digestive processes of lipids. The short-chain fatty acids (<12 carbon molecules) are absorbed by the small intestine by simple diffusion. The long-chain fatty acids (>12 carbon molecules) and monoglycerides are dissolved and absorbed into the center of structures called micelles, which consist of 20–50 molecules of bile salt. As the micelle comes into contact with the intestinal cells, the fatty acids, cholesterol, and monoglycerides cross the luminal membranes into the intestinal cell wall, leaving the empty micelles in the chyme to repeat the process. Several transporter-mediated mechanisms have been postulated for the uptake of fatty acids such as CD36 [67] and FATP4 [68], among others [69,70]; however, some postulate that the transport is strictly passive diffusion [71]. It has been suggested that the mode of lipid uptake by the intestinal cells is dependent on the concentration of available fatty acids; that is, if the concentration of lipids is low and the body needs fatty acids, an active component appears to be a key factor in lipid transport. On the other hand, when the lipid concentration is high, most transport is postulated to be passive [77]. The bile acids are reabsorbed primarily in the ileum and returned to the liver in a cycle called *enterohepatic circulation*. Once the fatty acids and monoglycerides are in the epithelial cells, they are re-esterified to triglycerides, cholesterol ester, and phospholipids, which become coated with apoproteins. These newly formed structures, called *chylomicrons*, are transported out of the epithelial cells into the lymphatic system by exocytosis. Once in the circulatory system, the triglycerides in the chylomicrons are removed from the circulatory system as they pass through the liver. This removal is mediated by lipoprotein lipase, which is present in the capillary endothelial cells and breaks down the triglycerides into fatty acids and glycerol. To be mobile and functional in the blood, plasma lipids are combined with apoproteins. These structures are termed *lipoproteins*. There are several types of lipoproteins, depending on their specific composition of triglycerides, phospholipids, cholesterol, and protein. These lipoproteins include high-density lipoproteins (HDLs), low-density lipoproteins (LDLs), and very-low-density lipoproteins (VLDLs). Table 31.11 provides a summary of the critical absorption mechanisms of lipids.

Nucleic Acids

A wide variety of plant and animal foods contain DNA, RNA, nucleotides, and free nucleic acids. Once in the GI tract, DNA and RNA are broken down into free nucleic acids and nucleotides by various nucleases found in both intestinal and

pancreatic digestive juices. The pancreatic nucleases convert DNA and RNA into nucleotides along the length of the small intestines. DNA nucleotides include the following bases: adenine, thymine, guanine, and cytosine. RNA nucleotides contain the following bases: adenine, uracil, guanine, and cytosine. These nucleotides are further digested by enzymes produced by the small intestinal epithelial cells, including nucleosidase and phosphatase. Nucleotidase enzymes found in the membrane of the ileum epithelial cells further break down the nucleotides into pentoses, phosphates, and nitrogenous bases. Table 31.12 is a summary of the critical digestive processes of nucleic acids. Nucleotides can be partially absorbed in the duodenum and the jejunum. The nucleosides are absorbed in greater amounts than the nucleotides because they lack the phosphoric acids. Transport of nucleosides into the mucosal cell wall occurs by facilitated diffusion and specific sodium-dependent carrier-mediated transport mechanisms [78]. When the nucleic acids have been broken down into their component sugars, phosphates, and nitrogenous bases, they are absorbed directly into the epithelial cells by sodium-dependent active transport. Table 31.13 provides a summary of the critical absorption mechanisms of nucleic acids. Nutrients are absorbed along the length of the small intestine as shown in Table 31.14.

Large Intestine

The large intestine, also referred to as the colon, is the final part of the digestive tract; it measures about 5 ft in length and 2–3 in. in diameter and extends from the ileocecal sphincter at the end of the termination of the small intestine through the rectum, which connects to the anus. The large intestine is divided into several segments. Immediately below the ileocecal sphincter is the cecum, a saclike enlargement at the junction of the small and large intestines that measures about 2–3 in. in length. Attached to the cecum is a small tube called the *appendix*, which measures approximately a quarter of an inch wide and 2–3 in. in length; its function remains unclear [80]. Adjacent to the cecum on the right side of the abdomen is the ascending colon, which ascends to the bottom of the liver, where it turns left and forms the right colic flexure, which becomes the transverse colon. When the ascending colon reaches the end of the spleen, it turns downward and forms the left colic flexure, which becomes the descending colon. The next segment is the sigmoid colon, which descends into the pelvis and connects to the rectum. The last 8 in. of the large intestine comprises the rectum, which is a reservoir for waste. The final inch of the rectum is the anal canal, which ultimately becomes the anus. The anus has two sphincters, one that is involuntary and comprised of smooth muscle and a second external voluntary sphincter that is comprised of skeletal muscle. The anus remains closed except during the elimination of wastes [81]. The wall of the large intestine is comprised of the same layers as the rest of the GI tract; however, there are several differences. First, the muscularis layer consists of two layers, but the external layer of longitudinal muscles is thickened and forms three conspicuous

TABLE 31.12
Summary of Nucleic Acid Digestion

Enzyme/Digestive Fluid	Source	Process	Result
Ribonuclease	Pancreas and small intestine	Converts ribonucleic acid into nucleotides	Nucleotides
Deoxyribonuclease	Pancreas and small intestine	Converts deoxyribonucleic acid into nucleotides	Nucleotides
Nucleosidase	Small intestine epithelial cells	Converts nucleosides into purines and pyrimidines	Nucleosides, purines, and pyrimidines
Phosphatase	Small intestine epithelial cells	Catalyzes hydrolysis of esters of phosphoric acid	Phosphate
Nucleotidase	Ileum epithelial cells	Converts nucleotides to sugars, pentose, phosphates, and nitrogenous bases	Sugars, pentose, phosphates, and nitrogenous bases

longitudinal bands called *teniae coli*. See Figure 31.10 for the overall structure and general organization of the large intestine. Together, the three bands run the length of the large intestine. By virtue of their tonic contractions, the walls of the colon pucker into pocket-like sacs called *haustra*, which give the colon its segmented appearance. Epiploic appendages or fat-filled bags of visceral peritoneum are attached to the teniae coli. Their function remains largely unknown.

Digestion

After the small intestine absorption is completed, the remaining fluid passes into the cecum of the large intestine. The ileocecal sphincter acts as a governor because it is normally slightly contracted and slows the passage of chyme from the small intestine to the cecum. Not only does this sphincter control the rate of chyme passage, but it also prevents the reverse flow of chyme back into the ileum. Interestingly, when the chyme reaches the colon, the primary mechanism of digestion is by bacterial action. The secretion of glands in the mucosal epithelial cell wall is a protective measure against potential damage from bacterial activity. The bacteria ferment carbohydrates, further break down amino acids, decompose bilirubin, and synthesize some B complex vitamins as well as vitamin K.

Bacteria

Bacteria are present throughout the length of the GI tract; however, a significant bacterial concentration is present in the large intestine. A critical step in the preparation of chyme for elimination is the fermenting action of bacteria normally present in the colon; therefore, in addition to the actions of the digestive juices and mixing action of the contents, most of the final phase of digestion in the large intestine depends on the symbiotic activity of bacteria in the system. Few bacteria are present in the gut at birth; however, rapid colonization occurs shortly after birth. It has been estimated that the average adult has 10^{14} intestinal flora, which equates to about 4–5 lb that is critical to the digestive process. The large intestine contains as many as 400 different species of bacteria, and an individual's flora is immunologically unique to that person [80]. The stomach has the least amount of microflora ($<10^3$ CFU/mL), primarily because the low pH destroys many organisms; in contrast, almost the entire digestion process can be attributed to the large number ($>10^{14}$ CFU/mL) of anaerobic bacteria present in the large intestine [80]. Table 31.15 provides a summary of the various types of microflora found in the GI tract from the stomach through the large intestine.

Most of the final phase of digestion in the large intestine depends on the symbiotic activity of bacteria in the system. The normal microflora digest materials that enter through the ileocecal sphincter and maintain a barrier to infections that could develop from hostile organisms. This barrier consists of an overwhelming number of resident microflora that give invaders little space or food, as well as a by-product of

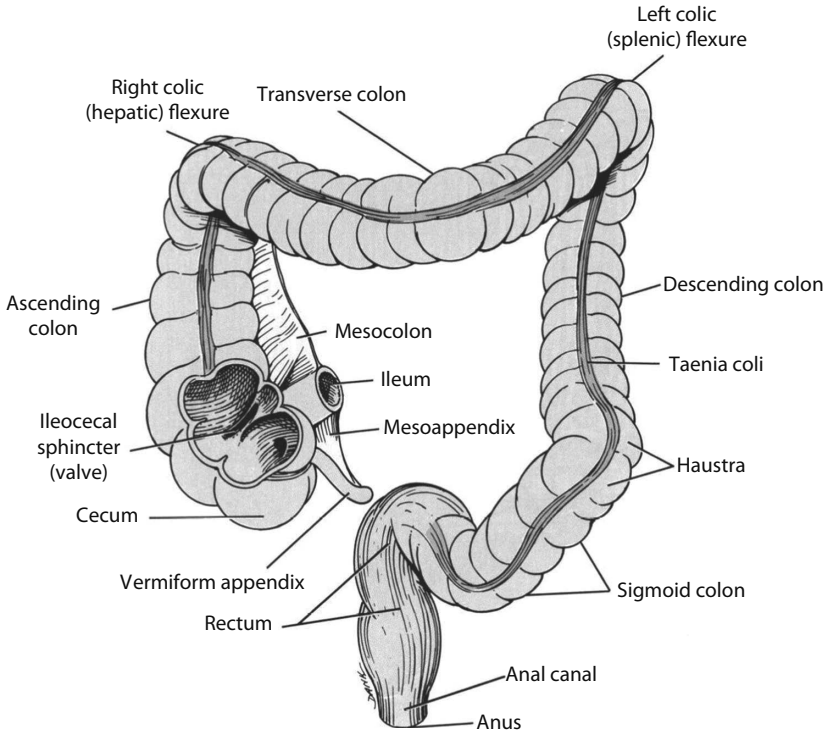

FIGURE 31.10 Structure and general organization of the large intestine. (From Tortora, G.J. and Anagnostakos, N.P., The digestive system, Chapter 24, in: *Principles of Anatomy and Physiology*, 6th edn., HarperCollins, New York, p. 760. With permission.)

metabolism that tends to reduce the reproductive capacity of foreign microflora. When foreign bacteria enter the GI tract, the resident bacteria are immunologically activated and help prevent colonization by the invading organisms. Normal intestinal bacteria help to prevent infections because the normal bacteria occupy all of the available niches for bacteria, thus depriving the invading bacteria of suitable places to begin reproduction. Further, the robust occupying bacteria will utilize available food, which keeps the invading flora from multiplying. Finally, some of the normal bacteria produce antibacterial chemicals (called bacteriocins) as a result of their metabolism. This by-product can generate a local antibiotic effect that hinders the reproduction of invading flora. Secretions in the large intestine consist primarily of alkaline mucus that protects the epithelium and neutralizes acids produced by bacterial metabolism. The most common include *Enterobacteriaceae*, *Bacteroides*, *Bifidobacterium*, *Streptococcus faecalis*, *Eubacterium*, *Peptococcus*, *Peptostreptococcus*, *Ruminococcus*, *Clostridia*, and *Lactobacillus*. The environment of the large intestine is primarily anaerobic, which favors obligate anaerobes. Table 31.16 provides a summary of bacterial action in the large intestine.

Motility

When the chyme enters the cecum, the peristaltic action is triggered by distention of the wall in the colon; however, it occurs at a rate much slower than in the small intestine. The movement of fecal contents from the cecum to the rectum for elimination can take several days. The movements of the cecum and ascending colon are more vigorous and promote mixing to hasten the absorption process; however, the movements of the descending and sigmoid colon and rectum are slower and more deliberate to permit the formation of stool, which collects in the rectum. Although the origin of these coordinated contractions is not well understood, they appear to be dependent on a combination of internal rhythmic contractions and neural, paracrine, and humoral factors. Following a meal, colonic motility increases significantly, due to signals propagated throughout the ENS from the walls of the stomach, which triggers the gastrocolic reflex. Several times a day, mass movements push feces into the rectum in this manner. In addition, the presence of fats in the duodenum appears to trigger another mass peristalsis reflex, termed the duodenocolic reflex, through the ENS. The general state of the large intestine musculature also depends upon the distention of the colon walls that can initiate contractions within the colon. The large intestine has six types of movement as summarized in Table 31.17.

Absorption

Of the about 1 L of fluid that enters the large intestine each day, approximately 90% is reabsorbed, leaving only about 100 mL to be excreted with the feces. When the chyme reaches the cecum of the large intestine, most of the digestion and secretion have been completed. The primary functions of the large intestine are the absorption of water, vitamins, and electrolytes; the formation of feces; and movement of the feces to the anus for elimination. The intestinal mucosal of

the large intestine absorbs water, sodium, and chloride and secretes potassium and bicarbonate.

Water is absorbed in the large intestine in response to an osmotic gradient. Absorption of water in the large intestine is passive and requires the movement of solutes (primarily sodium); thus, the rate of water uptake is a function of the solute absorption. The mechanism responsible for generating this osmotic pressure involves sodium ions being transported from the lumen across the epithelium because of the sodium pumps and the ability of the luminal membrane to absorb sodium. In fact, the colonic epithelium is very effective at absorbing water and sodium (95% retention rate). Absorption in the colon is enhanced by the hormone aldosterone. This uptake of water serves to concentrate the contents of the large intestine to a semisolid form. Sodium and subsequently water are absorbed primarily in the cecum, the ascending colon, and, to a lesser extent, the transverse colon. Bicarbonate is secreted against a concentration gradient, and chloride absorption is linked to both bicarbonate secretion and sodium transport. The resulting secretion of bicarbonate ions into the lumen aids in neutralization of the acids generated by microbial fermentation in the large intestine. Potassium, on the other hand, is passively transported and can be absorbed if the potassium concentration is greater than 15 mEq/L or secreted if the potassium concentration is less than 15 mEq/L. Under normal circumstances, the luminal concentration of potassium is less than 15 mEq/L, which favors secretion.

Vitamins are important to the body as cofactors or coenzymes in numerous metabolic pathways. Some critical vitamins produced by intestinal bacteria are also absorbed in the large intestine. Approximately 50% of the daily requirement

TABLE 31.17
Muscular Action of the Large Intestine

Type of Motion	Description	Function
Haustral churning	Haustrum pouch relaxes and fills to capacity and then, as it becomes distended, contracts and moves the contents to the next haustrum.	This action provides a mixing motion to the contents that facilitates fluid extraction, creates larger masses, and helps advance the contents through the colon.
Peristalsis	A wave motion is produced by joint muscular coordination between the interior and exterior muscles of the muscularis layer.	This wave motion propels the contents forward through the colon; slower than similar action in the small intestine.
Mass peristalsis reflexes		
Gastrocolic reflex	As foodstuffs enter the stomach, a reflex is triggered at the midtransverse colon that initiates a strong mass peristaltic action.	The strong wave action forces any latent contents in the lower large intestine into the rectum to make room for the new stomach contents.
Duodenocolic reflex	As fats enter the duodenum, a reflex is triggered at the midtransverse colon that initiates a strong mass peristaltic action.	The strong wave action forces any latent contents in the lower large intestine into the rectum to make room for the new stomach contents.
Defecation reflex	As colon contents move into the rectum, a signal is sent to the brain.	This signal tells the conscious brain that the rectum is full and defecation must occur.
Cooperative abdominal effort	As defecation occurs, voluntary and involuntary abdominal muscles are contracted.	This cooperative action of the abdominal muscles assists in pushing the waste from the rectum and anus.

for vitamin K is produced by bacteria found in the large intestine. Pantothenic acid (vitamin B_5), which is necessary in the production of steroids and some neurotransmitters, is also produced by intestinal bacteria. Finally, biotin, a necessary cofactor in glucose metabolism, is also produced by intestinal bacteria. Although each of these is generated by various intestinal bacteria, the resulting vitamins are absorbed primarily in the cecum and ascending colon. Organic wastes from the breakdown of heme produce bilirubin, which is broken down into urobilinogens and stercobilinogens. Ultimately, these are converted to urobilins and stercobilins, respectively. Bacterial activity on these latter substances in the large intestine generates

- Ammonium ions (NH^{4+})
- Hydrogen sulfide (H_2S), which produces a characteristic odor
- Indole, which produces characteristic odor
- Skatole, which produces a characteristic odor

Ammonia and some other organic wastes are absorbed by the large intestinal mucosal epithelial cells and enter the hepatic portal circulatory system, where they are processed by the liver and ultimately eliminated by the kidneys. Indigestible polysaccharides are also eventually deposited in the large intestine. The resident bacteria begin to break down these substances and utilize them as a source of nutrients.

The large intestine has a delicate lining that is moisturized by mucus and also by a gel that is a by-product of the bacterial fermentation process. Despite the many similarities in the cellular structure of the mucosa in the large and small intestines, clearly the most obvious difference is that the mucosa of the large intestine lacks absorptive villi. The mucosal epithelial walls of the large intestine have numerous crypts that extend deep into and open onto a flat luminal surface. The stem cells that support the process of renewal of the epithelium are located in the crypts. These cells divide to populate the crypt and surface epithelium. Mucus-secreting goblet cells are also much more abundant in the colonic epithelium than in the small intestine. These cells secret mucus in response to parasympathetic stimuli and the presence of lumen contents. The lining of the large intestine has numerous functions, as summarized in Table 31.18.

The chyme remains in the colon for 3–24 h. During that time, numerous processes occur. In addition to the muscular activity and the bacterial actions noted previously, several cellular exchanges take place, as summarized in Table 31.19. After 90% of the water is absorbed and completion of a myriad of additional actions in the large intestine, the chyme is transformed into a semisolid called *feces*, consisting of residual water, inorganic salts, bacteria, products of bacterial decomposition, mucus cells, cell fragments from the GI tract mucosa, and any undigested food. Under normal physiological conditions, normal feces consist of approximately 75% water and 25% solids. The characteristic brown color of feces is due to stercobilin and urobilin, both of which are produced by bacterial degradation of bilirubin. The characteristic fecal odor is a result of gases produced by bacterial metabolism, including skatole, mercaptans, and hydrogen sulfide.

Defecation Reflex

As described previously, mass peristalsis moves the fecal material from the transverse, descending, and sigmoid colon into

TABLE 31.18
Function of the Lining of the Large Intestine

Function	Location	Result
Protection	Nerve endings in wall of large intestine	Permits intact neural messages between the CNS and the colon
Lubrication	Entire large intestinal wall	Promotes stool transit
Facilitation	Movement of fluids through the wall of the large intestine	Optimizes nutritional uptake of vitamins and electrolytes
Bacterial growth	Large intestine wall	Promotes growth of healthy intestinal bacteria, which break down waste, create additional lubrication, cleanse the colon, and protect the colon against infection

TABLE 31.19
Cellular Exchanges of the Colon

Function	Process	Location	Result
Secretion	Secretion of mucus by goblet cells	Goblet cells located in tubular intestinal glands	Secreted mucus lubricates and protects the colon lining and nerve tissues.
Fluid absorption	Secondary to solute absorption, passive diffusion into epithelium cells	Primarily occurs in the columnar cells of the cecum and ascending colon	Approximately 80% of the water entering the colon is absorbed; maintains water balance.
Electrolyte absorption	Passive diffusion via sodium channels by columnar cells	Columnar cells located in tubular intestinal glands	Na^+, Cl^-, and K^+ are absorbed; maintains water balance.

Source: Keely, S.J. et al., Electrolyte secretion and absorption: Small intestine and colon, Chapter 14, in: *Textbook of Gastroenterology*, 5th edn., ed. T. Yamada, Wiley Blackwell Publishing, London, U.K., 2009, pp. 330–367.

the rectum. When distention at 25% or more is detected in the rectal wall, a stimulus is sent from pressure-sensitive receptors that initiate the defecation reflex, which empties the rectum. When distention is detected, receptors send nerve impulses to the spinal cord and then back through the parasympathetic nervous system to the descending colon, sigmoid colon, rectum, and anus. This impulse contracts the rectum and increases the pressure along the diaphragm and abdominal muscles, forcing the internal sphincter open and ultimately expelling the feces through the rectum and out of the anus. The external sphincter is striate muscle and is voluntarily controlled. If it is relaxed, the defecation process is completed. If it is voluntarily constricted, defecation can be temporarily postponed. As described previously, the voluntary cooperative abdominal and diaphragm effort increases the pressure inside the abdomen, which creates a backup into the sigmoid colon until the next mass peristalsis reflex occurs once again, stimulating the pressure-sensitive receptors that signal the CNS of the need to defecate.

EXPOSURE TO TOXIC SUBSTANCES

Because the GI tract is the normal portal of entry for foodstuff, exposure to any kind of ingestible toxic agent is possible, and the degree of exposure can be high. A toxicant can enter the body via water, foodstuff, pharmacological agents, or even inhaled substances that are subsequently swallowed via the resulting secretions from the lungs, trachea, or oral cavity. Toxicants enter the body by the same absorption pathways as necessary nutrients; they pass through the GI tract mucosa membranes and subsequently make their way into either the blood or lymphatic system. These substances may exert toxic events locally within the GI tract itself or at a distant site, depending on the nature of the ingested material, the rate of absorption, the biochemistry of the toxicant, and the physiology of the target organ. The degree of toxicity depends on the concentration and duration of exposure of a toxicant at the sensitive site. Several factors can alter the extent of potential toxicity when a toxicant has gained entrance into the lumen of the GI tract, including poor absorption from the GI tract, intestinal and hepatic first-pass effects as mediated by biotransformation, and the rate of incorporation of lipid-soluble substances into micelles. A toxicant can interact with the specific moieties at the site of action, or it can alter the microenvironment in such a way that the resulting action is toxic to the functioning of the specific site. The critical factors affecting the degree of toxicity are summarized in Table 31.20.

Biotransformation

The process by which substances are changed into different chemicals by enzyme reactions in the organism is called *biotransformation*, and it can be an important defense

TABLE 31.20
Factors Affecting Degree of Toxicity

Factor	Location	Effect
Chemical characteristics of toxicant	Lumen of GI tract	Lipophilicity, molecular weight, pH, and pK_a; affect extent and rate of absorption
Dissolution rate of chemical	Cell wall of GI tract	Absorption rate due to particulate size
Hydrochloric acid concentration	Stomach	Hydrolysis of toxicant into another compound
Dilution in gastric secretions	Lumen of GI tract	Absorption rate due to competition and concentration
Dilution in food content	Lumen of GI tract	Absorption rate due to competition and diluted concentration
Time of residence at absorption site	Lumen of various GI tract locations	Absorption rate due to time at absorption site
Microflora	Lumen of GI tract	Chemical changes to the toxicant that alter its absorption characteristics
Biotransformation	Lumen of GI tract, liver	Clearance of toxicant
Fecal excretion	Large intestine	Clearance of toxicant

Toxicol.*, 43, 149, 2003; Burks, T.F., Pathophysiological mechanisms of gastrointestinal toxicants, Chapter 8, in: *Comprehensive Toxicology*, 2nd edn., vol. 10, Elsevier, London, U.K., 2010, pp. 117–144; International Programme on Chemical Safety, Environmental Health Criteria 6, Principles and Methods for Evaluating the Toxicity of Chemicals, Part I, World Health Organization, Geneva, Switzerland, 1978. http://www.inchem.org/documents/ehc/ehc/ehc006.htm, accessed March 6, 2014.

mechanism. This is possible because some toxicants and even some body wastes are changed into less toxic substances or are simply prevented from forming toxic derivatives. A chemical can be toxic in its original form as it enters the body, or toxic derivatives of a nontoxic parent compound can be produced by biotransformation. Biotransformation occurs in GI tract mucosal cells, in the liver, and, to a lesser extent, at various other places throughout the circulatory system.

Biotransformation reactions can be divided into two basic types of reactions: phase I and phase II. Generally, in phase I reactions, the structure of the toxicant is changed in such a way that it is readied for additional changes during the next step in the process. Toxicants are neutralized in three ways during phase I: (1) the chemical structure is changed so it is hydrophilic, (2) the toxicant is broken down into two or more less toxic substances, or (3) the toxicant is transformed into an activated form that can be detoxified by other enzymes. Most of the phase I reactions are mediated by the cytochrome P450 enzymes, which primarily oxidize lipophilic toxicants and are responsible for adding polar groups to the molecule. Interestingly, the creation of these activated toxins can result in a more toxic derivative, so it is critical for the activated toxin to move forward to phase II reactions [97]. Seven major biochemical reactions occur in phase II: glutathione conjugation, amino acid conjugation, methylation, acetylation, sulfation, glucuronidation, and sulfoxidation. Each of these reactions transforms specific types of activated toxins by adding a molecule to the activated toxicant. A brief overview of the critical factors is summarized in Tables 31.21 and 31.22.

TABLE 31.21
Phase I Reaction Summary

Type of Reaction	Specific Function
Oxidation	Aromatic and aliphatic hydroxylation; epoxidation; N-hydroxylation; O-, N-, and S-dealkylation; S-oxidation; dechlorination; oxidative desulfuration; amine oxidation; dehydrogenation.
Reduction	Azoreduction, nitroreduction, carbonyl reduction.
Hydrolyses	Esterases, amidases, proteases.
Mixed function oxidase system	In many of the preceding reactions, the substrate binds to cytochrome P450, transferring electrons and oxygen in the following general reaction: $SH + NADPH + H^+ + O_2 \rightarrow SOH + NADP^+ + H_2O$.

Note: Phase I reactions tend to make the substrates more polar and more readily excreted from the organism by exposing the functional group and readying it to be changed further during phase II. Some of these reactions result in bioactivation of the substance.

TABLE 31.22
Phase II Reaction Summary

Type of Reaction	Specific Function
Glucuronidation	Diphosphate glucuronosyl transferase forms glucuronides with activated glucuronic acid, which can catalyze the conjugation of a substance with a polar group.
Sulfation	Sulfotransferase activates sulfate, which can react with a polar compound becoming more water soluble.
Glutathione conjugation	Glutathione *S*-transferase catalyzes the formation of strong electrophiles such as epoxides, haloalkanes, nitroalkanes, alkenes, and aromatic halo and nitrocompounds.
Epoxide hydrolase	The reaction proceeds through the activation of water that detoxifies the epoxides of hydration.
Acetylation	Acetyl CoA is attached to aromatic amines and sulfonamides.
Methylation	Several methyltransferases are utilized to increase lipophilicity.
Amino acid conjugation	Proceeds by two pathways: (1) the COOH group conjugated with NH_2 requires CoA activation and (2) aromatic NH_2 or NHOH conjugated with COOH requires ATP activation.

Note: Phase II reactions are generally the result of the formation of compounds less biologically reactive and are conjugated with endogenous substances in order to make them more water soluble. The final product can be eliminated from the body either in the urine or in the bile.

The metabolic activity of the small intestine is referred to as *intestinal first-pass effect*. The small intestine is considered an absorptive organ, but it also has the ability to metabolize drugs via many pathways involving preconjugation (phase I) and conjugation (phase II) reactions [98–103]. Virtually all of the drug-metabolizing enzymes present in the liver are also found in the small intestine; however, the enzyme levels are considerably lower in the small intestine than in the liver [104]. Another factor that plays a critical role in the amount of nutrient or toxicant absorbed is referred to as the *hepatic first-pass effect*. In this case, orally ingested nutrients or toxicants are absorbed by the intestinal mucosal cells, enter the capillaries and veins of the GI tract, and are transported by the portal vein directly to the liver before entering the general circulation of the body. The absorbed substance is exposed to the liver before its first pass through the body. Because most toxicants are lipophilic and nonpolar and have low molecular weights, they are easily absorbable through the GI tract mucosal cells and yet are difficult to eliminate and can accumulate throughout the body to toxic levels. Most lipophilic toxicants are difficult for the body to eliminate, and they accumulate to toxic levels. Many lipophilic toxicants are biotransformed into hydrophilic metabolites that do not easily enter the membranes of the target tissues. Endogenous materials such as bilirubin are also biotransformed into hydrophilic derivatives that are excreted into the bile and ultimately eliminated in the feces. This process is termed *detoxication*, and the general pathways are summarized in Table 31.23. When a toxicant is biotransformed to another compound whose derivative can be more toxic than the parent compound, this process is known as *bioactivation*, and it can be very toxic to the organism. This process, also referred to as *toxication*, has several pathways depending on the chemical (see Table 31.24).

Factors Affecting Absorption

The rate at which a toxicant is absorbed across the mucosal cell wall in the GI tract is a function of a number of physical and chemical factors. Some toxicants may directly increase the permeability of the intestinal mucosal cell wall, such as ethylenediaminetetraacetic acid (EDTA). Also, the longer the exposure time to the mucosal membranes, the higher the rate of absorption, so another factor affecting the rate of toxicant absorption is the rate of peristalsis. Agents such as laxatives or sedatives work indirectly on the rate of absorption by speeding or slowing the rate of motility through the GI tract. If the substance is subject to a high hepatic clearance (i.e., it is rapidly metabolized by the liver), then a substantial fraction of the absorbed substance is extracted from the blood and metabolized and excreted as bile before it reaches the systemic circulation. The bile is then reintroduced into the GI tract and eventually eliminated through the feces. The consequence of this phenomenon is a significant reduction in bioavailability, which can be an excellent protective mechanism if the material is a toxicant and can make therapeutic treatment difficult if, in fact, the substance orally ingested is part of a drug therapy regimen [14].

With a few notable exceptions, most substances (toxicants and nutrients alike) are poorly absorbed from either the oral cavity or the esophagus. This is due primarily to the fact that the transit time in these two sections is relatively brief. In addition, these structures have no villi or similar such absorbing cells. Exceptions include nicotine from tobacco

TABLE 31.23
Summary of Common Detoxication Pathways

Detoxication Pathway	Description	Result
Nucleophiles	Hydroxylated nucleophilic groups are conjugated by sulfation, glucuronidation, or methylation; thiols are conjugated by methylation or glucuronidation; and amines and hydrazines are conjugated by acetylation or oxidation.	Reduction in the rate of nucleophilic conversion to free radicals and/or electrophilic quinines and quinone imines
Electrophiles	Electrophilic toxicants are conjugated by conjugation with thiol nucleophile glutathione.	Reduction in the rate of electrophilic conversion to reactive free radicals
Free radicals	Superoxide anion radical is converted by superoxide dismutase (SOD), glutathione peroxidase (GPO), and catalase (CAT) to HOOH and H_2O.	Reduction in the amount of superoxide anion radical available for conversion to free radicals such as peroxynitrite, nitrosoperoxy carbonate, and carbonate anion radical
No functional groups	Functional groups such as hydroxyl or carboxyl are first added to the substance by the cytochrome P450 enzymes, and then a transferase adds a glucuronic acid, a sulfuric acid, or an amino acid to the functional group.	Toxicants rendered much less active or more easily eliminated
Proteins	Intra- and extracellular proteases interact with polypeptides.	Inactivation of toxic polypeptides

Sources: Data from Gregus, Z., Mechanisms of toxicity, Chapter 3, in: *Casarett & Doull's Toxicolog: The Basic Acience of Poisons*, 7th edn., ed. C.D. Klaassen, McGraw-Hill Companies, New York, 2008, pp. 45–106; Sreedharan, R. and Mehta, D.L., *Pediatrics*, 113(4), 4, 2004.

TABLE 31.24
Summary of Common Toxication Pathways

Toxication Pathway	Description	Result
Nucleophile formation	Nucleophile activation is rare; some nucleophiles such as HCN and CO are reactive as nucleophiles, but many can be further activated to electrophiles.	These reactions increase the rate of nucleophile conversion to free radicals or electrophilic quinines and quinone imines.
Electrophilic formation	Electrophiles are often produced by adding an oxygen atom to a molecule that removes electrons and results in an electronic-deficient structure that is electrophilic.	These electrophiles are electron deficient and are reactive, creating polarized substances that are frequently catalyzed by cytochrome P450.
Free radical formation	Free radicals contain one or more unpaired electrons and are formed by the addition of an electron, loss of an electron, or hemolytic fission of a covalent bond.	Free radicals can increase the amount of superoxide anion radical available for conversion to free radicals such as peroxynitrite, nitrosoperoxy carbonate, and carbonate anion radical.
Redox-active reactants	Conversion of superoxide anion radicals to hydroxyl radicals by SOD and catalyzed by transition metal ions.	Reactive metabolites such as some electrophiles and neutral or cationic free radicals can be activated by conversion to electrophiles, while free radicals with extra electrons can produce hydroxyl radicals upon hemolytic cleavage.

products, alcohol, and nitroglycerin, which is immediately absorbed when placed sublingually for treatment in certain heart conditions.

As the toxicant passes into the stomach and on through the small intestine, it can be absorbed by one and more of several mechanisms. Although no known mechanisms specifically transport only toxicants into the body, many of existing pathways for nutrient absorption in the GI tract are also used by foreign substances to gain entry into the body. Generally, if a toxicant is an organic acid or base, it most likely will be absorbed via simple diffusion. By virtue of the structure of these substances, one can assume that an organic acid exists primarily in lipid-soluble form in the stomach and in the ionized form in the small intestines. Based on that assumption, an organic acid would be absorbed more readily in the acid stomach than in the neutral small intestine. Organic bases, on the other hand, would be absorbed more readily in the neutral small intestine rather than the acidic stomach; however, because the pH is about neutral in the small intestine (pH 5.0–8.0), both weak acids and bases are nonionized and readily absorbed by passive diffusion. Significant exceptions to this situation do arise, primarily due to the large surface

area of the small intestine, varying blood flow rate, and law of mass action maintaining a gradient. It should be noted, however, that small lipid-soluble substances generally enter the mucosal epithelial cells by passive diffusion.

In addition, a variety of active transport and facilitated mechanisms are responsible for transporting nutrients, including monosaccharides, amino acids, and minerals, into the mucosal epithelial cells. A xenobiotic transport mechanism that has been identified features multidrug resistance (MDR) proteins or P-glycoprotein. Unfortunately, this transport system moves some chemotherapeutic agents out of some tumor cells, rendering these agents less effective, but it also transports some other potentially toxic chemicals out of cells, thus protecting the organism from toxic doses. This mechanism, then, functions to move certain xenobiotics out of the cell and reduce the net amount of GI absorption of some toxic chemicals. MDR-associated proteins (MRPs) have been shown to transport glucuronides and glutathione metabolites out of cells as well [14]. The iron transport mechanism also absorbs toxins such as thallium, and manganese and cobalt both utilize and compete for access to the iron transport system. The calcium transport mechanism absorbs lead, and the pyrimidine transport system absorbs 5-fluorouracil. These toxicants are actively transported into the mucosal epithelial cells of the GI tract, but the vast majority of toxicants enter by simple passive diffusion. Low molecular weight, lipid-insoluble compounds are absorbed through aqueous membrane pores at the tight junctions in the membrane via passive diffusion. Another factor in the absorption of toxicants is that particulate toxicants can be absorbed via vesicular transport, either by pinocytosis or by phagocytosis.

In addition, another phenomenon has been identified as a rate-limiting barrier to the absorption of toxicants in the small intestine: the unstirred water layer. Normally, the intestinal mucosal cell membranes are separated from the aqueous phase in the lumen by an unstirred water layer. This layer surrounds the villi and becomes a significant rate-limiting step with regard to the entry of all substances (nutrients and toxicants alike) into the mucosal cells. This water layer is not well mixed, and the solute molecules in the chyme must diffuse across the unstirred water layer to gain access to the membrane of the mucosal cells [107]. Micellar solubilization, on the other hand, greatly enhances the number of molecules that are available for uptake by the mucosal cells in the lumen. Tso et al. [77] suggest that micellar molecules are in equilibrium with molecules in the unstirred water, so the momeric fatty acids, monoglycerides, and amino acids cross the microvillar membrane. The large, polar bile salts are not absorbed well by intestinal mucosa, so the bile salts remain in the chyme to participate in forming more mixed micelles as they cycle within the intestine. The integration of segmentation and propulsion enhances absorption by mixing luminal contents with digestive juices and by increasing the contact time between chyme and absorptive cell surfaces. Intestinal motility also decreases the thickness of the unstirred layer of water so nutrients and electrolytes can diffuse readily to mucosal cell membranes. The noninvasive techniques used to assess the integrity and function of the human GI system have been recently reviewed by Grootjans et al. [283].

