears to satisfy several of the criteria for being an ideal biomarker of effect for renal injury: Kim-1 is stable in urine for prolonged periods of time; it is specific to the kidneys; its expression increases markedly from a baseline of essentially zero; and its increased expression occurs early in the pathologic or toxic event, thus indicating a high degree of sensitivity. Both protein and mRNA expressions are increased in injured renal tissue. It also satisfies the criterion of being absent in normal kidney tissue and only being detectable in tissue that has been injured and/or is undergoing repair and proliferation.

Besides the biologic markers discussed earlier, several other markers have been suggested to be linked to cell injury. These and the ones discussed earlier may be divided into several categories[1]: (1) immunologic factors (e.g., humoral factors such as antibodies and antibody fragments, components of the complement cascade, and coagulation factors) (2) lymphokines (3) major histocompatibility antigens (4) growth factors and cytokines (e.g., platelet-derived growth factor, transforming growth factor, tumor necrosis factor, interleukins, etc.) (5) lipid mediators (e.g., prostaglandins, thromboxanes, leukotrienes) (6) extracellular-matrix components (e.g., collagens, laminin, fibronectin) (7) adhesion molecules (8) reactive oxygen and nitrogen species (9) transcription factors and proto-oncogenes (e.g., c-*myc*, c-*fos*, c-*jun*, c-Ha-*ras*, *Egr-1*) (10) tubule antigens (e.g., Tamm-Horsfall protein, brush-border enzymes, cystatin) (11) heat shock proteins and (12) endothelin. Validation is required, however, for many of these markers.

Assays of Cell Death: Necrosis, Apoptosis, and Autophagy

Most of our knowledge about mechanisms of renal cell injury comes from studies that either focus on or use preparations of proximal tubular cells. This is because the proximal tubule is the easiest nephron cell type to obtain in high purity and is the primary target site for the majority of drugs and other toxic chemicals that target the kidneys, due to the large array of plasma membrane carriers and drug metabolism enzymes present. Although most of the mechanistic information about cell death has come from in vitro studies, some information, particularly about target cell identity and involvement of hormonal, neuronal, or other extrarenal factors, has come from in vivo studies. Renal cells that are intoxicated by drugs or other chemicals can undergo several potential responses, including cell death, growth arrest, or proliferation and repair. It has become clear over the past several years of research, that for a very large number of toxic chemicals, exposure can elicit all three responses. The interplay between these responses is illustrated in Figure 30.7. Hence, as a response to a toxic insult, epithelial cells may either exhibit altered regulation of cellular function or cytotoxicity. The altered cells may either progress further to undergo neoplastic transformation or may be repaired. Cells experiencing cytotoxicity may either be repaired or, depending on exposure conditions, may undergo cell death by either apoptosis or necrosis. We have proposed such a scheme for trichloroethylene-induced nephrotoxicity.[103,104] While the kidney can repair itself after sublethal injury, it has been hypothesized that repeated cycles of sublethal injury followed by repair may lead to uncontrolled cell proliferation and neoplastic transformation.[38] The factors that determine which response occurs and predominates are not completely understood, but certainly include dose and time of exposure.

Cell death, both in general and for renal tubular epithelial cells in particular, can occur by two basic mechanisms, apoptosis or necrosis (oncosis).[111] Some basic features of necrosis

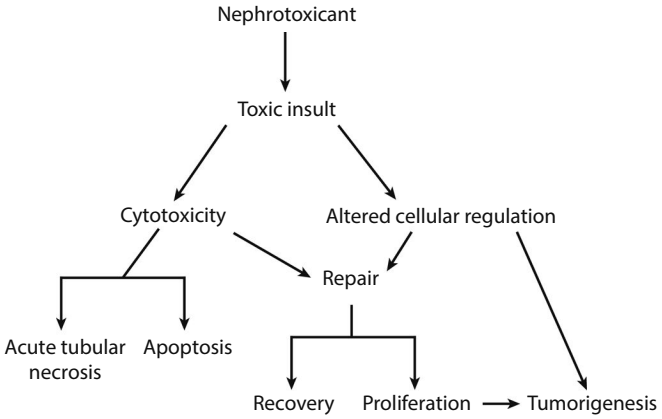

FIGURE 30.7 General scheme of renal cellular responses to nephrotoxicants.

TABLE 30.8
Comparison of Selected Features of Necrotic and Apoptotic Mechanisms of Cell Death

Parameter	Necrosis	Apoptosis
Cell shape	Swelling	Shrinkage
Membrane	Increased permeability	Intact
Energy dependence	No	Yes
Protein synthesis required	No	Yes
Toxicant dose	Relatively high	Relatively low
ATP depletion	Yes; early effect	Not until just before cell death
Second messengers	Not involved	Often involved
DNA damage	Random SS/DS breaks	Laddering
Nuclear damage	Chromatin damage, lysis	Chromatin condensation

and apoptosis are compared in Table 30.8. The many differences between the two forms of cell death are very dramatic. Thus, whereas apoptosis is a highly regulated, energy-dependent process, necrosis can be viewed as an uncontrolled, pathological response; whereas apoptosis involves events in single cells, necrosis typically involves large numbers of cells in a wide area of tissue and is often mediated in vivo by infiltrating macrophages and similar inflammatory mechanisms.

Cell death by necrosis is typically measured by assays for plasma membrane permeability, such as LDH release or trypan blue uptake (see preceding text). The LDH release assay method is shown schematically in Figure 30.8 and illustrates typical results for a control incubation (left panel), which exhibits a small amount of LDH release, and an incubation with a highly cytotoxic concentration of a chemical (right panel), which exhibits a large amount of LDH release. Results with trypan blue exclusion (or with another vital dye) would be similar to those with LDH release. Trypan blue exclusion is measured by mixing an aliquot of cells with the dye and applying it to a hemacytometer; this enables not only the assessment of viability by dye exclusion but also the determination of cell number. For routine assessments of cell viability, LDH release is recommended because of its simplicity, widespread use that has been validated in numerous studies with isolated cells from multiple tissues, and its lack of potential bias as can exist with the counting of stained cells under a microscope.

The LDH release assay was originally developed and used in suspensions of isolated cells.[85] With the advent of so many studies being conducted with either primary cell cultures or continuous cell lines, some variation to the basic method is needed, although the principles of the assay remain the same. For adherent cells attached to a stationery matrix, LDH activity is first measured in media as NADH oxidation at A_{340}. After removal of media and washing with phosphate-buffered saline (PBS), cells are solubilized with 0.1% (v/v) Triton X-100, and LDH activity is determined in the total cell extract. The fraction of LDH release is then used as an index of irreversible injury or necrosis, and is calculated according to the following:

$$\%\ \text{LDH release} = \left[\frac{\text{LDH activity in media}}{(\text{LDH activity in media} + \text{LDH activity in total cells})}\right] \times 100\%$$

In some cases, however, LDH release cannot be used as a measure of cell viability because the toxicant directly inhibits its LDH activity, such as occurs with inorganic mercury.[49,50] The likely mechanism of inhibition is direct binding to the

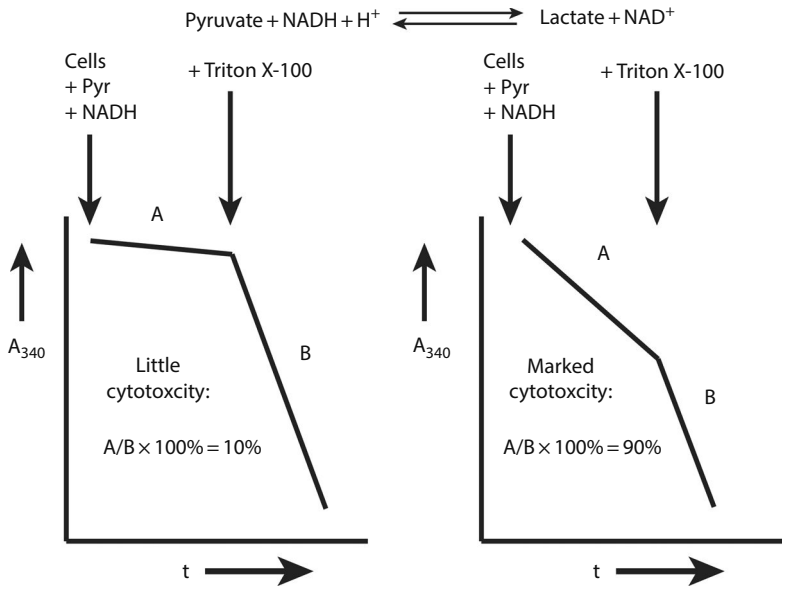

FIGURE 30.8 LDH release assay.

critical cysteinyl sulfhydryl group of LDH. Hence, any sulfhydryl-reactive chemical, or a chemical that is metabolized to a sulfhydryl-reactive species, will likely inhibit LDH, although potency will likely vary among compounds. In the situation in which LDH activity is inhibited, total LDH activity can be used as an estimate of cell viability, with activity calculated according to:

$$\text{Total LDH activity} = \text{LDH activity in media} + \text{LDH activity in total cells}$$

An additional assay that can be used to estimate cell viability is the MTT cell proliferation assay. MTT, or 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, is reduced by live cells to a strongly pigmented, purple formazan product. After solubilization, the absorbance of the formazan product can be measured in a microplate reader at 570 nm. A kit is available from Molecular Probes (http://probes.invitrogen.com) that is designed as a high-throughput assay of cell viability and proliferation. The manufacturer cautions that because MTT can be reduced intracellularly by both various dehydrogenases and GSTs, MTT may not always be a reliable probe of cell viability in cells exposed to chemicals that affect these enzymes. Nonetheless, it has become a commonly used and convenient assay.

Cells undergoing apoptosis, in contrast to necrosis, exhibit several unique morphological features (cf. Table 30.8). Detection of these features has been used in several assays to detect apoptosis. One common method involves in situ histochemical staining of cells and light microscopy.[112] This method, called the TUNEL method (*t*erminal deoxynucleotidyltransferase [TdT]-mediated d*U*TP-biotin *n*ick *e*nd *l*abeling), relies on the in situ labeling of DNA breaks in individual nuclei in tissue sections processed by routine histopathology procedures. TdT specifically binds to 3′-OH ends of DNA that are exposed by proteolytic treatment. This is followed by the synthesis of a labeled polydeoxynucleotide molecule, formed by the use of TdT to incorporate biotinylated deoxyuridine into the sites of DNA breaks. Signal is amplified by avidin peroxidase, enabling detection by light microscopy.

Some forms of apoptosis can be detected by running agarose gels with ethidium bromide staining to detect DNA laddering that often, but not always, occurs in cells undergoing this form of cell death. The laddering is based on activation of endonucleases that cleave the DNA between nucleosomes, producing 200 bp multimers. While this is a useful method, it is not quantitative, and such DNA laddering is not obligatorily associated with apoptosis.

Several flow cytometry methods have been developed to analyze the cell cycle or to label cellular components with, for example, fluorescent tags, and then sort cells according to their content of the fluorescently labeled component. Advantages of methods using flow cytometry include their ability to identify and readily quantify multiple subpopulations of cells based on a large variety of parameters, and their ease of use. Flow cytometers can quantify the proportion of cells in G_0/G_1, S, and G_2/M phases of the cell cycle by the use of fluorescent DNA dyes. For example, one can easily identify cells in G_2/M phase as compared to those in G_0/G_1 phase because the former have twice the amount of DNA as the latter. Besides emitted light, the flow cytometer also analyzes scattered light from cells passing through the laser beam. Forward scatter and side scatter indicate cell size and granularity (density), respectively. Because apoptotic cells are typically condensed, the flow cytometer detects them as smaller, less fluorescent entities. Cells are stained with propidium iodide (PI), which is a DNA-intercalating agent like ethidium bromide. The analytical procedure used to detect the different cell populations is called fluorescence-activated cell sorting (FACS) analysis. An example of such an analysis is shown in Figure 30.9, where primary cultures of human proximal tubular cells were incubated with either medium alone (= Control) or with 50 μM DCVC.[103] A marked increase in the fraction of apoptotic cells is evident after incubation with DCVC.

Another flow cytometric assay for apoptosis involves assessment of the changes in plasma membrane morphology, which is an early effect involved in cells that undergo apoptosis. In such cells, the membrane phospholipid phosphatidylserine is translocated to the outer face of the plasma membrane, thereby exposing it to the extracellular environment. Annexin V is a 35–36 kDa Ca^{2+}-dependent, phospholipid-binding protein with a high affinity for phosphatidylserine. In measurement of apoptosis, Annexin V is conjugated to a fluorochrome such as fluoroscein isothiocyanate (FITC), enabling binding of Annexin V-FITC to be a sensitive probe of early apoptosis. Cells are stained with both Annexin V-FITC and a vital dye such as PI, are subjected to flow cytometry and FACS analysis, and are identified as early apoptotic (Annexin V-FITC positive and PI negative), late apoptotic or necrotic (Annexin V-FITC positive and PI-positive), or viable (Annexin V-FITC negative and PI-negative).

A number of other assays for apoptosis in renal epithelial cells are available, involving flow cytometry, Western blotting, or enzymatic assays. Examples include measurements of apoptosis-associated proteins, such as Bcl-2 family members, cytochrome c, and cleavage products of poly(ADP-ribose)-polymerase (PARP). For more details on mechanisms of apoptosis and assays used to quantify apoptosis, the reader is referred to recent reviews.[113] As a general rule, it is advisable to assess cell death, and apoptosis in particular, by more than one method and to study cellular responses over a long enough time course and a broad enough concentration range of test chemical.

Renal Cellular Function

Although measurements of cell death by necrosis or apoptosis provide end-points for screening potentially nephrotoxic chemicals, it is often important to assess the effects of chemical exposures or pathological states that are more subtle or that provide an indication of potential toxic effects prior to irreversible cell death. These would include

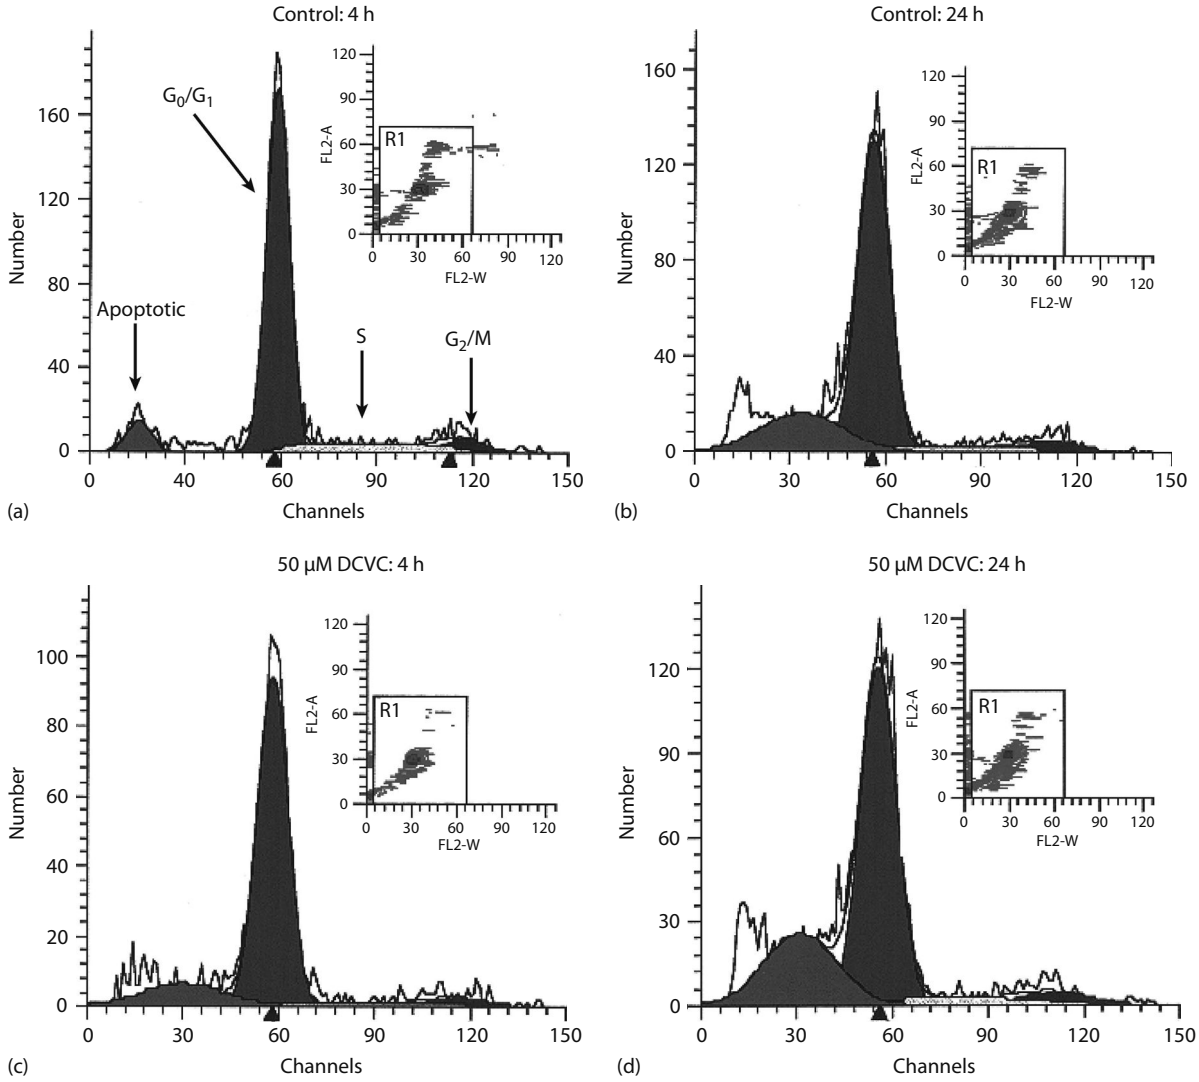

FIGURE 30.9 Flow cytometry analysis of PI-stained hPT cells treated for 4 or 24 h with 50 μM DCVC. Confluent hPT cells were grown on 35 mm polystyrene culture dishes and were treated with PBS (= Control) for 4 h (a) or 24 h (b) or 50 μM DCVC for 4 h (c) or 24 h (d). Cells were then harvested by trypsin-EDTA digestion, washed in sterile PBS, fixed overnight in ethanol, stained with PI, and then analyzed by flow cytometry with a Becton Dickinson FACSCalibur flow cytometer. Peaks from left to right represent apoptotic cells, cells in G_0/G_1, cells in S phase, and cells in G_2/M. Results are from a single preparation and are typical of those from six separate experiments. Note that G_0/G_1 peaks comprise the majority of cells in most incubations and are somewhat broad because the cells are confluent. The coefficient of variation (CV) for these peaks ranged between 3% and 18%, with approximately 80% of the peaks in samples exhibiting CV values of 5%–8%. Insets: Distribution of cells according to fluorescence intensity. Cells outside the box are those that were excluded from the analysis due to aggregation.

measurements of cellular respiration, active ion transport (e.g., $(Na^+ + K^+)$-stimulated ATPase activity), cellular redox status, and concentrations of key intracellular metabolites, such as ATP and GSH. Mitochondria are common and early targets for many nephrotoxic chemicals. Hence, sensitive assessments of cellular energetics and mitochondrial function should provide good indicators of agents whose effects can be mediated through this organelle.[114] One reason the mitochondria are such a critical and prominent intracellular target for nephrotoxicants is that they contain a large number of protein thiol groups that can become inactivated by oxidation or alkylation and many toxic chemicals are bioactivated to oxidants and reactive electrophiles.

Molecular Markers of Renal Cellular Repair, Regeneration, and Proliferation

As illustrated in Figure 30.7, renal epithelial cells can respond to toxicant exposures in a variety of ways, depending in part on dose and time of exposure. Other factors are surely important in determining whether the exposure leads to cell death, repair, or uncontrolled proliferation. There are a number of markers for repair and proliferation for the kidneys.[115] For example, the normal, differentiated proximal tubular cell expresses cytokeratins but not vimentin, which is a marker for endothelial cells. Renal proximal tubular cells that have either undergone neoplastic transformation or have dedifferentiated

and are undergoing repair and proliferation do express vimentin. Morphologically, dedifferentiated proximal tubular cells exhibit differences from the normal, differentiated state, such as the lack of a brush border and an elongated rather than a cuboidal shape. While the renal epithelium has regenerative capacity, the normal, terminally differentiated renal epithelium is nonproliferating, as evidenced by the flow cytometry FACS analysis shown in Figure 30.9, which shows that <10% of control cells are in S phase. Assays such as radiolabeled thymidine incorporation, 5-bromo-2′-deoxyuridine (BrdU) incorporation, and expression of proliferating cell nuclear antigen (PCNA) can be used to demonstrate repair and proliferation of the renal tubular epithelium.

Use of Genomics, Proteomics, and Metabolomics in Renal Physiology and Toxicology

Recent advances in genomics, proteomics, and metabolomics provide new opportunities for studying the molecular and cell biology of the renal cellular response to toxicant exposure and renal disease. Moreover, the increasing proportion of high-throughput assays creates both opportunities and challenges. In terms of opportunities, large amounts of data are obtainable that can uncover relationships that were previously unknown. In terms of challenges, however, these same large amounts of data generate a computational nightmare and can produce both false negatives and, more importantly, false positives. Nonetheless, a systems biology approach to understanding the influence of environment and organ and cellular function is now viewed by many as the only true way to provide a fundamental understanding of physiologic, pathologic, and toxicological processes.[116,117]

In the area of genomics, cDNA microarrays can be used to determine genes or classes of genes that are either upregulated or downregulated as a consequence of toxicant exposure. A threshold for a change to be significant (1.5-fold or 2-fold if being more conservative) is typically applied in the analysis. Patterns of gene expression changes can provide a signature for a chemical or class of chemicals that modulate renal function.

While microarrays are indicative of changes in mRNA expression, they may not translate into functional changes. Hence, the additional application of proteomics approaches can provide more detailed information on changes in both protein expression and posttranslational modifications of proteins (e.g., phosphorylation status), which can thus provide functional information.[118] Proteomics can also be used to determine the identity of proteins that are specifically modified by reactive species generated by xenobiotic metabolism. In this manner, detailed molecular information about how a toxicant produces its effects can be gained.

Metabolomics methods can also be used to provide insight into how nephrotoxicants produce their effects.[119,120] The general approach relies on measurements of intermediary metabolites in urine, using such techniques as ^{13}C-nuclear magnetic resonance spectroscopy. Just as cDNA microarrays can provide a signature for the effects of a toxicant on mRNA expression, metabolomics can provide a signature for the effects of a toxicant on pathways such as glycolysis, oxidative phosphorylation, and amino acid metabolism. Although none of these approaches can be readily performed in most laboratories, due to the requirement for specialized equipment, they are becoming more commonly used in toxicology and promise to open up new areas of investigation for the future.

While methods to modify the genetics of renal proteins in in vitro models, particularly established cell lines, by approaches such as cDNA transfection, antisense oligonucleotides, and small-interfering RNA (siRNA) treatment are well developed, similar methods in whole animals are in their early stages of development and application. Masereeuw and colleagues[121] demonstrated that intravenous administration of siRNA directed against Mrp2 resulted in selective silencing of Mrp2 expression in renal proximal tubules. These findings support the concept that intravenous administration of siRNAs can be a potential therapeutic tool for gene silencing in the kidneys.

HUMAN DISEASE AND RISK ASSESSMENT

Experimental Models of Renal Diseases

An important experimental approach to improve the understanding of disease etiology and to design improved treatments for human diseases is the development of experimental models that mimic various aspects of the disease under study. Genetically modified animals, such as transgenic mice,[122] have been used to study the functions of specific proteins. An interesting approach along these lines, designed to mimic conditions that exist in a variety of human renal diseases is the expression of human proteins in mice, creating so-called *humanized mice*.[123] Renal diseases that have been studied include diabetic nephropathy, polycystic kidney disease, various glomerular nephropathies, to name a few. Special rat strains are also available, such as the spontaneously hypertensive rat,[124] to study the role of renal function in specific pathologies. Experimental approaches used to study renal function and toxicity will be similar with these animals and normal animals. Caution must be exercised, however, in the interpretation of findings because a genetic modification may alter multiple processes. Hence, a complete characterization of these animals is necessary.

Extrapolation of Animal Data to Humans

Although experimental animals such as rats and mice are frequently used to study nephrotoxicity and renal function, humans are the ultimate species of interest. Laboratory animals or in vitro preparations derived from such animals are used instead of humans or tissue from humans for several reasons. First, the design of clinical studies cannot include investigator-initiated study of mechanisms of nephrotoxicity. It is only when humans are inadvertently exposed to a nephrotoxic chemical, such as might occur in an occupational

setting, an environmental contamination, or a poisoning, can information about toxicity be gleaned. Several limitations exist, however, with such studies. For example, exposure information is often incomplete and/or limited, requiring the use of assumptions and approximations. The level of control of experimental design that exists with animal studies is not possible with clinical studies. Second, although in vitro studies with renal tissue from humans are possible and allow the investigator to exert the same degree of control over exposure conditions as are available with in vitro studies from animal tissues, human tissue is not always available and is significantly more expensive than studies with animal tissues.

Nonetheless, mechanistic studies with renal tissue from humans are feasible and have many advantages. The use of human tissue for studies of chemically induced nephrotoxicity and renal function removes the need for interspecies extrapolation. While such extrapolations have been applied successfully for many chemicals, they have been much less successful for other chemicals. A prime example of a situation where rodent-to-human extrapolations have yielded equivocal results for human health risk assessments is that of trichloroethylene.[38] For halogenated solvents such as trichloroethylene, rodents appear to be poor surrogates for humans because of inherent differences that cannot be readily corrected. Hence, while rodent data are used, the uncertainty factors applied to the human health risk assessments are rather large compared to those used for many other classes of chemicals.

Future Considerations

While many advances have been achieved in recent years in the study of nephrotoxicity, several areas of research require continued development or refinement and many new techniques and methods are only beginning to be exploited for the study of renal function and toxicity. Examples of the former include the various cell culture models and biomarkers of effect, exposure, and susceptibility. Continued application of molecular biology techniques to cell culture can help improve the ability of these models to mimic the in vivo renal cell. Application of approaches such as siRNA technology to and the use of transgenic animals in renal toxicology should also improve our ability to define exposure conditions, understand susceptibility to renal cellular injury, and better define mechanisms of action. Although numerous markers of effect are available for the kidneys, most do not satisfy enough of the criteria to be truly useful as indicators of early stages of damage. Continued development of biomarkers that can indicate mild alterations in some parameter of renal function at early times postexposure is needed. Some recently developed markers, such as Kim-1, appear to satisfy the criteria needed for an effective biomarker.

Summary

When considering the kidneys as a target organ for chemically induced toxicity, many unique features are apparent that determine susceptibility. Four major factors are critical: (1) the high rate of renal blood flow, (2) the ability of the kidneys to concentrate chemicals in the intraluminal fluid, (3) the ability to actively reabsorb and/or secrete chemicals through the tubular epithelial cells with high activity, and (4) the presence of enzymes for the bioactivation of a protoxicant to reactive intermediates.