Factors Affecting Distribution

When a toxicant gains entry into either the lymphatic or blood circulatory system, it can move rapidly throughout the body. Its effect at the target tissue is based on the affinity of the toxicant to the target. The routes of entry into various target tissues include either active transport or simple passive diffusion. As previously noted, small, low molecular weight, water-soluble toxicants are able to pass through pores in the membrane via filtration and diffusion, while polar toxicants with larger molecular weights must be actively transported across the membrane. Lipid-soluble toxicants are able to easily penetrate the membrane. The rate of uptake is ultimately determined by either the diffusion rate, which is governed by the specific characteristics of the toxicant, or the perfusion rate, which is governed by the physical rate of delivery to the target tissue [14].

Generally, the concentration of a toxicant is dependent on the volume of distribution through the body compartments. Some toxicants are limited in their distribution by size, charge, or shape; others can pass through the various compartments and become distributed throughout the organism. The plasma concentration of a toxicant is critical, as it reflects the available concentration of the substance at the target tissue. Generally, if the concentration in plasma is high and the interstitial and intracellular concentrations are low, the amount of unbound toxicant available at the target tissue increases. Once a toxicant has entered the blood plasma, it may be excreted or biotransformed into more or less toxic substances, or it may be stored. Because of protein binding, active transport, or some other physiological factor, some toxicants accumulate in certain areas of the body. This can be a protective measure if the site of accumulation is other than a potential target tissue. In this particular case, the compartment in which a certain toxicant is accumulated is termed a *storage depot*. Because the toxicant is in equilibrium with its counterparts in the plasma and elsewhere, it can be released from the storage depot as the plasma level decreases over time. Interestingly, the initial distribution of various toxicants can change based on flow rates and toxicant affinities. The details and chemical characteristics of the common storage depots available to many organisms are described elsewhere in this book. For our discussion here, the reader should be aware of the following storage depots and how they influence the distribution of toxicants in the organism.

Albumin is the major plasma protein that functions as a storage depot. Although there are other plasma proteins, albumin can bind a large number of toxicants; at least six binding regions have been identified on the protein [108,109]. The binding of various toxicants as well as endogenous substances to plasma proteins such as albumin inhibits that substance from crossing the capillary beds and entering into extracellular space for distribution. The binding mechanism

is reversible, so equilibrium can be maintained as various compartmental concentration levels change over time.

The liver and kidney both function as storage depots and can store a considerable number and amount of toxicants; both organs concentrate and remove toxicants as a primary function. Proteins found in these organs, such as metallothionein and ligandin, have been shown to bind organic acids, cadmium, and zinc, which are concentrated in these organs. It is estimated that more toxicants are stored in these two organs than in all of the other organs combined [14].

Body fat functions as a storage depot. Because of the lipophilic nature of many toxicants, many are stored in neutral body fat in large amounts. Bone also functions as a storage depot. The hydroxyapatite crystals of bone provide a very large surface area for toxicants such as lead, strontium, and fluoride to easily penetrate. The toxicants in bone are reversibly bound, so these materials can be released back into the plasma by ionic exchange and dissolution of bone lattice by osteoclastic activity.

Factors Affecting Elimination

Fecal elimination is another pathway for the GI tract to effectively remove toxicants. Three major components contribute to the process of toxicant excretion through the feces.

Biliary Excretion

Because the liver is first in line for the newly absorbed nutrients or toxicants, it can and does extract and biotransform toxicants of all sorts so the metabolites can be excreted into the bile. The bile is then reintroduced into the GI tract and excreted in the feces unless it is reabsorbed in the enterohepatic circulation system. An increase in the amount of biliary excretion can lessen the ultimate toxicity of a toxicant unless some biological effect such as hydrolysis occurs that increases the lipophilic nature and absorbability of the toxicant. Bile components are divided into three classes of compounds based on their bile/plasma concentration ratios. Class A compounds have a bile/plasma ratio of ~1 and include substances such as sodium, potassium, glucose, mercury, and thallium. Class B compounds have a bile/plasma ratio of >1 but usually between 10 and 1000. Some class B compounds would include bile acids, lead, arsenic, and many more common toxicants. Class C compounds have a bile/plasma ratio of <1 and include materials such as inulin, albumin, zinc, and chromium. Class B compounds are usually rapidly excreted by active transport directly into the bile. In general, conjugates with molecular weights greater than 325 and conjugates of both glutathione and glucuronide appear to have a higher concentration in the bile. Numerous transport systems in the hepatocytes have been identified whose function is to move these various substances to and from the liver and back into the GI tract [4,10,277,286].

Table 31.25 provides a summary of the better-known transport systems in the liver hepatocytes.

Intestinal Excretion

Studies have been performed in bile-duct-ligated animals in which the presence of a number of substances in the feces could only be attributed to direct transfer from the circulating blood to lumen of the small intestine [138–141,279]. Hence, direct excretion into the small intestine from the mucosal epithelial cells constitutes a portion of the source of toxicants excreted in the feces. In addition to the secretion of various chemicals

TABLE 31.25
Transport Systems in the Liver Hepatocyte

Transport System	Abbreviation	Function	Location	Refs.
Na^+-taurocholate cotransporting polypeptide or liver bile acid transporter	NTCP or LBAT	Transports bile acid taurocholate into the liver—part of the enterohepatic circulation of bile acids	Sinusoidal side	[110–113]
Organic-anion polypeptides	OATP1A2	Transport organic polypeptides into the liver—hepatic uptake	Sinusoidal side	[111,114–119]
	OATP1B1			
	OATP1B3			
	OATP2B1			
	OATP2A1			
	OATP3A1			
	OATP4A1			
	OATP5A1			
	OAT7			
Liver-specific transporter	LST1, LST2	Transports toxicants into the liver	Sinusoidal side	[120–122]
Organic-cation transporter	OCT1, OCT2, OCT3, OCT6	Transports toxicants into the liver	Sinusoidal side	[123–126]
Bile salt excretory protein	BSEP	Transports bile acids out of the liver	Bile canaliculi side	[127]
Multidrug-resistant protein 1	MDR1	Transports toxicants into the bile	Bile canaliculi side	[128–130]
Multiresistant drug protein 2	MRP2	Transports toxicants into the bile	Bile canaliculi side	[131–133]
Multiresistant drug proteins 3 and 6	MRP3, MRP6	Transport toxicants back into blood circulation	Blood capillaries	[134–137]

directly into the GI tract, the microflora have been shown to biotransform some toxicants to forms that become eliminated through the feces rather than reabsorbed. Because toxicants in the lumen of the intestine are also ingested by the resident microflora, it is estimated that some portion of the toxicant has been biotransformed by these intestinal microflora.

Nonabsorbed Excretion

Some ingested nutrients and toxicants simply do not get absorbed during their transit through the GI tract; for example, because of their chemical characteristics, ingested sucrose polyester, cholestyramine, and ionized compounds such as quaternary ammonium are not well absorbed and are found in fecal excretions.

TESTING THE GASTROINTESTINAL TRACT FOR TOXICANTS

A number of tests are available to detect any effects caused by the entry of toxic agents. Among them are tests that examine the structural integrity of the luminal cell well. Table 31.26 provides a summary of the types of testing utilized to examine the structural integrity and continuity of the GI tract. Toxicants can also effect changes in the rate of cell proliferation in the intestinal mucosal walls. Antineoplastic agents tend to slow the rate of cell division as part of their therapeutic mechanism, but some effects are indirect in that the toxicant can interfere with normal cell regulatory mechanisms, such as hormones, or cause tissue injury [165,166]. Several tests have been developed to examine the proliferation of cells of the mucosa. Table 31.27 is a summary of some of the available tests for mucosal cell proliferation.

The gastric secretion of hydrogen chloride from the parietal cells is a critical factor for the initiation and optimal functioning of pepsinogen and prochymosin within the stomach; therefore, toxicants that alter the gastric secretory activity can have a profound effect on the functioning of the stomach. The rate of acid secretion in the parietal cells is under both neurological and hormonal control, so the measurement of acid secretion provides an index of measurement for the status of digestion. Table 31.28 summarizes some of the procedures available for measuring gastric secretion.

Gastric emptying is a critical process in the GI tract because it controls the rate at which properly triturated chyme is released into the small intestine for optimal absorption [188–191]. The pylorus (from the Greek word for *keeper of the gate*) determines what enters the small intestine from the stomach. Under normal circumstances, it allows only chyme of the proper texture and size to enter the small intestine. The control of gastric emptying is complex and can be altered by stress [192], meal composition and size [193], pathological processes, and pharmacological interactions [190]. Methods for the assessment of gastric emptying can be divided into three basic types: (1) tracer studies, (2) imaging studies, and (3) electrical resistance studies. Representative studies from each of these categories are summarized in Table 31.29.

TABLE 31.26
Testing for Structural Integrity

Test	Description	Examined Entity	Notes	Refs.
Direct observation of mucosal cell wall	Invasive visual inspection of GI tract for lesions; quantitation of damage	GI walls	Duodenal and gastric ulcer indices are created to quantitate findings.	[142,143]
	Invasive examination of the structure and organization of the GI tract wall	GI walls	Slides are prepared to evaluate cellular organization and structure; endoscopic examination and biopsy methods.	[144–147]
	Invasive visual inspection of GI tract pretreated with dyes for lesions; quantification of damage	GI walls	Sky Blue Dye 6, Evans blue dye, or Monastral Fast Blue B is injected intravenously.	[148–151]
Mucosal permeability	Invasive exam of blood to lumen clearance of ^{51}Cr-EDTA	Assessment of leakage into lumen from blood stream	Blood and perfusate are collected to measure EDTA clearance.	[152,153]
Fecal blood loss	Noninvasive examination of feces for occult blood	Assessment of blood leakage into the GI tract by colorimetric methods	Guaiac (hemoccult) is the least sensitive and *o*-toluidine the most sensitive. HemoQuant measures fluorescence of porphyrins. Recent studies indicate these tests are insensitive.	[154–158]
	Intravenous injection of ^{59}Fe sulfate for in vivo labeling of red blood cells	Assessment of blood leakage into the GI tract by radioisotopic methods	Procedure is more sensitive than colorimetric methods; 24 h fecal collection and assay for radioactivity.	[159,160]
Cell shedding	Monitoring rate of cell loss in the GI tract	Measure DNA content of luminal fluid from surgically implanted GI tubes	Fluid is quantified for displacement of ^{125}iododeoxyuridine DNA from DNA antibodies.	[161–164,275,276]

TABLE 31.27
Testing for Mucosal Cell Proliferation

Test	Description	Examined Entity	Notes	Refs.
Cell kinetic analysis	Invasive intravenous injection of ^{3}H-thymidine to label crypt cell DNA	Assessment of the duration of the cell cycle and cell migration progress	Pulse exposure to ^{3}H-thymidine with tissue harvest and fixed slides is a 2- to 4-week process.	[167,168]
Antibodies to cell cycle antigens	Use of proliferation cell nuclear antigen (PCNA) to label S-phase cells in crypts requiring incubation of the tissues	Assessment of proliferation of GI cells	Method can be completed more quickly than autoradiography.	[169]
Flow cytometry	Incubation of intestinal crypt and villa cells and separation by DNA content	Assessment of proliferation of GI cells	Method can be completed more quickly than autoradiography.	[170,171]

TABLE 31.28
Testing for Gastric Secretory Activity

Test	Description	Examined Entity	Notes	Refs.
In vivo direct gastric acid collection	In this invasive procedure, the pylorus is tied off in an anesthetized animal; the gastric content is sampled periodically via syringe.	The sample is titrated to pH 7.0 for hydrogen ions associated with specific endogenous compounds (i.e., mucoproteins).	Titration to pH 3.5 provides an estimate of total HCl present.	[172–174]
In vivo Azure A measurement	In this noninvasive procedure, Azure A–resin complex (azuresin, Diagnex Blue) is administered by gavage, and the animal is housed to collect a 24 h urine.	Allows the quantification of the breakdown of Azure A from azuresin, which is pH dependent.	The 24 h urine is measured for the concentration of Azure A by spectrophotometry.	[175,176]
In vivo fundic pouch	In this invasive model, a dog is surgically fitted with a Heidenhain pouch to permit controlled exposures.	Permits repeated measurement of volume changes, electrolyte concentrations, and mucosal blood flow.	The denervated pouch decreases the basal acid secretory rate, which must be factored in to the findings.	[177–179]
In vitro tissue in a Ussing chamber	Segment of the stomach is surgically removed and used to separate two solutions.	Acid secretion and electrolyte flux can be quantified.	The muscle layer is removed prior to use in the Ussing chamber.	[50,180–182,287]
In vitro culturing of gastric gland cell types	Gastric tissue is prepared with pronase and collagenase, and the cell types can be isolated and examined with no anatomical barriers between the mucosal and serosal surfaces.	With appropriate corrected measures, oxygen consumption can be measured with a polarographic electrode or a Gilson respirometer as an index of secretory activity.	A variation of this method is monitoring the uptake of aminopyrine; this substance moves into the intracellular space of the parietal cell and becomes trapped in the secretory vesicles.	[50,183—188]

Understanding the factors affecting absorption of the GI tract is important in order to characterize the absorption, metabolism, and excretion of toxicants and what effect toxicants may have on the absorption and metabolism of necessary nutrients or pharmacological substances being used for therapeutic purposes. In vitro models have been developed that mimic the human GI tract in an attempt to predict reactions of food and bioactive components in physiological conditions. These simulated digestion studies have been used for a number of years to investigate the digestion, behavior, and ultimate bioaccessibility (amount of a contaminant that reaches the systemic circulation and exerts a toxic effect) of animal proteins [212], plant proteins [213], and food additives [214]; to study the effects of the foodstuff matrix on the bioavailability and bioaccessibility of ingested contaminants [36]; to examine carotenoids in biological emulsions [215,216]; and to determine the effects of ingesting contaminants from soil [217]. In vitro digestion models reflecting the conditions of the GI tract in the presence or absence of food have been used to study the bioaccessibility of compounds from soil. It is known that fasting can have a significant impact on the oral bioavailability of compounds, as the presence of food alters conditions in the GI tract. To mimic intestinal absorption, the Caco-2 transport model was used [218].

The general procedure for studies such as these is that the digestion process of the GI tract is simplified by applying physiologically based conditions such as synthetic saliva, gastric juice, duodenal juice, and bile to samples with controlled

TABLE 31.29
Testing for Gastric Emptying Activity

Test	Description	Examined Entity	Notes	Refs.
Tracer studies	*Breath tracers* are a noninvasive procedure involving ingestion of a ^{13}C-labeled substrate that produces a detectable increase in $^{13}CO_2$.	After gastric emptying, the ^{13}C-labeled substrate can be measured in the exhaled breath as $^{13}CO_2$.	Exhaled breath samples are examined by isotope-ratio mass spectrometry for the $^{13}C/^{12}C$ ratio over time.	[194–196]
	Gastric tracers are an invasive procedure involving gastric gavage of a known amount of nonabsorbable marker.	Serial aspiration samples are taken through a nasogastric tube or a catheter in the gastric wall.	The serial gastric samples are assumed to be homogeneous and are examined over time.	[190,197,198]
	Plasma tracers are an invasive procedure involving ingestion of paracetamol, which is slowly absorbed into the blood in the stomach and rapidly absorbed in the small intestine.	Serial blood samples are taken via an intravenous catheter.	The paracetamol concentration is measured in the blood L\plasma levels over time and is an indirect measure of gastric emptying.	[190,199]
Imaging studies	*Radiography* is a noninvasive procedure involving ingestion of radiopaque solids and liquids.	After ingestion, serial lateral and ventral radiographic images are taken over 4–12 h.	The movement of the radiopaque material is monitored qualitatively via the radiographic images.	[190,200,201]
	Radioscintigraphy is a noninvasive procedure involving ingestion of food containing radioisotopes.	Radiographic images are integrated with an integrated nuclear medicine computer system, and the radioactive counts are recorded over time.	With the application of various correction factors to allow for radioactive decay, the movement of gastric contents can be recorded over time.	[202]
	Ultrasonography is a noninvasive procedure used to measure flow through areas of the antral portion of the stomach.	Ultrasonographic images are taken as materials move through the stomach in real time.	Movement is measured in real time; however, further validation of this method is necessary at this time.	[203]
	Magnetic resonance imaging is a noninvasive procedure used to examine liquid- and solid-phase gastric emptying and motility.	Magnetic resonance images provide a 3D image of the stomach emptying.	Emptying and motility are measured simultaneously.	[204–206]
Electrical resistance studies	*Impedance epigastrography* is a noninvasive procedure that uses two pairs of electrodes to monitor electric current after the ingestion of food.	An electric current is applied to the epigastric region with a pair of electrodes, while another pair of electrodes monitors the changes in the current.	Ingestion of food causes changes in the pattern of electrical resistance, which is an indirect measure of gastric emptying.	[190,207,208]
	Applied potential tomography is a noninvasive procedure that uses multiple pairs of electrodes to monitor electric current after the ingestion of food.	An electric current is applied to the epigastric region with multiple pairs of electrodes that monitor the changes in electric current over the entire upper abdomen.	Ingestion of food causes changes in the pattern of electrical resistance, which is an indirect measure of gastric emptying.	[209–211]

pH and residence time periods that mimic each compartment of the GI tract. Two-stage digestion systems represent the stomach and the small intestine, and three-stage digestion systems represent either (1) the mouth, stomach, and small intestine or (2) the stomach, small intestine, and large intestine [36]. Because practically no absorption occurs in the mouth or the stomach, bioaccessibility is usually determined from the chyme resulting from the small intestine compartment. Figure 31.11 is a flow diagram of a typical in vitro digestion model.

The Bioavailability Research Group Europe (BARGE; http://www.bgs.ac.uk/barge/home.html, accessed June, 2012.) was established in 1999 to promote cooperation among European countries interested in developing and comparing data and protocols for in vitro digestion systems designed to analyze data on oral bioavailability of soil contaminants. BARGE has published comparison studies of the findings of various European laboratories [219,220], and data collected by BARGE are summarized in Table 31.30. Table 31.31 summarizes tests that can be used to help characterize and quantify absorption within the GI tract.

Normal peristalsis is necessary for digestion, the delivery of chyme to various areas for absorption, and waste elimination. Factors that control peristalsis are numerous and complex. The motility characteristics change in pattern and periodicity from one segment of the GI tract to the next.

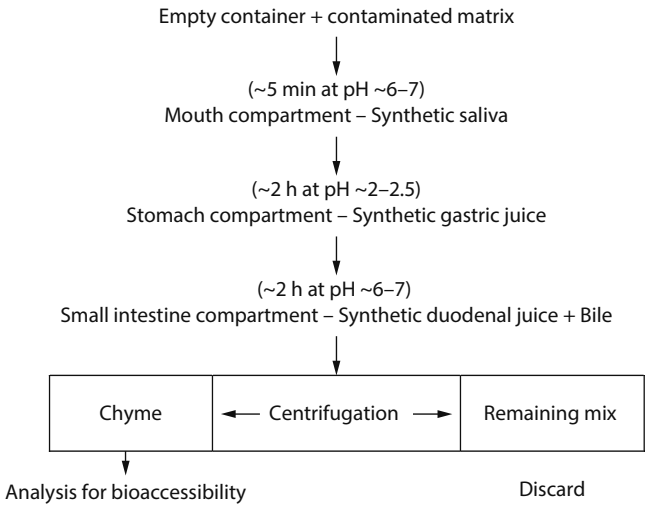

FIGURE 31.11 Depiction of a typical in vitro digestion study. (Adapted from Versantvoort, C.H.M. et al., Development and applicability of an *in vitro* digestion model in assessing the bioaccessibility of contaminants in food, RIVM Rep. No. 320102002/2004, National Institute for Public Health and the Environment, Bilthoven, the Netherlands, 2004. Available online: http://rivm.openrepository.com/rivm/bitstream/10029/8885/1/320102002.pdf)

The activity is mediated by a complex system of neurons in the wall of the GI tract that coordinate contractions between the longitudinal and circular musculature. The contractions are both neurologically and hormonally controlled. The neurological control is dependent on the following enteric (intrinsic) neurotransmitters: vasoactive intestinal peptide, enkephalin, substance P, gastrin-releasing peptide, NPY, and somatotropin. Extrinsic neurotransmitters from the vagus and pelvic nerves include choline, acetylcholine, and norepinephrine. The hormonal control is mediated by gastrin, secretin, and cholescystokinin, all of which are secreted by the walls of the GI tract in response to certain dietary components. Table 31.32 summarizes the more common methods used to analyze motility in the GI tract. Further details on common techniques used to assess gastric motility were recently reviewed by Szarka and Camilleri [258].

As noted previously, the entire length of the GI tract contains microflora, many of which are located in the large intestine [85,266]. Pathogenic strains of some bacteria such as *Shigella* and *Helicobacter pylori* can mediate some toxic effects because they invade the GI mucosa and produce physical changes in the cell wall that can lead to gastritis and peptic ulcers. Intestinal bacteria, such as *Vibrio cholerae*, *Clostridium difficile*, and *Escherichia coli*, are also capable of generating toxins that change water and electrolyte flux rates in the cell wall and ultimately produce diarrhea [285]. Other bacteria are able to activate certain foreign chemicals, such as cycasin, which is found in the nuts of cycad plants, to a form that is carcinogenic and can cause tumors in the liver, kidneys, and colon [267,268]. Table 31.33 provides a summary of some methods used to test for the potential toxic effects of bacteria in the GI tract.

CONCLUSION

The effect of a toxicant on an organism depends primarily on the relative effective concentration and the duration or persistence of the ultimate toxicant at a specific site of action. Numerous portals of entry exist for toxicants. This chapter has focused on the normal structure and function of the GI tract and how the processes of digestion and absorption influence and are influenced by toxicants that enter the GI tract. The intensity of effect of the toxicant is determined by a number of factors that are part of the normal functioning of the GI tract, such as digestion, absorption, biotransformation, distribution, and elimination. Finally, the last part of this chapter briefly describes some of the types of testing that have been developed to examine the effects of toxicants on various aspects of the normal functioning of the GI tract.

TABLE 31.30
Various In Vitro Digestion Methods Assessed by BARGE

Test	Description	Stomach pH	Stomach Incubation Interval	Intestine pH	Intestine Incubation Time	Bile Concentration	Separation Method for Chyme	Refs.
SBET[a]	Static gastric model	1.5	1 h	NA	NA	NA	0.45 μm filter	[221]
RIVM[b]	Static GI model	1.1	2 h	5.5	2 h	0.9 g/L	Centrifugation at 3000 g	[217,222]
SHIME[c]	Static GI model	4.0	3 h	6.5	5 h	1.5 g/L	Centrifugation at 7000 g	[223–225]
DIN[d]	Static GI model	2.0	2 h	7.5	6 h	4.5 g/L	Centrifugation at 7000 g	[226,227]
TIM[e]	Dynamic GI model	5.0 → 2.0 over 90 min	Gradual secretion at 0.5 mL/min	6.5–7.2	Gradual secretion at 1 mL/min	Variable	Hollow-fiber membrane	[228–230]

TABLE 31.31
Testing of GI Tract Absorptive Function

Test	Description	Examined Entity	Notes	Refs.
In vivo determination of GI absorption	Follows a predetermined amount of a substance administered orally over time by determination of its concentration in systemic fluids	Test measures the bioavailability of a xenobiotic and the absorption kinetics on systemic exposure via a metabolic cage.	This is the least precise method to quantify GI tract absorption kinetics due to the many uncontrollable variables.	[231]
	Quantification of absorption	Depending on the substance, measurements can be made in plasma, urine, feces, saliva, and breath.	After oral dietary or gavage administration, samples must be collected over adequate time and with adequate volume but should not affect total blood volume.	[232,233]
	Malabsorption test (D-xylose test)	Test measures the functional integrity of the proximal small intestine.	D-xylose is given by oral gavage, and blood samples are taken periodically for 3 h; D-Xylose concentration is evaluated spectrophotometrically.	[174,234]
In vivo determination of overall GI absorption	Malabsorption test (disaccharides)	Test measures the functional integrity of the disaccharidases ability to cleave disaccharides into monosaccharides.	Disaccharide substrate is given by oral gavage and the changes in blood glucose or the by-product of glucose metabolism (hydrogen gas) measured against known blood and breath values.	[234,235]
	Malabsorption test (fats)	The focus of fat test is to distinguish between defects in the digestion of fats to fatty acids from fatty acid resorption.	An examination of feces for increased fat content (steatorrhea) is followed by oral dosing with radiolabeled triglyceride assay or ^{33}P; the reduction of triglycerides indicates digestive defect, and a reduction in fatty acid absorption suggests bile salt defect or other mucosal defects.	[82,84,236,278,290]
In vivo closed intestinal segment	Invasive procedure where an intact intestinal segment is evaluated for absorption kinetics	An intact segment of the intestine is closed off and injected with the test substance; after a period of time, the intestinal segment is removed and the rate of substance reduction is quantified.	If metabolism of the test substance occurs in the lumen, for the test results to be valid, the fate of all metabolites must be known.	[237,238]
In vivo intestinal perfusion	Invasive procedure for quantifying intestinal transport by measuring the amount of substance in the effluent against the amount infused into GI tract over time	The net flux of water transport into the GI tract can be evaluated by monitoring changes in a nonabsorbable marker.	The proximal and distal ends of the intestine to be examined are cannulated, and the test substance is administered through the proximal cannula; after a period of equilibration, samples are drawn from the distal cannula and the volumes of the test substance are compared.	[239,240]
In vitro inverted sac technique	Characterizes the carrier-mediated processes by quantification of the test substance inside an inverted length of intestine	A small segment of intestine is everted and filled with a fluid and tied at both ends; absorption is quantified by monitoring the appearance of the test substance in the fluid on the inside of the everted sac.	Because of inadequate oxygen diffusion and tissue distention, the incubations must be no longer than 5 min with rat intestine.	[241–243]

(*continued*)

TABLE 31.31 (continued)
Testing of GI Tract Absorptive Function

Test	Description	Examined Entity	Notes	Refs.
In vitro isolated GI tract mucosal cells	Isolation of various GI tract mucosal cells	GI tract mucosal cells are isolated in cultures that permit analysis of membrane transport kinetics without contamination from extraneous substance metabolism.	Isolation of these cells has facilitated more detailed understanding of the biochemical and structural characteristics of cellular membranes.	[244,245,281]
In vitro electrical potential with a Ussing chamber	Short-term exposure of a segment of GI tract suspended in a Ussing chamber to defined solutions with a voltmeter to measure electric current	In addition to voltage, the flux of electrolytes can be measured by a pulse of isotope to one side of the chamber with subsequent quantification on the other side of the membrane.	In a variation of this technique, a unidirectional flux chamber is used to assess mucosal cell transport mechanisms.	[246–248]
In vitro organ cultures	Examination of mucosal explants for studies of cell proliferation and differentiation over longer periods of time	Test permits the study of colonic carcinogenesis and chemotherapy with measurement of toxicants and their effects.	Some colonic cultures have been extended to up to 28 days with normal anatomical cell arrangement.	[249–252,280]
In vitro $CaCO_2$, T^{84}, and HT^{29} cultures	Utilizes cultures of colonic carcinoma T^{84} and subclone HT^{29}, which exhibit normal colon cell and goblet cell characteristics, respectively, in cell cultures	These cultures can be examined for electrolyte transport of nutrients and toxicants.	These cell lines exhibit normal cell characteristics, including tight junctions, apical microvilli, and vectorial electrolyte transport.	[253–256]

TABLE 31.32
Testing of GI Tract Motility

Test	Description	Examined Entity	Notes	Refs.
In vivo measurement of transit time	Gastric or duodenal administration of a suitable marker such as a ^{51}Cr-labeled sodium chromate or ^{125}I- or ^{131}I-labeled polyvinyl pyrrolidine or ^{99m}technetium and subsequent recovery of sample	Using gamma-emitting radioisotopes allows for direct GI segment assay without any processing. Small intestine movements must be administered to the duodenum via an indwelling catheter.	A rapid euthanization procedure is used to quickly extract the GI tract; to stop movement within the tract, ligatures are placed every 3–5 cm. Counts are recorded within each segment.	[257,258]
In vitro rabbit jejunum	Maintenance of rhythmic contractions in vitro	This technique is used to analyze substances that manifest inhibitory effects on GI smooth muscle.	—	[259–262]
In vitro guinea pig ileum	Excision of a guinea pig ileum with the mesenteric plexus	This technique is used to examine substances that influence neuronal conduction and neurotransmitter release and to evaluate GI smooth muscle contractions.	This method has been used extensively to assess changes in contractility in smooth muscle.	[260,263–265]

TABLE 31.33
Testing of GI Tract Microflora

Test	Description	Examined Entity	Notes	Refs.
Toxin study: rabbit ileum	Bacterial toxins are injected into closed segments of surgically ligated 3 in. sections of rabbit ileum; data have revealed surface receptors for enterotoxins.	The toxins cause fluid accumulation when injected into the intestine; quantification of the fluid can provide information about intestinal antiabsorptive or secretory activity.	Rabbit ileum provides more consistent results; the ligated segments are placed at 6 in. intervals, and samples are taken at 4–6 h intervals for examination.	[269,270]
In vivo bacterial metabolism study in germfree animals	Aseptically delivered animals maintained in germfree conditions are treated against normal rats.	Various toxicants are administered to both types of animals, which are housed in metabolism cages where their urine and feces can be quantitated.	Differences in metabolites in urine and feces can indicate changes mediated by the intestinal microflora.	[271,272]
In vitro bacterial metabolism study	Defined bacterial cultures of luminal contents are cultured with various substances.	Demonstration of enzymatic activity in a bacterial strain in vitro can provide evidence of possible bacterial role in metabolite production.	Data can be flawed by synergistic action between an extract of *Bacteroides fragilis* and the microsomal enzyme activity of the mucosa of the large intestine.	[273,274]

QUESTIONS

31.1 Describe the functions of each of the various parts of the digestive system and accessory organs.
31.2 Describe the various cellular absorption processes.
31.3 Describe the excretions of and digestive functions of the accessory organs.
31.4 Explain how substances are chemically altered when they are ingested.
31.5 Describe the intestinal first-pass effect and how it influences toxicity.
31.6 What is enterohepatic circulation?
31.7 Describe the critical factors influencing toxicity of ingested substances.
31.8 Describe the critical factors influencing distribution of ingested substances.
31.9 Describe the use of SHIME, SBET, and RIVM tests in food and soil contamination studies.
31.10 How do storage depots influence gastric toxicity?

32 Pathophysiology and Toxicology of the Heart

Khalid Almuti, Shahid Rahman, and Daniel Acosta, Jr.

CONTENTS

OVERVIEW/INTRODUCTION

The discipline of cardiac toxicology is concerned with the adverse effects of drugs, chemicals, and xenobiotics on the heart and vascular system. These chemicals may directly and adversely cause changes in the structure and function of the myocardium. In addition, there may be indirect effects secondary to changes in other organ systems, such as the nervous systems (both central and autonomic) and the endocrine system.

Examples of functional abnormalities caused by chemicals include alterations in the heart rhythm potentially leading to lethal arrhythmias even in the absence of any preexisting cardiovascular structural abnormalities. Structural myocardial alterations may also result from the direct actions of certain chemicals including degenerative necrosis and inflammatory reactions.

This chapter presents an overview of normal and abnormal cardiac structure and physiology with selected examples of cardiotoxicants and their major mechanisms of cardiotoxicity. It also discusses the topic of myocardial cell death including the processes of apoptosis and necrosis. The reader may also wish to consult other monographs on the toxicology of the heart, found in general toxicology texts [1] or specific references on cardiovascular toxicology [2].

NORMAL CARDIAC PHYSIOLOGY

Understanding normal cardiac structure and function facilitates a better appreciation of the toxic mechanisms of different substances on the heart and vasculature. The purpose of the cardiovascular system is to provide oxygen delivery to meet the metabolic demands of the body. This is achieved by the heart acting as a pump to drive oxygenated red blood cells to the various tissue beds. The stimulus for regular cardiac contraction is the electrical action potential, which in turn leads to intracellular calcium release and subsequent force generation via actin and myosin cross-bridge formation [3]. The ultrastructure of cardiac myocytes facilitates force generation by both mechanical and electrical cell-to-cell coupling and an abundance of ATP-producing mitochondria, which fuel the metabolic demands of the myocyte.

With a thorough understanding of the normal physiology of the cardiovascular system, the major pathophysiologic mechanisms of cardiovascular disease will be addressed. We will also explore the roles by which some toxicants may precipitate or exacerbate cardiac dysfunction.

Cardiac Function and Metabolic Homeostasis

The cardiac chambers act as reservoirs that fill with and eject blood. There are multiple metabolic and neurohormonal systems that influence cardiac function. These varied inputs modulating cardiac function alter cardiac output to meet the physiologic demand for oxygen. Oxygen demand is the amount of oxygen needed to satisfy the metabolic demand of all body tissues. Oxygen delivery from the heart to distal tissues is the product of cardiac output and the oxygen content of arterial blood:

$$\text{Oxygen delivery} = \text{Cardiac output} \times \text{Oxygen content}$$

The oxygen content of arterial blood is influenced by multiple factors including the amount of oxygen delivered to the blood stream via respiration and the oxygen-carrying capacity of the blood. Hemoglobin is a major determinant of blood oxygen content and normally carries 98% of dissolved oxygen. Under a steady state of blood oxygen content, cardiac output becomes the primary determinant of changes in oxygen delivery.

Cardiac output is the product of stroke volume and the heart rate (cardiac output = stroke volume × heart rate). The stroke volume is the difference between the blood volume in the ventricle before and after contraction. The capacity of the heart to contract independently of changes in pressure conditions (i.e., preload and afterload) is defined as the contractility of the ventricle. These variables are modulated to achieve a desired stroke volume from each ventricular beat [4].

The ventricular pressure and volume are not linearly related. This is due to a property termed compliance of the heart. Unlike a rigid box, the ventricle is able to stretch as it fills with blood. Due to its compliance ability, abrupt volume changes do not cause large swings in intraventricular pressure readings. In the absence of compliance, changes in ventricular volume would otherwise cause abrupt increases in venous pressure leading to possible consequences such as pulmonary edema. The relationship of the ventricular volume and pressure may be graphically depicted as the pressure–volume curve (Figure 32.1).

Understanding the relationship between ventricular pressure and volume helps to explain how toxicants causing left ventricular fibrosis and stiffening (e.g., anthracyclines) may increase ventricular pressure at a given preload volume potentially leading to clinical disease manifestations.

Afterload is often thought of as the pressure against which the heart must work to eject blood out of the ventricle. One of the main determinants of afterload is the systemic blood pressure and arterial stiffness [5]. This pressure must be overcome to propel blood from the heart to the aorta.

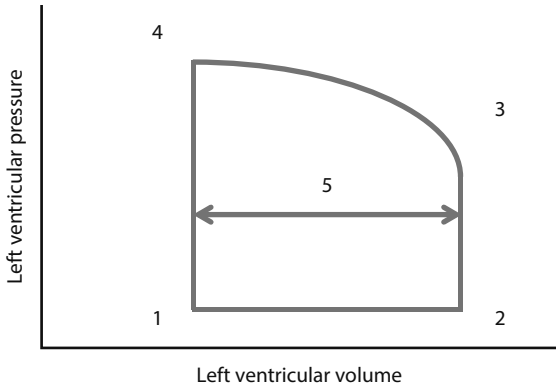

FIGURE 32.1 Pressure–volume loop. (1) End of isovolumetric relaxation, (2) end diastolic pressure, (3) end of isovolumetric contraction, (4) end systolic pressure, and (5) stroke volume.

Toxicants that cause abrupt increases in systemic blood pressure will increase the afterload and consequently the amount of work the heart must perform to overcome this pressure and to eject blood. Hence, severe hypertension, caused by drugs such as cocaine or amphetamines, may cause myocardial ischemia even without significant obstructive coronary artery disease [6].

Multiple systems modulate the contractile state of the heart to change the stroke volume to meet the demands of the body. At the level of the myocyte, increased contractility is often achieved by increasing intracellular calcium. The calcium ions interact with troponin leading to a conformational change in the inhibitory troponin molecule [7]. Subsequently, this change allows for cross-bridge formation between actin and myosin, which are the contractile components in the myocyte. Increased calcium thus leads to increased interaction between actin and myosin and increased force of contraction.

One of the primary determinants of contractility is the autonomic nervous system via the beta-adrenergic system. The beta-adrenergic receptor in the heart is a G-coupled protein receptor. When this receptor is stimulated, it leads to a downstream cascade of signals resulting in phosphorylation of the calcium channel and eventually increased calcium release [8].