In choosing an experimental model with which to study renal function and toxicity, several questions should be asked first: (1) What is known about tissue and/or nephron cell type specificity? (2) What is known about metabolism? (3) What is known about transport? (4) Are extrarenal factors or processes required for the expression of nephrotoxicity? (5) What is the time frame over which the nephrotoxic response occurs? Choices of models using experimental animals (e.g., rat, mouse, rabbit) range from the whole animal to a range of in vitro model systems, including the isolated perfused kidney, isolated perfused tubules, renal slices, isolated tubular fragments, isolated cells, primary cell culture, and immortalized renal cell lines. Each model has distinct advantages and limitations. Depending on answers to the preceding questions, one should choose multiple models to address renal function and toxicity.

Once certain types of information about a putative nephrotoxicant are known, the model can then be chosen. The whole animal model is important for determining target organ specificity and the influence of extrarenal factors, including immunological and hormonal factors. Certain of the in vitro models have the advantage of maintaining tubular structure and epithelial membrane polarity. A critical issue in using many of the isolated tubule or cell models, including primary cell culture and immortalized cell lines, is how well-differentiated function is maintained. The importance of this issue is dependent on the process being studied, as some models that only express some of the normal, in vivo phenotype will be good models if the process being studied is retained. Several of the in vitro models have the added advantage of being amenable to being used for screening of potentially nephrotoxic chemicals. High-throughput assays, such as those that can use a plate reader, are available for many of the assays of renal cellular function and toxicity. The screening approach is particularly useful to eliminate candidate drugs in the earliest phases of investigation.

QUESTIONS

30.1 Describe procedures used to measure GFR.
30.2 Explain the biological significance of high-molecular-weight and low-molecular-weight proteinuria.
30.3 Explain how nephron heterogeneity determines the pattern of effects of nephrotoxicants.
30.4 Explain how tubuloglomerular feedback regulates GFR.
30.5 Describe the properties of a chemical that would be ideal for use in renal clearance measurements.
30.6 Compare and contrast whole animals and various in vitro models for their use in studies of nephrotoxicity and renal function in terms of their advantages and limitations.

30.7 Describe the properties of an ideal biomarker of effect for use in human health studies.

30.8 Describe the differences between necrotic and apoptotic cell death at both cellular and organ levels.

31 Gastrointestinal Toxicology

Robert W. Kapp, Jr.

CONTENTS

INTRODUCTION

The intensity of the effect of a toxicant on an organism is dependent primarily upon the relative effective concentration and the duration or persistence of the ultimate toxicant at a septic site of action. There are numerous portals of entry for toxicants. The oral exposure route is the primary route of exposure to all substances including toxicants. In order to assess the potential adverse effects of toxicants by oral exposure, it is necessary to understand the structure, function, and mechanisms involved in the adsorption, distribution, metabolism/biotransformation, and excretion of toxicants that enter

the gastrointestinal (GI) tract. This chapter focuses on the normal structure and function of the GI tract and how the process of digestion and absorption influences and is influenced by toxicants that enter the GI tract. For those toxicants, the intensity of the ultimate toxicant is determined by a number of factors that are part of the normal functioning of the GI tract including digestion, absorption, biotransformation, distribution, and elimination. The last part of this chapter describes the types of testing that can be performed to examine the effects of toxicants on various aspects of the normal functioning of the GI tract.

OVERVIEW OF THE GASTROINTESTINAL TRACT

All living cells require energy in the form of nutrients. Nutrients are substances that provide energy to basic body processes. In addition, nutrients are critical to the building of new or the replacement of old components for various body structures. Basically, nutrients are divided into two classes: macronutrients and micronutrients. In comparative terms, macronutrients are required in larger quantities than are micronutrients, which are required in much smaller amounts. The daily diet of most individuals consists of about 2–3 lb of food and 1.5 L of fluid containing perhaps 100,000 different substances in amounts varying from 1 or 2 L to as little as nanogram units. Of those 100,000 substances, only about 300 are classified as nutrients, and of that number, 45 are essential for the survival of the individual. Many of the consumed substances have value in preserving the food or add aroma or color to improve or enhance the taste or appearance of the food. Some of the substances are helpful in the digestion process, such as fibers and cellulose [2]. The vast majority of ingested food is broken down into more elemental units for use by the body. Table 31.1 provides a summary of the most common macronutrients and micronutrients consumed by humans.

The resulting breakdown products of these nutrient classes provide the organism with energy for the numerous life processes necessary to sustain the organism, such as active transport, protein and enzyme synthesis, and synthesis of structural molecules for cells. The minerals and vitamins can act as catalysts in thousands of body functions and are needed for the growth and maintenance of body structures. Water is necessary as a means to regulate body temperature, as a solvent, and as a lubricant, plus it plays a role in hydrolysis reactions.

Although single-cell organisms can obtain nutrients directly from their surroundings, multicellular organisms have developed highly specialized structures to collect, digest, and absorb these nutrients. The GI tract or alimentary canal is that specialized structure in multicellular organisms that essentially obtains nourishment by the ingestion of organic material, generally termed *holozoic nutrition*. This process of nutrition provides trillions of body cells with nutrients in order to function as described previously. Table 31.2 identifies the five basic stages of holozoic nutrition.

To complete these various stages of nutrition, the GI tract has specialized structures. The cell wall of the GI tract is composed of numerous tissue types that serve not only to break down foodstuff and fluid into absorbable components but also to create an environment for these components, as well as vitamins and minerals, to be absorbed into the bloodstream, assimilated, and then ultimately eliminated from the body. The GI tract is essentially a 25–30 ft series of hollow organs connected together to form a pathway that starts at the mouth and proceeds through the pharynx, esophagus, stomach, small intestines, large intestines, rectum, and anus. Although the lumen is found within the body, the contents within the lumen of the GI tract are considered to be external to the body. The digestive system functions to modify the ingested luminal contents so they can be absorbed from the lumen (exterior of the body) by the blood and lymph circulatory system (interior of the body). Traditionally, the digestion system is organized into two divisions: (1) the GI tract or alimentary canal, which includes the mouth, pharynx, esophagus, stomach, small intestine, large intestine, rectum, and anus, and (2) accessory structures that include teeth, tongue, salivary glands, pharynx, liver, gallbladder, and pancreas.

TABLE 31.1
Summary of Common Macro- and Micronutrients in Humans

Nutrient Classification	Nutrient Types	End Product
Macronutrients	Carbohydrates	Monosaccharides
	Lipids	Fatty acids and cholesterol and monoglycerides
	Proteins and nucleic acids	Amino acids, bases
	Water	Water
Micronutrients	Minerals	Calcium, chromium, copper, fluorine, iodine, iron, magnesium, manganese, molybdenum, phosphorus, potassium, selenium, sodium, zinc
	Fat-soluble vitamins	A, D, E, K
	Water-soluble vitamins	B_1 (thiamine), B_2 (riboflavin), B_3 (niacin), B_5 (pantothenic acid), B_6 (pyridoxine), B_7 (biotin), B_9 (folacin), B_{12} (cobalamin), C

TABLE 31.2
Stages of Holozoic Nutrition

Stage	Function
Ingestion	Physical act of engulfing foodstuff into the alimentary canal
Digestion	Mechanical and chemical reductions of foodstuff to elemental particles
Absorption	Passive and active mechanisms involved in transporting the nutrients across mucosal cell membranes
Assimilation	The body's ultimate use of the absorbed nutrients
Egestion	The elimination of the unused and undigested GI tract contents

The major organs of the digestive tract and their relationship to one another are shown in Figure 31.1.

Each portion of the GI tract is highly specialized with respect to both structure and function. Accessory digestive organs are connected to the GI tract through a series of ducts, including the salivary glands, the pancreas, the liver, and the gall bladder. The teeth aid in the physical breakdown of foodstuffs that enter the mouth. The tongue assists in mastication and swallowing. The pharynx assists in sealing the respiratory tract during the swallowing reflex. The esophagus transports the ingested foodstuff to the stomach. The stomach serves to mix the foodstuffs with acidic gastric secretions and prepare the resulting mixture, which is now a semiliquid mass of partially digested food (termed *chyme*), for entrance into the small intestine. The small intestine is a 20–25 ft tube in which the vast majority of the digestion and absorption of chyme occurs. The large intestine absorbs some electrolytes and water and prepares the contents for expulsion through the rectum and anus [5].

HISTOLOGICAL ORGANIZATION OF THE GASTROINTESTINAL TRACT

To understand the GI tract, it is necessary to understand its microscopic as well as macroscopic structures. Throughout the length of the GI tract, a cross section of the tissue consists of a series of four concentric layers or tunics. The intestinal

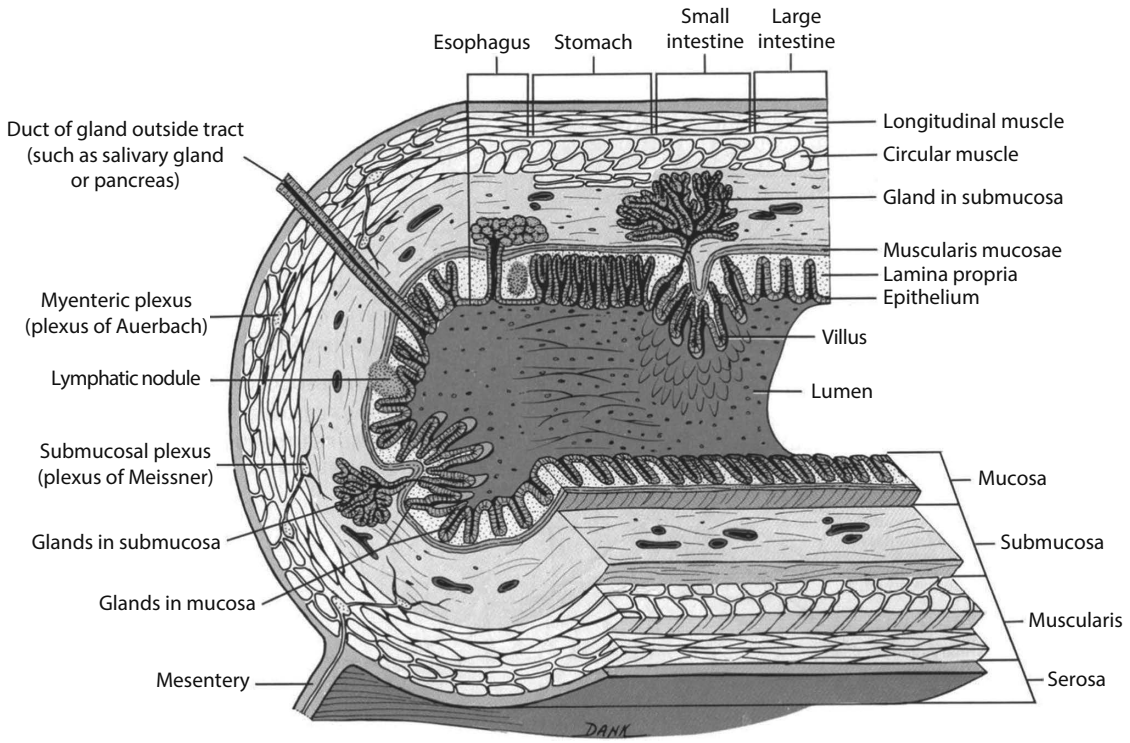

FIGURE 31.2 Representative sections of the GI tract. (From Tortora, G.J. and Anagnostakos, N.P., The digestive system, Chapter 24, in: *Principles of Anatomy and Physiology*, 6th edn., HarperCollins: New York, 1990, p. 735. With permission.)

wall varies in the various sections of the alimentary canal, reflecting the different roles in each locality; however, the basic structure remains the same (Figure 31.2).

Serosa

The outermost layer is the adventitia or serosa, which includes loose supportive tissue proximally and is contained by a thin membrane distally that covers the entire GI tract. Those portions located within the abdominal cavity are covered by a layer of squamous cells and an underlying connective tissue. The entire GI tube is suspended within the body cavity by a mesentery through which blood vessels, nerves, and lymphatics pass to the organ systems. It is part of the peritoneum and facilitates movement of the structure within the body cavity.

Muscularis

The next layer is the muscularis, which usually contains the inner circular layer of smooth muscle fibers and an outer longitudinal layer of smooth muscle fibers and the myenteric plexus. These muscle layers provide coordinated movements that allow for the mixing, digestion, and motility of ingested substances through the GI tract. The primary control of GI motility is centered in the myenteric plexus (plexus of Auerbach), which contains connections from both autonomic innervation connections, and is also found in the muscularis layer. The muscularis layer in the mouth, pharynx, and upper third of the esophagus has not only smooth muscles but also skeletal or striated muscles that produce the voluntary initial phase of swallowing.

Submucosa

The next layer, moving toward the lumen, is the submucosa, which is comprised primarily of loose connective tissue, lymphatic and blood vessels, glands, and the submucosal plexus. It is a very vascular layer and contains much of the plexus of Meissner, which is critical in controlling gland secretion and blood flow to the GI tract.

Mucosa

The innermost layer of the GI tract is the mucosa, which is in contact with the external environment and actually allows for the absorption of the nutrients. It is comprised of three additional subdivisions. Starting from the layer proximate to the submucosa, the muscularis mucosa includes a smooth muscle and elastic connective tissue layer which creates the folds in the mucous membrane that enhance the area of absorption throughout the GI tract. The next distinctive layer of the mucosa is the lamina propria, which is composed of loose connective tissue and contains blood vessels, lymphatics, and perhaps some glands. This layer supports the epithelial cells, provides the blood and lymph supply, and binds the layer to the muscularis mucosa. The final layer of the mucosa that lines the lumen of the GI tract and is in direct contact with nutrients is the epithelial layer. The structure and function of these epithelial cells vary along the course of the tract.

Depending on the location, the epithelial cells may be stratified squamous cells, such as in the esophagus, or secretory cells found in the stomach or absorptive cells in the small intestines. The functions of the stratified epithelium are secretion and protection. The functions of the simple epithelium, on the other hand, are secretion and absorption.

Cellular Absorption

Cell membranes are plasma barriers between the environment and the cell cytoplasm. The membrane is specialized in that it contains specific proteins and lipid components that allow it to perform its unique roles for that particular cell. Because the lumen of the GI tract is considered external to the body itself, a critical factor in the nutrient absorption process is crossing this mucosal epithelial cell membrane. The membranes are essential for the integrity and function of the cell. The functions of GI tract cell membranes include the following:

- Protection
- Transport into and out of the cell
- Enzymatic activity
- Providing receptors for signal transduction
- Providing intercellular adhesion proteins
- Cell-to-cell recognition via glycocalyx
- Attachment to the cytoskeleton and extracellular matrix

In 1972, Singer and Nicholson presented a fluid mosaic model for the gross organization and structure of the proteins and lipids of biological membranes in general [7]. In this model, the 7–9 nm thick lipid bilayer is a neutral, 2D structure with a mosaic of proteins embedded in it. Further, the phospholipids are amphipathic, meaning they are both hydrophilic and hydrophobic. Each phospholipid possesses a polar phosphate group at the head facing the outside of the membrane and two nonpolar fatty acids at the tail facing inward. Within model bilayers, lipids can exist in different phases: as gels or as liquid-ordered or liquid-disordered states (as described in the Singer–Nicholson model). See Figure 31.3 for the overall basic membrane structure. In the liquid-ordered state, saturated hydrocarbonic chains of phospholipids are tightly packed with cholesterol and glycolipids; thus, horizontal mobility in the membrane is limited. The cells that line the GI tract are similar in thickness (7–9 nm) and structure (phospholipid bilayer), with polar head groups consisting of phosphatidylcholine and phosphatidylethanolamine. These polar groups are arranged perpendicularly to the cell membrane and are located facing the inner and outer membrane surfaces. The zonula occludens or tight junction is the outer layer of the junctional complex between other epithelial cells that line the luminal surface of the digestive tube. The tight junction is a series of integral membrane proteins that form a fused ring around intestinal cells to help prevent molecules from passing between cells. Cell membranes display a tremendous complexity of lipids and proteins designed to perform the functions cells require. To coordinate these functions, the membrane is able to laterally segregate its constituents. The model predicts the interspersion of proteins and lipids that undergo dynamic rearrangement through Brownian motion. Recent study data show that the compartmentalization of membrane components can be as important for effective signal transduction as the fluidity of the membrane. Studies directed at the plasma membrane have provided evidence for the existence of distinct domains in the submicron range [8]. The term *lipid rafts* was coined based on studies of epithelial cell polarity and gained widespread popularity in the past years [9]. Analysis suggested that *rafts* consist of cholesterol and sphingolipids in the exoplasmic leaflet of the lipid bilayer and cholesterol and phospholipids with saturated fatty acids in the endoplasmic leaflet. Isolating

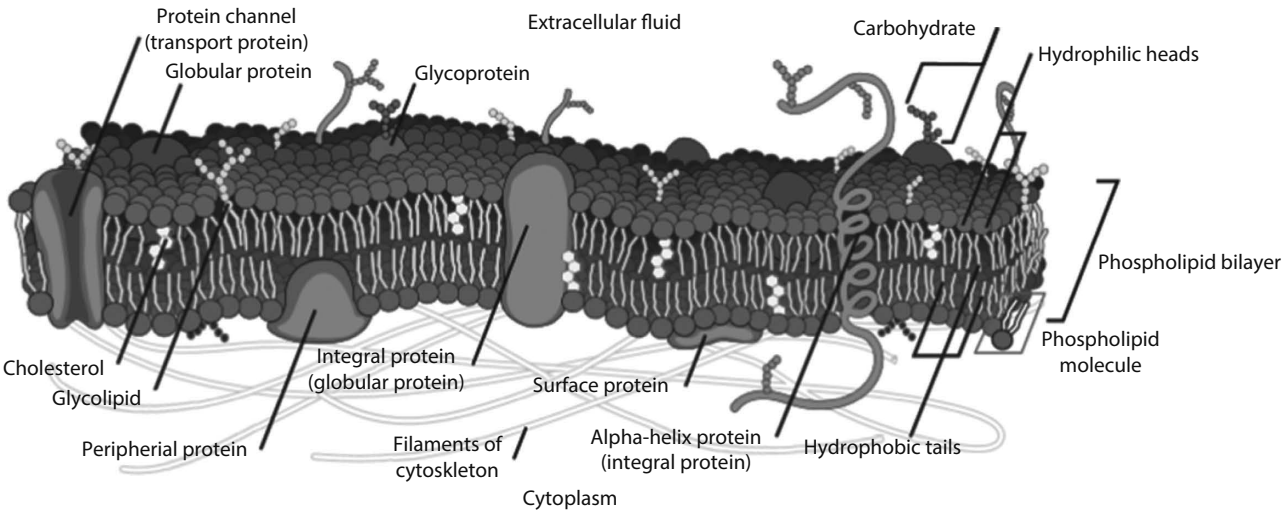

FIGURE 31.3 Schematic representation of the Singer–Nicolson membrane model. (From Wikipedia, Cell membrane detailed diagram, available online: http://en.wikipedia.org/wiki/File:Cell_membrane_detailed_diagram_en.svg, accessed March 5, 2014.)

lipid rafts as detergent-resistant membrane domains, followed by Western blotting, indicated that rafts indeed are efficient concentrators of various proteins, many of them active in cell signaling. This signaling capability is based on dynamic liquid–liquid immiscibility and underlies the raft concept of membrane subcompartmentalization. The roles of lipid rafts in cancer, in microbial pathogenesis, and in insulin resistance are not yet determined, but compelling evidence indicates the growing importance of membranes in health and disease. The *dynamically structured mosaic model* views the fluidity of the model as permitting the changes of the membrane architecture to the continuous dynamic restructuring of the clusters, which adapt to the needs of the cell and as determined by external factors [10–13].

Nutrients are absorbed across cellular membranes in the GI tract by five critical processes [14,15]:

1. *Simple passive diffusion* is the movement of substances through aqueous pores in cell membranes without the expenditure of energy. Most hydrophilic substances (molecular weight < 600) cross the membranes of the intestinal mucosa by passive transport via these aqueous pores in the mucosa. Small hydrophobic substances can also access the epithelial cell's aqueous pores by simple diffusion; however, as the size of the hydrophobic substance increases, it must cross through the lipid portions of the membrane. This movement is due primarily to the random motion that attempts to equalize the concentration of that substance on either side of the membrane. If higher concentrations of a substance exist on one side of a membrane, the law of mass tends to equilibrate the concentrations. The membrane is constructed of fat-soluble components that permit fat-soluble substances such as oxygen, nitrogen, carbon dioxide, and alcohols to easily diffuse across it.
2. *Filtration* occurs when water flows across membranes in large quantities because of hydrostatic or osmotic pressure. This water flow tends to pull some substances with molecular weights of 150–300 kDa through the same channels and tight epithelial junctions in the cells within the GI tract. The substances do not cross the membrane because of random motion, but rather they are forced through the membrane by the movement of the water. The transport of molecules via hydrostatic forces is also referred to as *solvent drag* or *bulk transport*. This type of nutrient absorption is more common in the kidney but does occur in the intestines [15].
3. *Facilitated diffusion* also known as facilitated transport or passive-mediated transport is the common mode of passive transport postulated for glucose, sodium ions, and chloride ions to migrate across the plasma membrane but to which the lipid bilayer of the membrane is virtually impermeable. In this case, the facilitated carriers are proteins that reside in the cell membrane. According to the alternating access model, the substrate binding site of a transport protein is alternately exposed to one or the other side of the membrane such that at no time is there an open and unrestricted permeation pathway through the transporter connecting the two fluid compartments separated by the membrane. The substance moves as if it were actively transported, except no energy is expended, and it is not moved against the concentration gradient. The carrier then returns to the outside of the membrane.
4. *Active transport* occurs when compounds require assistance in moving across the mucosal epithelial membrane. This is generally because the substance is large or insoluble or it is moving against a concentration gradient or otherwise defying the logics of physics in its direction of movement. Because these substances nonetheless do successfully traverse the membrane, a system of transport mechanisms has been suggested to explain the appearance of the sugars glucose and galactose; most amino acids; and minerals such as sodium, potassium, calcium, iron, chloride, and iodine, as well as some toxicants inside the mucosal epithelial cells. The divalent metal-ion transporter (DMT) assists in the GI tract absorption of metals, while the nucleotide transporter (nt) and peptide transporter (pept) are active in the transport of nucleotides and peptides, respectively. Certain characteristics exhibited by most active transport systems include the following: (1) the system is structurally specific for certain chemical features; (2) the transport system utilizes energy to function; (3) the system is competitive among other similarly structured chemicals that utilize the same transport system; (4) the system is transport-rate limiting, by either saturation or competition, and exhibits a transport maximum (Tm); and (5) the system moves substances against concentration and energy gradients. Generally, a substance being actively transported across the mucosal epithelial cell forms a membrane-bound complex on the low-concentration side of the membrane; subsequently, the substance then crosses the membrane through specific channels by the expenditure of energy, where it is released on the opposite, or high-concentration, side of the membrane.
5. *Vesicular transport*—most substances either diffuse or are actively transported into the mucosal cell membrane; however, some are ingested by a process known as vesicular transport, which includes both endocytosis (the movement of substances from extracellular spaces into intracellular spaces by engulfing them) and exocytosis (the movement of substances from the cell interior to extracellular spaces where there is transient vesicle fusion with the cell membrane at a structure called the porosome that dumps its contents out of the cell's environment). This process can be further broken down

into *pinocytosis* (or fluid-phase endocytosis), where the cell membrane engulfs dissolved substances and fluids, and *phagocytosis* (solid-phase endocytosis), where the cell membrane engulfs microscopically visible particles. The exocytic vesicles are created from a number of sources, including endosomes traversing the cell, while others are derived from the endoplasmic reticulum and Golgi apparatus expelling various substances from the intracellular space.

DIGESTIVE SYSTEM ORGANIZATION OVERVIEW

An average adult consumes about 1100 lb of food and about 150 gal of water each year. On average, approximately 10 L of chyme flows through the alimentary canal per day; about 100–150 mL of fluid remains in the feces and is egested through the anus [16,289]. The major subdivisions of the GI tract from the proximal to distal end include the mouth, where preparation of the nutrients occurs by mastication; the pharynx, which participates in swallowing; the esophagus, which functions as a conduit; the stomach, which serves as a reservoir for mixing and digestion and regulates content delivery; the small intestine, which serves as a digestive and absorptive organ; the large intestine, which absorbs water and electrolytes and processes the luminal contents for elimination; the rectum, which serves to accumulate and expel fecal material; and the anus, which controls defecation.

Digestion itself includes mechanical as well as chemical functions. The mechanical functions include chewing to reduce the size of the food to smaller particles, churning activities of the stomach that continue the reduction process, and finally the peristaltic action of the small and large intestines that propels food through the system. The chemical functions include a series of catabolic chemical reactions that ultimately break down protein into basic amino acids, convert carbohydrates into glucose, or convert fat into fatty acids and glycerol. As the food moves through the GI tract, it is mixed with various secretions that, combined with mechanical digestion, allow nutrients to pass through the walls of the epithelium cells into the body's blood and lymph capillaries.

Control of Digestive System Function

Because the digestive system is critical for survival of the organism, the entire GI tract is under robust control by electrical and chemical regulatory processes. Some of the signals originate from within the digestive tract and some originate external to the GI tract [17]. Some signals coordinate various sections of the digestive system, while others link the digestive system and the conscious brain. The central nervous system (CNS) and the GI system are in communication with each other. The CNS receives signals about gut tension, the chemical environment, and tissue conditions through afferent neurons from the GI tract [18]. The CNS, in turn, through efferent neurons, modulates the GI tract responses during the cephalic phases of digestion. The primary route of communication is through the vagal, splanchnic, and sacral nerve trunks [19].

The GI tract is unique among mammalian organs because it has its own nervous system—referred to as the *intrinsic* or *enteric nervous system* (ENS)—which is quite complex and is recognized as an integrative neuronal system separate from the CNS [20]. The ENS consists of nerve cell bodies that are embedded in the wall of the GI tract. There are about 100 million enteric neurons that are grouped in aggregates (termed enteric ganglia) that connect to one of two major ganglionated plexi in the GI tract: the myenteric or Auerbach plexus and the submucosal or Meissner plexus [21,22].

The GI tract is also affected by hormones produced in distant endocrine glands as well as many hormones produced within the GI tract itself [20,284]. The endocrine cells within the GI tract are collectively referred to as the *enteric endocrine system* (EES). The EES is scattered as single cells throughout the intestinal tract, located within the intestinal crypts and villi, and comprised 1% of the epithelial cell population [23]. There are at least 15 subtypes of enteroendocrine cells, which make up the EES that secrete multiple peptide hormones that assist in the control of physiological and homeostatic functions in the digestive tract, particularly postprandial secretion and motility [21].

Enteric Nervous System

The ENS can and does perform many of its tasks with little or no CNS control; however, normal digestive function requires coordination between the ENS and the CNS. These links are either parasympathetic connections (usually excitatory signals from the vagus and spinal nerves that stimulate motility and GI secretions) or sympathetic connections (usually inhibitory signals from the postganglionic fibers that reduce peristalsis and secretory activity), which permit signals from the CNS or the ENS to directly connect to the GI tract [21].