Electrophysiological Basis of Contraction

The normal pacemaker cells in the heart have the capacity to modulate their function in response to extrinsic inputs from the autonomic nervous system. An increase in heart rate will lead to an increase in cardiac output via the formula stated earlier (cardiac output = heart rate × stroke volume). An appropriate increase in heart rate in response to a stimulus (i.e., exercise, pain, fever) can reach levels that depend, in part, on the person's age (younger persons can usually achieve faster heart rates). The cardiac electrical system is both sophisticated and multilayered. It is composed of cardiac myocytes that have the capacity to both generate and conduct electrical impulses.

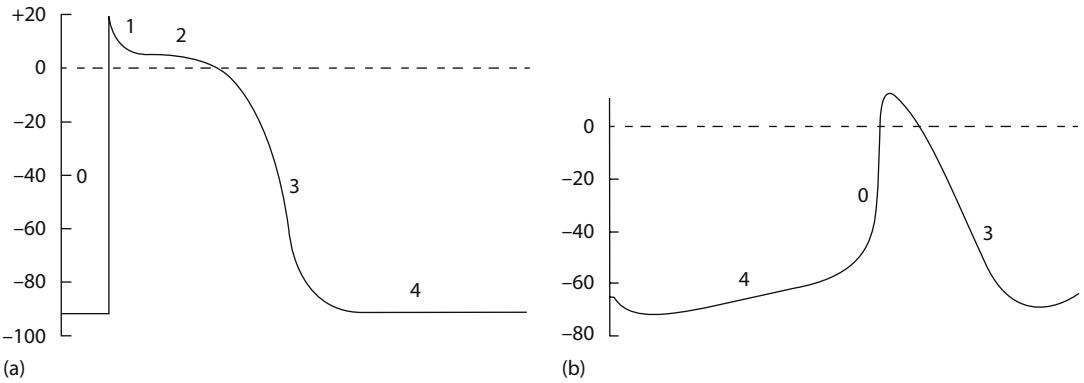

FIGURE 32.2 Typical action potentials (in mVs) recorded from cells in the (a) ventricle and (b) SA node. (Adapted from Hoffman, B.F. and Cranefield, P.E., *Electrophysiology of the Heart*, McGraw-Hill, New York, 1960.)

Cardiac myocytes are organized in a hierarchical system with one group of the cells, the sinoatrial (SA) node, being the principal pacemaker of the heart. Other cell types (i.e., atrioventricular [AV] node, His–Purkinje system, and ventricular myocytes) function as conductors of the electrical signal while retaining the capacity to generate electrical impulses themselves if called upon to do so with failure of the SA node. Under normal circumstances, the pacemaker cells of the heart produce myocardial action potentials with a great deal of regularity and dependability. This property is termed normal automaticity. Automaticity is highly regulated and depends on the interplay between multiple intracellular and extracellular (including extracardiac) factors. Such interplay allows the heart to beat with variable rates based on the various inputs and circumstances. Assuming a resting adult heart rate of 60–80 beats/min, the typical heart beats approximately 100,000 times daily. Over an average lifespan of 75 years, the heart may beat close to 2.75 billion times. This demonstrates the robustness and reliability of the system.

The SA node is a spindle-like structure that resides just below the epicardial surface of the right atrium near its junction with the superior vena cava (SVC). It receives, interprets, and acts upon signals received from its own myocyte membrane ion channels and other intracellular mechanisms. All of these data have to be consolidated in a very rapid and efficient manner with inputs from various neurotransmitters, hormones, and stretch receptors. These mechanisms collectively function as an internal clock that triggers the next myocardial action potential.

Myocardial Action Potential

The depolarization of the SA node subsequently triggers electrical impulses through the myocardium. Under normal circumstances, the resting potential of a myocyte is about −60 to −90 mV relative to the extracellular fluid potential. A slow potential change occurs just prior to initiation of a subsequent action potential. A sudden depolarization then dramatically changes the membrane potential from negative inside to positive inside. Depolarization is ultimately followed by repolarization, which resets the cell's resting potential. The process of an action potential from depolarization to the completion of repolarization is divided into five phases in cardiac Purkinje fibers, as shown in Figure 32.2. Phase 0 represents a rapid depolarization due to the inward current of Na^+. Phase 1 is associated with an immediate rapid repolarization, during which Na^+ inward current is inactivated and a transient K^+ outward current is activated, which is followed by an action potential plateau, or phase 2, which is characterized by a slowly decreasing inward Ca^{2+} current and slow activation of an outward K^+ current. Phase 3 reflects a fast K^+ outward current and inactivation of the plateau Ca^{2+} inward current, and phase 4 is the diastolic interval for the resetting of the resting potential.

The cells of the SA node are unique in that they are not dependent on the inward Na^+ current (I_{Na}) for their upstroke. Instead, the action potential upstroke is predominantly due to action of the L-type calcium current (I_{CaL}). It is thought that local oscillation in Ca^{2+} channels contributes to the depolarization of the cell membrane. The resultant Ca^{2+} influx itself results in the release of calcium stores from the sarcoplasmic reticulum (SR). This phenomenon is known as calcium-induced calcium release and plays an important role in the process of muscle contraction. Eventually, outward potassium currents repolarize the cell membrane by reestablishing a negative potential.

Electrical Mechanical Coupling

Myocyte contraction occurs when an action potential depolarizes the cardiac membrane. The depolarization causes a conformational change in L-type calcium channels, which allows a small amount of calcium to enter the myocyte. These L-type calcium channels are located in close proximity to the SR, an intramyocyte calcium storage structure. The calcium then binds to the ryanodine receptor on the SR, which subsequently leads to a conformational change in its structure resulting in the release of large amounts of stored calcium. The increase in calcium concentration in the cell allows calcium to bind to troponin, causing a conformational change in this inhibitory molecule. This conformational change permits interaction between the actin and myosin filaments

through cross-bridge formation. Adenosine triphosphate (ATP) is hydrolyzed by ATPase, present in the cross bridges, to release energy so the cross bridges can move in a ratchet-like fashion. This action increases the overlap of the actin and myosin filaments, resulting in shortening of the sarcomeres and contraction of the myocardium. This action-potential-triggered calcium increase in the plasma and myocyte contraction is referred to as excitation–contraction coupling [9].

The heart muscle as a whole has to synchronize the contraction and relaxation of individual myocytes to perform its pump function. This is achieved by gap junctions, which are special structural features of cell-to-cell interaction. Through the gap junction, major ionic fluxes between adjacent cardiomyocytes are spread, thus allowing electrical synchronization of contraction. Each single gap junction is composed of 12 connexin 43 (Cx43) units assembled in two hexametric connexons (hemichannels), which are contributed, one each, by the two participating cells. On average, a given cardiomyocyte is electrically coupled via gap junctions to 11 adjacent cells [10].

CARDIAC PATHOPHYSIOLOGY AND TOXICANTS

Arrhythmias

Tachyarrhythmias may result from one of three main mechanisms:

1. Reentry
2. Abnormal automaticity
3. Triggered activity

1. Reentry: This is the most common mechanism of arrhythmias (both atrial and ventricular) [11]. It requires a specific setup that is created by a variety of anatomic and physiologic factors. In essence, two pathways are needed, each with distinct electrophysiological properties [12,13]. An arrhythmia is initiated when an electrical impulse (usually a premature electrical impulse) reaches these two pathways, and the electrical signal travels down one of the two pathways and back up the other (Figure 32.3.). This circuit continues up and then down the two pathways in a continuous manner until interrupted [12,13]. Certain pharmacologic agents can alter some of the electrical properties of the myocytes, which are crucial for initiation and maintenance of such reentrant arrhythmias. These include the antiarrhythmic drugs amiodarone, sotalol, and lidocaine among others. They also include drugs such as beta-blockers and calcium channel blockers. In this manner, antiarrhythmic medications "break" the circuit and prevent the arrhythmia from occurring. Paradoxically, sometimes the use of antiarrhythmic drugs may promote the induction and maintenance of these circuits [14].
2. Abnormal automaticity: This phenomenon occurs when a group of myocytes develops altered electrical activity (e.g., enhanced phase 4 depolarization of the myocyte action potential). Such an alteration of the action potential properties allows myocytes to fire rapidly in the absence of an appropriate extrinsic stimulus [15]. These rapidly firing cells

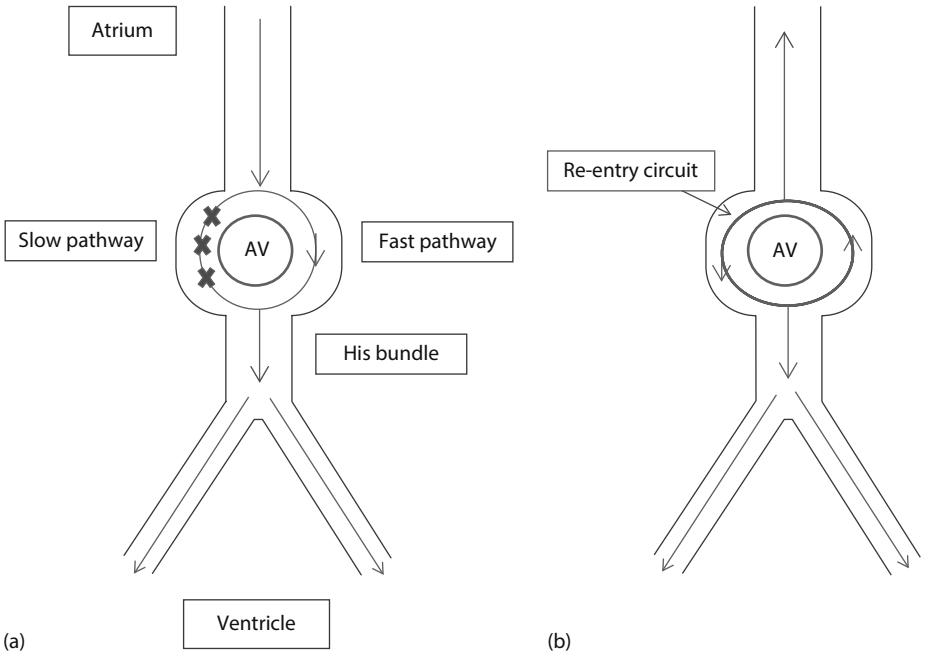

FIGURE 32.3 Schematic representation of a reentry circuit (in this case, the circuit for atrioventricular nodal reentrant tachycardia [AVNRT]). (a) Sinus rhythm is depicted; the electrical impulse enters the AV node and uses both the fast and slow pathways antegrade continuing down to the ventricles. (b) A reentrant tachycardia circuit is observed with the impulse going down one limb of the circuit, turning around, and going up the other limb (activating the atria and ventricles simultaneously).

suppress the SA node and can continue with their abnormal function for prolonged periods of time. The nature of such arrhythmias may be incessant in some cases and episodic in others. Increased automaticity may be caused by increased sympathetic tone or stimulants such as caffeine, nicotine, or amphetamines [16].

3. Triggered activity: These arrhythmias result from abnormal interruptions of the normal repolarization portion of the myocyte action potential. Such interruptions are called afterdepolarization and are further classified as either early or delayed [17]. Arrhythmias result when afterdepolarizations gain enough amplitude that a premature action potential is generated. Certain arrhythmias caused by drug toxicity (e.g., digoxin or theophylline) are related to this mechanism [18]. Such tachyarrhythmias can lead to mechanical cardiac abnormalities (e.g., tachycardia-mediated cardiomyopathy).

QT interval prolongation and related tachyarrhythmias (i.e., torsades de pointes [TdP]) may result from intrinsic or extrinsic factors. Certain inherited channelopathies may result in QT interval prolongation [19].

Alternatively, such QT interval prolongation may result from the toxic effects of certain drugs and substances.

A host of cardiac and noncardiac drugs account for most cases of acquired QT interval prolongation (Table 32.1) [20,21]. When TdP results, it may be of limited duration or it may be persistent. It may also degenerate into life-threatening ventricular fibrillation. Patients experiencing drug-induced QT interval prolongation may already have subclinical abnormalities in repolarization and the addition of the offending drug results in clinical manifestations of these abnormalities as the QT interval prolongs further. These repolarization abnormalities specifically affect phase 3 of the myocyte action potential. Such prolongation of repolarization provides more time for ectopy (i.e., early afterdepolarizations) to trigger episodes of TdP [22]. Some well-known drugs associated with TdP are methadone, phenothiazines, Haldol, and sotalol.

TABLE 32.1
QT Interval–Prolonging Substances

1. Antiarrhythmics
   A. Sotalol
   B. Dofetilide
   C. Ibutilide
2. Antimicrobials
   A. Ciprofloxacin
   B. Erythromycin
   C. Ketoconazole
3. Antipsychotics
   A. Haloperidol
   B. Phenothiazines
4. Anesthetics and opiates
   A. Sevofluran
   B. Methadone

It has been proposed that drug-related QT interval prolongation results from blockade of the outward delayed rectifier potassium (I_{kr}) channels [23]. The D,L-isomer of sotalol, an I_{kr} blocker, is estimated to have a 0.3%–7% risk of TdP. The risk increases with higher doses and the presence of conditions such as hypokalemia, renal failure, and other QT-prolonging agents among others [21,24].

Women appear to be at a higher risk of developing acquired QT interval prolongation with its clinical manifestations [25].

Bradyarrhythmias may result from failure of impulse generation and/or impulse conduction. Such failure may result from intrinsic factors related to either aging or certain disease states. In some cases, however, bradyarrhythmias can result from the toxic effects of various pharmacologic agents (i.e., beta-blockers, digoxin, antiarrhythmic agents, and calcium channel blockers). In some cases, the use of implantable pacemakers is necessary to treat marked symptomatic bradyarrhythmias.

Infarction

Myocardial infarction (known colloquially as a heart attack) occurs when the blood supply to the heart is inadequate to meet the metabolic demands of the tissue. When the myocyte does not receive adequate oxygen delivery, aerobic metabolic activity is unable to proceed and tissue ATP stores become depleted. The myocyte requires ATP for force generation and to maintain electrochemical gradients between the intracellular and extracellular space. If blood flow is stopped completely, irreversible myocardial injury begins after approximately 20 min of ischemia, and within 4–6 h, the affected myocardial segment may become completely infarcted.

The clinical syndrome of myocardial infarction is diagnosed by the occurrence of typical chest pain, electrocardiographic (ECG) findings indicative of ischemia, and the rise of cardiac biomarkers. Ischemia may lead to myocyte cell death and the release of intracellular proteins into the systemic circulation. Multiple serum assays are used to detect myocardial infarction. The primary assay in clinical use today is the troponin (either troponin I or troponin T). Troponin is the intracellular protein that inhibits actin and myosin binding. When myocyte cell injury occurs, intracellular troponin begins to leak out of the cell membrane. Troponin may be detected in the serum within 2–4 h after injury to the myocyte.

There are multiple toxic substances that may lead to myocardial infarction. One such substance is cocaine, which may cause an oxygen supply demand mismatch by several mechanisms. Cocaine exerts sympathomimetic effects on the cardiovascular system causing increased blood pressure, heart rate, and contractility. All of these sympathomimetic factors increase myocardial oxygen demand. Concurrent with the increase oxygen demand, cocaine may also cause

vasoconstriction of coronary arteries via alpha-adrenergic stimulation. During acute intoxication, the sum of these mechanisms may lead to myocardial infarction, arrhythmias, and death.

Cardiomyopathy

Cardiomyopathy is a pathologic disease process that affects cardiac myocytes. When this pathologic process impairs the ability of the ventricle to fill with or eject blood, then the clinical syndrome of heart failure may develop. When the heart's ability to maintain an adequate stroke volume is jeopardized, a cascade of events occurs to maintain cardiac output. After the acute injury to the myocardial contractile function, the body sets in motion a complex set of neurohormonal signals, which may initially stabilize cardiac output but which eventually lead to the deterioration in cardiac function. One of the earliest adaptations of the cardiovascular system to a decrease in stroke volume, as sensed by a decrease in pressure by receptors in the aorta and carotid bodies, is the stimulation of the sympathetic nervous system. This leads to an increase in heart rate to maintain cardiac output (cardiac output = HR × SV). Thus, sinus tachycardia may be a clue to depressed cardiac function. Decreased blood flow to the kidneys leads to the activation of the renin–angiotensin–aldosterone (RAAS) system. This causes sodium and water retention, peripheral vasoconstriction, and myocardial hypertrophy and fibrosis. The eventual outcome is worsened cardiac function, and clinical signs and symptoms of fluid overload, such as shortness of breath or lower extremity edema. The ventricle attempts to maintain stroke volume via increasing preload. This may lead to elevated intraventricular pressure, increased wall stress, and subsequent ischemia. Ventricular dilation and further deterioration of cardiac function may ensue [26]. Multiple toxic substances have been implicated in the development of cardiomyopathy and subsequent heart failure. Anthracyclines cause cardiac toxicity in a dose-dependent manner. Along with cumulative doses of anthracycline, risk factors have been recognized to place patients at risk of cardiac toxicity from these medications including age (both old and young), mediastinal radiation, poor cardiac function at baseline, or coadministration of other agents such as trastuzumab. The suspected mechanism of toxicity from anthracyclines is due to oxidative stress. Some studies have noted up to a 40% mortality with anthracycline-associated toxicity.

As opposed to direct myocyte toxicity posed by anthracyclines, other modes of cardiac toxicity leading to cardiomyopathy include intracellular accumulation of toxic substances. Deterioration in cardiac function is seen in hemochromatosis due to excessive iron deposition in the cardiomyocyte. This disease process has been linked to a mutation in the HFE gene, which codes for a transmembrane protein responsible for iron regulation. Regardless of the mechanism of toxicity, the overt clinical findings of heart failure are manifested when the mechanical dysfunction of the heart due to the toxic substance leads to hemodynamic compromise.

MYOCARDIAL CELL DEATH: APOPTOSIS AND NECROSIS

Toxic insults trigger a series of reactions in cardiac cells leading to measurable changes. Mild injuries can be repaired; however, severe injuries will lead to cell death via apoptosis and necrosis. If the cell survives the insults, structural and functional adaptations will take place. Apoptosis was found to be involved in cardiomyopathy in 1994 [27]. The loss of cardiac myocytes is a fundamental part of myocardial injury that initiates or aggravates cardiomyopathy. Apoptosis is an important mode of myocardial cell loss, as has been demonstrated in heart failure patients [28]. Myocardial apoptosis has been shown to play an important role in the cardiac toxic effects induced by Adriamycin® [29,30], an important anticancer agent whose clinical application is limited by its major side effect, cardiotoxicity. Exposure of primary cultures of cardiomyocytes to cadmium also induces apoptosis [31].

Many in vivo studies have shown that only a very small percentage of myocardial cell population undergo apoptosis under pathological conditions; for example, less than 0.5% of cells appeared apoptotic in myocardial tissue under the stress of dietary copper deficiency in mice [32]. At first glance, this number seems to be too insignificant to account for myocardial pathogenesis; however, this would be a false statement. In a carefully designed time course study [33], it has been estimated that cardiomyocyte apoptosis may be completed in less than 20 h in rats. Because the heart is a terminally differentiated organ, myocytes undergoing apoptosis will be lost; thus, the total cell loss can simply be accounted for by the rate of apoptosis plus necrosis. If apoptosis occurs at a constant rate of about 0.5% myocytes a day [32], the potential contribution of apoptosis to the overall loss of myocytes over a long period of time is significant.

Necrosis is a term that was widely used to describe myocardial cell death in the past. Myocardial infarction, in particular, had been considered as a consequence of necrosis [34]. Although it is now recognized that apoptosis contributes significantly to myocardial infarction [35], the significance of necrosis in myocardial pathogenesis cannot be underestimated. The contribution of necrosis to cardiomyopathy induced by environmental toxicants and pollutants is particularly important. A critical issue is how to distinguish apoptosis from necrosis.

Apoptosis and necrosis were originally described as two distinct forms of cell death that can be clearly distinguished [36]; however, these two modes of cell death can occur simultaneously in tissues and cultured cells. The intensity and duration of insults may decide the outcome; thus, triggering events can be common for both types of cell death. A downstream controller, however, may direct cells toward a programmed execution of apoptosis. If the apoptotic program is aborted before this control point and the initiating stimulus is severe, cell death may occur by necrosis [37]. Alternatively, in acute injury, apoptotic cells can progress along a continuum to eventual necrosis. To distinguish

apoptosis from necrosis, more specific oligonucleotide probes have been developed to allow the recognition of different aspects of DNA damage [38]. They have been successfully applied, in combination with confocal microscopy, to identify apoptotic and necrotic cell death in the heart with different pathogenic challenges.

Selected Cardiotoxicants

This section will focus on representative chemicals and drugs, which have been reported to have major cardiotoxic effects, and will not describe the adverse effects of cardiovascular drugs used therapeutically in the treatment of heart disease and disorders. For example, these drugs, such as beta-blockers, nitrates, calcium channel blockers, antihypertensive drugs, antiarrhythmic drugs, and digitalis and other inotropic drugs used for heart failure, may be cited for possible adverse cardiac effects in the other sections of the chapter. For the sake of completeness, some of the drugs described in the previous sections will be discussed in this section to stress their unique cardiotoxicities.

Alcoholic Cardiomyopathy

For over 150 years, the abuse of alcohol in the form of ethanol has been associated with a variety of cardiovascular diseases. Chronic, heavy use of alcohol may lead to nonischemic dilated cardiomyopathy or alcoholic cardiomyopathy, which results in decreased cardiac function and structural disease [39]. Clinically, a patient with alcoholic cardiomyopathy will demonstrate low cardiac output, four chamber dilatation, wall thinning, ventricular dysfunction, and heart failure. Alcohol abuse may also be associated with arrhythmias, hypertension, stroke, and sudden death.

The pathogenesis of alcoholic cardiomyopathy is not clearly understood, but several sources of research suggest that alterations in membrane stability of cardiac cells, decreased excitation/contraction coupling, and formation of reactive oxidative metabolites may contribute to its pathogenesis.

For example, the hepatic biotransformation of ethanol by alcohol dehydrogenase and cytochrome P45O II EI to the toxic metabolite acetaldehyde, may damage the membranes of cardiomyocytes [40]. This reactive metabolite and other oxidative by-products may cause lipid peroxidation of the cardiac cell membranes or may damage cytosolic and membrane protein thiols.

As suggested by Kang [1], the use of rats as an experimental model to investigate the chronic effects of ethanol on cardiac structure and production of myocardial fibrosis is difficult to reproduce the effects of alcohol on the human heart because of the shorter life span of the animals. However, a more recent study with a mouse model of alcoholic cardiomyopathy produced heart hypertrophy and fibrosis by genetically deleting the zinc—regulatory protein, metallothionein (MT) [41]. This study and others, as summarized by Kang [1], suggest a role for zinc deficiency in the induction of alcohol-induced myocardial fibrosis and the possible involvement of oxidative stress in the fibrogenesis because of the antioxidant properties of MT.

Other possible hypotheses of alcoholic cardiomyopathy include inflammatory and immunologic changes, disruption of calcium-mediated contractile elements, inhibition of ATP formation, apoptosis, inhibition of protein synthesis, and receptor alterations.

Cocaine

Pharmacologically, cocaine is a local anesthetic, which blocks nerve impulses by reversible inhibition of Na^+ channels and subsequent decrease in transitory Na^+ conductance in nerve fibers. In addition, cocaine produces local vasoconstriction as the result of the inhibition of norepinephrine (NE) reuptake. Cocaine may increase heart rate and blood pressure and stimulate the CNS, resulting in enhanced alertness and self-confidence. Because of its euphoric-producing effects, cocaine may be abused chronically, resulting in altered behavior and addiction.

Chronic use of cocaine may have adverse effects on the heart because of its direct and indirect actions on myocardial contractility, increase in cytosolic calcium and disruption of NE reuptake, and subsequent stimulation of beta- and alpha-adrenergic receptors. The net effect of the chronic use of cocaine is the production of cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, and seizures [42]. As pointed out by Kloner et al. [43], in their review on cocaine effects on the heart, cocaine abuse is a major risk factor for heart disease. It has been suggested that cocaine may directly injure cardiomyocytes, cause cell death, and result in myocardial infarction. The mechanism of cell death is not clearly understood, although it is postulated that coronary artery vasoconstriction, accelerated atherosclerosis, and thrombus formation may be factors in the production of myocardial infarction.

Antidepressants and Antipsychotics

Tricyclic antidepressants (TCAs) have been used since the 1960s for the treatment of major depressive disorder. It is now well known that TCAs can have major cardiotoxic effects in overdose situations and cardiovascular side effects are well documented [44]. These adverse effects are linked to their inhibitory actions on cardiac and vascular ion channels, anticholinergic- and quinidine-like actions, inhibition of reuptake of adrenergic amines, disruption of membrane permeability, and direct myocardial depression. Clinical signs of TCA cardiotoxicity may include sinus tachycardia, postural hypotension, QT prolongation and possible TdP arrhythmias, congestive heart failure, and AV block, leading to asystole and sudden death. Although TCAs are no longer considered the major therapeutic course of treatment for depressive disorders, TCAs are still reported as one of the most commonly prescribed drugs implicated in overdose fatalities [44].

Several major antipsychotics have been associated with sudden cardiac death, QTc prolongation, and TdP. These effects by antipsychotics on the QT interval are thought to be mediated by the blockade of the delayed rectifier K^+ current [44]. Other adverse side effects of the antipsychotics include tachycardia, orthostatic hypertension, and certain metabolic disorders, such as increased risk for weight gain, insulin resistance, and type 2 diabetes.

Androgenic–Anabolic Steroids

These agents are divided into structural classes: nonalkylated testosterone derivatives, such as testosterone, ester testosterone derivatives, nandrolone, and esters of nandrolone, and 17-alpha-alkylated androgenic–anabolic steroids (AASs), such as fluoxymesterone, methandrostenolone, stanozolol, and other related compounds. There is growing evidence for adverse cardiac effects of AASs on the heart [45], resulting in pathological changes such as hypertrophy, impaired diastolic function, myocardial necrosis and/or apoptosis, and possible ventricular fibrillation. Thus, the illegal use of exogenous androgens, especially in high doses, may induce cardiac hypertrophy and other cardiovascular problems. These actions on the heart are most likely associated with receptor and genomic mechanisms, but because a variety of acute effects may be produced in a short period of time by androgens on the heart suggest that nongenomic mechanisms may be involved in their cardiotoxicity.

Antineoplastic Agents

Anthracyclines are natural products derived from *Streptomyces peucetius* var. caesius, with doxorubicin and daunorubicin as the major ones initially isolated from the fungus. Idarubicin and epirubicin are analogs of the latter two, differing only slightly in structure. Daunorubicin and idarubicin are used extensively in the treatment of acute leukemias, whereas doxorubicin and epirubicin are more effective against solid tumors. Because of the quinone groups found as part of their chemical structures, anthracyclines can generate free radicals or semiquinone radical intermediates in malignant and normal tissues that can react with O_2 to produce superoxide anion radicals, hydrogen peroxide, and hydroxyl radicals [46]. Because these deleterious free radicals have a prominent action on cardiac tissue, cardiotoxicity is a major result of treatment of patients with these analogs [47]. A rare form of cardiotoxicity is acute or subacute injury, resulting in transient arrhythmias, a pericarditis–myocarditis syndrome, or acute failure of the left ventricle. A more serious adverse effect is the induction of cardiomyopathy (Figure 32.4), which is the more common form of cardiotoxicity. Thirdly, a type of toxicity may be shown years after treatment with the anthracyclines: arrhythmias and late-onset ventricular dysfunction.

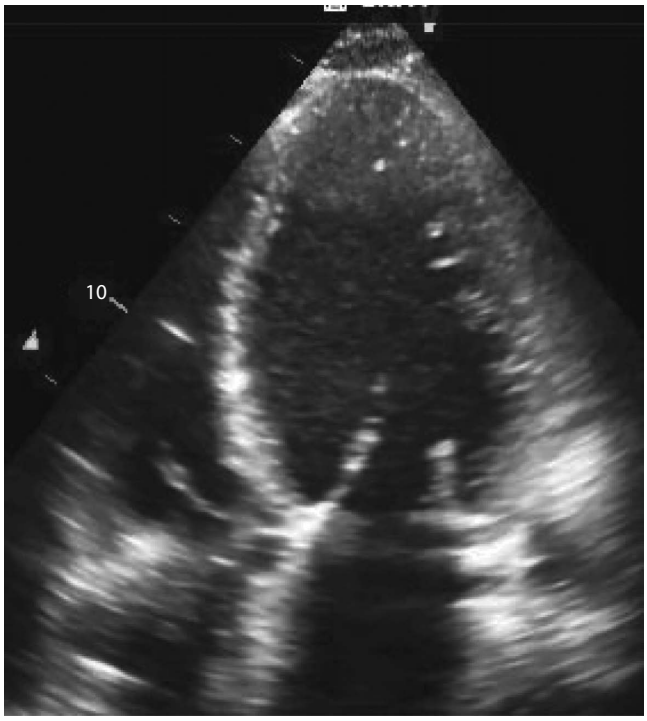

FIGURE 32.4 Transthoracic echocardiogram of a cardiomyopathy caused by the anthracycline doxorubicin in a 65-year-old patient.

The precise mechanism(s) of the cardiotoxicity of anthracyclines may be related to several biochemical and molecular events [47]:

1. The already-mentioned formation of quinone free radicals and the generation of reactive oxygen species with resulting DNA and membrane damage
2. Formation of a toxic metabolite
3. Alteration of calcium metabolism
4. Involvement of histamine and other catecholamines

Other antineoplastic agents shown to have cardiotoxic actions include cyclophosphamide, fluorouracil, bleomycin, cisplatin, arsenic trioxide, and interferons. The cardiotoxicity may be manifested clinically as arrhythmias, cardiomyopathies, myocardial ischemia, and other toxicities.

Nonsteroidal Anti-Inflammatory Agents

The major NSAIDs are aspirin, propionic acid derivatives (ibuprofen, naproxen), acetic acid derivatives (indomethacin), selective inhibitors of Cox-2 (celecoxib, etoricoxib, lumiracoxib), and enolic acids (piroxicam). Many of these agents have a variety of common and shared side effects, including GI effects, platelet actions, renal toxicity, CNS actions, uterine effects, hypersensitivity reactions, and cardiovascular toxicities [48]. The main cardiotoxic effects may be myocardial infarction, stroke, thrombosis, and closure of ductus arteriosus. It has only been most recently that the cardiovascular toxicity of NSAIDs has gained much prominence with the

TABLE 32.2
Selected Cardiotoxicants

Drug/Chemical	Proposed Mechanism(s) of Cardiotoxicity
Alcohol	Formation of reactive oxidative metabolites, zinc deficiency, induction of ATP/protein synthesis
Cocaine	Coronary artery vasoconstriction, thrombus formation
Antidepressants	Inhibitory actions on cardiac ion channels, inhibition of reuptake of adrenergic amines, disruption of membrane permeability
Antipsychotics	QT prolongation by blockade of the delayed rectifier potassium current
AASs	Unclear but may be related to receptor, genomic and nongenomic mechanisms
Anthracyclines	Formation of quinone free radicals; alteration of calcium metabolism
NSAIDs	Inhibition of COX-2, leading to thrombus formation and increased blood pressure
Erythromycin, clarithromycin, ketoconazole, terfenadine, etc.	QT prolongation, leading to TdP

withdrawal from the market of rofecoxib and valdecoxib due to increased risk for serious cardiovascular adverse events. The other NSAIDs on the market have also been suggested to have the potential to increase the risk of heart attack and stroke. The most probable explanation for the cardiotoxicity of the NSAIDs is that the inhibition of COX-2 increases the formation of thrombi and elevates blood pressure, which would them enhance the potential for cardiovascular risk in humans.

Miscellaneous Therapeutic Agents

Antimicrobial Agents [49]

Of the macrolide antibiotics, erythromycin and clarithromycin are associated with an increased risk of TdP as a result of QT prolongation. Telithromycin and azithromycin are classified as possible risks of TdP.

Fluoroquinolones were the most widely prescribed class of antibiotics for many years but are now used less frequently (ciprofloxacin, levofloxacin, and moxifloxacin). Sparfloxacin and grepafloxacin were removed from the market because of nonfatal and fatal arrhythmias secondary to QT prolongation with TdP.

The azole antifungals, such as ketoconazole and itraconazole, have been reported to cause QT prolongation and TdP, and more attention should be paid to possible adverse cardiac events in patients taking these antibiotics.

The antimicrobial agent, pentamidine, used to treat protozoal infections, has been reported to be associated with cases of QT prolongation and TdP. Similarly, certain antimalarial agents, chloroquine and halofantrine, have been associated with significant QT prolongation.

Other Drugs

Cisapride, once used as a prokinetic drug for gastrointestinal hypomotility, was removed from the market because of enhanced risk of arrhythmias associated with TdP. Sildenafil, used for the treatment of erectile dysfunction, may have some possible cardiotoxic effects by increasing cAMP in cardiac tissue. Certain antihistamines, notably terfenadine and astemizole, were removed from the market because of life-threatening ventricular arrhythmias, most likely caused by prolongation of the action potential and by blocking the delayed rectifier K^+ channel.

To mechanistically summarize the cardiotoxicants, Table 32.2 provides a brief overview of their cardiotoxicities.

QUESTIONS

32.1 Toxicants that increase the systemic blood pressure, such as cocaine, increase which hemodynamic variable leading to increase oxygen demand?
- Afterload—acute increases in afterload increase the pressure that the heart must pump against, thus increasing oxygen demand.
- Contractility and heart rate are also increased by many stimulants, which will increase myocardial oxygen demand.

32.2 What is the mechanism by which the autonomic nervous system increases contractility?
- By the stimulation of the beta-adrenergic receptor that activates G-coupled protein receptors leading to the phosphorylation of calcium channels and subsequent increased calcium release

32.3 What is the resting potential of a myocyte under normal conditions?
- 60 to −90 mVs.
- Sodium ion entry in to the cell thus leads to depolarization of the myocyte membrane.

32.4 How does the action potential cause myocardial contraction?
- Via calcium-mediated calcium release. Calcium enters the myocyte when the action potential causes depolarization of L-type Ca channels, which leads to calcium entering the cell and subsequently stimulating larger calcium release from intercellular stores.

32.5 What is the most common mechanism of action for arrhythmias to occur?
- Reentry

32.6 How do many antiarrhythmic medications suppress reentrant arrhythmias?
- By changing the electrical properties of the two separate limbs of the reentrant circuit, the circuit may be broken.

32.7 Stimulants such as caffeine, nicotine, and amphetamines may cause sinus tachycardia via which mechanism?
- Increased automaticity

32.8 TdP is precipitated by which type of arrhythmic mechanism?
- Triggered activity—afterdepolarization during the recovery phase of the action potential may lead to TdP.

32.9 When does myocardial ischemia occur?
- When the myocardial oxygen supply is not sufficient to meet the myocardial oxygen demand

32.10 Why would a cardiomyopathy lead to sympathetic nervous system stimulation?
- When the cardiac pumping function becomes jeopardized, stroke volume decreases. This decreased forward blood flow leads to stimulation of the baroreceptors in the carotid body and aorta, with subsequent stimulation of the sympathetic nervous system to cause reflex tachycardia.

32.11 How does decreased blood flow to the kidney lead to sodium and water retention in heart failure?
- Via activation of the renin–angiotensin–aldosterone system. This system is also implicated in peripheral vasoconstriction and myocardial hypertrophy and fibrosis.

33 Neurotoxicology

Stephanie J.B. Fretham, Samuel Caito,* Ebany J. Martinez-Finley, Gennaro Giordano, Lucio G. Costa, and Michael Aschner*

CONTENTS

OVERVIEW

Assessment of neurotoxicity encompasses a broad range of chemical, structural, and behavioral outcomes that can be affected by numerous types of toxicants. Most narrowly defined, a neurotoxin is a toxicant that directly affects the function of the nervous system. Due to the complex nature of the nervous system and a vast array of chemical, environmental, and endogenous neurotoxins, neurotoxicity takes many forms including acute distress and neuropathies, developmental abnormalities, and *silent* or latent symptoms, which become apparent only with aging and/or additional insults. Furthermore, these effects often extend beyond the nervous system and can cause systemic disturbances. This chapter aims to provide an overview of the anatomy and physiology of the nervous system including factors unique to the nervous system that increase susceptibility to neurotoxins.

* These authors contributed equally to the preparation of this chapter.

INTRODUCTION TO THE NERVOUS SYSTEM

The nervous system has numerous functions including coordination and regulation of homeostasis of systems such as the respiratory, digestive, circulatory, and endocrine systems to name a few. The nervous system also mediates movement and provides mechanisms for sensory perception. In addition, innate and acquired behaviors originate within the nervous system as well as higher cognitive functions, which define personality and enable learning, memory, and emotion. As a result, toxins that affect the nervous system can have broad and devastating effects across many physiological and psychological domains.

Anatomical Organization

The nervous system is anatomically divided into the central and peripheral nervous systems (CNS and PNS, respectively). The CNS is comprised of the spinal cord, brain stem, and forebrain and the PNS is comprised of the nerves and ganglia outside of the brain and spinal cord (Table 33.1). Structurally, the spinal cord is a bundle of nervous tissue including neuronal cell bodies, axons, glia, and structural proteins within the vertebral column stretching from the base of the skull to approximately the first lumbar vertebrae. Functionally, the spinal cord receives, sends, and processes sensory and motor information between the PNS and the brain. The brain stem is made up of the medulla, pons, and midbrain, which are critical for the regulation of vital blood pressure and respiration functions and the origination of cranial nerves that involved special senses such as taste and hearing and conveying sensory and motor information relating to the head and neck. The cerebellum is also considered part of the midbrain and receives many sensory and motor inputs and functions in part to regulate balance, posture, and fine motor skills. The forebrain consists of the diencephalon (thalamus and hypothalamus) and the cerebral hemispheres including cerebral cortex, white matter, and subcortical structures such as the basal ganglia and hippocampus. The thalamus relays sensory and motor signals to and from the cortex and acts to regulate sleep and wakefulness. Underneath the thalamus is a small set of distinct nuclei called the hypothalamus, which links the nervous system with the endocrine system to regulate sex hormones, hunger and satiety signals, and circadian rhythms. The remaining cortical and subcortical structures of the forebrain function as higher processing systems, including sensory and motor cortices, the limbic system, the basal ganglia, and the hippocampus.

The PNS can also be divided into several distinct anatomical and physiological components (Table 33.1). The somatic nervous system is composed of sensory neurons in the skin, muscles, and joints and motor neuron axons that control skeletal muscles, while the autonomic nervous system contains neurons and axons involved in visceral sensation and control of smooth muscles and exocrine glands. The autonomic system is further divided into the sympathetic nervous system that underlies the *fight or flight* response, the parasympathetic nervous system that restores homeostasis, and the enteric nervous system that is relatively autonomous and regulates the smooth muscle in the gut.

TABLE 33.1
Anatomical Organization of the Nervous System

	Major Divisions	Components	Primary Functions
CNS	Spinal cord	Cell bodies, projections, and structural matrix proteins	Receives, sends, and processes signals between the CNS and PNS
	Brain stem	Medulla	Origination of cranial nerves
		Pons	Regulation of vital functions
		Midbrain	Motor and sensory information for head and neck
		Cerebellum	Balance, posture, fine motor skills
	Forebrain	Hypothalamus	Relay and process information between the cortex and other brain regions
		Thalamus	
		Cortex	Circadian rhythm
		Subcortical ganglia	Hormonal release
			Higher-order cognitive and emotional processing
PNS	Somatic nervous system	Sensory and motor neurons innervating skin and skeletal muscle	Reception of sensory stimulation
			Innervation and stimulation of skeletal muscle
	Autonomic nervous system	Sensory and motor neurons and ganglia innervating smooth muscle and exocrine glands	Sympathetic: fight or flight response
			Parasympathetic: restoration of homeostasis
			Enteric: relatively autonomic regulation of digestion
Anatomical barriers	BBB	Capillary endothelial cells	Generate CSF
		Astrocytic feet	Isolate CNS from foreign substances and immune proteins found in systemic circulation
	Blood–CSF barrier	Ependymal cells	
	Blood–retina barrier	Retinal epithelial cells	

Notes: CSF, cerebral spinal fluid; CNS, central nervous system; PNS, peripheral nervous system.

The CNS is uniquely sequestered from the PNS and the rest of the body by several anatomical barriers—the blood–brain barrier (BBB), the blood–cerebrospinal fluid (CSF) barrier, and the blood–retina barrier (Table 33.1). The function of these barriers is to isolate the CNS, including the retina, from toxins and other damaging substances in the blood such as bacteria, viruses, and inflammatory agents and to regulate the nutritional and ionic composition of the CSF.

Development

Formation of the nervous system begins early in development when the three embryonic layers (endoderm, ectoderm, mesoderm) are formed during gastrulation. The nervous system originates primarily from ectodermal cells, which also give rise to integumentary tissue. During the third week of human gestation, the ectoderm undergoes neurulation to form the neural tube and neural crest. The neural tube and neural crest proliferate rapidly to produce neural progenitor cells, which become the CNS and PNS, respectively. These neural precursors migrate and continue to differentiate into neurons and glia; form axons, dendrites, and synapses; and establish functional circuitry including myelination of gross anatomical structures. The vast majority of nervous system development occurs during the first 2 years of life; however, several processes such as myelination, synaptogenesis, and the development of higher-order cognitive systems continue into early adulthood (Figure 33.1). Many of these processes are restricted to distinct windows in development, creating critical periods during which toxicant exposure is especially devastating for specific brain regions, and sensory, motor, and cognitive domains.

Cells of the Nervous System

There are three basic cell types found in the nervous system—neurons, glia, and microglia. Each cell type is characterized by distinct structural and physiological characteristics that determine its role within the nervous system.

Neurons

There are many types of neurons in the nervous system; however, they all share basic structural and functional features that enable formation of simple and complex networks through which sensory and motor information is processed and transmitted. All neurons are electrically excitable, postmitotic cells consisting of a cell body, dendrites, and an axon (Table 33.2). As in other cells, the neuronal cell body contains the nucleus, endoplasmic reticulum, Golgi, mitochondria, and other membranous organelles. Dendrites are specialized protrusions of the cell body that contain membrane neurotransmitter receptors or specialized sensory receptors that respond to receptor activation and sensory cues through changes in membrane potential and intracellular signaling pathways. Most neurons have a single axon extending millimeters or meters from the cell body to form synapses with target neurons or organs. Neurons can be divided into several distinct classes based on shape, location, excitability, and the expression of neurotransmitters and receptors, all of which affect neuronal signaling and processing.

Macroglia

Macroglia, commonly called glia or neuroglia, are a class of nonneuronal mitotic cells that provide energy and nutrients to neurons, maintain the extracellular environment through ion and neurotransmitter clearance, form myelin, respond to injury, and modulate neuronal signaling and plasticity. As with neurons, there are several distinct types of glia including astrocytes, oligodendrocytes, Schwann cells, ependymal cells, and radial glia (Table 33.2). Astrocytes are the most abundant glial cell and contribute to BBB formation, neurovascular coupling, regulation of extracellular ionic concentration, and neurotransmitter clearance. They have an important role in the modulation of neuronal activity through

the release of glutamate and adenosine triphosphate (ATP). Astrocytes signal within networks formed by astrocyte–astrocyte gap junctions that allow diffusion of Ca^{2+}-induced second messengers such as inositol triphosphate (IP_3), which stimulate Ca^{2+} wave propagation across a relatively large cortical area. Elevated Ca^{2+} can stimulate glutamate release from some astrocytes. Myelin is formed by membrane projections from specialized glia cells called oligodendrocytes in the CNS and Schwann cells that wrap around axons to provide electric insulation and concentrate ion channels at the nodes of Ranvier. Myelin increases the speed and energy efficiency of action potential propagation by up to tenfold. Other types of glial cells include ependymal cells, which line the ventricles to produce CSF and form the blood–CSF barrier, and radial glia, which are neuroprogenitors and scaffolding for migrating cells during development. In adults, radial glia persist in the cerebellum and retina where they facilitate plasticity and neuronal transmission.

Microglia

Microglia differ from macroglia in that they do not originate from neural ectoderm but instead from mesodermal monocytes that have entered the brain and further differentiated into microglia (Table 33.2). Due to the BBB, the CNS is immune privileged and most systemic infections do not enter the brain; however, in cases where bacteria, viruses, and other harmful substances do cross the BBB, microglia provide an immune defense system. Microglia are distributed throughout the brain and rapidly respond to foreign substances and infections by reducing inflammation, phagocytizing foreign substances and signaling to neighboring microglia, glia, and neurons through the release of cytokines. Microglia can also kill infected cells through release of large amounts of NO and H_2O_2 and glutamate. In addition, microglia phagocytize dead cells and other naturally occurring debris.

Chemoelectric Transmission

Neurons transmit information throughout the nervous system by changes in membrane potential that are propagated along axons (electric transmission) and cause release of neurotransmitters at synapses (chemical transmission). Synapses are the junctions formed between axon terminals of a presynaptic neuron and a postsynaptic cell (Figure 33.2). Postsynaptic cells can include neurons, muscles, and endocrine tissue (such as the adrenal or pituitary glands) and may contain synapses from a single presynaptic cell or from several presynaptic cells. Astrocytes have a functional role in many synapses, forming a three-part, or tripartite, synapse with the pre- and postsynaptic cell. Astrocyte processes can surround the synapse, tightly regulating the extracellular environment through ion and neurotransmitter transport and also the release of glutamate and propagation of Ca^{2+} signaling.

Action Potential

Membrane ion channels and transporters expressed by neurons create a resting membrane potential near –70 mV. These channels establish both a chemical and electrical gradient with high intracellular K^+ and low intracellular Na^+, Cl^-, and Ca^{2+} relative to the extracellular environment. Dendrites and synapses contain a number of ligand-gated and G protein–coupled ion channels that can be activated by sensory stimuli or neurotransmitters and cause local alterations in the membrane potential. Membrane depolarization caused by Na^+ or Ca^{2+} influx is considered excitatory, while hyperpolarization due to K^+ efflux or Cl^- influx is considered inhibitory. In the dendrites, these local changes in membrane potential can spread through the cell body, and with sufficient excitatory stimulation, the depolarization can reach the axon hillock, the junction between the cell body and axon, and activate voltage-gated (v-gated) Na^+ channels. Once activated, Na^+ rapidly enters the cell driven by both chemical and electric gradients where it diffuses into the cell body and along the axon, depolarizing the membrane and activating neighboring v-gated Na^+ channels (Figure 33.2). The depolarization is propagated in an all-or-none manner along the entire length of the axon to the axon terminal where v-gated Ca^{2+} channels are activated. Ca^{2+} entry through these channels stimulates fusion of synaptic vesicles with the membrane, releasing neurotransmitters and neuromodulators.

Several events occur during action potential propagation that rapidly restore resting membrane potential (Figure 33.2). The axon contains v-gated K^+ channels that open more slowly than v-gated Na^+ channels, and in depolarized cells, K^+ flows rapidly out of the cell through these channels along the chemical and electrical gradient (recall that neurons have high intracellular K^+ levels). At the same time, v-gated Na^+ channels are inactivated by the sustained membrane depolarization, preventing further Na^+ entry. These events combined with the ongoing action of Na^+/K^+ ATPase pumps, which export three Na^+ ions from the cytoplasm and import two K^+ ions using an ATP molecule, quickly restore the membrane potential and enable the neuron to fire another action potential within milliseconds.

Several well-known toxins act by disrupting the ion channels and transporters involved in maintaining resting membrane potential and action potential generation. For example, v-gated Na^+ channels are blocked by tetrodotoxin, a toxin found in puffer fish; in low doses, it temporarily inhibits neural transmission but can cause death at high doses. Tetraethylammonium inhibits K^+ channels necessary for restoration of membrane polarization following action potentials.

Neurotransmitter Signaling

Synaptic transmission, also known as chemical transmission, involves the synthesis and release of neurotransmitters by the presynaptic cell, the interaction of the neurotransmitter with receptors on postsynaptic cells, and the subsequent neurotransmitter removal from the synapse through reuptake or degradation. Neurotransmitters can be categorized as amino acids, biogenic amines, acetylcholine (ACh), or ATP. For each neurotransmitter, there are several distinct receptors, including both ionotropic (ligand-gated ion channels) and metabotropic

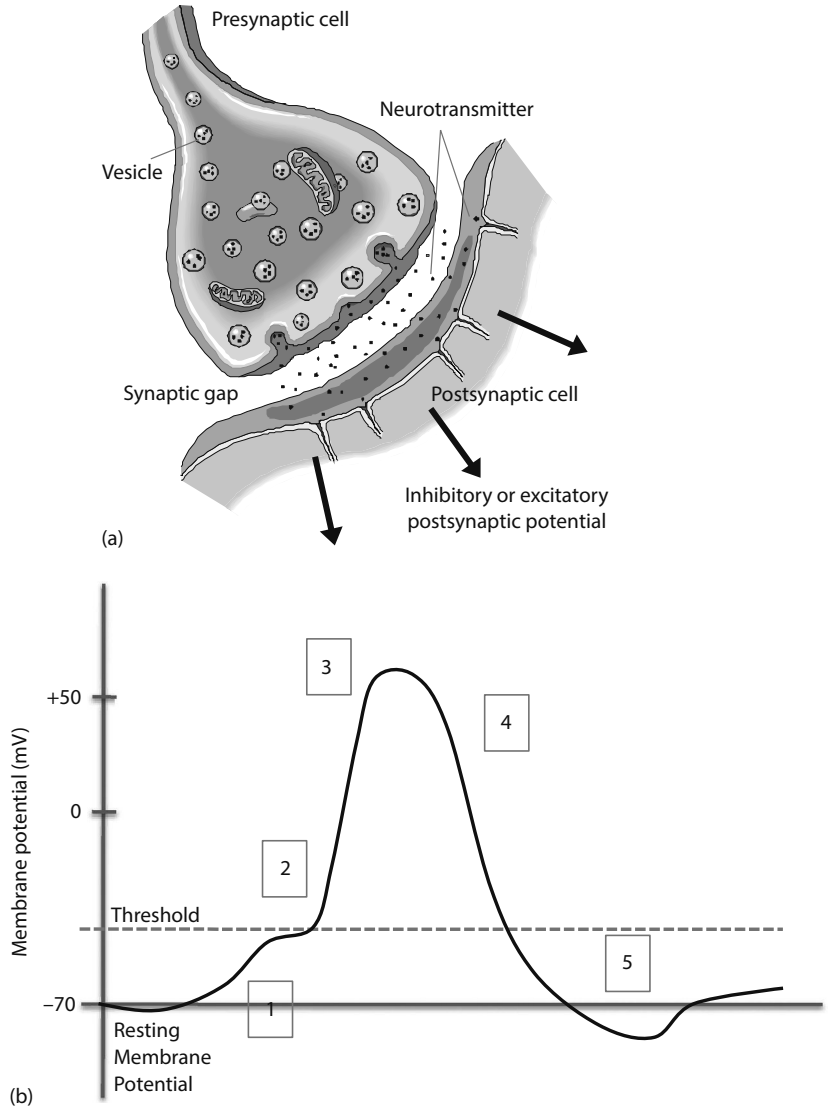

FIGURE 33.2 Chemoelectric transmission. (a) At the synapse, neurotransmitters are released from axon terminals of presynaptic neurons where they cross the synaptic cleft and bind to and activate membrane receptors on the postsynaptic cell (neurons, glia, muscles, exocrine glands). Once activated, the receptors change the postsynaptic membrane potential through local depolarization or hyperpolarization (excitatory or inhibitory postsynaptic currents, respectively). (b) Illustration of the membrane potential changes that occur during action potential propagation: (1) ion channels on dendrites cause excitatory postsynaptic currents; (2) the membrane reaches threshold depolarization at axon hillock, opening v-gated Na^+ channels, and Na^+ enters cell, further depolarizing the membrane; (3) v-gated K^+ channels open and v-gated Na channels close; (4) K^+ flows out of cell; and (5) v-gated K^+ channels close and Na^+/K^+ ATPase pumps restore resting electrochemical gradients. (LifeART collection images Copyright 1989–2001 by Lippincott Williams & Wilkins, Baltimore, MD.)

receptors (G protein–coupled receptors) (Table 33.3). The number and type of postsynaptic receptors activated as well as the length of time the neurotransmitter remains in the synapse determine the effect it has on the postsynaptic cell.

Glutamate, γ-aminobutyric acid (GABA), and glycine comprise the amino acid neurotransmitters. Glutamate is the most common excitatory neurotransmitter. The most common glutamate receptors are the AMPA and NMDA ligand-gated Na^+ and Ca^{2+} channels, which cause excitatory depolarization of the postsynaptic cell. There are also several types of metabotropic glutamate receptors, that can be excitatory or inhibitory depending on the associated G-protein. Glutamate is rapidly cleared from the synapse by glutamate transporters on both neurons and surrounding astrocytes. GABA is the most common inhibitory neurotransmitter and is synthesized from glutamate within the nervous system. $GABA_A$ receptors are ionotropic Cl^- channels, which cause hyperpolarization and inhibit action potential generation, and $GABA_B$ receptors are metabotropic receptors, which activate G protein–linked K^+ channels, also causing hyperpolarization and decreasing neuronal excitability. Glycine is the primary inhibitory transmitter used by spinal cord interneurons. Similar to $GABA_A$ receptors, glycine receptors are ionotropic Cl^- channels and decrease postsynaptic excitability.

TABLE 33.3
Major Neurotransmitters, Receptors, and Toxicants

Class	Neurotransmitter	Receptor	Postsynaptic Actions	Synaptic Clearance	Toxins
Amino acid	Glutamate	NMDAR AMPAR	Ionotropic Na^+ and Ca^{2+} channels (excitatory)	Reuptake by neuronal and astrocytic glutamate transporters	PCP
		mGluRs	Metabotropic effect dependent on associated G-protein		
	GABA	$GABA_A$	Ionotropic Cl^- channels (inhibitory)	Reuptake by GABA transporter	Hemlock Alcohol
		$GABA_B$	Metabotropic stimulation of G protein–activated K^+ channels (inhibitory)	Degradation by GABA transaminase	Picrotoxin
	Glycine	Glycine receptor	Ionotropic Cl^- channels (inhibitory)	Reuptake by transporters on neurons and astrocytes	Strychnine Bicuculline
Biogenic amine	Dopamine	Dopamine receptors	Metabotropic effect dependent on associated G-protein	Reuptake by dopamine transporter Degradation by MAO or COMT	Amphetamines Heavy metals Oxidative substances
	Norepinephrine Epinephrine	α- and β-adrenergic receptors	Metabotropic effect dependent on associated G-protein	Reuptake by norepinephrine transporter Degradation by MAO and COMT	
	Serotonin	$5\text{-}HT_3$	Ionotropic Na^+/K^+ channel (excitatory)	Reuptake by serotonin transporter	
		$5\text{-}HT_{1,2,4–7}$	Metabotropic effect dependent on associated G-protein	Degradation by MAO or COMT	
	Histamine	Histamine receptors	Metabotropic effect dependent on associated G-protein	Degradation by histamine-*N*-methyltransferase	
Other	ACh	nAChR	Ionotropic nonselective cation channel (excitatory)	Degradation by acetycholinesterase	Bungarotoxin Anatoxin Sarin Methylmercury
		mAChR	Metabotropic effect dependent on associated G-protein		Curare
	ATP and adenosine	Purinergic receptors	Metabotropic effect dependent on associated G-protein		

Notes: PCP, phencyclidine; GABA, γ-aminobutyric acid; MAO, monoamine oxidase; COMT, catechol-*O*-methyltransferase; nAChR, nicotinic acetylcholine receptor; mAChR, muscarinic acetylcholine receptor; ACh, acetylcholine; 5-HT, 5-hydroxytryptamine; NMDAR, *N*-methyl D-aspartate receptor; AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; mGluR, metabotropic glutamate receptor.

Biogenic amines are synthesized from amino acids and include the catecholamines, dopamine, norepinephrine, and epinephrine, derived from tyrosine through a common synthetic pathway. Dopamine is primarily released by midbrain neurons and has an important role in movement, affect, emotion, reward, addiction, motivation, and hormone secretion by the pituitary gland. There are at least five subtypes of metabotropic dopamine receptors, which either stimulate or inhibit cyclic adenosine monophosphate (cAMP) production through G-protein signaling. The relative expression level of receptor subtypes determines the effect in the postsynaptic cells. Norepinephrine is found in neurons of the locus ceruleus. These neurons are few in number; however, they project throughout the cortex, cerebellum, and spinal cord as well as the sympathetic PNS. Epinephrine acts as a hormone when released into the blood stream but is also found in a small number of neurons in the nervous system. The catecholamines are cleared from the synapse by specific transport proteins such as dopamine transporter and norepinephrine transporter or are degraded by monoamine oxidase (MAO) or catechol-*o*-methyltransferase (COMT) enzymes.

Serotonin (5-hydroxytryptamine [5-HT]) is another biogenic amine synthesized from tryptophan. The vast majority of systemic serotonin is found in the digestive system, although serotonergic neurons in the brain stem project throughout the brain and spinal cord and are involved in mood, appetite, and sleep regulation. There are many types of serotonergic receptors, and with the exception of the ionotropic $5\text{-}HT_3$ receptor, the receptors are metabotropic and exert excitatory or inhibitory effects depending on the subtype. Serotonin is cleared

from the synaptic cleft by the serotonin transporter or can be degraded by MAO and COMT. Histamine is also a biogenic amine derived from amino acid histidine. Histamine is best known as a proinflammatory substance released from mast cells in the immune system. In the CNS and PNS, however, it is produced and released by some hypothalamic neurons and acts as a neurotransmitter to contribute to sleep–wake cycle regulation. There are several subtypes of neuronal metabotropic histamine receptors with varying excitatory and inhibitory effects. Histamine is degraded in the synapse by histamine-*N*-methyltransferase.

ACh is the only neurotransmitter not derived from an amino acid. ACh is a polyatomic ion synthesized from choline and acetyl coenzyme A by choline acetyltransferase. ACh is used by motor neurons in the spinal cord and extensively in the autonomic nervous system. It is also synthesized in nucleus basalis neurons with widespread cortical projections. In the periphery, it is released by motor neurons and activates ionotropic nicotinic ACh receptors (nAChR) to stimulate skeletal muscle contraction. In the CNS, ACh acts largely to modulate plasticity, attention, reward, and arousal through metabotropic G protein–coupled muscarinic ACh receptors (mAChR). In the synaptic cleft, ACh is degraded by acetylcholinesterase.

ATP, ADP, AMP, and adenosine are most often considered in the context of cellular energy; however, these compounds are released in an activity-dependent manner from neurons and glia. These transmitters act on both ionotropic and metabotropic purinergic receptors to modulate autonomic function, immune response, neuronal development, and chronic pain.

In addition to these classical neurotransmitters, there are also many neuroactive substances that can affect transmission and plasticity, which are not defined as neurotransmitters. Most of these neuromodulators are small neuroactive peptides such as angiotensin-, oxytocin-, somatostatin-, and thyrotropin-releasing hormones with well-identified hormonal and endocrine functions. In addition, within the nervous system, these peptides can modulate synaptic transmission and are often found in the same vesicles as neurotransmitters. Gasses such as nitric oxide (NO) and carbon monoxide (CO) also have important signaling roles in the nervous system. They are naturally produced by nitric oxide synthases (NOSs) and by heme oxygenase, respectively, and can easily diffuse across membranes to signal to surrounding cells and have a role in inflammation signaling, redox signaling, and plasticity.

Neurotoxins can affect many aspects of neurotransmitter signaling, any of which can significantly disrupt neuronal signaling and cause physiological impairments and even death. ACh is affected by many neurotoxins and is used here as an example of the diversity of toxins that can significantly disrupt neuronal signaling. Methylmercury (MeHg), discussed in more detail in the following, disrupts ACh synthesis by inhibiting choline acetyltransferase and ACh release is impaired in the PNS by the botulinum toxin, which degrades proteins necessary for synaptic vesicle release. Botulinum does not cross the BBB so the effects are evident at neuromuscular junctions where ACh release is reduced, preventing diaphragm contraction and causing death by asphyxiation. ACh receptors are targeted by several toxins, including bungarotoxin, which blocks Ca^{2+} entry through nAChRs, thus preventing signal transmission. Anatoxin, produced by cyanobacteria, is a nondegradable nACh agonist that causes persistent muscle contraction and subsequent asphyxiation. Sarin, organophosphates, and carbamates inhibit acetylcholinesterase, prolonging the duration of signaling by preventing degradation of ACh in the synapse.

ASSESSING NEUROTOXICITY

There are a variety of markers of neurotoxicity and experimental model systems available to examine them. Histology on fixed neural tissues, magnetic resonance imaging (MRI) in living subjects, and immunocytochemistry of cell culture systems can be used to address changes in neuronal structure and physiology (macro/micro), gross deformities, and more subtle structural and even microstructural disturbances induced by a neurotoxin. Deleterious compounds can also affect neuronal metabolism, plasticity, and neurochemistry, which can likewise be measured with biochemical and electrophysiological assays. The ultimate function of the nervous system is to produce behavior and enable learning, memory, and cognition. Behavioral and cognitive disruptions are often the first indicators of the neurotoxic potential of a substance. There are a number of behavioral and cognitive assays ranging from simple associative learning to complex higher-order processing that are discussed elsewhere in this book. These behavioral assays can be helpful in assessing overt aspects of neurotoxicity in humans, rodents, and even invertebrate model systems.

Mammalian Model Systems

The use of human subjects and postmortem brains has been invaluable in the history of neuroscience. Histology on postmortem brains is useful in examining pathological changes in brain structure and composition as a result of a given disease process, such as amyloid plaques in Alzheimer's disease and Lewy bodies in Parkinson's disease (PD). Additionally, any protein, DNA, or chemical analysis can be performed on individual dissected tissues. Research using living subjects is also possible using imaging techniques, such as assessment of motor, sensory, and cognitive function, structural and metabolic measurements using MRI, and biochemical analysis of CSF. Not only do imaging technologies provide tools for research in brain function and structure in living humans, but they can be used repeatedly in the same subject to provide insight on disease progression.

Rodents, such as mice and rats, have been and continue to be widely used to study structural, biochemical, electrophysiological, developmental, epigenetic, and behavioral effects of toxicant exposure on nervous system function. As mammals, rodents have very similar genomes as humans and have all of the major brain structures, organizational patterns, and

neurotransmitters present in the human brain. In addition, neurodevelopment in rodents follows a similar progression as in humans. These features enable the assessment of nearly any neurological outcome in rodent systems.

Nonmammalian Vertebrate and Invertebrate Model Systems

Nonmammalian vertebrates, such as zebra fish (*Danio rerio*), and invertebrates are growing in popularity as a model for neurotoxicity. Zebra fish and invertebrate systems such as *Drosophila melanogaster* (fruit fly) and the nematode *Caenorhabditis elegans* are classic genetic models for neurodevelopmental research, and their small, albeit complex, nervous systems and genomes have been extensively characterized. Although invertebrates lack brains, they utilize many of the same, or very similar, neurotransmitters, receptors, and synthesis mechanisms as mammals and can exhibit neuropathologies consistent with observations in rodents and humans. In addition, mutagenesis and transgene manipulation has generated an impressive library of mutations, fluorescent reporters, and inducible expression systems in zebra fish, flies, and worms that facilitate neuronal imaging and screens for genes that modify response to toxicant exposure.[1–3] These systems are usually less expensive than mammalian models and allow for quick genetic screens, which are good for identifying genes involved in toxicity and stress responses.

In Vitro Model Systems

There are a variety of in vitro model systems that can be used to look at molecular and biochemical aspects of neurotoxicity. One of the most common in vitro models is primary culture of neurons, astrocytes, or microglia from rodent brains. There are also immortalized neuronal cell lines that can be either rodent or human in origin. One of the biggest advantages of cell culture systems is that biochemical and molecular genetic assays, such as gene silencing and florescent reporter assays, can be performed in mammalian cells that may be difficult or too costly in live animals. An emerging in vitro system for examining cellular and biochemical mechanisms of human neurotoxicity is human-induced pluripotent stem cells generated from skin fibroblasts of normal individuals as well as individuals with genetic risk factors or prior toxicant exposure. While cell culture systems provide many advantages over in vivo systems, caution in interpreting results should be used, as a single cell type rarely functions in isolation from the other surrounding cell types. Cell-based systems combined with in vivo experiments can provide complimentary data.

NERVOUS SYSTEM SUSCEPTIBILITY

The nervous system is highly susceptible to xenobiotics due to its complex and specialized components as well as its physiological functions. There are several characteristics that make the nervous system vulnerable to toxins and toxicants, which include complex structure and long period of development, interconnectivity to other organ systems, composition of differentiated postmitotic cells, selective transport into the CNS, high rate of metabolism, and myelination. In the following sections, these susceptibility factors will be discussed. It is important to note that xenobiotics can affect the nervous system through various pathways and take advantage of multiple susceptibility factors simultaneously.

Interconnectivity among Organ Systems

The nervous system is unique in that it connects to every tissue and organ system in the body, from the internal organs to the skin. Nervous system functions can be altered by inflammatory mediators, such as cytokines and chemokines, as well as hormones produced in peripheral glands, such as insulin, cortisol, and epinephrine. Indeed, many neurodegenerative diseases have been shown to have an inflammatory component to their pathology. Since the nervous system is highly interconnected to the other organ systems, it is vulnerable to not only neurospecific toxins but also toxins with broad general effects. For this reason, it is often necessary to determine whether the observed pathology is due to direct damage to the nervous system or an indirect effect of damage elsewhere. Both the liver and the kidney are involved in excretion of xenobiotics from the body. For example, diseases that alter liver and kidney function, as well as exposure to substances that reduce organ function, will cause a buildup of toxic substances or metabolites that enter the circulatory system and affect the nervous system. Additionally, if a toxin affects the nervous system, there may be pathological sequelae in other tissues. One classic example being cocaine, which affects both the release and reuptake of dopamine and norepinephrine in the brain, which is known to cause addiction, paranoia, hyperactivity, and aggression, but also increases blood pressure and causes abnormal heart rhythms leading to myocardial infarction and congestive heart failure.[4]

Differentiated Postmitotic Cells

Neurons, which are the functional cells of the nervous system required for the transmission of action potentials, are considered terminally differentiated postmitotic cells. The majority of neurons that are present in an adult individual are formed during development and differentiate into mature neurons during critical developmental windows. This is in contrast to other organ systems, such as the liver and immune systems, with regular turnover of the cells that comprise the tissues. For this reason, toxic substances that cause damage to cellular structure or cause neuronal death are especially harmful.

The loss of a neuron in the majority of the nervous system is irreversible. Neuronal loss, termed neuropathy, includes the degeneration of the cell body, axon, dendrites, and myelin sheath surrounding the axon. Cell loss may be due to either apoptosis or necrosis depending on the type of insult that led to death. Loss of neurons after xenobiotic exposure can

either be general or specific, with the loss of specific neurons resulting from a susceptibility of a particular subpopulation of neurons to the toxic substance that is not present in every neuron. Neurotoxins that cause neuropathies can either affect multiple cell types or be specific for neurons, taking advantage of vulnerabilities not present in other cell types, such as high metabolic rate or excitability. Due to the large variety of functions performed by the nervous system, neuropathies can have various functional consequences. Toxicants that produce overall damage to the nervous system, such as thallium, can produce diffuse encephalopathy and brain swelling.[5] In contrast, xenobiotics that affect subpopulations of neurons have specific functional effects. For example, quinine targets retinal ganglion cells, causing vacuolization and vision loss, while methanol causes degeneration of the putamen and retinal ganglion cells resulting in headaches, vision loss, and comas.[6,7] Death by either apoptosis or necrosis is usually cleared by phagocytosis performed by microglia. Phagocytosis by cell bodies usually occurs faster than for the axons and myelin, and for this reason, if there is extensive damage to axons and myelin in the CNS or PNS after toxicant exposure, it is prudent to investigate whether the cell bodies are affected.

Oftentimes, neurotoxins can cause axonal degeneration without affecting the cell body; this is called an axonopathy. Following an injury to the axon, the distal portion of the axon proceeds through a process of degeneration, which includes proteolysis and axonal swelling, followed by fragmentation of the axon and clearance of debris by microglia. In the PNS system, the Schwann cells proximal to the surviving portion of the axon release growth factors, which can allow for regeneration of the axon; however, if the axon is not restored, Schwann cells will decrease in number and regeneration will cease. In the CNS, oligodendrocytes secrete inhibitory factors that impede axonal regeneration while promoting astrocyte proliferation and the formation of a glial scar, making an axonopathy in the CNS permanent.

Neuropathy, axonopathy, and degeneration can be studied using a variety of histological stains in fixed tissues. One of the most thorough ways to detect degenerated axons and neurons is the amino cupric silver stain.[8] Briefly, brain tissue is imbedded in paraffin blocks and serial sectioned on a microtome. These sections are soaked in a preimpregnation solution containing cupric nitrate, silver nitrate, cadmium nitrate, lanthanum nitrate, neutral red dye, α-amino butyric acid, alanine, pyridine, triethanolamine, isopropanol, and deionized water (dH_2O). Sections are then heated in the microwave and cooled overnight before being rinsed in dH_2O, then acetone, and placed in the impregnation solution containing silver nitrate, 100% ethanol, acetone, lithium hydroxide, and ammonium hydroxide. After impregnation, the sections are transferred to a reducer solution (100% ethanol, 10% formalin, 1% citric acid, and dH_2O) while in a water bath. The sections are then rinsed in dH_2O and rapidly placed in a bleaching solution (potassium ferricyanide, potassium chlorate, lactic acid, potassium permanganate, and sulfuric acid) before being fixed in sodium thiosulfate and a rapid fixer solution and mounted on glass slides. Any degenerated axons or neurons will appear black in color as compared to normal tissues, which can be counterstained with neutral red.

While the majority of neurons are postmitotic cells, which once lost cannot be replaced, limited neurogenesis does occur during adulthood particularly in the hippocampus. Hippocampal neurogenesis results in the formation of new granule cells that incorporate into the existing cortical circuitry and is important for structural plasticity and network maintenance necessary for learning and memory. New neurons originate from adult neural stem cells of the subgranular zone of the dentate gyrus. These quiescent self-replicating type 1 cells have radial processes spanning the entire granule cell layer of the dentate gyrus and are identified by glial fibrillary acidic protein (GFAP), Sox2, and Nestin molecular markers. These cells are thought to give rise to the type 2 neural stem cells, which are intermediate cells identified as expressing Sox2 and Nestin, but not GFAP. Type 2 cells give rise to neuroblasts capable of differentiating into mature neurons.[9] Not all new neurons survive, but the ones that live are extremely sensitive to their environment. Neurotransmitters, such as GABA, as well as growth factors, neurotrophins, cytokines, hormones, and miRNAs are all known to affect the maturation of the progenitor cells. These cells can be visualized and quantified using well-defined molecular markers described earlier using immunostaining and flow cytometry protocols in order to evaluate the effects of environmental factors on adult neurogenesis. Recent evidence suggests that bisphenol A, alcohol, MeHg, cadmium, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin disrupt neurogenesis[10–14]; however, molecular mechanisms that lead to altered neurogenesis are unknown.

Anatomic Barriers

The BBB is comprised of an extensive network of specialized endothelial cells of the microvasculature of the brain, spinal cord, retina, and PNS as well as glial cells. Endothelial cells of the BBB form tight junctions around the vascular lumen of the capillaries creating a tighter seal between the blood and surrounding nervous tissue than the fenestrae present in systemic capillaries. The glial cells that comprise the BBB are primarily astrocytes, which project *astrocytic feet*, also called *glia limitans*, to surround the endothelial cells to provide structure and regulation of the tightness of the barrier. There are a small number of sites in the brain, which line the ventricles and are not protected by the BBB; these are termed the circumventricular organs and include structures such as the pineal gland, posterior pituitary, and area postrema. The lack of complete BBB in these regions allows circumventricular organs to sense and respond to signals in the bloodstream such as osmolality, toxins, and peptide hormones.