The entire length of the walls of the GI tract contains two complete networks of neurons. These neuronal networks include (1) the myenteric plexus (also known as the plexus of Auerbach), which is located between the circular and longitudinal layers in the muscularis and is active in the control of motility in the GI tract, and (2) the submucosal plexus (also known as the plexus of Meissner), which is located in the submucosa and is active in controlling blood flow and cellular secretions. Three basic types of neurons are located throughout the enteric plexuses. Sensory neurons respond to mechanical, osmotic, thermal, and chemical stimulation and provide the enteric plexus with a continuous and comprehensive status report on the state of the GI tract wall. Interneurons process signals from the sensory neurons and relay them to the enteric motor neurons. Motor neurons exert control over GI tract motility and some gastric secretions. These neurons secrete many neurotransmitters, but the primary excitatory neurotransmitter is acetylcholine; the primary inhibitory neurotransmitter is norepinephrine.

Enteric Endocrine System

The GI tract is the largest endocrine organ in the body, and it controls digestive function by producing hormones from many single-hormone-secreting cells that are located throughout the

mucosal of the stomach and small intestine. Over 25 hormones have been identified throughout the length of the GI tract. In 1969, Pearse [24] coined the term *amine precursor uptake and decarboxylation* (APUD) cells to describe cells dispersed throughout the body having a common ability to add and decarboxylate monoamines to bioactive amines. Characteristic amines and peptides have since been found widely distributed in not only APUD cells but also neurons located in different organs, thus giving rise to the concept of a common regulatory system termed the *diffuse neuroendocrine system* (DNES) [25,26]. APUD cells have been identified in many organs and include over 60 cell types, such as hypothalamus, adenohypophysis, pineal, parathyroid, thyroid, adrenal, placental, pancreas, GI tract, lung, urogenital tract, skin, carotid body, and sympathetic ganglia cells. These cell types have the common ability to produce biogenic amines by absorbing 5-hydroxytryptophan and L-dihydroxyphenylalanine and subsequently decarboxylating them.

Regulation of the GI tract and most other biological systems is very complex. Complicated interactions occur among the endocrine system, the CNS, the peripheral nervous system, and cells located throughout the organism. These systems communicate with neurotransmitters and neurohormones both locally and distally; thus, they appear to have regulatory roles through neurocrine, endocrine, and paracrine mechanisms. Paracrine hormones are those released by endocrine cells within the GI tract that can affect other local endocrine cells that are normally not targets for these hormones. Several peptides are active endocrine modulators of GI function and can act in a paracrine fashion as well. Some of the paracrine hormones include guanylin, histamine, motilin, neuropeptide Y (NPY), serotonin, somatostatin, substance P, uroguanylin, and vasoactive intestinal peptide. Studies have shown that immune cells produce regulatory peptides as well as antibodies that can affect cells locally and at other mucosal sites, as well as within the brain itself. This finding has led researchers to utilize the phrase *common mucosal immune system* (CMIS) [27,28]. Hence, there is an intricate and critical commonality among the endocrine, nervous, and immune systems, which act in concert to regulate the GI tract [29,282]. APUD and DNES cells are polypeptide-secreting cells that are able to act upon contiguous or nearby cells (paracrine), distant cells (endocrine), or neuronal cells (neurocrine) to regulate numerous signals. It has recently been suggested, however, that the term *diffuse neuroimmunoendocrine system* (DNIES) be used instead of DNES to more correctly describe the total integration of signaling mechanisms found in GI tract regulation [30,31]. Table 31.3 summarizes some of the most common hormones found in the alimentary canal.

Mouth and Tongue

Food enters the digestive system through the oral or buccal cavity, the outer opening of which is protected by the lips (or labia). The oral cavity is lined with mucous membranes and has as its lateral walls the cheeks; the hard palate, which forms the anterior roof, and the soft palate, which forms the posterior roof. The tongue constitutes the floor of the oral cavity and is a muscular organ that is attached underneath by the frenulum. The teeth (primarily the anterior incisors) begin the ingestion process by biting off suitable portions that can be retained in the mouth. When sufficient food is retained in the mouth, it is masticated by the molars and premolars and mechanically broken down into smaller particles by tearing, grinding, and chewing. The tongue is made up of six different muscles that allow for finite control during the mastication process. The process is aided by saliva, which is secreted from three pairs of salivary glands: parotid, submaxillary, and sublingual. A total of 1.5 L of saliva is secreted by these three glands every 24 hours [35]. Ordinarily, the mucous membranes produce only enough saliva to simply keep the mouth and pharynx moist by the parasympathetic nervous system; however, when food is introduced into the mouth, salivary secretions increase dramatically.

Food stimulates some of the 2000 taste bud receptors located primarily on the tongue. The taste buds not only provide a sense of taste to the brain but also send impulses to the salivary nuclei located in the medulla and pons. Impulses returning to the salivary glands from the salivary nuclei activate the increased secretion of saliva. Saliva contains two main types of protein secretions: (1) serous secretion by the parotid glands, which contains α-amylase and digests starches, and (2) mucous secretion by the submandibular and sublingual glands, which contains mucin for lubrication. Saliva itself is 99.5% water and 0.5% solutes [36]. The solutes include chlorides, bicarbonates, sodium phosphates, urea, uric acid, serum albumin, serum globulin, mucin, lysozyme, and α-amylase [37].

The saliva contents help liquefy the food for ease of passage through the GI tract. Ptyalin or salivary amylase initiates the breakdown of starches into glucose that also begins the chemical digestion process. Only a small portion (<5%) of the starch is actually digested in the mouth because of the quick transit time from the mouth to the esophagus and beyond. Bicarbonate ions tend to neutralize acids, and lysozyme helps to inhibit the bacteria present in many foodstuffs. Saliva also helps to cleanse the mouth and protect the teeth, as they are constantly bathed in fresh saliva. In addition to saliva, lingual lipase is secreted at the base of the tongue to initiate the process of fat digestion. It appears to have a minor impact on fat digestion [38].

Pharynx, Larynx, and Swallowing

The posterior exit of the mouth leads to the pharynx through a ring of palatine and lingual tonsils. The pharynx is the passageway for the foodstuff from the mouth to the esophagus and also serves as a conduit to the respiratory tract. Food movement must be coordinated to keep the respiratory tract clear of food as it passes on its way to the esophagus. The *swallowing reflex*, or *deglutition*, moves food into the esophagus by a combination of voluntary and involuntary muscle movements. The swallowing action moves food from the

TABLE 31.3
Enteric Hormones

Hormone	Location	Function
α-Amylase	Salivary glands and pancreas	Breaks down long-chain carbohydrates, yielding maltotriose and maltose from amylose or maltose, glucose, and *limit dextrin* from amylopectin.
Calcitonin receptor–like receptor (CALCRL)	GI tract	Receptor for peptide vasodilator; can function in the transmission of pain.
CCK	Duodenum (small intestine)	Control of pancreatic enzymes and bile secretion.
Galanin	CNS and duodenum	Implicated in many biologically diverse functions, including nociception, waking and sleep regulation, cognition, feeding, regulation of mood, and regulation of blood pressure.
Gastrin	Stomach	Control of gastric acid secretion.
Gastric-inhibitory peptide	Duodenum and jejunum (small intestine)	Control of gastric acid secretion and fatty acid metabolism.
Ghrelin	Stomach and pancreas	Promotes intestinal cell proliferation and inhibits its apoptosis during inflammatory states and oxidative stress and enhances the motility of GI tract.
Glucagon-like peptides	Ileum and the cecum, where proglucagon is cleaved into glucagon-like peptide 1 (GLP-1), GLP-2, and oxyntomodulin	GLP-1 lowers blood glucose levels and inhibits gastric and pancreatic secretions; GLP-2 may increase proliferation rate of GI tract cells; oxyntomodulin may inhibit gastric and pancreatic secretions and slow motility.
Guanylin	Small intestine	Activates production of cGMP; inhibits sodium absorption.
Ghrelin	Stomach	Control of growth hormone and energy balance.
Histamine	Small intestine	Activates acid secretion.
Insulin		
Leptin	Gastric chief cells and P/D1 cells in the stomach	Controls appetite and metabolism.
Motilin	Duodenum (small intestine)	Control of motility pattern in the small intestine.
Neuromedin U	Receptors located in CNS and GI tract	NmUR1 receptor located in the GI tract that regulates internal calcium concentration and inhibits cAMP production.
NPY	Small intestine	Stimulates appetite and increases fat storage.
Neurotensin	Endocrine cells and neurons in GI tract	Initiates smooth muscle contraction.
Peptide $YY_{3–36}$	Small intestine	Inhibits appetite and stimulates pancreatic and gall bladder secretions.
Secretin	Small intestine	Control of bicarbonate-rich secretions from the pancreas and liver.
Serotonin (5-HT)	Small intestine	Activates intrinsic motor neurons.
Somatostatin	Small intestine	Control of gastric secretions.
Substance P	Endocrine cells and neurons in GI tract	Activates pancreatic and bile secretion, increases motility, increases release of histamine.
Uroguanylin	Small intestine	Binds to guanylyl cyclase receptors and activates synthesis of cGMP.
Vasoactive intestinal peptide	GI tract	Control of musculature of GI tract; control of water and gastric acid secretions.

rear of the mouth through the pharynx and past the larynx into the esophagus and ultimately into the stomach. It can be divided into three separate functions: (1) the voluntary stage, where the bolus is directed to the rear of the oral cavity and into the pharynx; (2) the pharyngeal stage, an involuntary stage where the bolus moves through the pharynx, past the larynx, and into the top of the esophagus; and (3) the esophageal stage, also an involuntary stage, where the bolus moves through the esophagus into the stomach.

When an appropriate mass of food is chewed and moistened, a bolus is moved toward the pharynx primarily by the voluntary action of the tongue and lips, which direct the food toward the pharynx. As the bolus moves out of the mouth, it produces pressure on the rear of the pharynx, which sends an impulse to the deglutition center in the medulla and pons in the brain stem. The returning impulses trigger a complicated set of involuntary muscular contractions and relaxations in the pharynx that elevate the soft palate, close off the nasopharynx,

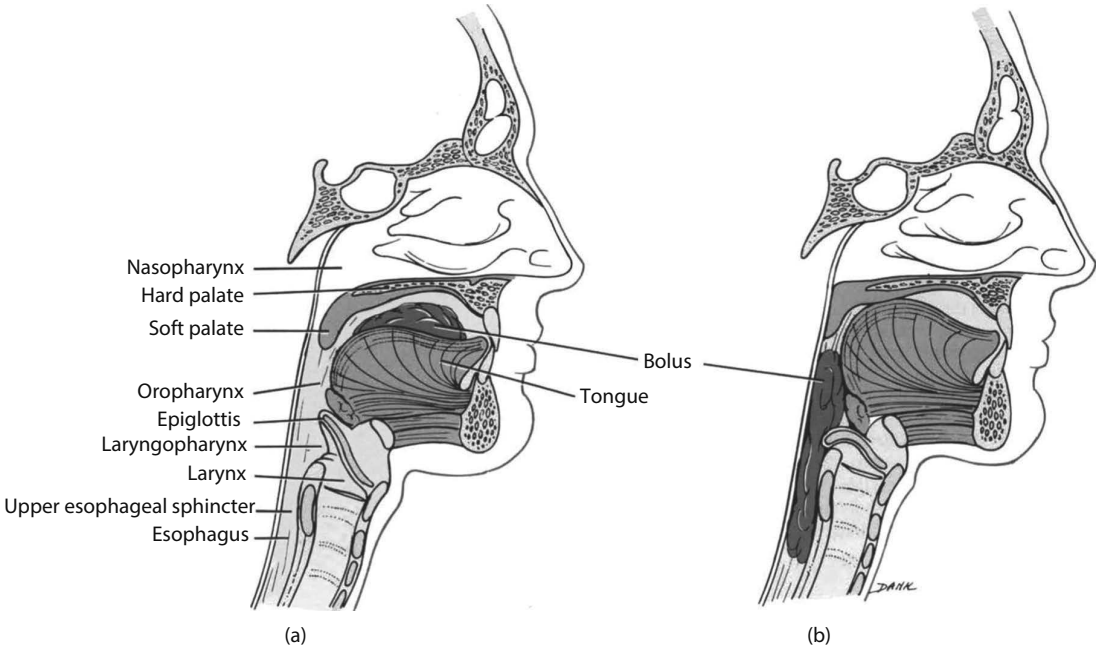

FIGURE 31.4 (a) Oral and (b) pharyngeal movements during deglutition, or the swallowing reflex. (From Tortora, G.J. and Anagnostakos, N.P., The digestive system, Chapter 24, in: *Principles of Anatomy and Physiology*, 6th edn., HarperCollins: New York, 1990, p. 743. With permission.)

and push the food downward toward the larynx. These contractions elevate the hyoid and larynx and move the epiglottis downward, closing the entrance to the trachea to prevent food from entering the respiratory tract. When the bolus has passed the larynx and entered the esophagus, the epiglottis reopens and breathing resumes. Figure 31.4 illustrates the swallowing process. A summary of the basic interactions and functions of the swallowing reflex is presented in Table 31.4.