Under normal circumstances, small lipophilic substances and water can passively diffuse across the BBB; however, most other molecules must be actively transported in and out of the nervous system across the BBB. Several transport systems are used to move essential anions, cations, and metals

from the vascular lumen to the neuronal tissues. Some of these transporter systems are known to transport xenobiotics, such as the multidrug resistant protein family of transporters. Hydrophilic or large substances often pass through the BBB by molecular mimicry, a phenomenon where a xenobiotic that resembles an endogenous substrate enters the cell by hijacking the endogenous transporter or carrier molecule. MeHg is a potent neurotoxin and enters the CNS through molecular mimicry. MeHg is very nucleophilic with high affinity for the thiol group of cysteine. This MeHg–cysteine conjugate structurally resembles methionine, which is transported across the BBB via the large neutral amino acid transporter. MeHg enters the brain by taking advantage of this structural similarity.[15]

The blood–CSF barrier is comprised of modified epithelial cells of the choroid plexus and surrounding capillaries called ependymal cells. There are four choroid plexuses in the brain located in the third and fourth ventricles. The choroid plexus is responsible for the synthesis of CSF and acts as a filtration unit removing xenobiotics, excess neurotransmitters, and metabolic waste products from the CSF. The ependymal cells of the choroid plexus contain tight junctions to create a barrier between the capillary lumen and the ventricles similar to, but not as tight as, the BBB. The ependymal cells contain numerous villi and microvilli, which increases the total surface area for filtration and transport. The choroid plexus contains transporters, which can be the target for xenobiotic entry, and many of the xenobiotics that cross the BBB also enter the CNS through the blood–CSF barrier and accumulate in the CSF.

Lead (Pb) is one such metal that enters the brain through both the blood–CSF barrier and BBB. Pb exposure is known to cause the microvasculature of the brain to become leaky, resulting in increased permeability of the BBB, brain swelling, herniation, ventricular compression, petechial and cerebral hemorrhages, thrombosis, and arteriosclerosis.[16] The endothelial cells in both the microvasculature and choroid plexus cells accumulate Pb, which activates protein kinase C (PKC) signaling due to Pb-induced disruption of intracellular Ca^{2+} levels. Activation of PKC has been shown to increase endothelial permeability, which is observed during Pb toxicity.[17] Pb also inhibits functioning of the choroid plexus epithelial cells, decreasing the amount of transthyretin produced.[18] Transthyretin is an important protein involved in thyroid hormone binding and delivery and is only produced by the choroid plexus; Pb exposure decreases transthyretin and disrupts thyroid hormone signaling.

Metabolism

Neurons are energetically costly cells that are highly dependent on aerobic respiration to sustain sufficient energy to generate action potentials and maintain electrical conductivity. Even at rest, the membrane potential must be maintained by ion channels and energy requiring ion pumps. Dysregulation of these channels and pumps alters membrane potential and the ability of a neuron to depolarize or repolarize, impeding initiation and propagation of action potentials. Indeed, in conditions like epilepsy, where there is hyperactivity, and thus more frequent depolarizations and repolarizations, there is an increased energy demand, which if not met can lead to damage. Because of this high-energy need, a continual source of energy must be available to keep the neurons healthy. The brain relies heavily on aerobic glycolysis as its primary energy source, which means that any change in delivery of glucose or oxygen can be detrimental. Hypoxic and ischemic injury to the brain can result from exposure to various toxicants that either directly inhibit components of aerobic respiration machinery or decrease oxygen delivery. The production of ATP by the mitochondria involves several proteins working collectively to transfer electrons, produce ATP, and keep reactive oxygen species (ROS) production to a minimum.

It is not surprising that some of the classic neurotoxins produce their effects by the proteins involved in cellular respiration. 3-Nitropropionic acid (3-NP) is a mycotoxin produced by certain plants and fungi that decreases neuronal ATP production by specifically inhibiting succinate dehydrogenase (mitochondrial respiratory complex II). 3-NP is a suicide inhibitor of succinate dehydrogenase, meaning that 3-NP forms an irreversible complex with the enzyme, effectively making the enzyme unusable.[19] Ingestion of 3-NP by humans or livestock causes motor dysfunctions similar to Huntington's disease, and it is often used as an agent to study Huntington's in animal models. Direct injection into the brain of rats has shown that 3-NP can cause neurodegeneration through an excitotoxic mechanism.[20] Another classic neurotoxicant often used in animal models to study neurodegeneration is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). In the 1970s, MPTP was synthesized as an impurity in the synthesis of 1-methyl-4-phenyl-4-propionoxypiperidine (MPPP), a synthetic opioid, and was eventually identified as the source of Parkinsonian symptoms displayed by drug abusers. MPTP itself is nontoxic; however, metabolism by MAO B in glial cells forms the toxic cation 1-methyl-4-phenylpyridinium (MPP^+). MPP^+ is a potent reduced nicotinamide adenine dinucleotide (NADH) dehydrogenase (mitochondrial complex I) inhibitor and leads to the disruption of the mitochondrial electron transport chain involved in respiration, free radical formation, and apoptosis. MPP^+ is thought to be selective to dopaminergic neurons by entering the cells via the synaptic dopamine reuptake transporter found primarily on dopamine neurons. Heavy metals are well-known neurotoxicants that decrease ATP production in the brain by inhibiting cellular respiration components. Rats exposed to low levels of Pb, below the threshold of safe for humans, had decreased ATP levels and reduced Na^+/K^+ ATPase activity. Rats exposed to arsenic inhibited complex I, complex II, and complex IV.[21,22]

Decreased oxygen delivery to the brain after exposure to a toxicant usually results either from a global phenomenon affecting all organs in the body or from alterations in the circulatory system. In the brain, the most metabolically active regions are severely affected by reduced oxygen including the basal ganglia, hippocampus, cerebral cortex,

and cerebellar Purkinje cells. Carbon monoxide poisoning produces hypoxia by competitively binding to hemoglobin in place of oxygen, which has effect on the entire body. Acute CO exposure severely damages these metabolic brain regions and may also cause white matter damage and cortical atrophy.[23] Decreased oxygen delivery to the brain may also be caused by toxicants that cause hypoperfusion, a condition where there is decreased blood flow to an organ or tissue, which if prolonged can result in tissue damage or death. Research performed in rats and monkeys suggests that global hypoperfusion caused by cyanide (CN^-) is responsible for the brain lesions characteristic of cyanide poisoning rather than other direct forms of CN^- damage to the CNS.

Although a xenobiotic may affect metabolic pathways, its neurotoxicity does not have to depend on its alterations in metabolism. Acrylonitrile is a widely used vinyl monomer used in the manufacturing of acrylic fibers, plastics, and synthetic rubber with known neurotoxic effects. In humans, acute acrylonitrile exposure causes limb weakness, labored or irregular breathing, dizziness, impaired judgment, hallucinations, cyanosis, nausea, collapse, loss of consciousness, convulsions, and death. Chronic exposure to acrylonitrile causes depression and lability of autonomic functions such as lowered arterial pressure, labile pulse, diffuse dermographia, increased sweating, and change in orthostatic reflex. Similar effects, including agitation, seizure, and death, have been observed in rats exposed to acrylonitrile. The precise mechanism for acrylonitrile's neurotoxicity is unknown. Acrylonitrile has been shown to undergo Michael addition reactions with nucleophiles including glutathione (GSH), the cell's must abundant thiol responsible for maintaining cellular redox status. Exposure to high levels of acrylonitrile can deplete GSH. This depletion of GSH and subsequent change in redox status results in acrylonitrile metabolism by cytochrome P450 and formation of CYP2E1 and CN^-, the initially proposed mechanism of toxicity. However, inhibition of CYP2E1 with 1-benzylimidazole reduced blood levels of CN^- in rats exposed to acrylonitrile, but did not protect the animals from acrylonitrile-induced mortality.[24] In addition to being able to bind to GSH, acrylonitrile can covalently bind to proteins, including the catalytically active cysteine of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), an enzyme involved in glycolysis and ATP production.[25] Acrylonitrile decreases some glycolytic intermediates, but in spite of this, there is no evidence for ATP depletion in the brains of rats exposed to acrylonitrile.[25] This illustrates that although there may be the potential to alter the metabolism critical for neuronal functioning, xenobiotic neurotoxicity may involve several other mechanisms.

Myelination

Myelination is a unique characteristic only found in the nervous system. Myelin consists of lipid-rich sheath that encases neurons of both the CNS and PNS. Its primary function is to insulate the neuron and allow for rapid conductance of the action potential along the neuron. The presence of myelin decreases membrane capacitance and increases the electrical resistance of the neuron, allowing for significantly faster rates of action potential propagation as compared to unmyelinated neurons. In the CNS, myelin is formed by oligodendrocytes, while in the PNS, it is formed by Schwann cells. Both Schwann cells and oligodendrocytes form myelin by wrapping concentric layers of membrane and cytoplasm around the axons, excluding cytoplasm from the inner surface of their membranes and reducing the extracellular surfaces of the bilayers allowing for a compact stack of lipid- and protein-rich myelin. The lipids that comprise myelin are predominantly galactocerebroside and sphingomyelin. Structural proteins are required to form and maintain proper myelin structure. Myelin basic protein (MBP), myelin oligodendrocyte glycoprotein, and proteolipid protein are adhesion proteins associated with the intracellular spaces of wrapped myelin sheath in the CNS, which when mutated can cause genetic diseases of poorly formed or maintained myelin. Demyelination, the loss of myelin while the axon is preserved, occurs through a variety of pathological mechanisms.

Loss of myelin results in slowing or aberrant action potential conductance. Demyelination by toxins can result from intramyelinic edema or direct damage to the myelinating cell. Intramyelinic edema occurs when the myelin sheets separate, which can be reversible or can progress to demyelination of the axon. A variety of toxicological mechanisms can lead to intramyelinic edema, including disruption of MBP transcription by triethyltin, disruption of ion gradients by hexachlorophene, and vacuole formation resulting in the splitting of myelin sheets by closantel.[26–28] Intramyelinic edema can lead to swelling and spongiosis of the brain, which is often not reversible. Direct damage to the myelinating cells has been observed following exposure to dideoxycytidine, cuprizone, and dithiocarbamate pesticides.[29–31] It was once thought that oligodendrocytes were incapable of reforming myelin after demyelination in the CNS; however, it is now known that oligodendrocyte precursor cells can be stimulated to remyelinate damaged axons in mouse models of demyelination/remyelination.[32] The functional consequences of demyelination depend on the extent of demyelination that occurs after exposure to a toxic substance. Diffuse demyelination may result in global nonspecific effects including headache and photophobia, whereas demyelination confined to the PNS can present as a peripheral neuropathy such as limb paralysis.

RECEPTORS AND SIGNALING

The mechanisms by which extracellular signals are transferred to the cell cytosol and nucleus, commonly referred to as *cell signaling* or *signal transduction*, are receiving much attention in all areas of biology and medicine. Neurotransmitters, hormones, and growth factors serve as first messengers to transfer information from one cell to another by binding to specific cell membrane receptors. This interaction results in activation or inhibition of specific enzymes and/or opening of ion channels, which lead to changes in intracellular metabolism and, in turn, to a variety of effects, including activation

of protein kinases and transcription factors. These intracellular pathways can be activated by totally different receptors and are very interactive or *cross talking*, so they can control and modulate each other. As the area of signal transduction is very broad, a review of all its aspects is well beyond the scope of this chapter, and only a few examples are discussed in the following for illustrative purposes.

Some of the most studied signaling pathways are those activated by membrane receptors. These include, for example, enzyme-linked receptors and G protein–linked receptors.[33,34] Enzyme-linked receptors (such as those of insulin or of epidermal growth factor) are receptors in which the ligand-binding domain, the membrane-spanning region, and the effector enzyme are usually separate domains of the same protein. Binding of the ligand to the receptor activates the effector enzyme. The most widely studied of these receptors are those with tyrosine kinase activity. Tyrosine kinase autophosphorylates the receptor and also phosphorylates other substrate proteins. This initiates a cascade of processes whereby a large number of proteins are activated, including Ras, Raf-1, JAK-STAT, as well as mitogen-activated protein kinases (MAPKs) and p70S6 kinase.[33]

G Protein–Mediated Signaling

G Protein–linked receptors are activated by a wide variety of ligands, including neurotransmitters and hormones. These receptors have a seven-transmembrane domain, extracellular loops with the ligand-binding domain, and intracellular loops, which interact with G-proteins. The G (for guanosine diphosphate (GDP)/guanosine triphosphate (GTP)-binding)-proteins consist of three subunits, α, β, and γ. Upon interaction with the ligand, the GDP bound to the α-subunit is replaced by GTP, and Gα dissociates from Gβγ. Gα-GTP then activates an effector enzyme, which starts a signal transduction cascade. Depending on the nature of the G-protein, a receptor can activate or inhibit the same enzyme (e.g., adenylate cyclase), or activate a totally different enzyme. Furthermore, in addition to Gα, Gβγ has also been shown to activate an array of effector enzymes, including those also activated by Gα.[35] This model of G protein–linked receptor is utilized, for example, by the adenylate cyclase system. Upon activation by Gα-GTP, adenylate cyclase catalyzes the conversion of ATP to cAMP; the latter acts as a second messenger by activating protein kinase A (PKA). This occurs via the binding of two cAMP molecules to each of the regulatory subunits of PKA, thus releasing the catalytic subunit. In turn, PKA phosphorylates, and thus changes the activity of substrate proteins in the cytoplasm, in the membrane, as well as in the nucleus (e.g. the transcription factor cAMP response element-binding protein (CREB)). If the Gα-subunit is of the inhibitory type (Gi), then inhibition of adenylate cyclase and a decrease of cAMP levels will ensue.

Another pathway that utilizes this system regulates the metabolism of membrane phosphoinositides. In this case, Gα-GTP (Gq) activates the enzyme phospholipase Cb (PLCb), which catalyzes the breakdown of the membrane phospholipid phosphatidylinositol 4,5-bisphosphate to inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG), both of which act as second messengers. It should be noted that PLCs can also be activated by other receptors (e.g., that of nerve growth factor), thus underlining the complex entangled web of interactions in signal transduction pathways.[33] $InsP_3$ binds to specific receptors in the endoplasmic reticulum and mobilizes calcium from intracellular stores, thereby allowing activation of a variety of cellular enzymes. DAG, in concert with calcium and phosphatidylserine, activates certain subtypes of PKC. In turn, PKC phosphorylates a number of cellular substrates, including transcription factors. Only classical PKCs (such as a and g) are activated as indicated; novel PKCs (e.g., PKC e) do not need calcium for activation, and atypical PKCs (e.g., PKC z) are activated by other means. In addition to DAG, other important lipid mediators can be generated in cells by G protein–linked receptors through multiple pathways.

An important pathway is represented by the hydrolysis of phosphatidylcholine, one of the major membrane phospholipids, by phospholipase D (PLD), to generate phosphatidic acid (PA), which can activate atypical PKC z. Activation of classical and novel PKCs stimulates PLD activity, thus generating PA; this can also be converted to DAG by a PA hydrolase, thus providing a mean for a prolonged stimulation of PKCs. Other important lipid mediators are arachidonic acid, the precursor of all prostanoids, which is generated by hydrolysis of membrane phospholipids by phospholipase A_2, and ceramide, which is released from sphingomyelin by sphingomyelinase.

Phosphoinositide-3 Kinase Signaling

Phosphoinositide-3 kinase (PI3K) represents another important cell-signaling pathway, which plays important roles in the control of cell growth, proliferation, and survival.[36] When activated by surface receptors or interaction with Ras, class I PI3K produce phosphatidylinositol (3,4,5)-trisphosphate [$PtdIns(3,4,5)P_3$]. PI3K regulates cellular functions by recruiting $PtdIns(3,4,5)P_3$-binding proteins to the plasma membrane. The prototype of these molecules is protein kinase B (PKB), also known as Akt, which is activated by ligation of $PtdIns(3,4,5)P_3$ and by phosphorylation by 3′-phosphoinositide-dependent kinase 1 (PDK1).[37] PDK1 also phosphorylates some PKC isoforms (e.g., PKC z) and downstream kinases (e.g., p70S6 kinase). The ability of certain receptors to increase intracellular levels of cyclic GMP (cGMP) and the fact that such effect was indirect, that is, it necessitated an additional second messenger, has been known for quite some time. Initial candidates for such role included calcium ions and arachidonic acid metabolites. However, it was later discovered that NO, synthesized from L-arginine by NOS, binds to a heme moiety attached to guanylate cyclase and stimulates the formation of cGMP.[38,39] The NOS family consists of three isoforms: neuronal NOS (nNOS) and endothelial NOS (eNOS), which are constitutively expressed and require the formation of calcium–calmodulin complexes for their activation, and inducible NOS (iNOS), which exerts its activity in a calcium-independent manner. NO is involved in

a wide array of cellular effects in the CNS, ranging from neuroprotection to neurotoxicity.[40,41] The diversity in response appears to be related to the steady-state concentration of NO. In general, low concentrations of NO (1–300 nM) would promote cell survival, whereas at higher concentrations (1 mM), nitrosative stress would prevail, leading to cell cycle arrest and apoptosis.[42]

Lead, A Case Study for Cell Signaling: Neurotoxicant Interaction

In recent years, investigation of the molecular mechanisms of neurotoxicity has started to consider a variety of signal transduction pathways as potential targets for neurotoxicants. Such studies have followed three basic experimental approaches: the study of the direct effects of a chemical on a particular step in cell signaling (e.g., a protein kinase); the study of the direct effects of a neurotoxicant on second messenger responses activated by an endogenous compound (e.g., a neurotransmitter-induced activation of phospholipid hydrolysis); and, to a limited extent, the alterations in signal transduction resulting from other toxic actions (e.g., oxidative stress).

Interactions of neurotoxicants with signal transduction pathways may occur in neuronal or in glial cells, and may lead to inhibition or stimulation of cell proliferation and/or cell differentiation, to the direct induction of cell death, to inhibition of pathways that provide protection against cell death, or to other effects on cellular function. As such, such interaction may be relevant to neurotoxicity in adults, to developmental neurotoxicity, as well as to neurooncology. The relevance of interactions with signal transduction pathways in the neurotoxicity and developmental neurotoxicity of a number of chemicals (mostly ethanol, polychlorinated biphenyls [PCBs], domoic acid, aluminum, cyanide, organotin compounds, and certain pesticides) has been discussed in a number of reviews and book chapters in the past two decades.[43–47] In this chapter, one example of such interactions is discussed, related to mechanisms possibly underlying the developmental neurotoxicity of Pb.

Pb was discovered thousands of years ago and has been used extensively ever since. In the 1800s, commercial use of Pb increased further, as it was found to be highly effective in paints. In the early 1920s, an organic form of Pb (tetraethyl lead) was found to be very effective as an antiknocking agent in gasoline, starting the long successful sale of leaded fuels. The toxic effects of Pb, however, did not go unrecognized. In recent decades, several efforts to reduce the use of Pb (e.g., banning of Pb paints in the 1970s, phasing out of leaded gasoline in the 1980s) significantly curtailed Pb contamination; yet Pb remains a major, ubiquitous, ecosystem pollutant. Pb is a neurotoxic metal both in adults and in children. In adults, the main effects of Pb poisoning are a peripheral neuropathy, precisely a myelinopathy, which is reversible upon chelation and cessation of exposure. At higher concentrations (100 μg/dL in blood), an encephalopathy can also develop. In contrast, the developing CNS is exquisitely sensitive to the effects of Pb, even at much lower blood levels. In the 1970s, the blood Pb action level in children was 60 μg/mL, the level associated with clinical signs of toxicity in adults.[48] In those years, epidemiological studies clearly showed an association between body burden of Pb in children and adverse neurobehavioral outcomes, namely, lower academic performance and shortened attention span.[49] The phasing out of leaded gasoline and the limitation on smokestack Pb emissions caused Pb blood level in children in the United States to decrease by 80% in the period 1978–1991. Over the years, the level of concern for blood Pb has decreased to 25 μg/mL, then in 1991 to 10 μg/mL, where it stands today. However, blood Pb levels as low as 2 μg/mL have been associated with declines in IQ and various adverse behavioral effects,[50] and there is widespread belief that there is no proven safe lower limit for Pb exposure.[51]

Animal studies in multiple species have confirmed that developmental Pb exposure causes similar cognitive dysfunctions, learning impairment, and distractibility.[52] Pb has been shown to exert neurotoxicity during differentiation and synaptogenesis[53]; however, the greatest adverse effects are seen during the latest stages of brain development, suggesting that Pb may interfere with the apoptotic process and the trimming/pruning of synaptic connections.[54] In vivo and in vitro studies have shown that Pb may disrupt the BBB by injuring astrocytes, with a secondary damage to the endothelial microvasculature.[55] Developmental Pb exposure has been shown to target the hippocampus, cerebral cortex, and cerebellum.[56]

Though the exact mechanisms of Pb neurotoxicity have not been fully elucidated, the prevailing hypothesis is that lead interferes with the action of calcium; indeed, in several systems, Pb can mimic calcium actions at the cellular level and/or disrupt calcium homeostasis.[57,58] Given the role of calcium as a cofactor in many cellular processes involved in signal transduction, it is not surprising that several cell-signaling pathways are affected by Pb. One of the most interesting findings is the ability of Pb to substitute for calcium in activating certain PKCs. The first observation was that Pb, in a concentration range of 0.1–10 mM, would activate PKC and cause translocation of PKC from the cytosol to the particulate fraction in isolated immature rat microvessels.[59] Pb was also shown to activate PKC, partially purified from rat brain, at concentrations as low as 10^{-15} M, several orders of magnitude lower than calcium itself.[17] A later study confirmed that Pb could activate PKC at 10^{-11} to 10^{-8} M, while calcium activates PKC in the range from 10^{-8} to 10^{-5} M.[60] Two studies, utilizing recombinant human PKCs, detailed the interactions of lead with these enzymes.[61,62] Calcium-dependent PKCs, but not all other PKCs, have a calcium-binding domain (C2) in the regulatory region. At low concentrations (10^{-12} M), Pb binds to a site (Ca1) within C2 that causes activation of PKC a; at higher concentrations, Pb binds to another site (Ca2), also in C2, which causes inhibition of enzyme activity by antagonizing calcium. In addition to the dual effects mediated through the interactions of Pb with the C2 domain, at still higher concentrations, Pb inhibits PKC activity by interacting with the catalytic domain. Indeed, Pb was found

to inhibit PKC e and PKC z, which lack the C2 domain.[62] These findings may explain the reports describing contrasting effects of lead on PKCs.[63]

Activation of PKC by Pb has been suggested to be involved in its inhibition of astroglia-induced microvessel formation[64] and to contribute to its ability to release neurotransmitters from bovine adrenal chromaffin cells, brain synaptosomes, and PC12 cells.[61,65,66] In vivo exposure to Pb during brain development has been shown to cause a decrease of PKC g in the hippocampus.[67,68] PKC inhibitors block long-term potentiation, a possible functional equivalent of memory storage, suggesting that Pb-induced decreased PKC activity (possibly resulting from down-regulation caused by sustained activation) may relate to learning and memory deficits caused by this metal. An increase in PKC e expression was also reported following in vivo developmental Pb exposure, perhaps as a compensatory mechanism due to prolonged inhibition.[69] In human astrocytoma cells, activation of PKC a, followed by the sequential activation of MAPK (Erk 1/2) and its target $p90^{RSK}$, was shown to mediate the mitogenic effect of Pb in these cells.[70,71] Such effects may be involved in the reported ability of Pb to induce CNS tumors (gliomas and astrocytomas) in both animals and humans.[72,73]

In summary, the ability of lead to substitute for calcium and/or to alter the action of calcium appears to be responsible for its effects on a number of cell-signaling systems. In particular, its interactions with PKCs may play a role in the ability of lead to cause cognitive alteration upon developmental exposure and may contribute to its mitogenic action possibly related to its carcinogenic effects.

VULNERABILITY OF THE DEVELOPING NERVOUS SYSTEM

Several lines of evidence suggest that the developing nervous system may be more susceptible, and/or differentially susceptible, to toxic insult than the adult nervous system. Different parts of the CNS develop at different stages (Figure 33.1); cell proliferation, migration, and differentiation contribute to the formation of definite brain structures, in which the correct number of cells in the proper location is necessary for proper function.[74,75] Even within a single brain region, subpopulations of neurons may have different rates of development; for example, in the cerebellum, Purkinje cells develop early (embryonic days 13–15 in the rat, corresponding to gestational weeks 5–7 in humans), while granule cells are generated much later (postnatal days 4–19 in the rat, corresponding to gestational weeks 24–36).[74] Failure in cell proliferation or cell migration because of exposure to toxic insults (e.g., irradiation or MeHg) has profound deleterious effects on the developing brain.[76] Though neurons maintain the ability to make new synapses throughout life, the period of brain development when synaptogenesis occurs is critical for the formation of the basic circuitry of the nervous system.[77] Furthermore, in the developing nervous system, neurotransmitters may have function other than neurotransmission, such as modulation of cell proliferation, survival, and differentiation.[78] Thus, any toxicant that interferes with neurotransmission during development may cause permanent defects in the CNS.

Developmental neurogenesis produces more neurons than those found in the mature nervous system, and excess neurons are pruned by finely regulated apoptotic processes at different developmental times.[79] Any chemical interfering with apoptotic processes may trigger degeneration of neurons that would not otherwise have been deleted or may promote survival of unnecessary cells.[80] In addition, pruning, defined as loss of synapses, also occurs physiologically in the developing brain, and chemicals interfering with this process (which is longer lasting than neuronal loss to apoptosis) would have most significant adverse effects on brain functions.[81]

While all these considerations relate to the development of neurons, it has become apparent that glial cells (astrocytes, oligodendrocytes, and microglia) also play a relevant role in brain development and may be the target of toxic action.[82] Indeed, several chemicals (e.g., alcohol, nicotine, and certain pesticides) exert profound neurotoxic effects when exposure occurs during the brain growth spurt, characterized by extensive glial cell proliferation and maturation.

Separate guidelines for developmental neurotoxicity testing have also been developed both in the United States and in Europe.[83,84] Maternal exposure to the test chemicals is from gestational day 6 to postnatal day 10 or 21 to ensure exposure in utero and through maternal milk. Tests involve measurements of developmental landmarks and reflexes, motor activity, auditory startle test, learning and memory tests, and neuropathology. As for neurotoxicity testing, developmental neurotoxicity testing has been proven to be useful and effective in identifying compounds with developmental neurotoxicity potential.[85] This is not to say that current developmental neurotoxicity testing guidelines cannot be improved; indeed, it has been pointed out that they may be overly sensitive and produce a high rate of false positives[86] or, in contrast, that they may be too insensitive and not comprehensive enough.[87] Furthermore, issues have been raised regarding historical control data, toxicokinetic parameters, maternally mediated toxicity versus direct effects, selection of tests, and their analysis and interpretation.[88,89]

In the past several years, the need to develop acceptable alternatives to conventional animal testing has been increasingly recognized by toxicologists in order to address the escalating costs and time required for toxicity assessments, the increasing number of chemicals being developed and commercialized, and the need to respond to recent legislation (e.g., Registration, Evaluation, Authorisation, and Restriction of Chemicals [REACH] and the Cosmetics Directive [76/768/EEC] in the EU). In addition, efforts have been directed toward the development of alternative models to reduce the number of animals used for toxicity testing, utilizing either mammalian cells in vitro or nonmammalian model systems (e.g., zebra fish or *C. elegans*), which could serve as tools for neurotoxicity and developmental neurotoxicity testing, particularly for screening purposes.[90] These alternative tests should serve as Tier 1 tests to allow the screening of

compounds whose potential developmental neurotoxicity is unknown. Given the complexity of the nervous system and the multiple facets of possible neurotoxic effects, it is highly unlikely that a single test (as the Ames test for mutagenicity) will cover the spectrum of neurotoxicity. Rather, a battery of tests should be considered, which may include some in vitro tests with mammalian cells and one or two tests with nonmammalian models. This may be complemented by quantitative structure–activity relationship-based computational approaches. Novel approaches, part of the *omics* technologies, may also find a role in such endeavors. Alternative models for developmental neurotoxicity should attempt to mimic several processes that may occur in vivo, and given the complexity of the CNS, the scenario for developmental neurotoxicity is much more complex than that for other target organs of toxicity.[90]

Examples of Developmental Neurotoxicants

There are approximately 200 chemicals that have been found to be neurotoxic in humans,[91] and for many more, there is at least some evidence of neurotoxicity deriving from animal studies. Of these, several are developmental neurotoxicants. However, of over 80,000 chemicals on the market, only a handful (about 200) have undergone developmental neurotoxicity testing according to the established guidelines.[85] As said, the developing brain is often more sensitive than the adult brain to toxic insult; thus, neurotoxicity is observed at much lower exposure levels. This is the case, for example, of lead or MeHg. In several cases, the effects of developmental chemical exposure are different from those observed in adults upon similar exposure, for example, ethanol or valproate exposure. In some instances, developmental exposure to neurotoxicants results in morphological alteration of the CNS, with accompanying changes in functions.[76] However, functional changes may result from more subtle biochemical/molecular alterations without major structural abnormalities. Exposure to chemicals that may adversely affect the nervous system has been suggested to be associated with a number of developmental disabilities that are diagnosed in children at an alarmingly increasing rate including learning disabilities, attention-deficit hyperactivity disorder, dyslexia, sensory deficits, mental retardation, and autism spectrum disorders.[48,91]

One example of a developmental neurotoxicant, MeHg, is presented in the following. Lead, discussed earlier as an example of neurotoxicant interfering with signal transduction, is another example. MeHg is probably one of the most studied developmental neurotoxicants due to several episodes of human poisoning over the years, and continued low-level exposure in many populations worldwide, mainly through the consumption of contaminated fish.[92–94] With the possible exception of a case in Sweden in the early 1950s, due to consumption of MeHg-contaminated seed grain, the first evidence of the deleterious effects of MeHg exposure on brain development emerged from Japan in the mid-1950s.[95] Many children born to mothers who consumed MeHg-contaminated fish around Minamata Bay presented with severe neurological deficits, while their mothers appeared unaffected or suffered only mild symptoms.[96] About a decade later, another extensive episode of poisoning occurred in Iraq, due to consumption of MeHg-contaminated grain.[97]

In both cases, notable differences were found in the distribution of pathological changes in the young, exposed in utero or as children, and in adults.[98] In particular, while damage in adults is restricted to the cerebellum and the visual cortex, diffuse damage is seen in the developing brain.[99] It was estimated that the in utero developing nervous system has a fivefold greater vulnerability to MeHg.[100] Signs and symptoms in MeHg-poisoned children included spastic paresis, mental retardation, movement disorders, seizures, primitive reflexes, and speech difficulty.[93,96] The mechanisms of MeHg developmental neurotoxicity have been studied extensively, and a very complex picture has emerged. MeHg binds with high affinity to sulfhydryl groups, which are relevant for the proper functioning of a large number of proteins. As such, several key cellular processes are affected by MeHg.[76,92,94] For example, MeHg has been reported to cause apoptotic cell death, to cause retraction of growth cones and extension, to impair the cytoskeleton, to affect cellular metabolism, and to reduce cell proliferation and neuronal migration.

The ban of alkylmercury compounds for use as fungicides and stricter controls on fish contamination have avoided further catastrophic events as those of Japan and Iraq. However, low-level contamination of fish is persistent and may be responsible for developmental neurotoxic effects, particularly in populations with high seafood consumption. Three major longitudinal studies have examined the potential effects of low-level MeHg exposure in New Zealand, the Seychelles, and the Faroe Islands.[100–102] In all locations, MeHg exposure is entirely due to diet, which consists mainly of marine animals. Two of these studies (in New Zealand and the Faroe Islands) reported a correlation between maternal levels of MeHg and subtle neurobehavioral deficits in the offspring. In particular, a small decrease in IQ points and deficits in memory attention and visuospatial perception were noted in both studies.[100,102] In the Seychelles study, such relation between MeHg exposure and neurodevelopmental effects was not apparent.[103] In the Faroe Islands population, concomitant exposure to PCBs present in whale meat and whale blubber may be an important confounder, as both MeHg and PCBs may have independent neurological effects in this population.[104,105] Another important confounder in these and more recent studies[95] is the beneficial effect of fish consumption ascribed to omega-3 fatty acids.[106,107] Thus, a balance exists between adverse (MeHg) and beneficial (omega-3) effects, which may dampen toxicity or obscure benefits. As MeHg contamination of fish is difficult to avoid, the best choice for the pregnant consumer is to choose fish species with minimal MeHg burden and relatively high omega-3 content (e.g., sardine, salmon), in order to minimize risk and maximize benefits.[107] Exposure limits for MeHg have been set, with provisional tolerable weekly intake values ranging from 0.7 to 1.6 μg/kg, depending on the regulatory agency.[107]

SILENT NEUROTOXICITY, LONG-TERM EFFECTS, AGING, AND RELATIONSHIP TO NEURODEGENERATIVE DISEASES

Manifestations of neurotoxic effects upon adult and/or developmental exposure are usually seen shortly after exposure. Yet, evidence is emerging that deleterious effects of toxicants may not become clinically evident for some months, or even several years after exposure. This period during which the individual may manifest no evidence of toxicity is referred to as the *silent* or latent period.[108] Silent toxicity is defined as persistent biochemical or morphological injury, which remains clinically unapparent unless unmasked by experimental or natural processes.[108,109] Silent toxicity may be compared to the process of carcinogenesis, in which molecular and cellular damages occurs years if not decades before any clinical manifestation of the disease.[110]

In case of neurotoxicity, an example of silent toxicity is represented by the Parkinsonism dementia known as Guam's disease, in which latencies of decades have been reported before clinical signs and symptoms from an undefined exposure.[111] Similarly, bovine spongiform encephalopathy (mad cow disease), a variant of Creutzfeldt–Jakob disease, can have a latency period of decades.[112] The delay between exposure and clinical expression of neurotoxic injury may be ascribed to various causes. For example, a selected population of neurons may be affected, but the known plasticity of the brain would compensate for such loss. However, further exposure to exogenous influences (e.g., stress, disease, additional chemical exposure) and/or the natural aging process unmasks the existing deficit. Alternatively, the organism may be initially able to compensate for a certain deficit, but progressive loss of function eventually overcomes the functional reserve and plasticity of the brain.[108]

The possibility that such latent period between exposure and clinical manifestation would occur in the context of development is even more probable. The concept that adult disease may have a fetal origin has been introduced by David Barker and is known as the *Barker hypothesis*.[112] Exposure to chemicals may cause direct damage or alter developmental programming, whose resulting functional deficits become apparent later in life. A famous example is that of diethylstilbestrol, in which in utero exposure leads to an increase in vaginal adenocarcinoma around the time of puberty.[114]

In the context of developmental neurotoxicity, prenatal infection has lasting effects on the dopaminergic system. Perinatal exposure of rats to the Gram (–) bacteriotoxin lipopolysaccharide causes a 30% loss in dopaminergic neurons in the substantia nigra and persistent injury to the dopaminergic system.[115,116] This study suggests that depending on the gestational time of infection, human infants with prenatal infections would be born with fewer dopaminergic neurons than nonexposed infants. This would be initially inconsequential, as clinical signs of PD are not apparent until about 80% of dopaminergic neurons are lost. However, this early-life damage would predispose an individual to develop PD as the aging process brings along a normal progressive loss of dopaminergic neurons.[117] Developmental exposures to certain pesticides, such as the herbicide paraquat and the fungicide maneb, which also target dopaminergic neurons, have also been implicated in the later development of PD.[118] Similarly, developmental exposure to the now banned organochlorine insecticide dieldrin has been shown to cause long-lasting alterations of the dopaminergic system, typical of a silent dopaminergic dysfunction.[119]

In some occasions, early mild damage may worsen as the individual matures and ages. For instance, neurotoxic effects of developmental exposure to MeHg may be unmasked only during aging.[120,121] In utero exposure to methylazoxymethanol, which causes microencephaly, caused a premature decline in cognitive functions,[122] and the neurotoxic effects of neonatal exposure of triethyltin, a glial neurotoxicant, were exacerbated by aging.[123] In other situations, this may not be the case, yet the neurotoxic effects of developmental exposure appear to be irreversible, and even if they do not worsen with age, they are certainly long lasting, as shown, for example, for PCB-126.[124] Perturbations of cognitive functions due to developmental Pb exposure remain for life,[125] and perinatal Pb exposure has been associated with the development of schizophrenia and of Alzheimer's disease.[126–128] It has also been suggested that exposure to Pb during critical periods of brain development may alter expression and regulation of amyloid precursor protein later in life, potentially altering the course of amyloidogenesis and acting as a risk factor for the onset of Alzheimer's disease–like pathology.[127,129,130]

In addition to direct effects on neurons and glia in the nervous system, chemicals that act as endocrine disruptors can also disrupt neurodevelopment. For example, polybrominated diphenyl ether (PBDE) flame retardants are thought to exert developmental neurotoxicity by two general, and not mutually exclusive, modes of action, one related to effects on thyroid hormones and the other involving direct effects of PBDEs on the developing brain.[106] Thyroid hormones are known to play a relevant role in brain development,[131] and hypothyroidism is associated with a large number of neuroanatomical and behavioral effects.[132,133] PBDEs perturb the thyroid system both during development and adulthood, leading to a reduction of circulating thyroid hormone.[134] The exact mechanism(s) underlying these effects are unclear, but reduction in thyroid hormones may contribute to developmental neurotoxicity of PBDEs although effects have also been seen in the absence of thyroid hormone changes.[135] Experimental compounds such as propylthiouracyl, which inhibits thyroid hormone synthesis and causes hypothyroidisms, are clear developmental neurotoxicants, as evidenced by behavioral and morphological alterations in the CNS.[133,136] Decreases of T_4 following developmental exposure to PBDEs or PCBs range from 10% to 60%. Such decreases may well contribute to their developmental neurotoxicity as evidenced by neurological decrements observed in children of mothers with 25% decrease in T_4.[132]

DRUGS OF ABUSE

There are many classes of *drugs* that have neuropharmacological properties. In cases where these drugs are misused or abused, they can result in severe toxicity to the system and thus can be considered neurotoxicants. While they may exert their toxicity in several organ systems, many of them have mechanisms of action that interfere with the physiology of the nervous system. Besides their primary actions, an additional concern for many of these drugs of abuse is their use in combination with other drugs or alcohol, which can often exacerbate toxicity. Other concerns include long-term abuse, which can lead to cognitive impairment, confusion, psychosis, coma, and death, and exposure during critical windows in brain development can result in altered development of brain circuitry. For many of these drugs of abuse, the full toxicological profiles are not worked out. While there are many and various neurotoxicological consequences of drug exposure, the following section details the effects on neurotransmitters.

Narcotics are usually used to treat pain, but according to the National Institute on Drug Abuse, they are some of the most highly abused prescription drugs.[137] CNS depressants, prescribed to treat anxiety and sleep disorders and stimulants are also highly abused.[137] Examples of narcotics include opium, morphine (Avinza), codeine, heroin, hydrocodone (e.g., Vicodin), and oxycodone (e.g., Percocet). These drugs bind to opioid receptors throughout the body and reduce the feeling of pain. For example, morphine and heroin are mu-opioid agonists.[138] These drugs, when used in combination with CNS depressants, increase the risk of respiratory depression.

Classical stimulants include nicotine, caffeine, cocaine (coke, blow, crack), and amphetamines. Nicotine affects the nicotinic cholinergic receptors.[139] Cocaine works on the dopaminergic system by blocking the dopamine reuptake transporter.[140] Amphetamines alter catecholamine neurotransmission both at the level of the transporter and by disrupting vesicular storage of dopamine.[141]

Depressants including alcohol, cannabinoids, barbiturates, benzodiazepines, gamma-hydroxybutyric acid (GHB), and paraldehyde act by slowing down the activity of the CNS by affecting neurotransmitters like GABA. They may also have hallucinogenic effects. For example, benzodiazepines activate a subset of $GABA_A$ receptors on ventral tegmental area interneurons, specifically the alpha-1 subtype, altering the dopamine effect.[142] Marijuana, hashish, and synthetic marijuana (known as K2 or *spice*) exert their toxicity via tetrahydrocannabinol (THC), the main psychoactive ingredient, acting through cannabinoid receptors.[137]

Hallucinogens, including D-lysergic acid diethylamide (LSD), peyote and mescaline, psilocybin (mushrooms), phencyclidine (PCP), MDMA (ecstasy), and other phenethylamines, affect the serotonergic system. LSD, peyote, and psilocybin disrupt the serotonergic system, while PCP acts primarily on the glutamatergic receptors. LSD has been shown to act as a partial agonist of $5\text{-}HT_{2A}$ and $5\text{-}HT_{1A}$ receptors, with stronger effects through $5\text{-}HT_{2A}$.[143,144] MDMA exerts its effects on the serotonergic system by binding to the serotonin transporter, resulting in increased and prolonged serotonin signaling; it can also be taken up by the transporter and cause release of serotonin.[145,146] The same effects are seen in the dopaminergic and norepinephrine systems, although to a lesser extent.

Inhalants, which can be any number of things that are delivered via the nasal passages or the mouth, are categorized into nitrites, gasses, aerosols, and volatile solvents.[137] Some classic examples include glue, lighters, and markers. They can affect many neurotransmitters through one of the primary acute effects of hypoxia and through long-term effects including myelin breakdown.

The United States Department of Justice regulates these drugs of abuse under the Controlled Substances Act, which has five schedules for regulation, based on the substance's medical use, potential for abuse, and safety or dependence liability. Drugs that fall under Schedule I categorization are those that have a high potential for abuse and have no currently accepted medical use in treatment in the United States. Examples include heroin, LSD, and marijuana. Schedule II includes those drugs that have a high potential for abuse yet have an accepted medical use in treatment, but abuse may lead to severe psychological or physical dependence; examples include morphine, PCP, cocaine, methadone, and methamphetamine. Schedule III includes those substances that have less potential for abuse than those in Schedules I and II and have accepted medical uses in treatment, and abuse may lead to moderate or low physical dependence or high psychological dependence. Examples include anabolic steroids and codeine. Schedule IV substances have low potential for abuse compared to higher schedules.

SUMMARY

In summary, the nervous system is a complex network of differentiated cells and signaling cascades, which are especially vulnerable to both neurospecific and global toxins and toxicants. Due to its complexity and unique vulnerability factors, no two exposures to the nervous system are alike, with toxic effects that may be seen immediately, only during development, or later in life. For this reason, careful analysis of neurotoxicity of a given agent should be assessed in a case-by-case basis across multiple experimental models and exposure paradigms. With such a large list of known neurotoxins and the even broader classes of potential neurotoxins, complete neurotoxic profiles rarely exist. The use of multiple cell– and invertebrate-based systems and high-throughput arrays and screens will prove indispensible in teasing out which chemicals and compounds we should be most concerned of.

QUESTIONS

33.1 What are functional consequences of altering sodium homeostasis in a neuron?

33.2 Why is it a common characteristic that mitochondrial electron transport chain inhibitors and uncouplers are neurotoxic?

33.3 A new small molecule has been synthesized that is structurally related to scopolamine, a known neurotoxin with anticholinergic activity found in the *Atropa belladonna* (deathly nightshade) plant, and you have been asked to assess its neurotoxic potential. What would be the expected sites of action? What kind of clinical symptoms in a rat dosed with a high or a low concentration?

33.4 It is observed that compound X causes abnormal myelination in the PNS. How might it be determined whether compound X causes demyelination or interferes with remyelination?

KEYWORDS

34 Assessment of Male Reproductive Toxicity

Gary R. Klinefelter and D.N. Rao Veeramachaneni

CONTENTS

INTRODUCTION

Reproduction is a complex process requiring exquisite integration of signals along the hypothalamic–pituitary–gonadal axis in both sexes. To be successful, functional gametes must be produced, matured, released, and transported effectively. Specific behavioral repertoires also must be executed precisely to ensure efficient mating and fertilization. Our current state of knowledge about the physiological, biochemical, and molecular orchestration of reproduction is captured in many excellent reference volumes [1–5]. Based on this understanding, male reproductive function would be expected to be impacted by chemicals that act through a variety of mechanisms, including disruption of the spermatogenic cycle in dividing cells (spermatogonia) as well as those undergoing meiotic processes (spermatocytes); damage to DNA, especially during DNA repair-deficient stages (condensed spermatids); and interference with a vast array of endocrine and paracrine signaling pathways vital to the regulation and integration of reproductive function.

Much of today's research in reproductive biology is motivated by the widely recognized need to understand both fertility and infertility in humans and wildlife so as to develop effective technologies for both contraception and treatment of infertility. Studying the extent to which industrial chemicals in the environment or therapeutic drugs may alter reproduction serves to facilitate our understanding of reproductive biology. Such understanding is essential if protective actions by regulatory agencies are to be based on sound science. The goal of this chapter is to summarize how information on the potential for chemicals to interfere with male reproductive capability is obtained and used by regulatory agencies, industry, and others.

The incidence of infertility is high in humans relative to many other species. It is estimated that 8% to 15% of couples seek medical treatment for infertility [6]. Although infertility is a function of the couple, in a sizable number of cases, the infertility can be attributable to deficiencies in the male. In fact it has been estimated that 98% of male subfertility cases result from deficits in sperm production (quantity) or sperm quality, while only 2% represent ejaculatory dysfunction [7].

In addition, male-mediated effects on offspring have been demonstrated [8,9]. The potential for the male to contribute to reproductive failure and adverse pregnancy outcomes is significant, but the causes of male infertility are only partially understood. We now know that genetic alterations (e.g., aneuploidy), chromosomal aberrations (e.g., translocations), and gene polymorphisms account for a significant proportion of male infertility cases [10–12]. It is inherently difficult to decipher the contribution of chemicals in the environment to the etiology of subfertility in men but despite difficulty, it is imperative to attempt to elucidate the contribution of environmental exposures because, unlike genetically based infertility, chemically induced infertility is presumably preventable.

An assessment of environmental risk factors is further complicated by the growing awareness that exposures during fetal and neonatal development have the potential to impact reproductive function during adulthood [13–15]. Accordingly, it is critical to consider the impact of exposures at all periods of the life cycle, not just on adults; therefore, male reproductive test protocols and epidemiological studies must be designed to evaluate critical windows of exposure and developmental bases of adult disease.

Whereas numerous environmental, occupational, and therapeutic agents have been identified as male reproductive toxicants in typical rodent models such as mice and rats, relatively few have been shown to cause similar effects in human males. This discrepancy is likely due to the reduced resolving power that is inherent in many human studies. Agents that have been shown to cause reproductive effects in men include heavy metals, chemotherapeutic agents, radiation, pesticides such as dibromochloropropane and ethylene dibromide, and other chemicals such as carbon disulfide, chloroprene, and 2-ethoxyethanol [16–18].

More is known about chemicals that are capable of causing adverse male reproductive system effects in animal models because experimental protocols are designed using controlled exposures over a range of doses [19]. The toxicology literature is rich in reviews of many studies relating male reproductive effects to exposures that target male germ cells at specific stages of development, the supporting Sertoli cells, and, importantly, the endocrine regulation of spermatogenesis and sperm maturation [3,4,20–24]. The outcomes of such exposures have included not only reduced fertility but also embryo/fetal loss, birth defects, cancer, and other postnatal structural or functional deficits.

Of particular relevance regarding animal toxicology studies is the growing awareness that exposures to chemicals that mimic or block endocrine signaling during fetal development can significantly alter male reproductive organ and tract development, sometimes with far-reaching impacts such as decreased sperm production or increased risk of testicular cancer later in life [13–15]. This literature indicates that, for certain agents, the developing male reproductive system could be the most affected or the most sensitive target.

Concerns about human male reproductive health have been elevated by reports of downward secular trends in sperm counts, as well as increases in incidences of male reproductive tract malformations (e.g., hypospadias and testicular maldescent) and testicular cancer observed during the latter half of the twentieth century [25–28]. It has been suggested that exposures during reproductive system development to environmental agents that mimic or antagonize endogenous hormones may be causally related to such effects and that low sperm counts are only part of a syndrome of testicular dysfunction in humans that also may include reproductive tract malformations such as hypospadias, cryptorchidism, and predisposition to testicular cancer [29,30]. These concerns prompted the U.S. Environmental Protection Agency (EPA) and international partners to design and launch a comprehensive, tiered testing program to screen for endocrine-active and endocrine-disrupting chemicals (EDCs) [31].

Any attempt to extrapolate effects observed in an animal model to humans must take into account that fertility of the

human male may be particularly susceptible to agents that reduce the number or quality of sperm produced. Whereas in some strains of mice and rats sperm production can be reduced by 90% before effects on fertility by natural mating are observed [32,33], the number of functionally normal sperm in men appears to be much closer to the threshold for reduced fertility. With that being the case, smaller decreases in sperm production in men could have serious consequences on their reproductive potential. If the number of normal sperm per ejaculate is sufficiently low and/or the number of qualitatively normal sperm is reduced, subfertility/infertility is likely to occur. The incidence of subfertility in men has been considered to increase at sperm concentrations below 20×10^6 sperm/mL of ejaculate [34]; nevertheless, some men with low sperm concentrations but otherwise healthy sperm are able to achieve conception, and many subfertile men have concentrations greater than 20×10^6, illustrating the importance of sperm quality. Results from a recent prospective study indicate that human conception rate may begin to decline when sperm concentrations fall below 60×10^6 sperm/mL [35]. Thus, it is reasonable to assume that reductions in sperm production and/or sperm quality by a toxic agent may further decrease the human male reproductive potential.

Ascertaining the relationships between environmental exposures and male reproductive risks for an informed risk assessment process requires not only a sufficient amount and type of experimental data but also a systematic approach to evaluating those data. The approach utilized by the U.S. EPA for male reproductive toxicity risk assessment [36] is presented in this chapter, with particular emphasis on a critical analysis of the strategies and endpoints that are available for male reproductive risk assessment. Although the focus of this chapter is on the assessment of reproductive risk in the male, it is important to recognize that studies that focus solely on the contribution of one parent, although valuable for better elucidation of path to phenotype in that parent, may either miss or substantially underestimate the true reproductive risk of a couple exposed to an environmental chemical. Thus, EPA's Guidelines for Reproductive Risk Assessment [36] is an initial study designed to thoroughly identify the potential for reproductive risk in either sex.

HAZARD CHARACTERIZATION AND DOSE–RESPONSE ASSESSMENT

A paradigm for the risk assessment process has been described in detail in two publications prepared by the National Academy of Sciences [37,38]. Although devised primarily for cancer risk assessment, many of the components also apply to the assessment of noncancer health effects such as reproductive toxicity. The major components of that paradigm are (1) hazard identification, (2) dose–response assessment, (3) exposure assessment, and (4) risk characterization. The EPA's Guidelines for Reproductive Toxicity Risk Assessment is best characterized by hazard characterization followed by quantitative dose–response analysis for risk assessments.

Protocol Selection

Testing protocols describe the procedures to be used to provide data for risk assessments. The quality and usefulness of those data are dependent on the design and conduct of the tests, including endpoint selection and resolving power. The most widely accepted comprehensive protocol is the multigeneration reproductive test [39]. This test detects reproductive toxicity in either sex and provides dose–response information but may not provide all of the information required for a comprehensive risk assessment. The protocol was revised in 1996 to add specific sperm measures (motility, morphology, and numbers) and is continually being evaluated for its effectiveness. It is noteworthy that recent recommendations would modify it further with the goal of enhancing its sensitivity to detect reproductive effects while expanding its scope to detect developmental immuno- and neurotoxicity [40]. The latter changes would also reduce the cost and number of animals necessary for noncancer health effects testing. The EPA has *harmonized* the multigenerational test protocol with those from other federal agencies such as the Food and Drug Administration (FDA) and international organizations such as the Organisation for Economic Co-operation and Development (OECD) to achieve uniformity of approaches at the international level [41]. Results of this protocol may indicate that modifications or follow-up testing should be conducted to determine the most affected sex or elucidate the path to phenotype underlying the observed toxicity [19]. Subacute or acute exposure protocols may be used to study the ontogeny of an effect or better confirm the path to phenotype.

Species Selection

It is intuitively obvious that data from human studies are desirable when estimating specific exposure levels below which there is no appreciable risk; however, human exposure data on single chemicals are rarely available, so it is necessary to extrapolate human risk from data derived from animal studies. Generally, the rat is the species of choice and the default species for reproductive toxicity testing. However, if pharmacokinetic and/or mechanistic data are available that suggest that the rat is not appropriate, a different species should be selected. In any case, confidence in the results of testing for male reproductive toxicity is increased when multiple species have been examined. Advantages of the rat as a test species include the availability of an extensive reproductive toxicity database for this species, uniformity of reproductive endpoints within strain, and consistently efficient reproductive performance. In addition, the basic mechanisms underlying male reproductive function in the rat are well researched and reasonably representative of those in human males.

For a second mammalian test species, the rabbit has specific advantages that make it a good choice. First, ejaculated semen can be collected from bucks using an artificial vagina, allowing longitudinal assessment of semen parameters. Second, by the feasibility of collecting semen ejaculates

TABLE 34.1
Duration (Days) of Spermatogenesis and Epididymal Transit to Provide Recommended Minimum Duration of Exposure in Various Test Species

Test Species	Rat	Mouse	Rabbit	Monkey	Dog	Human
One cycle of the seminiferous epithelium	12.9	8.9	10.7	9.5	13.6	16
Duration of spermatogenesis	59	41	48	43	61	72
Duration of epididymal transit	10	9	12.7	10.5	11.3	5.5
Minimum duration of exposure	69	50	61	54	72	78

(as opposed to cauda epididymal sperm only in rats), alterations in the accessory sex gland secretions can be assessed, and levels of toxicants and/or their metabolites can be measured in seminal fluid. This offers the opportunity to relate specific alterations in semen quality with levels of a given chemical in both rabbits and men. Furthermore, ejaculated semen samples can also be used for artificial insemination (AI). As discussed in detail later, the use of AI with a known number of sperm can be a highly effective strategy for detecting adverse effects on the sperm fertilizing ability in both rabbits and rats. Finally, the use of rabbits circumvent the strain differences associated with rats and has the additional advantage of detecting possible germ cell neoplasia following toxic exposures as this species, unlike rats, manifest germ cell tumors and their precursor lesion called carcinoma in situ (CIS) or intratubular germ cell neoplasia [42].

Under some circumstances, data from other mammalian or nonmammalian species may be appropriate for incorporation into human health risk assessments; for example, mice in which specific genes have been knocked out may make excellent models for elucidating the mechanisms of toxicant action. The use of invertebrate species (e.g., frogs, fish) has become increasingly important in the screening for potential EDCs; chemicals likely to affect all aspects of the ecosystem.

Dose Selection and Duration

To increase the likelihood of detecting toxicity, at least one relatively high, dose level and an array of endpoints are included in the study design. For toxicity testing, the test guidelines specify that the highest dose should produce systemic toxicity but not mortality. Dose–response assessment requires the generation of dose–response curves that adequately describe the increments in degree of effect as well as any changes in pattern of endpoints affected with changing dose level. Dose–response data should also include sufficiently low-dose levels such that a low level of response or no effect is produced. Spacing between doses is especially critical in dose–response assessment. If the gaps between dose levels are too large, the estimate of the lowest-observed adverse-effect level (LOAEL) could be too high, and the no-observed adverse-effect level (NOAEL) could be too conservative. Adequate coverage of a range of low doses is recommended for the testing of all suspected reproductive toxicants with at least one dose being less than 1000-fold the known or predicted maximum human exposure [43]. If a single chemical fails to alter a sensitive male reproductive endpoint at an exposure that is 1000-fold greater than a maximum human exposure, it is probably not a relevant reproductive health risk.

Adverse effects of a toxicant may not be observed in sperm or in fertility until at least 70 days of exposure has lapsed (Table 34.1). This is the length of time to cover the complete process of spermatogenesis (approximately 60 days) and epididymal sperm maturation (approximately 12 days) in the rat [44]. Damage that is limited to spermatogonial stem cells, for example, would not appear in cauda epididymal sperm or in ejaculates for 10 weeks in the rat. Regardless of species studied, the minimum exposure for an initial study to identify male reproductive toxicity should span the duration of spermatogenesis plus transit of sperm through the epididymis during maturation. The duration of one cycle of the seminiferous epithelium varies across species but the total duration of spermatogenesis is commonly equivalent to 4.5 cycles of the seminiferous epithelium. Duration of transit through the epididymis also varies widely among species [44–46] thereby necessitating different minimum durations of exposure for each test species.

This exposure recommendation assumes that levels and cumulative effects of the agent at the sites of attack reach steady state within one cycle of the seminiferous epithelium after initiation of treatment. If that assumption is not valid for an agent, the treatment period may need to be extended accordingly. In studies using shorter dosing periods, a prolonged follow-up may be necessary to determine the persistence of an effect, particularly effects on the earlier stages of spermatogenesis. So again, final assessments should be done on the above minimum exposure times. Knowledge of relevant pharmacokinetic and pharmacodynamic data can facilitate selection of doses, treatment duration, and interim, posttreatment assessments for shorter-duration studies.

Duration of Mating

In fertility testing, pairs of animals are cohabited for periods of time sufficient to ensure conception in healthy animals. This is generally 2 weeks in rats, which allows for at least two opportunities for normally cycling females to conceive. With natural mating, a large impact on sperm production (decreased quantity and/or quality) is necessary before an

adverse effect on fertility can be detected. Moreover, alterations in mating behavior or sperm number in a male may go undetected as a male has multiple mating opportunities during each estrus and the multiple estrous periods in a two week period. As a result, an adequate number of sperm may be ejaculated to ensure fertility even when the males have reduced sperm production as a consequence of treatment. During cohabitation, females should be examined daily for presence of seminal plugs or by vaginal lavage for evidence of mating. Females are usually separated from the male on the day following mating. This practice limits mating to one estrus but still allows numerous copulations during that estrus. Study designs that provide for only a single copulation can increase the sensitivity of fertility testing [47]. Control over the number of copulations is best done by maintaining the animals on a reverse light–dark schedule so estrus and matings occur during normal working hours. If sexually experienced rats are used, copulatory behavior can be rapidly and accurately monitored, with several males observed simultaneously [48].

Number of Animals

The number of animals per dose group in a toxicology study is determined by the number of animals expected to survive and yield data, the expected variation between animals in the endpoints to be examined, the magnitude of effect to be detected, and the level of probability selected for statistical significance. The number of animals required per treatment should be calculated by standard statistical methods as part of the study design process [49]. Estimates of the coefficients of variation for some parameters used for tests of the male rat reproductive system have been reported by several authors [50–52]. In general, when multiple endpoints are used in a study of male reproductive toxicity, 20 males per treatment are sufficient to detect effects. In tests designed to evaluate fertility via natural mating, it is often recommended to start with more males per treatment group to obtain 20 pregnancies per treatment, and some protocols specify mating two females per male. Given the inherent lack of sensitivity afforded by natural mating, it must be determined whether this increased numbers of animals is justified.

TESTING PROTOCOLS

Single- vs. Multigeneration Studies

Comprehensive reproductive toxicity studies in laboratory animals generally involve continuous exposure to a test substance and evaluation of reproductive capability for one or more generations. The objective is to detect effects on the integrated reproductive process as well as to study effects on the individual reproductive organs. The single-generation reproduction test evaluates effects of subchronic exposure of peripubertal and adult animals on reproductive organs and performance. In a multigenerational study, animals producing the first generation of offspring are considered the parental (P) generation, and the subsequent offspring generations

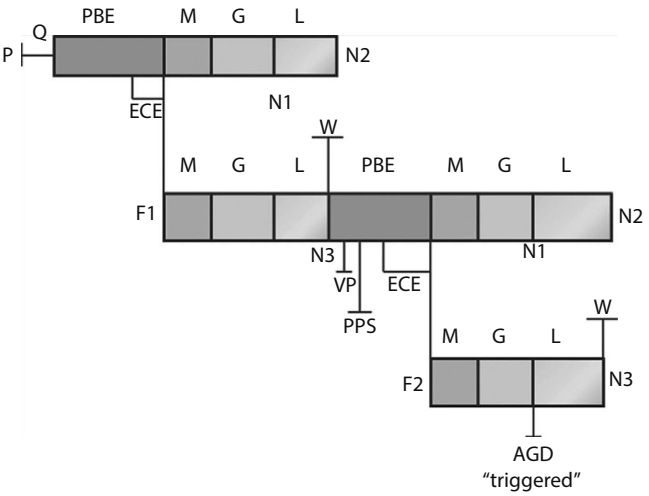

FIGURE 34.1 Schematic depicting the EPA's harmonized multigeneration reproduction test. Exposure in each generation continues until necropsy (N). Q, quarantine; PBE, prebreeding exposure (10 weeks); M, a 2-week mating; G, gestation; L, lactation; W, weaning on postnatal day 21; PPS, preputial separation monitored in F1 males from postnatal day 35; VP, vaginal patency monitored in F1 females from postnatal day 22; ECE, a 3-week evaluation of estrous cyclicity; AGD, anogenital distance measured in the F2 pups at birth if pubertal landmarks (PPS or VP) are affected in the F1; N1, necropsy of the parental males (assessments include organ weights, histology, and sperm measures); N2, necropsy of the parental females (assessments include organ weights and histology); N3, necropsy of three F1 and F2 weanlings per sex per litter (assessment is a macroscopic evaluation with organs weighed and preserved for histology).

are designated filial generations (e.g., F1, F2). Both the P and F1 generations are mated in a standard two-generation reproduction test.

According to the EPA's multigeneration protocol illustrated in Figure 34.1, both sexes of the P generation are dosed beginning at 5–9 weeks of age. This allows effects on spermatogenesis and sperm maturation in the epididymis to be expressed and increases the likelihood of detecting histologic lesions in the testis and epididymis. Both the P and F1 generations are exposed for 10 weeks (rats) prior to breeding. Dosing of the P and F1 males and females is continued until necropsy at the end of gestation and lactation, respectively. F1 and F2 offspring are exposed continuously during gestation and lactation until weaning on PND21. For F1 offspring, exposures are continued beyond weaning, through adulthood. This allows detection of effects that occur from exposures throughout reproductive development, from sexual differentiation through adulthood. Thus, males in the P, F1, and F2 generations have different exposure histories with P males exposed from puberty through adulthood, F1 males exposed throughout the differentiation and development of the male reproductive system, and F2 males exposed during sexual differentiation and early development. The study consists of three groups of increasing dose levels and a concurrent control group. Enough males and females are mated to ensure 20 pregnancies per dose group for each generation. Cohabitation

is terminated when evidence of mating is detected. Randomly selected F1 male and female offspring are dosed after weaning for at least 10 weeks. More than one litter may be produced from either P or F1 animals. Depending on the route of exposure of lactating females, it is important to consider that offspring may be exposed to a chemical by ingestion of maternal feed or water (diet or drinking water studies) as well as via the milk.

In single- and multigeneration reproduction tests, reproductive endpoints evaluated include visual examination of the reproductive organs, weights and histopathology of the pituitary (both sexes), testes, epididymides, male accessory sex glands, uterus, ovaries, and vagina. The parental and F1 animals are evaluated to obtain the number and quality of sperm produced, estrous cycle normality, number of ovarian primordial follicles, and pubertal landmarks associated with normal development of the reproductive system, including the age at vaginal opening in females and the age at preputial separation in males. In addition, anogenital distance (AGD), an endocrine-sensitive endpoint in pups, may be triggered in the F2 animals if developmental effects (e.g., delayed puberty) are observed in the F1 animals. Recent recommendations are to include AGD in an augmented test design and to increase the number of F1 and F2 pups maintained through weaning, puberty, and adulthood [52]. An evaluation of reproductive competence is standard for P and F1. Both male and female mating and fertility indices are calculated. Litters (and often individual pups) are weighed at birth and examined for the number of live and dead offspring, gender, gross abnormalities, and growth and survival to weaning.

Inclusion of testicular histopathology and sperm evaluations help risk assessors judge whether effects on fertility can be attributed specifically to the male, in which case the male alterations are used to set the NOAEL, LOAEL, and margin of exposure (MOE); however, identification of effects in one sex does not exclude the possibility that both sexes may have been affected adversely. Data from matings of treated males with untreated females and vice versa (crossover matings) are necessary to establish sex-specific dose–responses for specific effects.

An EPA workshop has considered the relative merits of one- vs. two-generation reproductive effects studies [53]. The participants concluded that a one-generation study is insufficient to identify all potential reproductive toxicants, because it would exclude detection of effects caused by prenatal exposure and unless exposure beginning prior to puberty also excludes peripubertal effects. A single-generation test would also miss effects on germ cells that could be transmitted to and expressed in the next generation, that is, epigenetic alterations. A one-generation test might also miss adverse effects with delayed or latent onset because of the shorter duration of exposure for the P generation. These limitations are shared with the shorter-term screening protocols described in the following. Because of these limitations, a comprehensive reproductive risk assessment should begin with a two-generation test or its equivalent.

In studies where parental and offspring generations are evaluated, additional risk assessment issues arise with regard to the relationships of reproductive outcomes across generations. Increasing vulnerability of subsequent generations is sometimes observed. Predictions of increased risk of subsequent generations could be strengthened by knowledge of the reproductive effects in the adult, the likelihood of bioaccumulation of the agent as duration of exposure is increased during reproductive development, and the potential for increased sensitivity resulting from exposure during critical periods of reproductive development [54], particularly exposure to endocrine-active agents [25]. An instructive example of the use and interpretation of multigenerational test data to evaluate the potential for effects to worsen across generations (or not) is provided by the Center for the Evaluation of Risks to Human Reproduction in its evaluation of bromopropane [55].

Several recent reports suggest that exposures during early phases of testis or prostate differentiation and development may alter the epigenetic programming of the organ, resulting in altered function during adulthood, including increased predisposition to cancer [56,57]. Such alterations may potentially be transmissible across subsequent generations, even in unexposed offspring. Such observations may impact both testing strategies and risk assessment approaches in the future.

On the other hand, subsequent generations may be less affected than the F1 offspring. This can occur when the F1 and F2 animals represent survivors who are (or become) more resistant to the agent than the P generation. Therefore, results between generations or between sequential litters within a generation should not necessarily be compared directly. Significant adverse effects in any generation should be considered a cause for concern unless inconsistencies in the data indicate otherwise.

A review of 20 positive multigeneration reproduction studies has provided some insights on the relationship of male toxicity to effects on offspring within a given generation and the relationships of reproductive outcomes across generations [58]:

- The presence of toxicity in the adult male (P), reproductive or otherwise, was not a prerequisite for the occurrence of effects on offspring.
- Approximately one-half of the studies were classified as *positive increasing*. In these cases, the second-generation (F1) animals exhibited effects that were more severe than those in the first generation or occurred at equivalent or lower doses.
- The increasing toxicity across generations is consistent for chemicals that bioaccumulate; however, exposure of sequential generations that involve different developmental stages (P vs. F1 adults) might also contribute to differential effects across generations.
- The multigeneration reproduction test does not address the issue of reversibility; however, inclusion of additional mated pairs in a study can provide additional animals for a reversibility test or developmental toxicity evaluation.

Subchronic Studies

Subchronic toxicity tests may have been conducted before a detailed reproduction study is initiated. In the subchronic toxicity test with rats, exposure usually begins at 6–8 weeks of age and is continued for at least 70 days. The initiation of exposure at 8 weeks of age (compared with 6) allows the animals to reach a more mature stage of sexual development and ensures an adequate length of dosing for observation of effects on the reproductive organs with most agents as discussed earlier. Dosing is often done orally (i.e., gavage, in diet, or in drinking water) but may be by inhalation or dermal application. Animals are monitored for clinical signs throughout the test and are necropsied at the end of dosing, without evaluating reproductive function. The endpoints evaluated for the male reproductive system include visual examination of the reproductive organs, plus weights and histopathology for the testes, epididymides, and accessory sex glands.

Scientists in the National Toxicology Program have examined the feasibility and value of incorporating some basic measures of male reproductive toxicity into the protocols of their standard 13-week, prechronic toxicity studies to serve as a reproductive screening battery. These include epididymal sperm morphology, quantitative evaluations of epididymal sperm motility, and enumeration of epididymal sperm reserves. Data were collected at the end of 50 13-week studies, of which 25 were conducted in mice and the remainder in rats [51]. In this evaluation, reproductive organ weights and sperm motility appeared to be the most statistically powerful endpoints. Based on the results of these studies, the authors recommended that multiple endpoints of spermatotoxicity be evaluated in screening tests. This test may be useful to identify an agent as a potential reproductive hazard but usually does not provide information about the integrated function of the reproductive systems (sexual behavior, fertility, and pregnancy outcomes) nor does it include effects of the agent on immature animals.

Short-Term Male Reproductive Studies

Although short-term tests (i.e., less than 70 days for the rat) have been proposed to screen chemicals for testicular toxicity, the risk of false negatives due to insufficient duration of exposure is high. A serious limitation, especially when using them for chemicals with unknown toxicity, is that effects of exposures during male reproductive development would not be evaluated. That said however, these tests are appropriate when prior information exists about the target organ (i.e., testis or epididymis) or if a chemical is suspected to alter spermatogenesis or epididymal sperm maturation based on a structure–function relationship with a known toxicant. Short-term tests are also of value, if not essential, in the elucidation of the path to phenotype, for example, determining which specific germ cells are compromised by exposure and how these cells might be altered to account for the observed phenotype (e.g., dysgenetic acrosomes). Because a wide variety of short-term tests have been used to assess reproductive toxicity, only a few examples are presented here.

Studies to Detect Toxicity in the Epididymis

This protocol was developed to identify toxicants that alter the structure or function of the epididymis within 5 days of toxicant exposure [59]. Based on the known transit rate of rat sperm through the epididymis, sperm that are within the proximal region of the epididymis at the onset of exposure (day 1) can be recovered from the proximal cauda epididymidis, the first site in which fertile sperm can be found, 4 days later (day 5). By limiting the exposure period in this manner, spermatids that would be within the testis at the onset of exposure are precluded from assessment. With toxicants that compromise testosterone production, it is possible to implant testosterone-filled Silastic® capsules to clamp serum testosterone at control levels. Also, the efferent ducts can be ligated to prevent toxicant-induced perturbations in testicular fluid from altering the epididymis. This protocol has been used to identify epididymal toxicity resulting from exposure to chloroethyl methanesulfonate [60], as well as epichlorohydrin and hydroxyflutamide [61]. To detect antiandrogenic effects from a chemical such as hydroxyflutamide, however, it is necessary to castrate the animals to lower endogenous androgen levels to the extent that competition of test chemical for the androgen receptor is effective. To prevent the loss of androgen-dependent function within the epididymis following castration, a testosterone-filled Silastic® capsule can be implanted to maintain androgen status at a level that maintains epididymal sperm maturation over 4 days [62]. A similar short exposure design has been used to identify sperm defects associated with cyclophosphamide-induced postimplantation loss [63], as well as infertility of epididymal sperm that results from the metabolic inhibitors ornidazole and α-chlorohydrin [64].

Importantly, one manifestation that seems to be common to the epididymal toxicants ethane dimethane sulfonate (EDS), chloroethyl methanesulfonate, hydroxyflutamide, and epichlorohydrin, as well as developmental exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and methoxychlor, is reduced epididymal sperm number without any concomitant reduction in testicular sperm number. This suggests that epididymal sperm transit is accelerated by certain chemical exposures. Indeed, when the short-term epididymal toxicity protocol was modified to test this hypothesis, accelerated transit was demonstrated [61]. The acceleration appeared to be independent of androgen status but was significantly correlated to several constitutive epididymal proteins. Accelerated sperm transit in humans, who have a much shorter period of epididymal transit, could have adverse effects on the process of sperm maturation and numbers of sperm ejaculated.

Studies to Detect Toxicity in the Testis

Linder et al. [65] originally proposed a short-duration test to screen chemicals for spermatotoxicity in structure–function studies or to set priorities for chemicals requiring further evaluation. Depending on the duration of dosing and the day on which necropsies are performed, the protocol may

cover a period of up to 2.5 weeks (e.g., dose for 5 days, necropsy 14 days later). The 14-day period allows for spermatids that are compromised at the onset of exposure to appear in the epididymis. In a validation study, groups of male rats were dosed for 1–5 days with 14 chemicals shown to produce minimal testicular effects in subchronic studies, and necropsies were performed 2–3 days and 13–14 days after dosing was terminated. Reproductive organ weights (testis, epididymis, seminal vesicle, and prostate), sperm counts (testicular and epididymal), and sperm motion parameters (computer-assisted sperm analysis [CASA]) were measured. Both the testes and epididymides were subjected to critical histopathologic evaluation. Spermatotoxicity was detected for the ten most potent testicular toxicants. Results for the other four chemicals, which were judged to be minimally toxic in a subchronic test, were essentially negative; thus, chemicals that produce moderate to severe damage to germ cells in latter stages of spermatogenesis are detectable with this short-duration test. More recently, this protocol has been abbreviated to encompass a 14-day exposure with a necropsy following administration of the last dose. With this, it has been established that the disubstituted haloacetic acid by-products of drinking water disinfection (i.e., dibromoacetic acid [66], dichloroacetic acid [67], and bromochloroacetic acid [68]) produce lesions in the latter stages of spermatogenesis. The histopathologic profile of these insults includes the formation of atypical residual bodies, fusion of sperm, and delayed spermiation.