Esophagus

The primary function of the esophagus is to simply transport masticated foodstuffs from the oral cavity to the stomach. A bolus of food leaves the oral cavity and continues to move through the cricopharyngeal sphincter located at the upper end of the esophagus that subsequently closes, preventing upward movement of the bolus. The esophagus is the third and final organ involved in the swallowing reflex process. Normally, this sphincter is contracted, closing the mouth of the esophagus. The esophagus is a muscle-walled tube about 10 inches long that connects the pharynx to the stomach. It passes behind the heart through the diaphragm and into the abdominal cavity. In its resting stage, the esophagus is collapsed. The upper third of the esophagus contains striated muscle, while the lower two-thirds contains smooth muscle. When the bolus has entered the esophagus, its movement is

TABLE 31.4
Summary of the Swallowing Reflex

Structure	Activity	Function	Control Status
Mouth/teeth/tongue	Tearing, mastication, and bolus manipulation	Preparation of appropriate-sized bolus; movement into the pharynx	Voluntary
	Secretion of mucus	Lubrication for passage into pharynx	Voluntary/involuntary
Pharynx	Triggers deglutination center in brainstem	Elevates the soft palate, closes off the nasopharynx	Involuntary
Larynx	Impulses received from brainstem	Elevates the hyoid and larynx and moves epiglottis over trachea	Involuntary
Esophagus	Receipt of bolus from pharynx	Opening of upper esophageal sphincter	Involuntary
	Initiation of peristalsis	Movement of bolus through esophagus	Involuntary
	Secretion of mucus	Lubrication for passage into stomach	Involuntary

Sources: Data from Tortora, G.J. and Derrickson, B., The digestive system, Chapter 24, in: *Principles of Anatomy and Physiology*, 13th edn., John Wiley, Hoboken, NJ, 2012, pp. 967–1023; Tamir, E., *The Human Body Made Simple*, 2nd edn., Churchill Livingstone, Edinburgh, U.K., 2002, pp. 71–92.

controlled by the smooth muscles in the wall of the esophagus; they contract in a rhythmic sequence and propel the bolus downward toward the stomach. These waves of muscular contractions are called *peristaltic waves* and are the mode of transit throughout the remainder of the GI tract. In the esophagus, the transit time is quite brief and no meaningful digestion occurs in the esophagus.

The lower end of the esophagus just above the level of the diaphragm has a sphincter called the *lower esophageal* or *gastroesophageal sphincter.* This structure helps separate the lumen of the esophagus from the lumen of the stomach and prevents reflux of the stomach contents backward into the esophagus. Unlike the rest of the GI tract, the esophagus does not have an outer serosa covering, which makes it susceptible to the spread of tumor cells. Blood is supplied from the inferior thyroid artery to the upper esophagus, the tracheobronchial arteries to the middle esophagus, and the left gastric artery to the middle esophagus. The esophagus is also drained of blood by three venous pathways: the upper third into the superior vena cava, the middle third into the azygous system, and the lower third into the portal vein.

Sensory stimulation of the esophagus is transported through the vagus nerve to the tractus solitarius. The thoracic sympathetic nerves also carry afferent nerve impulses to the esophagus. The parasympathetic nervous system is primarily derived from the vagus nerve, with supplemental impulses from the upper portion by the glossopharyngeal and spinal accessory nerves [40–42]. The peristaltic action in the esophagus is initiated by the presence of the bolus, which expands the esophageal walls; subsequently, stretch receptors are activated to contract behind the bolus and relax in front of the bolus. This occurs as one continuous wave that propels the bolus past the sphincter and into the stomach. The esophageal lumen is lined with stratified squamous epithelia, which are continually being renewed. As the squamous cells migrate toward the lumen, they change physical characteristics and are eventually sloughed off [43–45]. The outer lumen is protected by a coat of keratin that can resist degradation by the various proteolytic enzymes. Mucus-secreting glands located in the submucosal layer lubricate the esophagus and assist with the passage of the bolus. There are species differences in the amount of keratin present (e.g., dogs have less keratin than rodents do) and in the density of the mucous glands (e.g., rodents have none).

Stomach

The bolus continues from the lower esophageal sphincter into the stomach through an upper opening termed *cardia*. There is no circumferential muscle at the cardia; however, the anatomical structure of the area prevents the reflux of the stomach contents backward into the esophagus. The stomach is a J-shaped muscular structure with a capacity of about 2 L. It is located in the upper left anterior quadrant of the abdominal cavity. Much of the surface of the stomach is behind the lower rib cage. The stomach serves as a reservoir and as a digestive organ. It is divided into four distinct areas: the cardiac region, the fundus, the corpus, and the pyloric region [46]. The part of the corpus that is adjacent to the pyloric region is sometimes referred to as the *antrum* [47,48]. The structure and cellular composition of the tall columnar stomach epithelium remain constant throughout the different areas of the stomach. These cells contain mucus-producing apical vacuoles that produce a high-molecular-weight polymer consisting of a protein backbone with carbohydrate side chains that are held together by disulfide bonds [49]. This polymer forms a 1 mm thick secretory sheath that protects the mucosa from the acidic gastric fluids found in the stomach, most likely by retarding the normal diffusion of hydrogen ions [288]. These surface epithelia are renewed every 72 h by the isthmus of the gastric glands, where mitotic activity is increased and the new cells migrate toward the surface.

The major biochemical feature of the stomach is its acid-secreting properties. The stomach mucosa contains many folds, called *rugae*, which further contain narrow openings, termed *gastric pits*, which are formed as a result of mucosal cells penetrating the connective tissue downward into the lamina propria. The wall of the stomach is lined with gastric glands that are interspersed in the surface or in these gastric pits. The gastric pits contain, besides the previously noted mucous cells, three types of cells: parietal cells, which are found in the middle of the pits and produce hydrochloric acid and intrinsic factor; chief cells, also known as zymogenic cells, which are found at the bottom of the pits and produce pepsinogen, prochymosin, and gastric lipase; and enteroendocrine or G cells, which are found in the glands in the lower fundus or antrum and produce gastrin. During a meal, the stomach gradually fills up to a capacity of approximately 1–2 L. The secretions of the various cells types are controlled by impulses from the vagus nerve and by GI reflexes mediated through neural, autacoid, and endocrine signals [50,51]. Figure 31.5 shows the general organization of the stomach.

Hydrochloric acid does not directly function in the digestion process; however, it inhibits microorganisms and lowers the stomach acidity, which, in turn, inhibits emptying of the stomach. In addition, stomach pH is a critical determinant in the absorption kinetics of electrolytes and it activates pepsinogen. Carbohydrate digestion, which begins in the mouth upon exposure of the foodstuff to amylase, continues as the bolus passes into the stomach. The bolus is further broken down into acid chime in the lower third of the stomach that inhibits further carbohydrate breakdown. At this point, the enzyme pepsinogen initiates protein digestion. Pepsinogen is activated by hydrochloric acid cleaving off a portion of the molecule, thus creating the enzyme pepsin, which breaks off peptides from proteins. Intrinsic factor is a protein that binds vitamin B_{12} to enable absorption by the ileum of the small intestine. Table 31.5 presents a summary of mucosal secretions in humans.

When sufficient food enters the stomach, peristaltic movement, termed *mixing waves*, passes through the stomach every 15–25 s [37]. This movement combined with the stomach secretions reduces the foodstuff to a thin liquid termed *chyme*. The fundus section of the stomach shows little mixing movement and can function as a holding area for the chyme for up to an hour or more. During the time in the fundus,

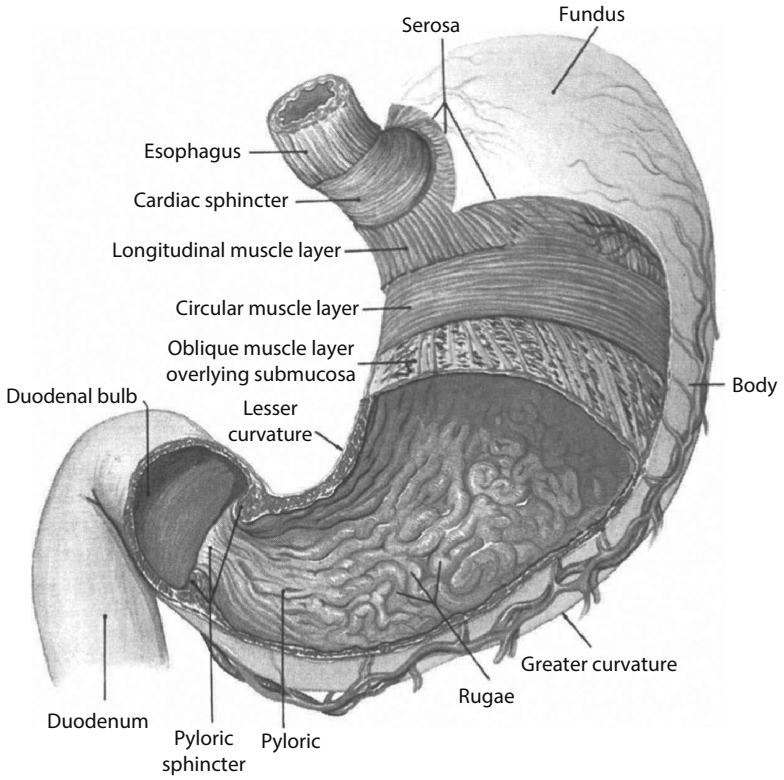

FIGURE 31.5 Structure and general organization of the stomach. (From Raufman, J.-P., Stomach: anatomy and structural anomalies, Chapter 64, in: *Textbook of Gastroenterology*, vol. 1, 4th edn., Yamada, T. et al. (eds.). Lippincott Williams & Wilkins, Philadelphia, PA, 2003, p. 1283. With permission.)

amylase digestion continues. The peristaltic wave action of the stomach walls propels the contents toward the pyloric sphincter. The pylorus is usually nearly closed and permits only very thin (and hence thoroughly digested) chyme into the duodenum of the small intestine. The larger contents are then turned back into the body of the stomach for further agitation and breakdown into smaller particles. Food remains in the stomach for variable periods of time depending on its size and composition. This period can be from 30 min to several hours or longer. The continuous peristaltic action of the stomach and the degree of contraction of the pyloric sphincter allow for the proper amount of chyme to enter the small intestine to allow proper absorption of nutrients. Little absorption occurs in the stomach because the stomach wall

TABLE 31.5
Summary of Stomach Mucosal Secretions

Structure	Activity	Function
Mucous cells	Secretion of mucus	Prevents mucosal wall digestion
Parietal cells	Secretion of hydrochloric acid	Converts pepsinogen to active form (pepsin); maintains pH at ~2 for optimal pepsin functioning
	Secretion of intrinsic factor	Necessary for vitamin B_{12} absorption (required for RBC formation)
	Secretion of hydrogen potassium ATPase	Necessary for the acidification of the stomach contents
Chief (zymogenic) cells	Secretion of pepsinogen	Provides pepsin precursor that breaks down protein chains into peptides for absorption
	Secretion of gastric lipase	Assists in the breakdown of certain triglycerides with short-chain fatty acids
	Secretion of prochymosin	Provides chymosin precursor that coagulates milk protein, allowing it to be retained longer in the stomach for more complete digestion
Enteroendocrine (G) cells	Secretion of gastrin	Stimulates further gastric secretion, closes lower esophageal sphincter, increases muscular activity in the stomach, and opens pyloric sphincter

Source: Data from Tortora, G.J. and Derrickson, B., The digestive system, Chapter 24, in: *Principles of Anatomy and Physiology*, 13th edn., John Wiley, Hoboken, NJ, 2012, pp. 967–1023.

is impermeable to most materials. However, there are a few exceptions because the stomach does absorb small amounts of electrolytes, water, alcohol, and acetosalicylic acid.

Regulation of Gastric Secretion

The secretion of gastric enzymes is controlled in three separate phases: (1) cephalic phase, (2) gastric phase, and (3) intestinal reflex [37,52]. The cephalic phase is stimulated by chemoreceptors and mechanoreceptors in the nasal and buccal cavities; these receptors send impulses from the cerebral cortex in the hypothalamus through the vagus nerve that cause the release of acetylcholine, gastric lipase, and gastrin-releasing peptides from interneurons in the stomach. These impulses arising from the sight, smell, or even thought of food act on the parietal cells and G cells. In this way, the body prepares gastric secretion levels in the stomach to receive the anticipated food.

The gastric phase is both nerve and hormonally controlled. When food reaches the stomach, it causes distention and stimulates nervous receptors in the stomach wall. Distention activates the long vagovagal reflexes and the short local reflexes, which, in turn, send impulse to the medulla and back to the stomach, which release acetylcholine [51]. The release of acetylcholine stimulates the flow of hydrochloric acid from parietal cells and gastrin from G cells. The presence of peptides will also stimulate the production of hydrochloric acid through gastrin release by direct action on the G cells. This phase controls about 80% of the secretions released from the stomach [52].

The intestinal phase accounts for a small amount of gastric secretion. The presence of chyme in the duodenum stimulates the mucosa to release enteric gastrin. This substance causes the circulating gastrin to increase acid production through activation of the G cells, but in limited amounts. A summary of the factors that influence the stimulation of gastric secretion is provided in Figure 31.6.

The inhibition of gastric secretion occurs when partially digested carbohydrates and lipids enter the duodenum and initiate the enterogastric reflex, which involves impulses sent from the walls of the duodenum to the medulla and back to the gastric glands in the stomach. Additional chemical regulatory actions that ensure that excess acid production does not accumulate in the stomach include the following [52]:

- *Lowered pH*—gastric secretion is inhibited at pH < 3.
- *Cholecystokinin* (*CCK*)—triggered by the presence of chyme lipids and carbohydrates, this hormone is secreted by the intestinal mucosa; it inhibits gastric secretions, decreases GI tract motility, stimulates secretions from the pancreas while relaxing the sphincter at the hepatopancreatic ampulla, and increases the ejection of bile from the gall bladder.
- *Gastric-inhibitory peptide*—in the presence of fatty acids in the duodenum, this hormone is secreted by the intestinal mucosa; it inhibits gastric secretions and decreases GI tract motility.