Studies Using Other Animal Models

As discussed earlier, while testicular toxicity has been demonstrated in rat model following exposure to water disinfection by-products, comparable or even longer-term exposure to dibromoacetic acid did not produce any significant testicular toxicity in mice [69]. As species and strain differences among rodent animal models have become apparent, alternative animal models including nonrodent, amphibian, and aquatic animal models have been used to test testicular toxicity of environmental chemical pollutants. For example, when rabbits were chronically exposed to dibromoacetic acid in drinking water [70] or a mixture of common chemical contaminants in groundwater near hazardous waste sites [71], testicular toxicity with persistent sperm abnormalities such as vesiculated acrosomes and acrosomes shared between two or more sperm was observed even at relatively low levels.

Studies to Identify EDCs

In Vivo and In Vitro Screens

A battery of in vivo and in vitro tests has been proposed to fulfill congressional mandates to screen for EDCs. The Tier I in vivo tests to screen for alterations in male reproductive development in the rat are the Hershberger and pubertal assays [72,73]. The Hershberger assay attempts to identify androgenic or antiandrogen influences by a particular chemical. Young castrate male rats are used to increase the sensitivity of detecting a change in androgen status in sex accessory organs; the rationale is the same as that used earlier when testing for effects of antiandrogens in the adult epididymis, that is, lower endogenous androgen levels via castration. Androgen-dependent sex accessory organs are weighed following exposure to the putative EDC in groups of animals without or with concurrent exogenous androgen supplementation. Testosterone propionate is given daily during exposure when antiandrogenic activity is tested [74]. Castration, by removal of both the testis and the epididymis, is done at 6 weeks of age [75], around the time of preputial separation but before biological puberty, that is, the appearance of sperm in the epididymis is attained around 55 days of age (Klinefelter, unpublished). One week after castration, treatment groups are assigned on the 49th day and typically animals are necropsied between 60 and 70 days of age. Thus, there is typically a 2–3-week exposure period. The androgen-dependent organs that are evaluated include the glans penis, the levator ani, bulbocavernosus muscles, ventral prostate, and seminal vesicles with coagulating glands. It should be noted that this assay could be performed equally well if castration involved removal of only the testis. In this case, the epididymis would also be weighed.

The pubertal male assay is similar in concept except dosing begins just after weaning, on postnatal day 23, and continues until postnatal day 53 [76]. Two dose groups are required in addition to the vehicle control group. This assay is capable of detecting alterations due to wider array of toxicants including estrogenic chemicals, chemicals that affect steroid hormone biosynthesis directly, and chemicals that alter the hormonal status of the hypothalamic/pituitary axis [77–81]. In addition to weights of the sex accessory organs including the epididymis, various serum hormones (e.g., Follicle-stimulating harmone (FSH), Luteinizing harmone (LH) testosterone) are measured, and histology of the testis and epididymis is evaluated. Due to the increased exposure in this assay, subsequent testing is required to confirm target organ(s) implicated in the observed toxicity and its time course.

A slightly longer protocol, but more comprehensive protocol than either the Hershberger or pubertal assays, would initiate dosing during pregnancy and continue through puberty. This assay would have the advantage of detecting alterations in male sexual differentiation and early development of the gonad and accessory sex glands. Abnormalities such as cleft phallus, cryptorchidism, ectopic testes, epididymal agenesis, altered AGD, and retained nipples would be detected.

As indicated earlier, nonmammalian assays are now increasingly popular to screen for endocrine-active chemicals. Here again, the focus has been on agonistic/antagonistic activities of androgenic and estrogenic pathways. The fish short-term assay [82–85] measures many endpoints common to mammalian reproduction, evaluates both sexes simultaneously, and actually assesses fertility. Briefly, four females and two male fish are housed in a flow-through tank of water containing one of three test concentrations or a vehicle control. Exposures continue for 21 days at which time fish

evaluated for alterations in gonadal histology, hormones, and secondary sex characteristics; fertility is assessed throughout the exposure period.

There are five primary in vitro tests screen for chemicals that bind estrogen and androgen receptors or affect steroidogenesis by altering the steroidogenic enzymes, including aromatase. There are multiple androgen and estrogen receptor–based assays being utilized today. Competitive binding assays are used to ascertain whether a test chemical has significant affinity for either the androgen or estrogen receptor in vitro [86,87]. Certainly, before denoting any chemical as either an agonist or antagonist for androgen or estrogen receptor–mediated action, binding to the steroid receptor must be demonstrated. However, receptor binding alone does not constitute an alteration in receptor-mediated action. Once bound to the receptor, the steroid–receptor complex must undergo conformational change to interact with the hormone response element in a responsive gene to initiate transcription of that gene.

Cell-based transcriptional activation assays have evolved to evaluate the ability of a chemical to up- or down-regulate steroid receptor–mediated gene transcription. For these assays, cells are transfected with a plasmid containing a hormone response element and coupled to a reporter gene such as luciferase. Often, the cells used in these assays have no endogenous steroid receptor so a vector coding for the steroid receptor is also transfected. Both androgen [88]- and estrogen [89,90]-based assays have been developed. In general, transcriptional activation assay, both mammalian cell and yeast based, has proven less standardized than receptor binding assays [91], and neither assay is particularly well suited for testing chemicals requiring metabolic activation. One factor that is typically ignored in both of these in vitro assays is that the level of endogenous ligand used in the assay is rarely added at physiological levels.

Screening for the ability of chemicals to alter steroidogenesis has been done using minced testis cultures, as well as cultures of transformed or dedifferentiated cells. For the minced testis cultures, small aliquots of testis parenchyma are weighed and incubated for several hours with and without LH stimulation [92,93]. This method is applicable to ex vivo evaluation using parenchyma derived from testes (at any age animal) following in vivo exposure. The use of transformed cells such the mouse MA-10 Leydig cell lines is limited because these cells lack the enzymes required for conversion of progesterone to testosterone [94]. The rat R2C Leydig cell line lacks the LH receptor precluding detection of alterations in LH-stimulated testosterone production [95]. Human H295 cells have been used recently. These cells are dedifferentiated cells isolated from an adrenocortical carcinoma capable of producing cortisol, androgens, and estrogen [96]. However, these cells also do not express a functional ACTH receptor and cannot respond to LH. Most recently, mouse BLTK1 cells have been used [97]. These cells were obtained from a testis tumor that developed in transgenic mice expressing the inhibin promoter. This cell line appears to respond to LH and contains the requisite steroidogenic enzymes. The disadvantage of these cells is that the amount of testosterone they produce seems quite low compared to normal Leydig cells. However, this is true for all cell lines.

There is no reason that preparations of highly purified rat Leydig cells [98,99] discussed in the succeeding text could not be used for 96-well plate cultures to screen for the potential of chemicals to alter steroidogenesis by the Leydig cell directly. These cells respond quite well to LH, obviously have all the requisite steroidogenic molecules in play, and produce hundreds of nanograms of testosterone in only a few hours, thereby increasing sensitivity to detect subtle, chemical-induced compromise in testosterone synthesis.

Hypothesis-Based Testing

As pointed out earlier, the in vivo screens to detect EDC activity are not designed to provide data regarding target organ/cell or path to phenotype. Most of the EDC research published today represents hypothesis-based testing. For example, if a chemical is known to alter steroidogenesis in an adult animal or in an in vitro screening assay, one might consider a test to evaluate the potential for this chemical to alter testosterone throughout reproductive development. In this case, exposures would continue in utero, through puberty, and into adulthood. At the end of gestation, during the pubertal period, and as adults, the exposed males would be evaluated. This approach leads to literally dozens of studies done on phthalates. The early work established that phthalates were capable of significantly reducing testosterone production by the fetal testis [100]. This decrease in testosterone production was associated with aggregation of fetal Leydig cells and subsequently linked to postnatal phenotypic alterations such as cryptorchidism, agenesis of the epididymis, and hypospadias [101]. Gene expression studies later established that at higher exposures, key steroidogenic molecules were compromised [102]. Most recently, we have learned that Leydig cell aggregation occurs at much lower dose levels and this dysgenesis precedes the decreased ability of the fetal Leydig cell to produce testosterone [103]. This is simply one example of how sophisticated studies with more targeted approach can be utilized to gain a better understanding of the underlying toxicity resulting from a chemical exposure. And, a better understanding such as this leads to the discovery of molecular targets that might be applicable to human studies and facilitate a better human risk assessment.

Such hypothesis-based, target-oriented studies using nonrodent models are also necessary as the outcomes in other animal models might provide additional information than those observed in rodent models. For example, when exposed to dibutyl phthalate (DBP) [104], it was found that rabbits manifest germ cell atypia with implications for the development of germ cell cancer (see in the succeeding text under "Histopathological Evaluation" section) that was not reported in rats. Likewise, when *Xenopus laevis* frog embryos [105,106] were chronically exposed to DBP at very low levels, survival, development (metamorphosis), and spermatogenesis were impacted.

IN VIVO ENDPOINTS TO EVALUATE MALE REPRODUCTIVE TOXICITY

The following sections describe various endpoints that can reflect male reproductive toxicity and their use in risk assessment. A comprehensive assessment of male reproductive toxicity requires information on multiple endpoints that are capable of detecting the range of potential adverse effects. These should include measures of fertility and reproductive behavior. Because the fertility assessed by natural mating in rodents has limited sensitivity, endpoints should also be included that are capable of detecting effects on components of the male reproductive system that support those functions (e.g., production of normal spermatozoa and normal differentiation of the reproductive tract and external genitalia).

Alterations in these reproductive endpoints may be the result of direct or indirect toxicity to the male reproductive system. In either case, exposure to an agent has caused a reproductive effect and there may be cause for concern. Careful evaluation of the dose–response curves for the various target organs and effects will hopefully point to the most sensitive target organ/tissue. This organ/tissue then would be the focus for setting the NOAEL, LOAEL, or benchmark dose and estimating human health risk. Statistical analyses are important in determining the effects of a particular agent, but the biological significance of data is most important. When many endpoints are investigated, statistically significant differences may occur by chance. On the other hand, apparent trends with dose may be relevant biologically even though statistical analysis does not indicate a significant effect. In the following discussion, endpoints are identified in which significant changes may be considered adverse, but there needs to be concordance between statistically significant results and known biological relevance of these results. The following sections describe various male-specific endpoints of reproductive toxicity that are useful in assessing male reproductive risk.

Reproductive Organ Weights

Monitoring body weight during treatment provides an index of the general health status of the animals, and such information may be important for the interpretation of reproductive effects. Reduction in body weight or weight gain may reflect a variety of responses, including rejection of chemical-containing food or water because of reduced palatability, treatment-induced anorexia, or systemic toxicity. Less than severe reductions in adult body weight induced by restricted nutrition have shown little effect on the male reproductive organs or on male reproductive function [107,108]. When a relationship between a body weight decline and a significant effect on male reproductive organ weight is not apparent, it is not appropriate to dismiss the altered organ weight as secondary to systemic toxicity. So an alteration in a reproductive organ (or other reproductive measure for that matter) is still considered adverse if more modest body weight changes exist. In the presence of severe body weight depression (i.e., >10% relative to control), the altered reproductive endpoint may have resulted from a more generalized toxic effect and is not typically considered a specific, adverse reproductive outcome.

The male reproductive organs for which weights may be useful for reproductive risk assessment in adults include the testes, epididymides, pituitary gland, seminal vesicles (with coagulating glands), and prostate. Organ weight data may be presented as both absolute weights and as relative weights (i.e., organ weight to body weight ratios). Organ weight data may also be reported relative to brain weight because, subsequent to development, the weight of the brain usually remains quite stable [109]. Evaluation of data on absolute organ weights is important, because a decrease in a reproductive organ weight may be quite independent of body weight. Typically, at the lower effective dose levels of most potent reproductive toxicants, there is no change in body weight.

Normal testis weight varies only modestly within a given test species [110]. This relatively low interanimal variability suggests that absolute testis weight should be a precise indicator of gonadal injury; however, damage to the testes may be detected as a weight change only at doses higher than those required to produce significant effects in other measures of gonadal status [111–113]. This contradiction may arise from several factors, including a delay before cell deaths are reflected in a weight decrease. The simultaneous occurrence of germ cell death and Leydig cell hyperplasia may offset any observed change in testis weight, and blockage of the efferent ducts by cells sloughed from the germinal epithelium or the efferent ducts themselves can lead to an increase in testis weight due to fluid accumulation [114,115], again, an effect that could offset the effect of germ cell depletion on testis weight. Nonetheless, a significant increase or decrease in testis weight in the absence of a comparable body weight change is indicative of an adverse effect.

Pituitary gland weight can provide valuable insight into the reproductive status of the animal; however, the pituitary gland contains cell types that are responsible for the regulation of a variety of physiologic functions, including some that are separate from reproduction, so changes in pituitary weight may not necessarily reflect reproductive impairment. If weight changes are observed, gonadotropin-specific histopathologic evaluations may be useful in identifying the affected cell types. This information may be used then to judge whether the observed effect on the pituitary is related to reproductive system function and therefore an adverse reproductive effect.

The weights of the epididymis, the prostate, and the seminal vesicles are androgen dependent and may reflect changes in the animal's endocrine status or testicular function. Separation of the seminal vesicles and coagulating gland is difficult in rodents; however, the seminal vesicle and prostate can be separated and results may be reported for these glands separately or together, with or without their secretory fluids. From a developmental perspective, the epididymis and seminal vesicles are considered to be testosterone-dependent organs, while the prostate is considered to be dependent on

dihydrotestosterone [116]. Because the developing seminal vesicles and prostate respond to hormone stimulation differently, these organs should be examined separately in any developmental study.

Significant changes in absolute male reproductive organ weights constitute an adverse reproductive effect. Such changes also may provide a basis for obtaining additional information on the reproductive toxicity of that agent, but significant changes in other important endpoints that are related to reproductive function may not be reflected in organ weight data. For this reason, the lack of an organ weight effect should not be used to negate significant changes in other endpoints that may be more sensitive.

Histopathological Evaluation

Histopathologic evaluations of test animal tissues have a prominent role in male reproductive risk assessment. Organs that are often evaluated include the testes, epididymides, prostate, seminal vesicles (often including coagulating glands), and pituitary. Tissues from lower dose exposures are often not examined histologically if the high dose produced no difference from controls. Histologic evaluations can be especially useful by (1) providing a relatively sensitive indicator of damage; (2) providing information on toxicity from a variety of protocols; (3) with short-term dosing, providing information on site (including target cells) and extent of toxicity; and (4) indicating the potential for recovery.

The quality of the information presented from histologic analyses of spermatogenesis is improved by proper fixation and embedding of testicular tissue. With adequately prepared tissue, a description of the nature and background level of lesions in control tissue, whether preparation induced or otherwise, can facilitate interpreting the nature and extent of the lesions observed in tissues obtained from exposed animals [117–120].

Many methods of histopathologic evaluations of the testis only record lesions if the germinal epithelium is severely depleted or degenerating, if multinucleated giant cells are obvious, or if sloughed cells are present in the tubule lumen. More subtle lesion, such as atypical germ cells, missing types of differentiating germ cells, or retained spermatids that can significantly affect spermiation may not be detected when testicular tissue is not optimally processed for histopathology. Also, familiarity with the intricacies of morphology of the testis and the kinetics of spermatogenesis of each test species is essential for the identification of less obvious lesions that may accompany lower dose exposures or lesions that result from short-term exposure [119]. Several approaches for qualitative or quantitative assessment of testicular tissue are available that can assist in the identification of less obvious lesions that may accompany lower dose exposures, including the use of the technique of staging. A text atlas that provides extensive information on tissue preparation, examination, and interpretation of observations for normal and high-resolution histology of the germinal epithelium of rats, mice, and dogs is available [119]. Also, a decision-tree scheme for staging rat spermatogenic cycle has been published [121].

Cell staging is based on the examination of cross sections of the seminiferous tubules. The proliferation and differentiation of germ cells is a highly ordered, time-dependent process; thus, the temporal and spatial relationships of the various spermatogenic cell types can be defined for the different stages of the spermatogenic cycle (Figure 34.2) [119,121]. Based on differences in light absorption of differentiating germ cells, transillumination has also proven useful for isolating segments of rat seminiferous tubules at specific stages for biochemical analyses [122]. Knowledge of the cytoarchitecture of the testis can allow identification of specific lesions that have resulted from toxicity to the germ cell at a given stage of development.

Quantification of cell staging may include analysis of frequency distributions of the cell stages present or the proportion of tubules that have identifiable stages with all expected cell types [119,121]. The cell-staging approach is being applied more frequently in the evaluation of environmental agents [123–130]. It is not, however, required for routine toxicology testing.

Similar to rodent animal models, kinetics and staging criteria for less frequently used animal model, the rabbit, have also been well documented and have been used to delineate the nature of seminiferous epithelial lesions in toxicological studies [131,132]. As a valid alternative vertebrate reference system for comparative analysis with higher vertebrates, frogs and fishes also constitute good animal models because of the simplicity of their testicular organization and cystic pattern of spermatogenesis; in fact, a nomenclature for fish germ cells to improve the comparability with higher vertebrates has been proposed [133,134]. These animal models perhaps simulate polluted aquatic environmental condition better than mammalian models. It has been demonstrated that simple, yet thorough, qualitative as well as quantitative evaluation of spermatogenic effects can be performed following exposure to ubiquitous waterborne toxicants such as phthalates (Figure 34.3) [106].

Morphometry is a term applied to a variety of specialized techniques to obtain quantitative data on cellular or organelle characteristics [111,119,135]. The methods may be applied to measure diameters, areas, or volumes of testicular compartments (e.g., tubular vs. interstitial), specific cell types, or subcellular structures. Cell counts may also be obtained as well as ratios of one cell type to another (e.g., pachytene spermatocytes to Sertoli cell). Although not required in test protocols, these specialized methods can be used in mechanistic studies, which, in turn, can inform the risk assessment. Aside from an evaluation of the seminiferous epithelium, the interstitium of the testis also warrants a careful evaluation. Some reproductive toxicants can result in Leydig cell hyperplasia, which may or may not progress to adenoma formation. While most, if not all, of the discussion to date regarding Leydig cell hyperplasia and its association with Leydig cell adenoma formation has centered around mechanisms of toxicant-induced hyperplasia in the adult testis [136,137], it is possible that the fetal or prepubertal Leydig cell is uniquely capable of becoming hyperplastic and that the mechanisms of initiation may

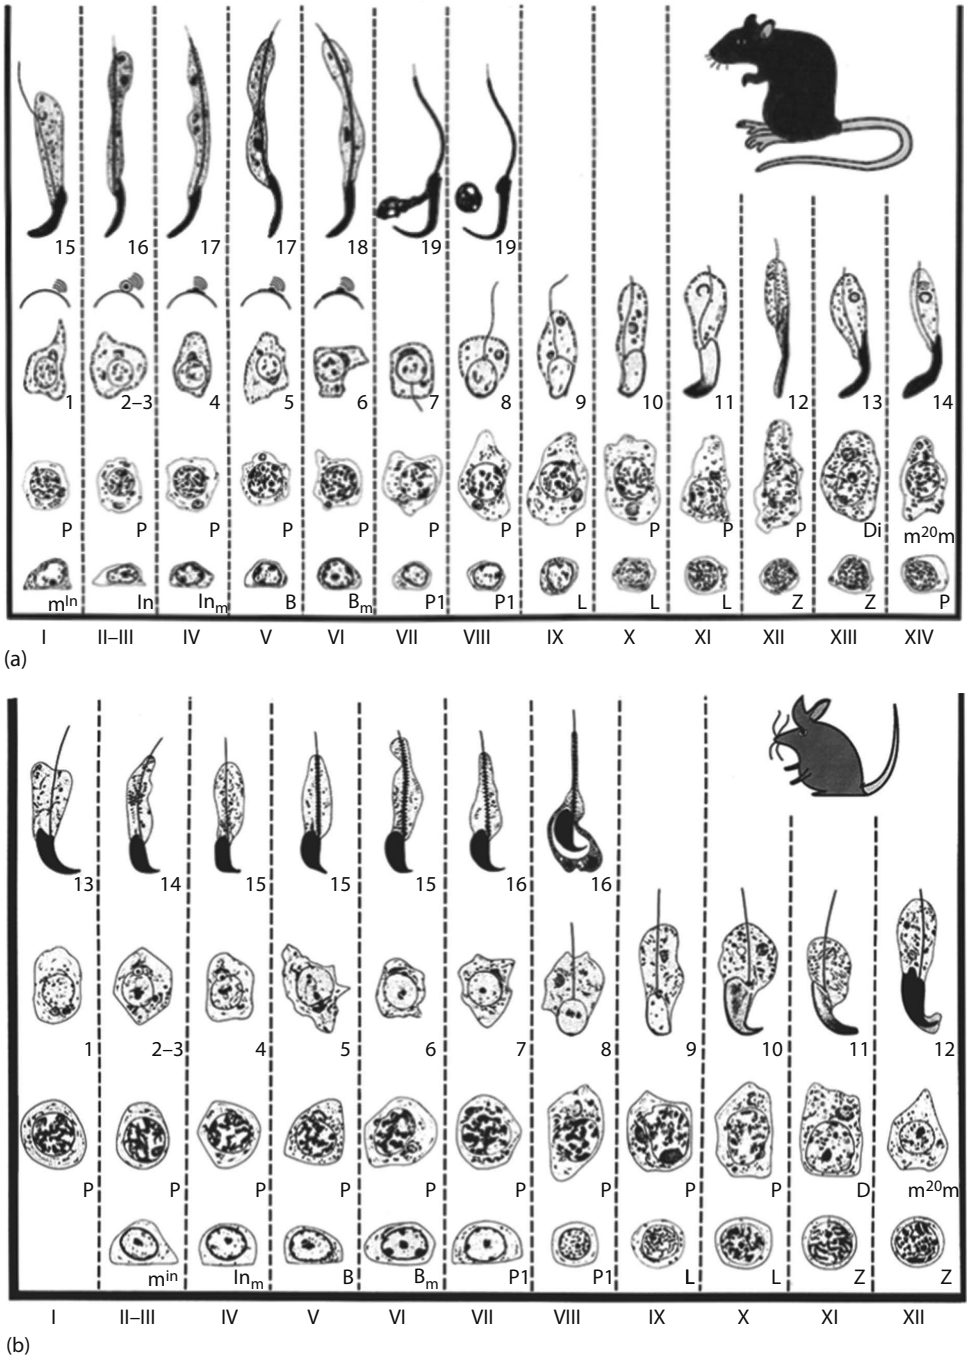

FIGURE 34.2 Cycle maps of spermatogenesis for the rat (a) and the mouse (b). The vertical columns, designated by Roman numerals, depict cell associations (stages). In the scheme provided, stages II and III are combined into a single stage called II–III. The developmental progression of a cell is followed horizontally until the right-hand border of the cycle map is reached. The cell progression continues at the left of the cycle map one row up. The cycle map ends with the completion of spermiation. The symbols used designate specific phases of cell development. (Reprinted from Russell, L.D., Ettlin, R., Sinha Hikim, A.P., and Clegg, E.D. et al., *Histological and Histopathological Evaluation of the Testes*, Cache River Press, Clearwater, FL, 1990. With permission of Cache River Press.)

differ. Transgenic mice that are deficient in anti-Mullerian hormone exhibit Leydig cell hyperplasia [138]. In this regard, gestational exposures to phthalates have been associated with an increased postnatal incidence of Leydig cell hyperplasia and adenoma formation [139,140], respectively.

Although adenoma formation does bear clinical significance, the relevance of Leydig cell hyperplasia alone, as a reproductive effect in test species, remains controversial [137]. Numerous modes of action have been postulated for induction of Leydig cell hyperplasia, including androgen receptor antagonists, testosterone biosynthesis inhibitors, aromatase inhibitors, and estrogen agonists. Each of these modes of action would result in a change in the testosterone-to-estradiol ratio within the Leydig cell. Even though the importance of

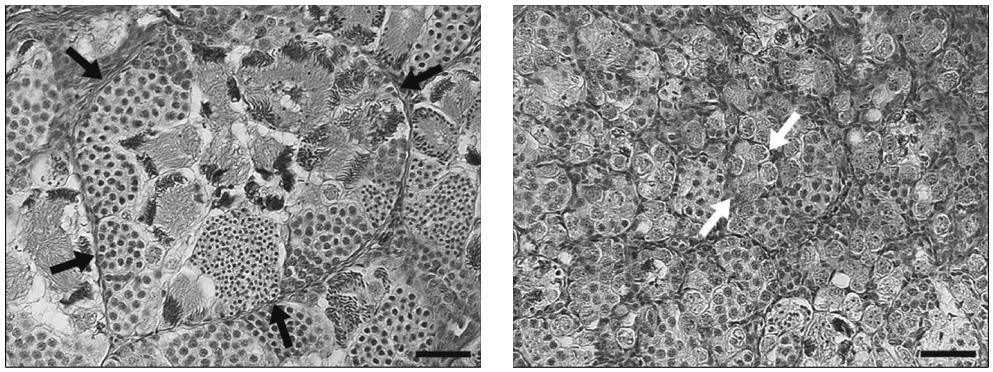

FIGURE 34.3 A typical seminiferous tubule cross section from a normal adult (33-week-old) African clawed frog, *Xenopus laevis* (a), is shown in contrast to regressed seminiferous tubules in an age-matched experimental animal (b) exposed to 10 ppm DBP beginning at sexual differentiation (Nieuwkoop and Faber stage 52; 3 weeks of age) continuing until metamorphosis (stage 66; 8 weeks of age). The number of germ cells in a nest in any stage of spermatogenesis is conspicuously less in the DBP-exposed animal compared to the control animal. Note the number and variety of cell nests that constitute a seminiferous tubule showing the pattern of organization and progression of spermatogenesis in *Xenopus laevis* in contrast to a mammal. This unique pattern of seminiferous tubular architecture in frogs makes it easier to evaluate the impact of toxicants on the process of spermatogenesis relative to commonly used laboratory animal models. Both images were photographed at the same magnification. Bar = 50 μm.

this ratio has been demonstrated in recent years [141], its direct association with Leydig cell hyperplasia has not been demonstrated. Moreover, few studies have demonstrated Leydig cell number in a definitive fashion [140,142]. There is really no way to confirm an increase in number of Leydig cells in the testis without performing a thorough morphometric analysis in which the number of Leydig cells are enumerated using Leydig cell–specific probes (i.e., antibodies that recognize steroidogenic enzymes specific to Leydig cells).

In utero exposure to the phthalates has been linked to fetal Leydig cell dysgenesis, specifically the formation of clusters of fetal Leydig cells [100,143]. Using the Leydig cell–specific marker, 3β-hydroxysteroid dehydrogenase, and the Sertoli cell marker, anti-Mullerian hormone, Mahood et al. [144] reported that fetal Leydig cells get trapped in seminiferous cords during cord formation and these Leydig cells persist in the seminiferous epithelium at adulthood. Similarly, Sertoli cells and/or germ cells were noted within the clusters of fetal Leydig cells in the interstitium. A morphometric study of Leydig cells within testes before and during pubertal, that is, progenitor and immature Leydig cells, and in the adult testis following in utero exposure to phthalates has not yet been performed. Leydig cell hyperplasia may occur after birth since prepubertal exposure to di(2-ethylhexyl)phthalate (DEHP) was shown to result in hyperplasia in adults [140]. If studied adequately, Leydig cell dysgenesis may become one of the early phenotypes associated with the testicular dysgenesis syndrome (TDS) in humans, which encompasses decreased sperm quantity/quality, hypospadias, cryptorchidism, and testicular germ cell cancer [145], assuming that Leydig cell dysgenesis occurs in humans exposed to phthalates.

Testicular dysgenesis has been linked to abnormal male reproductive development or masculinization that is now known to be dependent on testosterone as well as anti-Mullerian hormone and insulin-like factor 3 (Insl3) [15]. Indeed, Insl3 mRNA and protein have recently been shown to be decreased in cryptorchid testes of rats exposed to selected phthalate esters during gestation [146,147]. Cryptorchid testes frequently manifest testicular CIS cells prior to frank formation of germ cell tumors. Recently, light and electron microscopic evaluations have revealed that the driving force in the progression to CIS cells is the chemical nature of the toxic insult and not the abdominal location of the testis itself [148]. It is interesting that those chemicals that were shown to produce a progression from cryptorchid to CIS cell–containing testes—1,1-dichloro-2,2-bis-(*p*-chlorophenyl)ethylene (DDE) and estradiol—would each alter the normal testosterone-to-estrogen ratio during reproductive development. It should be noted that the manifestation of CIS and CIS-like lesions has been documented only in the rabbit testis either spontaneously [149] or following intentional exposures to DBP [104] or 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane (DDT) [150]. The morphological features of testicular CIS in rabbits duplicate CIS lesions encountered in deer [151], horses [152], and humans [153–155]. Testicular CIS is not known to occur in rats emphasizing the importance of use of nonrodent animal models in studying testicular dysgenesis and testicular cancer (Figure 34.4) [42,156].

The basic morphology of other male reproductive organs (e.g., efferent ducts, epididymides, accessory sex glands, and pituitary gland) has been described as well as the histopathologic alterations that may accompany certain disease states [137–160]. Compared with the testes, less is known about structural changes in these tissues that are associated with exposure to toxic agents. With the excurrent ducts and accessory sex glands, histologic evaluation is usually limited to the height and possibly the integrity of the secretory epithelium. Evaluation should include information on the efferent ducts and caput, corpus, and cauda segments of the epididymis. The presence of debris and sloughed cells in

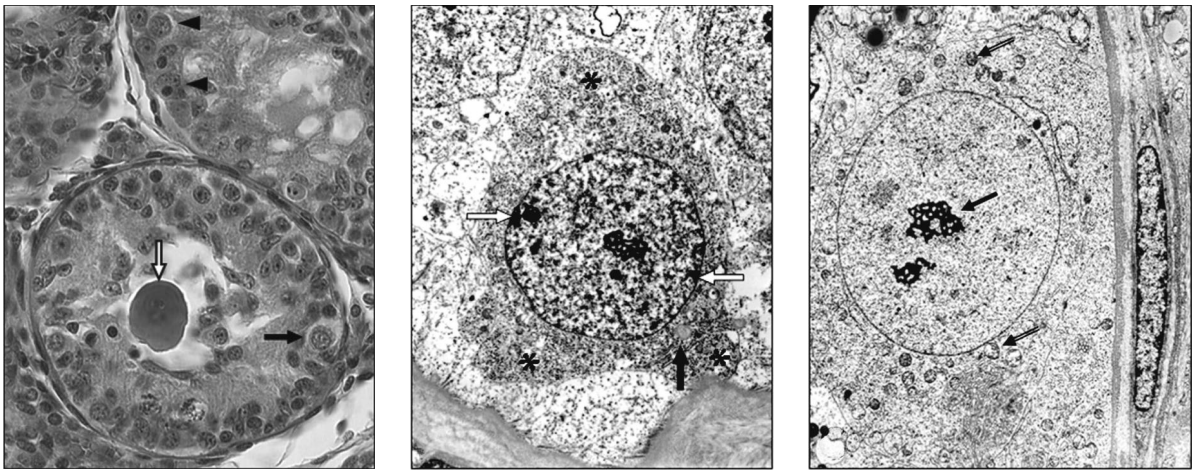

FIGURE 34.4 Light and transmission electron micrographs of rabbit testis showing germ cell atypia resembling CIS or intratubular germ cell neoplasia in humans. (a and b) Testes of 24-week-old rabbits exposed to DDT or a mixture of DDT and vinclozolin in utero and during the first 4 weeks of life. (a) Atypical germ cells resembling CIS (arrow heads and black arrow; ultrastructure of a cell similar to the one pointed by black arrow is shown in panel b). The CIS cell cluster indicated by arrow heads have irregular nuclear contours, and the large, gonocyte-like CIS cell (black arrow) has glycogen and lipid inclusions that can be discerned at ultrastructural level in panel b. A concretion or microlith (black arrow), commonly associated with neoplastic changes, is located in the lumen of the seminiferous tubule. (b) A CIS cell. Characteristic features include abundant aggregates of glycogen (asterisks) in the cytoplasm, lipid droplets (black arrow), and meandering nucleoli with fragments of nucleolonema (white arrows) adhering to nuclear membrane. (c) Atypical gonocyte resembling the precursor of CIS in the testis of a 25-week-old rabbit exposed to dibutyl phthalate. Cellular atypia ranged from alterations in the nucleolonema solid arrow to swollen mitochondria (arrowheads) in addition to accumulation of lipid and irregular membranous profiles in cytoplasm. These ultrastructural features are not typical of normally differentiating germ cells and have been attributed to neoplastic germ cells in humans (see text for references documenting identical electron microscopic profiles).

the epididymal lumen is a valuable indicator of damage to the germinal epithelium or the excurrent ducts. The presence of lesions such as sperm granulomas, leukocyte infiltration (inflammation), or the absence of clear cells in the cauda epididymal epithelium should be noted. Information from examinations of the pituitary gland should include evaluation of the morphology of the cell types that produce the gonadotropins and prolactin.

Historically, the degree to which histopathologic effects are quantified has been limited to classifying animals, within dose groups, as either affected or not affected using qualitative criteria. Little effort was made to quantify the extent of injury, and procedures for such classifications were not applied uniformly. This prompted the development of improved methods and more uniform approaches for evaluating the seminiferous epithelium [118–120]. These efforts have reinforced the importance of quantifying the extent of histopathologic damage per individual and have established high-quality histopathology as a sensitive and value-added endpoint in reproductive toxicity testing.

With proper tissue preparation and analysis, data from histopathologic evaluations provide a relatively sensitive tool that is useful for the detection of low-dose effects. Furthermore, changes in testis histology provide insights regarding the sites and mechanisms of action for the agent on that reproductive organ. When similar targets or mechanisms exist in humans, the basis for interspecies extrapolation is strengthened. Depending on the experimental design, information can also be obtained that may allow prediction of the eventual extent of injury and degree of recovery in that species and humans [161].

Significant and biologically meaningful histopathologic damage in excess of the level seen in control tissue of any of the male reproductive organs should be considered an adverse reproductive effect. Significant histopathologic damage in the pituitary gland should be considered as an adverse effect, but they should be shown to involve cells that control gonadotropin or prolactin production to be considered a reproductive effect. Although thorough histopathologic evaluations that fail to reveal any treatment-related effects may be quite convincing, consideration should be given to the possible presence of other testicular or epididymal effects that are not detected histologically (e.g., genetic damage to the germ cell, decreased sperm motility) but may affect reproductive function.

Sperm Evaluations

The EPA harmonized reproductive test guidelines [39] call for evaluation of epididymal (or vas) sperm number, sperm morphology, and sperm motility. Data on these parameters provide an estimation of both sperm quantity and quality and are therefore more informative than sperm numbers alone. Decreased sperm production will be reflected by reductions in both the number of homogenization-resistant spermatids in the testis and the number of sperm stored in the cauda

epididymidis. Likewise, alterations in sperm morphology or motility can be a reflection of a testicular insult as well as altered maturation in the epididymis. Data on sperm quantity and quality can be obtained noninvasively by collecting serially timed ejaculates from rabbits, thus enhancing the ability to confirm effects seen in rodents and establishing the feasibility to detect such effects in humans. Note that epididymal sperm measures in rodents are relatively consistent among animals of the same strain, whereas comparable measures in human semen are highly variable both between and within men [35]. Brief descriptions of these measures in rats are provided in the following, followed by a discussion of various additional sperm measures that are useful in a comprehensive male reproductive risk assessment.

Sperm Number

Sperm count has been frequently reported in the literature on humans [162]. Sperm number from test species may be derived from testicular, epididymal, or ejaculated samples [163]. Of the common test species, ejaculates can only be obtained readily from rabbits or dogs; however, ejaculates can be recovered from the reproductive tracts of mated females of other species including the rat. Indeed, by using hormonally primed, receptive females and limiting mating to only a few hours, numbers of ejaculated sperm can be recovered from the uterus of the mated females to differentiate the effects a chemical may have on mating behavior versus sperm number in the epididymis [164]. In this study, the chemical denervation induced by guanethidine exposure resulted in infertility that was linked to a deficit in mating behavior rather than to alterations in epididymal quantity or sperm quality.

Ejaculated sperm number from any species is influenced by several variables, including the length of abstinence and the ability to obtain the entire ejaculate. Intra- and interindividual variation is often high but is reduced somewhat if ejaculates are collected at regular intervals from the same male, as can be done with the rabbit [165]. Likewise, repeated measures study designs in epidemiology studies can improve detection sensitivity so fewer subjects are required [166]. When a preexposure baseline is obtained for each man, then changes during exposure or recovery can be better defined because each individual serves as his own control or baseline [167]. Unfortunately, in most epidemiology studies, abstinence is not strictly controlled and often only a single ejaculate is collected per man.