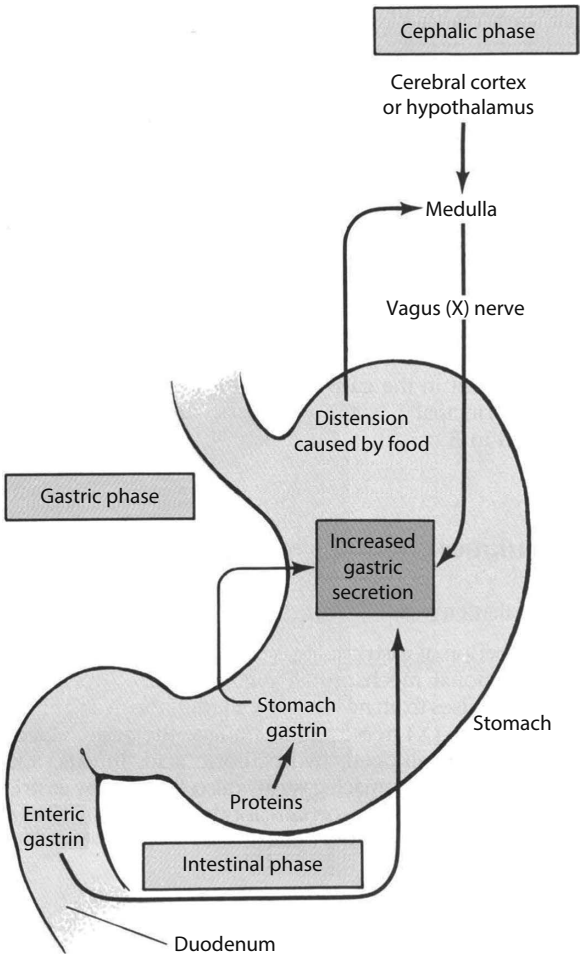

FIGURE 31.6 Schematic of the phases of gastric secretory regulation. (From Tortora, G.J. and Anagnostakos, N.P., The digestive system, Chapter 24, in: *Principles of Anatomy and Physiology*, 6th edn., HarperCollins, New York, 1990, p. 750. With permission.)

- *Secretin*—in the presence of acid, chyme, or fluids in the duodenum, this hormone is secreted by the intestinal mucosa; it inhibits gastric secretions, decreases GI tract motility, and stimulates secretions from the pancreas, liver, and small intestinal glands.

Small Intestine

The small intestine is where the digestion of fat, protein, and almost all carbohydrates is completed and much of the absorption of nutrients occurs. The small intestine begins at the pylorus of the lower end of the stomach and ends at the juncture of the large intestine, a 15–20 ft distance [37,53]. The tube averages approximately 1 in. in diameter and is subdivided into three segments. The duodenum connects to the stomach and is the shortest segment at about 10 in. The jejunum is about 8–10 ft in length and extends to the ileum. The ileum is about 10–12 ft in length and attaches to the large intestine at the ileocecal sphincter. Most digestion occurs in the duodenum, where digestive enzymes are added from the

pancreas, gallbladder, and glands in the wall of the duodenum. The jejunum and ileum primarily absorb the digested nutrients from the duodenum.

The entire small intestine is comprised of the four basic layers that make up the vast majority of the GI tract. There are some variations that permit the small intestine to finish the digestion process and initiate the majority of the absorption process. The small intestine mucosa contains gastric pits that are lined with glandular epithelium glands called the *crypts of Lieberkühn*. These glands secrete *intestinal juice*, which is a clear, yellow, alkaline fluid containing primarily water and mucus in amounts of up to 3 L/day. Additional enzymes such as maltose, α-dextrinase, sucrase, lactase, aminopeptidase, dipeptidase, ribonuclease, and deoxyribonuclease are added to the chyme in the small intestines. Many of these enzyme-producing cells digest the chyme on the cell surface rather than in the lumen of the intestine. This intestinal juice is quickly reabsorbed by the small intestinal villi, and that physical process brings the chyme into the proximity of epithelial cells that secrete intestinal enzymes. The submucosa contains duodenal Brunner's glands, which secrete alkaline mucus. As in the stomach, the mucus protects the mucosa from breakdown by the hydrochloric acid and helps to neutralize acid present in the chyme.

The structure of the small intestine is especially suited for digestion and absorption. Absorptive cells with finger-like projections, called *microvilla*, greatly expand the surface area of the membrane. The mucosa is arranged in a series of villa that protrude into the intestinal lumen and further increase the functional surface area. Each villus has a core of lamina propria. Embedded in this connective tissue are an arteriole, a venule, a capillary network, and a lymphatic vessel (lacteal), which allow nutrients to pass through the capillary wall directly into the lymphatic and cardiovascular systems. Additional projections, called plicae circulares, are located in the proximal end of the duodenum and terminate at about the middle portion of the ileum. These plicae circulares not only increase the surface area but also cause the chyme to swirl as peristalsis moves it through the small intestine, thus increasing the absorption process. These adaptations in surface area increase the absorptive surface area many times and provide an estimated 250–500 square yards of absorptive surface. Finally, located primarily in the lower part of the small intestine (the ileum) are 30–40 lymphatic nodules called Peyer's patches, which are part of the autoimmune system; they detect microorganisms and produce antibodies designed to fight infection [53,54]. In addition to its own enzyme secretions, the small intestine utilizes the fluid from three additional structures: (1) the pancreas, (2) the liver, and (3) the gallbladder. The contributions of each of these accessory organs are briefly summarized in the following.

Pancreas

The pancreas is a tubuloacinar gland that measures approximately 1 in. wide by 5 in. in length. The pancreas contains two types of glands. One type is hormonal in nature and consists of clusters of glandular epithelial cells called *pancreatic islets* (islets of Langerhans), which produce the hormones glucagon, insulin, and somatostatin. The remaining cells, called *asini*, comprise a vast majority of the organ; they represent the exocrine part of the pancreas and produce digestive enzymes or pancreatic juice. Up to 2 L of clear, colorless pancreatic juice is produced each day. The asini communicates directly with the intralobular ducts, which eventually collect into the major pancreatic duct or the duct of Wirsung. Generally, this duct unites with the common bile duct, which enters the upper end of the duodenum in a duct common to both organs, termed the *hepatopancreatic ampulla* or the *ampulla of Vater*. This digestive fluid consists of water, sodium, potassium, sodium bicarbonate, and various enzymes, including pancreatic amylase, trypsinogen, chymotrypsinogen, procarboxypeptidase, proelastase, pancreatic lipase, ribonuclease, and deoxyribonuclease. Trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase are activated by various enzymes within the small intestine; they are produced in an inactive form in the pancreas so as not to break down and digest the pancreas itself. The pancreas is regulated by nervous and hormonal mechanisms. Impulses are also sent along the vagus nerve concurrent with the cephalic and gastric phases of gastric regulation noted previously, which stimulates the production of pancreatic juice. Hormonal regulation includes responses from chyme entering the duodenum that can release secretin or CCK. Secretin, which is produced by S cells of the duodenum in response to hydrogen ions, stimulates the production of pancreatic juice rich in sodium bicarbonate ions; CCK, which is produced by the I cells of the duodenum in response to peptides and fatty acids, stimulates the production of pancreatic juice rich in digestive enzymes [56,57]. The general structure and relative location of the pancreas are shown in Figure 31.7.

Liver

The liver is a triangular/cone-shaped organ located under the diaphragm; it weighs about 3 lb in the average adult. In addition to its digestive functions, the liver also participates in the detoxification of blood, synthesis of blood proteins, replenishment of erythrocytes, storage of glucose as glycogen, and the production of urea. The digestive functions include the production of bile. The liver consists of two main lobes—a smaller left lobe and a larger right lobe—both of which are made up of thousands of lobules separated by the falciform ligament. Contained within each lobule are an arteriole, a venule, and a biliary duct. Arteriole blood and venous blood are mixed in the canals of these lobules. Hepatocytes are in direct contact with the blood flowing in these canals. The biliary ducts in the canals serve to drain the bile from hepatocytes into the lobules. These lobules are connected to small ducts that connect with larger ducts to ultimately form the hepatic duct. The liver produces and secretes as much as 1 L of bile each day, and the hepatic duct transports the bile to the gallbladder and upper section of the duodenum. Bile is a watery green fluid with a pH of 7.6–8.6; it contains bile salts,

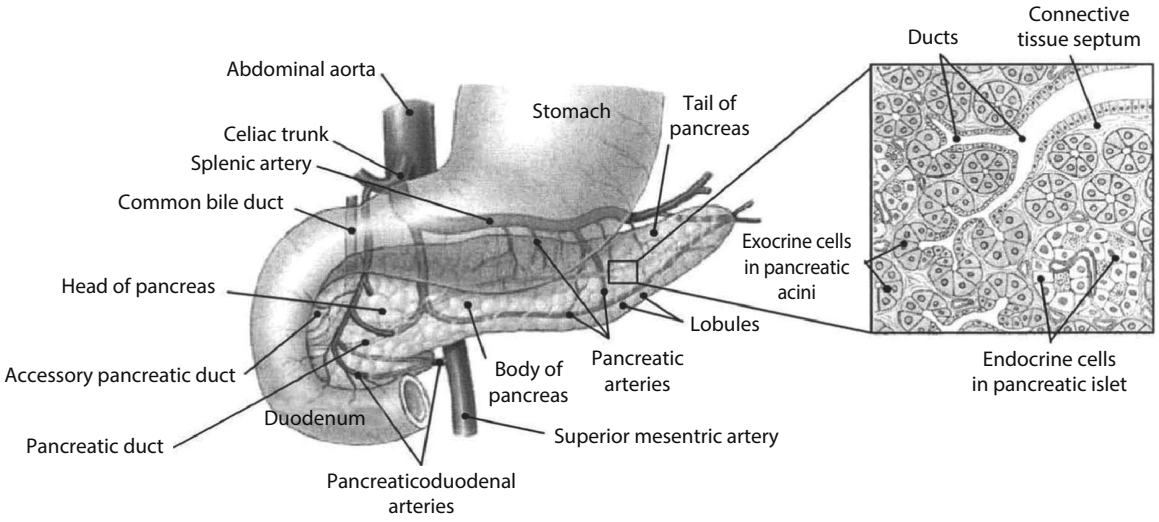

FIGURE 31.7 Structure and general organization of the pancreas. (From Martini, F.H., *Fundamentals of Anatomy and Physiology*, 7th edn., Pearson Education, Glenview, IL. Copyright © 2006 by Frederick H. Martini, Inc. With permission.)

bile pigments (primarily bilirubin), cholesterol, neutral fats, electrolytes, and a phospholipid called *lecithin*. Bile salts and lecithin emulsify fats, and the remaining fluid contents are excreted as waste. Bile salts are emulsifiers that break down fat globules into small (1 μm diameter) droplets that are more easily absorbed in the presence of pancreatic lipase. Absorption of cholesterol is enhanced by bile salts and lecithin. The liver is also regulated by nervous and hormonal mechanisms. Vagus nerve impulses concurrent with the cephalic and gastric phases of gastric regulation noted previously can double the production of bile. Hormonal regulation includes the release of secretin when chyme enters the duodenum. Secretin, which is produced by S cells of the duodenum in response to hydrogen ions, stimulates the production of bile. High blood concentrations of bile salts can also act to increase the rate of bile secretion [58,59]. The structure and general organization of the liver are shown in Figure 31.8.

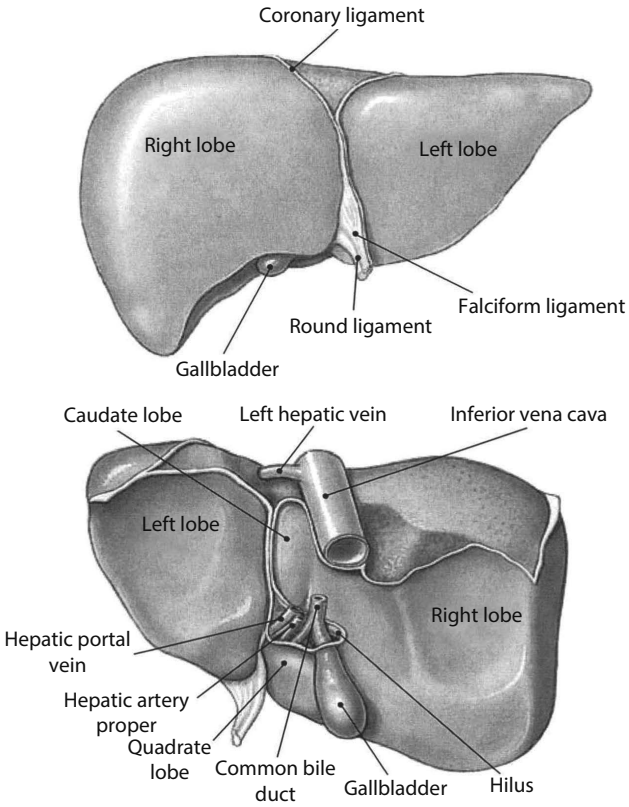

FIGURE 31.8 Structure and general organization of the liver. (From Martini, F.H., *Fundamentals of Anatomy and Physiology*, 7th edn., Pearson Education, Glenview, IL. Copyright © 2006 by Frederick H. Martini, Inc. With permission.)

Gallbladder

The gallbladder is a hollow, muscular, pear-shaped organ about 3–4 in. in length located immediately under the liver. The primary function of the gallbladder is to store, concentrate, and deliver bile from the liver to the small intestine. The gallbladder is normally relaxed and full of bile between meals. The gallbladder lumen mucosa contains simple columnar epithelial cells arranged in deep folds. The middle layer possesses smooth muscle instead of a submucosa that allows for the constriction process during the emptying of the organ. The outer layer consists of the visceral peritoneum. During the concentration of the liver bile, water and ions are absorbed through the mucosa. This organ delivers about 500 mL of bile to the duodenum each day. As noted in the sections on the pancreas, CCK, which is produced by the I cells of the duodenum in response to peptides and fatty acids, not only stimulates the production of pancreatic juice rich in digestive enzymes but also stimulates the contraction of the musculature of the walls of the gallbladder while simultaneously relaxing the sphincter at the mouth of the common bile duct, thus allowing the gallbladder to empty its contents into the duodenum [60,61]. The structure and general organization of the gallbladder and biliary ducts are shown in Figure 31.9.

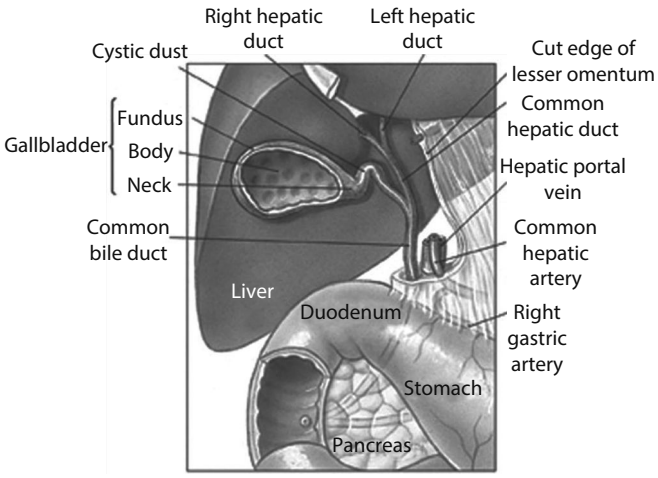

FIGURE 31.9 Structure and general organization of the gallbladder and biliary ducts. (From Martini, F.H., *Fundamentals of Anatomy and Physiology*, 7th edn., Pearson Education, Glenview, IL. Copyright © 2006 by Frederick H. Martini, Inc. With permission.)

Digestion and Absorption in the Small Intestine

The digestion process in the small intestine can be divided into the mechanics of movement and the chemical breakdown of foodstuffs. Movements in the small intestine include segmentation and peristalsis. Segmentation is a localized contraction that is not involved in the forward motion of the chyme through the GI tract. Segmentation simply forces the chyme into close proximity with the surface of the small intestine by contractions of 12–16 times/min [37]. Segmentation is primarily controlled by nerves in the intestinal walls that detect distention. Peristalsis, on the other hand, is a series of contractions and relaxations propelling the chyme through the GI tract. The peristalsis in the small intestine is very slow and deliberate, pushing the chyme through at a rate of about 1 cm/min and leaving the chyme in the small intestine for approximately 3–5 h. Peristalsis is similarly controlled by nerves in the intestinal walls that detect distention.

The chemical breakdown of the chyme begins as the article of food enters the GI tract in the mouth. The ptyalin in saliva initiates the conversion of starch to maltose. The stomach pepsin initiates the conversion of proteins to peptides. As the chyme enters the duodenum, it contains partially digested carbohydrates and proteins. The lipids are essentially undigested at this point in the process. As the chyme traverses the length of the small intestine, the digestive process is completed [62].

When the foodstuffs are prepared and digested as described earlier, the next critical phase is the absorption of the nutrients, which move across the epithelial cell lining of the GI tract and into the blood and lymphatic circulatory systems. It is estimated that about 90% of absorption occurs within the small intestine. The remainder occurs in the stomach prior to the foodstuff entering the small intestine or after the foodstuff leaves the small intestine and enters the large intestine. Absorption occurs in the villi by one of the following mechanisms: passive diffusion, facilitated diffusion, osmosis, or active transport. Roughly 10 L of fluid enters the small intestine and is absorbed each day. About 1–1.5 L is derived from saliva, 2–3 L is secreted by the stomach, about 2 L is secreted by the glands of the small intestine, about 1 L is contributed by the pancreas, and another liter enters as bile. Approximately 2 L is ingested as food and fluid each day. Of the 10 L, about 90% of the liquid is absorbed via osmosis by the blood capillaries of the villi in the small intestine [16,37,289]. The remaining 1 L is what actually passes through the ileocecal sphincter into the large intestine. The normal rate of absorption is approximately 200–400 mL/h.

It has been shown that the water moves in either direction across the intestinal mucosal cells to maintain an osmotic balance between the surface of the lumen, the cell interior, and the blood during uptake of elements of the chyme as well as electrolytes. Absorption in the small intestine is passive and requires the movement of solutes, so the rate of water uptake is a function of the solute absorption. Active transport of sugars and amino acids in the jejunum, in turn, causes passive movement of salt and water across the mucosal epithelial cells (cotransport). In the ileum, on the other hand, most of the water movement is by active transport via a specialized mechanism that pumps sodium into the lateral spaces within the cells. Water subsequently enters the lateral spaces from the cell (transcellular flux) or from the lumen (paracellular flux), resulting in an increased hydrostatic pressure and the transport of isotonic fluid into the extracellular space.

GI secretions and components of various ingested foods are sources of electrolytes for absorption in the small intestine. Intestinal transport of sodium has both active and passive mechanisms. Active transport can be independent or linked to the transport of other solutes such as sugar in a relationship referred to as cotransport. It is believed that cotransport accounts for most of the sodium absorption in the small intestine. The energy source for active sodium transport is the hydrolysis of adenosine triphosphate (ATP). Passive transport of sodium occurs primarily through the lateral spaces. Interestingly, in the presence of bicarbonate, sodium can be absorbed against an electrochemical gradient. It is suspected that a sodium–hydrogen exchange can account for this absorption. Chloride absorption is closely associated with sodium absorption by passive diffusion via the paracellular route, Na^+Cl^- cotransport, and Cl^-–HCO_3 exchange. Iodine and nitrate ion absorption is also closely related to sodium absorption and usually passively follows the sodium ions. Evidence suggests that these electrolytes can also be actively transported. Potassium absorption across the intestinal mucosal cells is determined by differences between two opposing unidirectional fluxes down the concentration gradient; it is passive in nature.

Gastric acid solubilizes calcium salts, which permits their being actively transported as the divalent cation. Parathyroid hormone in the presence of vitamin D (1,25-dihydroxycholecalciferol) increases the rate of Ca^{2+} absorption. Iron can be absorbed as heme iron, which is iron bound to hemoglobin, or as free Fe^{2+}. In the cytoplasm of the mucosal epithelial cells, the heme iron is broken down to the free Fe^{2+}, which

binds to apoferritin. As the free Fe^{2+} circulates in the blood, it binds to transferrin, which transports the free Fe^{2+} from the small intestine to the liver for storage.

Fat-soluble vitamins A, D, E, and K are incorporated into micelles and absorbed along with other lipids. Most water-soluble vitamins, including C and B complex (but not B_{12}, which requires intrinsic factor from the stomach), are absorbed by sodium-dependent cotransport or facilitated diffusion. Vitamin B_{12} absorption depends on gastric acid, pepsin, and intrinsic factor secreted from gastric parietal cells and the pancreatic duct cells. Intrinsic factor binds to and protects vitamin B_{12} from the digestion processes in the small intestine. Vitamin B_{12} binds to specific receptor sites in the mucosal epithelial cells of the ileum, where it enters by vesicular transport. Fat-soluble vitamins such as A, D, E, and K appear to be absorbed in micelles along with the dietary fats and are released into the lymphatic circulatory system. Water-soluble vitamins, such as the B vitamins and vitamin C, are absorbed across the GI tract by simple diffusion.

These digestion and absorption processes can also be categorized by type of substance entering the GI tract. The primary categories of foodstuffs include the following four major categories:

- Carbohydrates
- Proteins
- Lipids
- Nucleic acids

Carbohydrates

Generally, the digestion of carbohydrates occurs through the catalytic hydrolysis of α-1,4-glycosidic bonds situated between monosaccharides. The reaction is initiated by ptyalin, which is inactivated in the stomach by the acidic environment; however, it is completed by pancreatic amylase in the small intestine. These enzymes break down starches to the disaccharide maltose and to glucose polymers between three and nine molecules in length. It is believed that the rate of digestion of carbohydrate determines the place and form in which carbohydrate is absorbed [288]. Pancreatic amylase and ptyalin do not hydrolyze α-1,6-glycosidic bonds. As these maltose and other polysaccharides approach the lumen, they are exposed to maltose, sucrase, and lactase, which break down the disaccharides and glucose polymers to various monosaccharides such as glucose, fructose, and galactose. The branched polysaccharides are hydrolyzed by the action of the enzyme α-dextrinase. Table 31.6 provides a summary of the critical digestive processes of carbohydrates. Polysaccharides are not absorbable into the small intestine; hence, they must be reduced to monosaccharides, which are easily absorbed. Glucose and galactose are transported into cells by a sodium-dependent cotransport mechanism that transports glucose and sodium ions. The process uses energy generated by the sodium ion gradient to transport glucose and galactose into the epithelial cell. The transporter does not move sodium ions unless glucose is chemically bound to it. Once in the cell, fructose is converted from fructose to glucose. The resulting intracellular glucose from all sources is subsequently transported out of the cell into the extracellular space from that point by facilitated diffusion [63]. Table 31.7 provides a summary of the critical absorption mechanisms for carbohydrates found in the GI tract.

Proteins

Protein digestion is initiated in the stomach by the secretion of pepsinogen, which is activated to its active form—pepsin—in

TABLE 31.6
Summary of Carbohydrate Digestion

Enzyme/Digestive Fluid	Source	Process	Result
Ptyalin (α-amylase)	Salivary glands	Converts polysaccharides (starch) to disaccharides; the process is initiated in the mouth and is incomplete when the chyme reaches the small intestine.	Incomplete reaction to maltose (disaccharide); not absorbable in this form
Pancreatic amylase (α-amylase)	Pancreas	Completes the process initiated by the pytalin.	Maltose (disaccharide); not absorbable in this form
Maltase	Small intestine	Splits the disaccharide maltose into a monosaccharide.	Glucose (monosaccharide)
α-Dextrinase (isomaltase)	Small intestine	Hydrolyses 1,6-α-D-glucosidic bonds in dextrins and isomaltose produced after α-amylase degradation of starch and glycogen.	Glucose (monosaccharide)
Sucrase	Small intestine	Splits the disaccharide sucrose into two monosaccharides.	Glucose + fructose (monosaccharides)
Lactase (lactase–phlorizin hydrolase)	Small intestine	Splits the disaccharide lactose into two monosaccharides.	Glucose + galactose (monosaccharides)

the presence of hydrochloric acid. Interestingly, pepsin is the only enzyme capable of also digesting collagen. Additional inactive proteases are released by the pancreas in response to CCK. Trypsinogen is activated to trypsin, its active form, by enterokinase or enteropeptidase in the duodenum. Trypsin subsequently activates the additional pancreatic enzymes chymotrypsinogen and procarboxypeptidase to their active forms—chymotrypsin and carboxypeptidase. This protease activity converts proteins to one of the following: amino acids, dipeptides, or tripeptides. This breakdown of proteins is completed by the enzymes aminopeptidase and dipeptidase, both of which are secreted by enterocytes of the small intestine located on the lumen. Table 31.8 provides a summary of the critical digestive processes of proteins. In contrast to carbohydrates, which must be monosaccharides to be absorbed, the digested protein products of proteins can be absorbed as amino acids, dipeptides, and tripeptides. Once the dipeptides and tripeptides are transported into the intestinal cells, however, cytoplasmic peptidase hydrolyzes these peptides to amino acids. These substances are absorbed into and out of the epithelial cells by specific sodium-dependent amino acid cotransporters: neutral, acidic, basic, and imino [52]. Table 31.9 provides a summary of the critical absorption mechanisms of proteins.

Lipids

Lipids in the diet include triglycerides, neutral fats, cholesterol, cholesterol compounds, and phospholipids. As fats are ingested, they do not dissolve in water; fats tend to congeal into large masses, and this separation of lipids and water limits the effectiveness of the lipase–fat-digesting enzymes. Lipid digestion occurs primarily in the small intestine and involves the emulsification of fats by bile. Bile acids are derivatives of cholesterol synthesized within the hepatocytes in the liver. Interestingly, they are also facial amphipathic, meaning they possess both hydrophilic (water-soluble) and hydrophobic (fat-soluble) components. This amphipathic quality allows the bile acids to emulsify lipid aggregates and solubilize and transport lipids in an aqueous milieu. The process begins as triglycerides are broken down or emulsified in the duodenum by bile acids into monoglycerides and fatty acids [35,66]. Table 31.10 provides a summary of the critical

TABLE 31.8
Summary of Protein Digestion

Enzyme/Digestive Fluid	Source	Process	Result
Pepsin (derivative of pepsinogen)	Stomach (chief cells)	Initial breakdown of collagen and proteins into peptides	Peptide fragments
Endopeptidases (*hydrolyze interior peptide bonds*)			
Trypsin (derivative of trypsinogen)	Pancreas	Continues breakdown of proteins into peptides	Peptide fragments
Chymotrypsin (derivative of chymotrypsinogen)	Pancreas	Continues breakdown of proteins into peptides	Peptide fragments
Exopeptidases (*hydrolyze exterior peptide bonds*)			
Carboxypeptidase (derivative of procarboxypeptidase)	Pancreas	Continues breakdown of proteins into peptides	Peptide fragments
Aminopeptidase	Small intestine	Cleaves terminal amino acids at amino ends of peptides	Amino acids (dipeptides, tripeptides)
Dipeptidase	Small intestine	Cleaves two amino acid molecules joined by a peptide bond (dipeptide)	Amino acids (dipeptides, tripeptides)

TABLE 31.10
Summary of Lipid Digestion

Enzyme/Digestive Fluid	Source	Process	Result
Lingual lipase	Salivary glands at the base of the tongue	Minor digestion of triglycerides to monoglycerides and fatty acids	Monoglycerides and fatty acids.
Bile acids	Hepatocytes in liver lobules	Emulsification of lipid aggregates; solubilization and transport of lipids	Breakdown of triglycerides into 1 μm globules; hydrophobic products of lipid digestion are solubilized in micelles.
Pancreatic lipases (pancreatic lipase, cholesterol ester hydrolase, phospholipase A_2)	Pancreas	Removes two of the three fatty acids from glycerol	Fatty acids, monoglycerides, cholesterol, and lysolecithin.
Lipoprotein lipase	Capillary endothelial cells	Breaks down triglycerides into fatty acids and glycerol	Removal of chylomicrons from the circulation system.