In toxicity testing using rats, cauda epididymal sperm are enumerated to determine the epididymal sperm reserves. While samples for sperm motility and morphology may be derived from the vas deferens, the cauda epididymal sperm sample can be used for all evaluations of sperm quality including fertility via in utero insemination (IUI) [168]. In this manner, various endpoints such as sperm number, sperm motility, sperm morphology, the sperm membrane proteome, and fertility can be correlated from a given population of sperm from an individual animal (Figure 34.5).

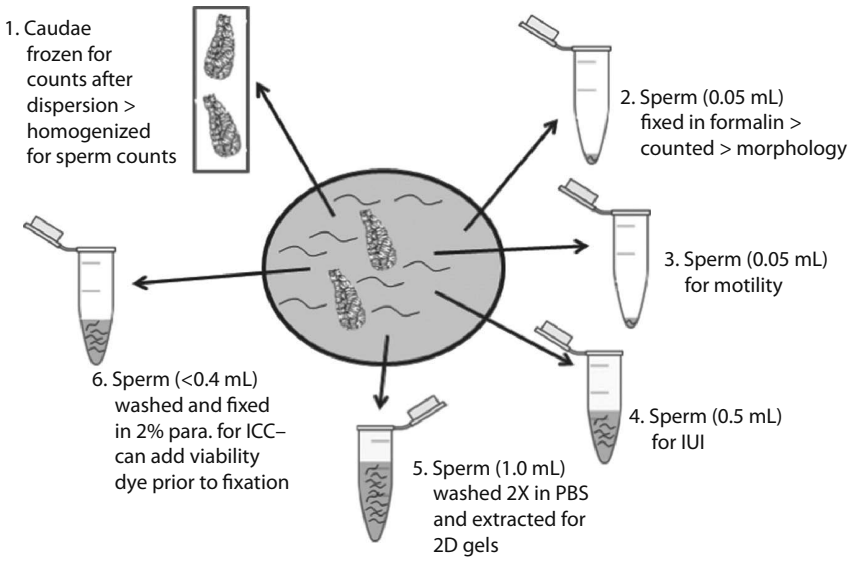

FIGURE 34.5 Diagram illustrating how multiple quantitative and qualitative endpoints can be obtained from a given population of sperm from an individual rat. Two caudae are placed in 2 mL of an isolation buffer [170], poked several times with a scalpel blade and sperm are allowed to disperse. (1) After several minutes of dispersion, the two caudae are frozen for subsequent homogenization to enumerate cauda sperm. (2) A fixed volume of the dispersed sperm is fixed in formalin, counted, and slides are prepared for an evaluation of morphology. For a total cauda sperm count, the sperm count obtained from this aliquot is corrected for 2 mL and added to the sperm number obtained from the cauda tissue homogenate. (3) Another aliquot of sperm is further diluted for an evaluation of sperm motion parameters. (4) Another, larger aliquot of sperm is used for IUI, typically 5 million cauda sperm are inseminated per horn in approximately 0.1–0.2 mL. (5) 1.0 mL is washed in buffer and the sperm extracted in detergent for subsequent analysis of the membrane proteome by 2D gel electrophoresis. (6) Remaining sperm are washed and fixed for immunocytochemical staining; these sperm also can be treated with a viability dye prior to fixation enabling dual fluorescent imaging for both viability and membrane marker of interest.

Automated counting has improved the efficiency with which this endpoint can be obtained [169]. It is not recommended to express the epididymal sperm count relative to the weight of the cauda epididymidis because sperm contribute very little to epididymal weight and ratio data may actually mask declines in sperm number. Thus, absolute sperm counts can improve resolution for detecting an effect. As is true for ejaculated sperm counts, epididymal sperm counts are influenced directly by the level of sexual activity [170].

As indicated, an estimate of sperm production in the testis may be derived from counts of the distinctive elongated spermatid nuclei that remain intact after homogenization of testes in a detergent-containing medium [170–172]. These elongated spermatid counts are a measure of sperm produced from spermatogonial stem cells [32]. If an evaluation was conducted when the effect of a lesion would be reflected adequately in the spermatid count, then spermatid count may serve as a substitute for quantitative histologic analysis of sperm production [120]. However, spermatid counts may be misleading if the duration of exposure (e.g., 14 days) is shorter than the time required for a spermatogonial stem cell to develop into an elongated spermatid (59 days in the rat). Also, spermatid counts reported from some laboratories have large coefficients of variation that may reduce the statistical power and thus the usefulness of that measure.

Sperm Morphology

Sperm morphology refers to structural aspects of sperm and can be evaluated in cauda epididymal, vas deferens, or ejaculated samples. A thorough morphologic evaluation identifies abnormalities in the sperm head and flagellum. Because of the suggested relationship between an agent's mutagenicity and its ability to induce abnormal sperm, sperm head morphology has been a frequently reported sperm variable in toxicology studies on test species [173]. The tendency has been to conclude that increased incidence of sperm head malformations reflects germ cell mutagenicity; however, not every mutagen induces sperm head abnormalities, and other nonmutagenic chemicals may alter sperm head morphology. For example, microtubule poisons may cause increases in abnormal sperm head incidence, presumably by interfering with spermiogenesis, a microtubule-dependent process [174]. Sperm morphology also may be altered due to degeneration subsequent to cell death; thus, the link between sperm morphology and mutagenicity is not consistent.

An increase in abnormal sperm morphology has been considered evidence that the agent has gained access to the germ cells [175]. There is evidence that stem germ cells (spermatogonia) are indeed targeted as occurrence of some unique sperm abnormalities, namely, acrosomal dysgenesis characterized by vesiculation and sharing between two or more spermatids was found to perpetuate long after cessation of exposure to a test chemical (lasting beyond more than at least one duration of spermatogenesis) [42]. These ramifications of experimentally induced testicular dysgenesis in rabbits arch across exposures to a variety of environmental agents including common chemical contaminants in drinking water, water disinfection by-products, and pesticides such as vinclozolin. Interestingly, similar unique sperm defects also have been observed in clinically subfertile stallions; and once observed on breeding soundness evaluation, these defects continue to occur over a lifetime indicating a possible permanent effect on stem germ cells [176]. Perhaps these domesticated animals are unwittingly exposed in feed and drinking water to the very chemical contaminants that the rabbits were exposed to in experimental paradigms (Figure 34.6).

Exposure of males to toxic agents may lead to sperm abnormalities in their progeny [177,178]; however, transmissible germ cell mutations might exist in the absence of any morphologic indicator such as abnormal sperm. The relationships between these morphologic alterations and other karyotypic changes remain uncertain [179].

The traditional approach to characterizing morphology in toxicologic testing has relied on subjective categorization of sperm head, midpiece, and tail defects in either stained preparations by bright field microscopy [180] or fixed, unstained preparations by phase contrast microscopy [163]. Such approaches may be adequate for mice and rats with their distinctly angular head shapes. Because human sperm exhibit considerable heterogeneity of structure and categorizing normal sperm involves subjectivity, the World Health Organization (WHO) has provided consensus guidance on classification of sperm morphology [34] and emphasizes that reference values relating this outcome to fertility depend largely on the strictness with which a normal sperm is defined. Data that categorize the types of abnormalities observed and quantify the frequencies of their occurrences may provide more information in a toxicology or epidemiology study than simply quantifying the percentage of normal sperm.

In comparison with other sperm measures, sperm morphology is a relatively stable endpoint in humans and test species. This feature may enhance its use in the detection of spermatotoxic events. The majority of studies in test species and humans have suggested that abnormally shaped sperm may not reach the oviduct or participate in fertilization [181,182]. The implication is that the greater the number of abnormal sperm or the smaller the number of normal sperm in the ejaculate, the greater the probability of reduced fertility. A prospective human male fertility study [35] has reported that the number of normal sperm (by strict criteria [183] in ejaculates) was highly related to the probability of couples achieving pregnancy within one year.

Sperm Motility

The biochemical environments in the testes and epididymides are highly regulated to ensure proper development and maturation of the sperm and the acquisition of critical functional characteristics such as progressive motility and the potential to fertilize [184]. With chemical exposures, perturbation of this balance may occur, producing alterations in sperm properties such as motility. Chemicals (e.g., epichlorohydrin) have been identified that selectively affect epididymal sperm motility and also reduce fertility [185]. Rat sperm motility is an established male reproductive toxicology

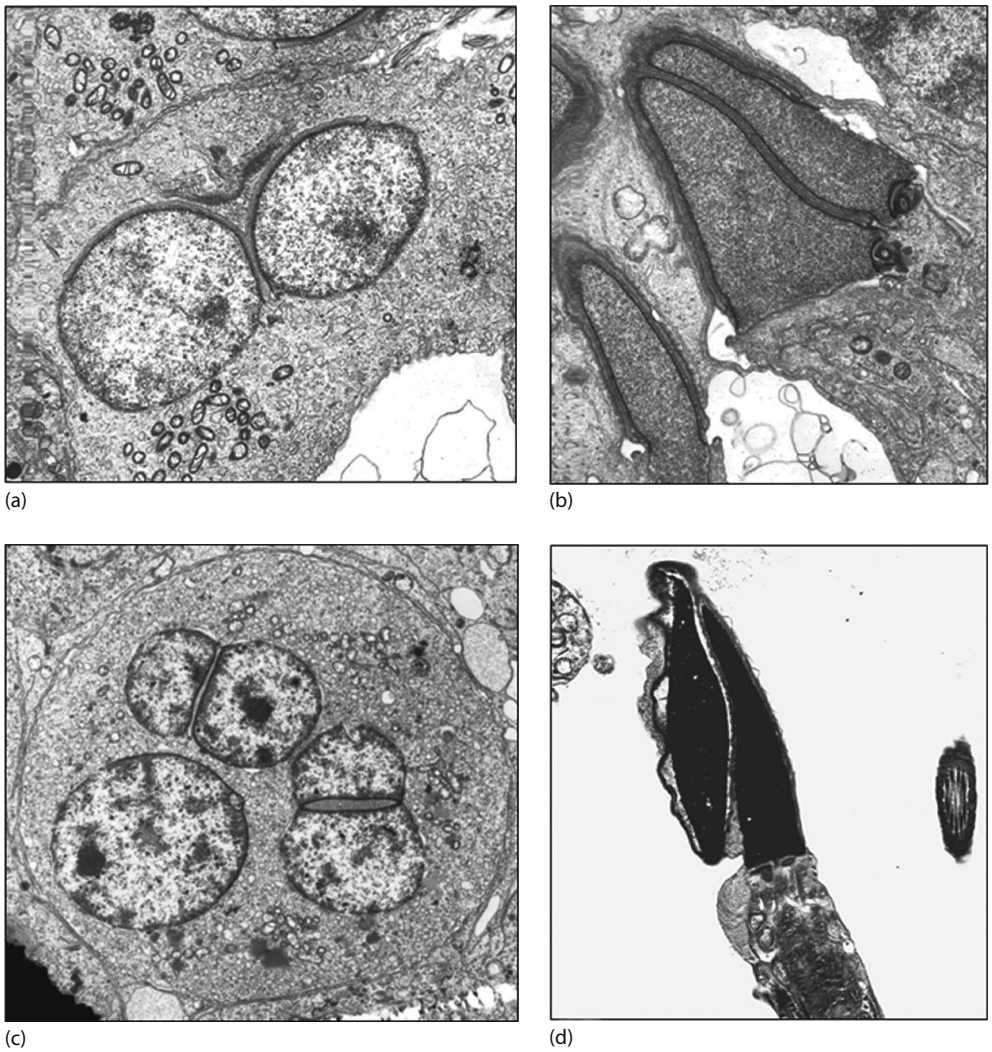

FIGURE 34.6 Transmission electron micrographs of acrosomal dysgenesis-shared acrosomes. Morphogenesis of this unique malformation as observed in rabbits exposed developmentally to common industrial chemical pollutants in drinking water (a, b) and antiandrogenic pesticide vinclozolin (c). As two adjacent round spermatids differentiate, they share a common Golgi apparatus (a) and acrosomal vesicle that spreads around both spermatid nuclei (b) as they condense and elongate resulting in conjoined sperm (d). These unique defects also have been shown to result from developmental exposure to a variety of environmental pollutants including water disinfection by-products in both rabbits and rodents. The profile shown in panel (d) is from an equine seminal ejaculate; once found in a stallion, it is not unusual to encounter such otherwise uncommon sperm morphological defects in follow-up breeding soundness evaluations. This clinical observation, together with the fact that these unique acrosomal-nuclear defects also are manifested in experimental rabbits long (5–10 months) after cessation of exposure, lends credence to our hypothesis that some stem spermatogonia and/or Sertoli cells are permanently affected perpetuating these malformations. Indeed, the multinucleated giant cell containing a cohort of postmeiotic germ cells showing syncytia of spermatid nuclei sharing acrosomes (panel c; from a rabbit exposed developmentally to an antiandrogenic pesticide, vinclozolin) indicates that this is a distinct possibility.

endpoint [186–189], and sperm motility assessments are an integral part of reproductive toxicity testing [40]. Motility measurements are typically obtained on epididymal rat spermatozoa, but sperm recovered from the vas deferens can be similarly analyzed [190].

Motility estimates may be obtained on ejaculated, vas deferens, or cauda epididymal samples. Standardized methods are necessary because motility is influenced by a number of experimental variables, including abstinence interval, method of sample collection and handling, elapsed time between sampling and observation, the temperature at which the sample is stored and analyzed, the extent of sperm dilution, the nature of the dilution medium, and the microscopic chamber employed for the observations [163,191–195].

Sperm motility can be evaluated in real time under phase contrast microscopy, or sperm images can be recorded and stored in video or digital format and analyzed later, either manually or by CASA [196–200]. For manual assessments, the percentage of motile and progressively motile sperm can be estimated and a simple scale used to describe the vigor of the sperm motion.

The application of video and digital technology to sperm analysis allows a more detailed and more objective evaluation of sperm motion, including information about the individual sperm tracks. It also provides a permanent record of the sperm tracks that can be reanalyzed as necessary (manually or computer assisted). With computer-assisted technology, information about sperm velocity (straight line and curvilinear) as well as the amplitude and frequency of the track is obtained rapidly and efficiently on large numbers of sperm [196]. Using this technology, chemically induced alterations in sperm motion have been detected [59,201,202], and such changes have been related to the fertility of the exposed animals [186,203,204]. These studies indicate that significant reductions in sperm velocity are associated with infertility, even when the percentage of motile sperm may not be affected. The ability to distinguish between the proportion of sperm only quivering in space with those that are progressively motile is important [163]. CASA parameters can be defined to provide various objective classifications for progressively motile sperm. This is done simply by setting user-defined thresholds for one or more CASA parameters (e.g., straightness) based on the motion characteristics of sperm from control animals [40,185]. The computer then calculates the percentage of motile sperm that exceed these thresholds and deems these progressive.

Sperm Membrane Integrity

Exclusion of vital dye remains a standard method for evaluating sperm viability by assessing sperm membrane integrity. A combination of the SYBR-14 dye and propidium iodide (PI) seems to be particular effective [205]. PI is impermeant and can bind to sperm DNA only if the cell membrane is compromised. SYBR-14 is a permeant dye that can bind DNA when the sperm membrane is intact. Cell permeant viability dyes can also be used to target specific organelles if the sperm membrane is damaged. For simultaneous evaluation of both viability and a specific membrane protein, a fixable impermeant live/dead stain can be used. These dyes will result in intracellular staining wherever the membrane is compromised.

Exposure of the sperm membrane to an increased level of reactive oxygen species results in lipid peroxidation of the sperm membrane, which in turn leads to loss membrane integrity. Lipid peroxidation assays can reveal whether the plasma membrane is damaged due to oxidation stress. Typically, the level of lipid peroxidation is determined by measuring malondialdehyde (MDA) [206] formed when the unstable lipid peroxides break down.

Numerous sperm membrane proteins have been identified over the years and deemed important for fertility. Most of these were considered pivotal based on their cellular localization (e.g., acrosome) and/or abundance in a sperm extract. We discovered a novel fertility protein by virtue of toxicity testing [168,207–210]. Diminutions in this protein (SP22) in extracts of cauda epididymal rat sperm were linked to toxicant-induced effects, particularly chemicals thought to alter epididymal function such as EDS, chloroethane methanesulfonate, epichlorohydrin, α-chlorohydrin, 6-chloro-6-deoxyglucose, ornidazole, and hydroxyflutamide. With each of these exposures, the decrease in SP22 was highly correlated with decreased fertility via IUI. We also demonstrated that testicular toxicants such as brominated haloacids also decrease the level of this protein on both rat cauda epididymal sperm and ejaculated rabbit sperm [70,210], and again, the decrease was correlated with fertility via IUI (rat) and intravaginal insemination (rabbit). Importantly, the toxicant-induced diminutions in the levels of SP22 proved to be more sensitive than other more typical measures of sperm quality (i.e., sperm motion and sperm morphology). Because SP22 actually originates in the testis, it is a feasible biomarker of effect following exposure to both testicular and epididymal toxicants. Antibodies to recombinant SP22, both rat and human, are now available to immunostain sperm from human and laboratory animals alike for chemical-induced alterations in fertility.

Sperm Nuclear Integrity

The ability of sperm to fertilize an egg does not guarantee fertility. The sperm genome must also be intact for embryonic/fetal development to proceed normally. A variety of assays for DNA and chromosome damage in sperm are being used in human epidemiology and rodent toxicology studies. Of these, the sperm chromatin structure assay has been most widely used [211,212]. This assay is based on the properties of the fluorescent, metachromatic dye acridine orange (AO), which fluoresces green when intercalated into normal double-stranded DNA but red when bound to denatured DNA (or RNA). In this assay, sperm are first acid denatured, then stained with AO and examined using flow cytometry. The relative abundance of red fluorescence is an indication of abnormal chromatin structure and DNA damage; increased percentages of sperm with excess red fluorescence have been correlated with infertility in humans [213]. Other tests for detecting DNA damage in human and rodent sperm, including the comet assay, the TUNEL assay, and measurement of oxidative DNA adduct sites, are being increasingly used to evaluate the effects of environmental contaminants on the genetic integrity of sperm [212]. Importantly, these assays can be measured in sperm from a single ejaculate. For example, DNA fragmentation assessed by TUNEL, oxidative DNA damage assessed by detection of 8-oxoguanine, and sperm membrane lipid peroxidation was studied recently and demonstrated that oxidative DNA damage is not necessarily related to membrane damage [214]. New assays for detecting aneuploidy and chromosome breakage in sperm are also beginning to be applied in epidemiology and toxicology studies. These are based on the use of chromosome-specific fluorescent probes detected by fluorescence in situ hybridization (FISH) methods [215]. For example, exposure to air pollution was recently reported to be associated with increased incidence of an extra Y chromosome [216], and a similar effect was found to be associated with smoking [217]. Because these methods are also being developed for use with rat sperm [218], it should be possible in the near future to design studies to compare responses in humans and rats for this endpoint.

Fertility Assessments

Animal data on reproductive success (or the lack thereof) are difficult to verify in human populations. First, humans are characterized by low rates of conception; thus, an insufficient number of pregnancies may occur in an exposed population to provide sufficient power to detect an effect. Moreover, both partners may be exposed to the toxicant, making it more difficult to ascribe reproductive failure solely to the male. Studies of gender-specific occupational work groups may provide some clarification as to the male's contribution. Such studies also provide the opportunity to study individuals with higher exposures than those encountered in the general population. By contrast, fertility measures in rodents that are mated naturally are inherently insensitive due to relative superior sperm quality compared to humans. Nonetheless, most studies rely on data obtained following natural mating. Table 34.2 illustrates some of the most important indices to evaluate. To distinguish between fertilization failure and early pregnancy loss, additional experimental approaches are needed [219]; for example, oocytes can be recovered from the oviduct the day after mating and examined to evaluate fertilization directly, and the zygotes can be cultured in vitro to the blastocyst stage to evaluate preimplantation developmental potential [220].

Since most test species produce numbers of qualitatively normal sperm that greatly exceed the minimum requirements for fertility as evaluated in current protocols, fertility data obtained by natural mating must be coupled with other male reproductive endpoints to provide the most comprehensive insight into an exposed animal's reproductive capability. Since human males appear to function nearer to the threshold for the number of normal sperm needed to ensure reproductive competence, a more sensitive means of evaluating fertility should be used to study exposures in test species.

A number of investigators have used the strategy proposed by Amann [44] that employs AI with a limited number of sperm from both control and treated males. AI by IUI in the rat does indeed increase the sensitivity of detection for toxicant-induced decreases in sperm quality [62,66,68,164,168]. Moreover, Robl and Dziuk [221] have successfully used IUI in three strains of mice. Dose–response curves for fertility as a function of number of sperm inseminated have been developed for both mice [221] and rats [62]. Robl and Dziuk [221] found that the EC_{50} sperm number for fertility varied among the strains: 1.5×10^6 (DBA/2N), 3×10^6 (CF1), and 6.3×10^6 (C57BL/6N) sperm. Klinefelter et al. [62] reported that the EC_{50} for rat sperm was 2.5×10^6 inseminated per uterine horn. However, an insemination dose of 5.0×10^6 sperm per uterine horn was selected to evaluate toxicant-induced alterations in fertility, as this concentration lies within the linear (i.e., sensitive) portion of the sperm dose–response curve and provides optimal control fertility (i.e., 75%); a dose of 2.5×10^6 sperm results in suboptimal control fertility and a dose of 10×10^6 sperm results in 100% fertility with no enhancement of sensitivity. Rather than recovering zygotes to calculate fertilization rates, these studies used vasectomized (sterile) males to cervically stimulate synchronized females and thereby prime them for implantation. Then, the number of postimplantation implants was determined on gestation day 9 or 20 [62,66]. These studies have been used to demonstrate the potential for epididymal toxicants and by-products of drinking water disinfection to produce low experimental dose alterations in fertility, as well as identify a novel sperm protein biomarker of fertility (SP22) mentioned earlier.

Changes in endpoints that measure effects on spermatogenesis (i.e., histopathology, homogenization-resistant spermatid numbers) and sperm maturation (i.e., epididymal sperm number, motility, and morphology) have been related to fertility in several test species, but the ability to predict infertility from these data (in the absence of fertility data) for test species is not reliable. This is in part due to the observation, in both test species and humans, that fertility is dependent not only on having adequate numbers of sperm but also on the degree to which those sperm are qualitatively normal. If sperm quality is high, sperm number must be reduced substantially before fertility by natural mating is affected. Similarly, if sperm numbers are normal in rodents, a relatively large effect on sperm motility is required before fertility is affected. Again, this is because rodents and other test species produce an excess of qualitatively normal sperm. In the presence of adequate numbers of sperm, average sperm velocity must be reduced substantially before fertility is affected [222]. Nevertheless, fertility in other species may be impaired by smaller changes in both number and motility (or other qualitative characteristics). Thus, relatively modest reductions in sperm number or quality may not cause infertility in species with relatively robust reproductive

TABLE 34.2
Selected Indices That May Be Calculated from Fertility Endpoints Following Exposure of Male Rats

Mating index

$$\frac{\text{Number of males or females mated}}{\text{Number of males or females cohabited}} \times 100$$

Fertility index

$$\frac{\text{Number of cohabited females becoming pregnant}}{\text{Number of unpregnant couples cohabited}} \times 100$$

Preimplantation loss

$$\frac{\left(\text{Number of corpora lutea} - \text{Number of implantation sites}\right)}{\text{Number of corpora lutea}} \times 100$$

Postimplantation loss

$$\frac{\left(\text{Number of implantation sites} - \text{Number of fetuses}\right)}{\text{Number of implantation sites}} \times 100$$

Note: Mating is based on evidence of copulation (observation or other evidence of ejaculation such as vaginal plug or sperm in vaginal smear) was obtained.

TABLE 34.3
Summary of Endpoints of Male Reproductive Toxicity Derived from In Vivo Studies

Organ weights	Testes, epididymides, seminal vesicles, prostate, pituitary
Gross examination and histopathology	Testes, epididymides, seminal vesicles, prostate, pituitary
Sperm evaluations[a]	Sperm number (testis and epididymal/ejaculated) and sperm quality (morphology, motility, viability, sperm membrane proteome, nuclear integrity, fertility via IUI, in vitro fertilization)
Sexual behavior[a]	Mounts, intromissions, ejaculations
Hormone levels[a]	Luteinizing hormone, FSH, testosterone, estrogen, prolactin
Developmental effects	Testis descent,[a] preputial separation, sperm production,[a] anogenital distance, structure of external genitalia[a]

[a] Reproductive endpoints that can be obtained or estimated relatively noninvasively with humans.

characteristics, but these changes can be predictive of infertility at higher exposure levels or in species that do not have the same level of excess sperm production.

In summary, sperm measures add considerable information and sensitivity to standard fertility measures in reproductive toxicity testing. Significant changes in any of these measures, even if modest in magnitude, may be considered adverse and used to set the no-effect or benchmark dose, particularly when they predict more severe effects, including infertility, at higher doses. Such changes are proving useful as critical endpoints for risk assessment; for example, sperm motility and morphology helped inform detailed assessments of several male reproductive toxicants (e.g., acrylamide and 1- and 2-bromopropane) by the National Institute of Environmental Health Sciences (NIEHS) Center for the Evaluation of Risks to Human Reproduction [55,223].

Additional Markers of Sperm Function

The functional capacity of sperm can be evaluated in vivo by recovering eggs at the appropriate time after copulation (species dependent) and determining whether fertilization and normal initial development (timing of cleavage divisions) occurred [224,225]. Alternatively, sperm can be collected and cultured in vitro under capacitating conditions and then cocultured with eggs. In vitro fertilization (IVF) assays have been used for years to study basic mechanisms of sperm maturation and function, but only recently have such methods been proposed for use in toxicology studies, where they may be applied after either in vitro or in vivo exposures. For example, the latter approach has been used to evaluate sperm function in rats exposed acutely to the testicular toxicant 1,3-dinitrobenzene [226]. Although labor intensive, such methods may prove valuable to test hypotheses regarding toxicant-induced effects on sperm function specifically.

The extrapolation of IVF data to predict the in vivo condition requires certain considerations. The ease with which IVF can be achieved varies across species, being readily accomplished in the mouse and hamster but rather difficult in the rat. Such test systems do not reflect the dynamic role played by the female reproductive tract in sperm transport, survival, and capacitation prior to fertilization. The conditions required to achieve successful fertilization in vitro may, in some instances, bear little resemblance to the state that exists in vivo [227,228]; for example, IVF typically employs far higher sperm concentrations than those found at the site of fertilization in vivo.

Another direct indicator of sperm function is the ability to undergo the acrosome reaction after in vitro incubation under conditions that support sperm capacitation. Fluorescent probes can be used to label the acrosome and permit determination of acrosomal status; for example, the plant lectin, *Pisum sativum* agglutinin (peanut agglutinin, PNA), can be used to identify acrosome-intact sperm [229]. In combination with viability stains, live acrosome-reacted sperm can be distinguished from live acrosome-intact sperm and from dead sperm that have shed their acrosomes and the percentages of each type quantified using flow cytometry. A combination of MitoTracker, a dye which stains active mitochondria, SYBR14+PI, to assess plasma membrane integrity and FITC-PNA to assess acrosomal integrity was used collectively to identify viable, acrosomal intact sperm following cryopreservation (Table 34.3) [230].

IN VITRO EVALUATIONS OF MALE REPRODUCTIVE TOXICITY

The following discussion highlights in vitro methods in use in male reproductive toxicology. In vitro methods have been proposed with two goals in mind: either as screens that would assist in prioritizing chemicals for in vivo testing or as specific tests for use in elucidating modes of toxicant action. For the latter purpose, it is important to consider linkage to a specific tissue or cell type that has been demonstrated to be altered by in vivo toxicant exposure. Even if appropriate preliminary in vivo data are obtained, one may fail to demonstrate an effect in vitro. This may reflect the need for a toxicant to interact in vivo with another tissue or cell type or to form an active metabolite; thus, it is advisable to ascertain both the metabolic fate and dosimetry of a toxicant and metabolites within the putative target tissue.

Today, given the rising practical and ethical concerns associated with the use of large numbers of animals for research and the growing number of environmental chemicals

requiring risk assessment, there is an increased emphasis on the use of cell lines for screening potential reproductive toxicants. Progress in this direction has been limited because cell lines frequently fail to retain specific aspects of normal differentiated function as mentioned earlier for cell lines used to screen for steroidogenic compromise. Nevertheless, they may prove to have utility in screening assays as long as provisions are made to test positive chemicals further using either a primary cell culture or an in vivo test system. It is also important to recognize that a chemical that tests negative in a cell line screen may actually test positive in a primary cell culture or in vivo system.

Seminiferous Tubule Culture

Toxicology studies that have demonstrated a disruption in the process of spermatogenesis have implicated virtually every cell type in the seminiferous tubule. A toxicant may perturb either one of the early germ cell types in the basal compartment of the seminiferous epithelium or one of the more mature germ cell types in the adluminal compartment. To affect the more advanced germ cells, a toxicant might either exert its effects directly by passing through the blood–testis barrier or indirectly by perturbing Sertoli cell function.

The cell–cell interactions that occur normally within the seminiferous tubule, particularly the interactions between Sertoli cells and germ cells [231], justify the use of in vitro models in which the whole seminiferous tubule is studied. Seminiferous tubule cultures from rats have been used to study the in vitro effects of 1,3-dinitrobenzene and methoxyacetic acid (MAA). These agents are toxic to Sertoli cells and pachytene spermatocytes, respectively [232]. However, the amount of inhibin, a Sertoli cell product, secreted by the seminiferous tubules in vitro was significantly increased by both compounds. More importantly, the stimulation in inhibin secretion was seen in rats exposed in vivo to doses resulting in intratesticular toxicant concentrations that approximated the effective in vitro concentrations. The seminiferous tubule culture reported by Allenby et al. [232] formed the basis of a series of elegant studies designed to determine the role germ cells play in the expression of androgen-dependent protein secretion [233,234]. Seminiferous tubules were isolated 4, 18, and 30 days following exposure to MAA when pachytene spermatocytes, round spermatids, and elongating spermatids, respectively, would be selectively depleted. Specific proteins were secreted selectively by these different germ cells. The effects of androgen depletion were then assessed 4 days following exposure to EDS, with or without exogenous androgen supplementation. Together, these studies present evidence that specific androgen-dependent proteins are synthesized by seminiferous tubules when different germ cell types are present. This may explain why it has been impossible to demonstrate androgen-dependent proteins in isolated Sertoli cell cultures. It is clear from this work that isolated seminiferous tubules can be used to identify in vitro effects on the seminiferous epithelium if a toxicant disrupts spermatogenesis in vivo.

Short-term seminiferous tubule culture has also been employed to elucidate modes of action of certain drinking water disinfection by-products—namely, the disubstituted haloacids—that have been identified as male reproductive toxicants in the rat. Low-dose effects after in vivo exposure include abnormal spermatid head morphology, delayed spermiation, and spermatid fusion, implicating a defect during spermiogenesis that could be mediated through the Sertoli cell or directly through the late germ cells. Stage-isolated seminiferous tubules from adult rats following a combination of ex vivo and in vitro exposures were used to explore the possibility that requisite Sertoli cell–germ cell interactions might be altered via changes in protein synthesis and secretion [235]. At least three specific proteins were diminished by either in vivo or in vitro exposure to dibromoacetic acid.

In the study by Allenby et al. [236] mentioned previously, a comparison was made between the response of optimized cultures of isolated seminiferous tubules and cultures of isolated Sertoli cells. The results clearly showed that inhibin production by isolated Sertoli cells was smaller and more variable in response to both toxicants. This may be attributed to the fact that the isolated Sertoli cells were derived from immature Sertoli cells. It would be useful to know whether the response of Sertoli cells from adult rats would better approximate the response of the isolated seminiferous tubules. Immature cells have been used in most of the Sertoli cell culture/toxicological studies to date, although the effects of various phthalate esters have been compared in cultures of Sertoli cells obtained from both immature and young adult rats [236]. Because differentiated function (i.e., transferrin, androgen-binding protein, and inhibin secretion) of the Sertoli cell changes with sexual maturity [237,238], an in vitro study should use Sertoli cells that are at the same ontogenic stage as those affected in the in vivo studies. This is important if in vitro data are to be useful in risk assessment. Recent advances in culturing adult Sertoli cells may provide promising in vitro models for male reproductive toxicology research [239,240]. For this and any system using testicular cells [241] or combinations of cells in vitro, it will be important to demonstrate the extent to which differentiated endpoints are maintained and can be evaluated following both in vivo and in vitro exposures.

The use of cell lines representing cells in a less differentiated state holds more promise for screening, particularly as it applies to perturbation in development of the male reproductive system. Testicular cells from neonatal rats and novel approaches for culturing cells on matrices have been used recently to generate Sertoli cell–germ cell cocultures [242]. In theory, these undifferentiated cells should be maintained well in culture and be capable of responding to developmental male reproductive toxicants in a manner similar to that observed in vivo. Recently, spermatogenesis has been reportedly maintained in an in vitro organ culture system [243]. In this system, immature testis fragments were used and spermatogenesis proceeded through meiosis to round spermatid development. After multiple refinements, the same laboratory more recently was able to demonstrate that functional sperm

could be produced by these cultures [244]. A challenge will be to demonstrate whether functional (i.e., cell–cell interactions) and molecular (i.e., transcriptional and proteomic) alterations observed following chemical exposure in vitro can be evaluated in neonatal Sertoli cells and spermatogonia following in vivo insult.

Advances in stem cell biology may lead to other approaches, including the use of pluripotent spermatogonial stem cells [245] at different stages of differentiation. Likewise, advances in bioengineering may produce novel systems wherein testis development can be reenacted and studied with respect to toxicant response. For example, dissociated immature testis cells from rats were recently reported to develop into structures resembling immature seminiferous tubules when they were grown in an extracellular matrix gel and then xenografted into a rat. Encouragingly, the xenografts became vascularized and the tubular structures exhibited lumena and a few putative spermatogonia, as well as an interstitium containing putative Leydig cells [246].

Leydig Cells

Today, a variety of well-accepted methods are available to identify and characterize Leydig cell toxicity in vitro. The choice of method depends largely on the available in vivo data, the tissue availability, and the sensitivity desired. As discussed earlier, a variety of Leydig cell lines have been used to screen for chemicals that might perturb steroidogenesis. Each of these cell lines has limitations such as inability to respond to LH, lack of steroidogenic enzymes representative of the entire pathway for testosterone biosynthesis, or simply an inability to produce sufficient amount of testosterone to afford adequate sensitivity. There seems to be no reason not to use highly purified preparations of purified Leydig cells [247]. These cells produce hundreds of nanograms of testosterone in a few hours in response to LH stimulation and more testosterone unstimulated than Leydig cell lines; only a 10^5 cells/well are needed in a 96-well culture format.

Highly purified Leydig cell preparations were used to establish the dose–response, intracellular site of action, and morphological integrity following in vitro EDS exposure [98]. Results from this study demonstrated clearly that the steroidogenic lesion induced by either in vivo or in vitro EDS exposure exists between the second messenger cyclic AMP and cytochrome P450 side-chain cleavage enzyme. In another study, highly purified Leydig cells were incubated with increasing concentrations of EDS and with either a maximally stimulating concentration of LH or with [^{35}S] methionine to discriminate between functional and cytotoxic effects [248]. Similarly, purified Leydig cells were used recently to study the interaction between Sertoli cells and Leydig cells during in vitro exposure to tri-*o*-cresyl phosphate (TOCP). This approach demonstrated that Leydig cells must first metabolize the toxicant for subsequent Sertoli cell toxicity to occur [249].

To evaluate the ability of the active metabolite of methoxychlor to produce differentiation-dependent alterations in the ability of the Leydig cell to produce testosterone during postnatal development, purified Leydig cells were isolated from rats on postnatal days 21, 35, and 90, when progenitor, immature, and adult Leydig cell populations, respectively, are present within the testis [250]. Results indicated that the prepubertal Leydig cell was more sensitive than the adult Leydig cell to disrupted cholesterol side-chain cleavage activity and cholesterol mobilization. More recently, Leydig cells were isolated from both prepubertal rats on postnatal day 21 and adult rats on postnatal day 90 following exposure to soy isoflavones during gestation and weaning [251]. Isoflavone treatment induced proliferative activity in the prepubertal Leydig cells resulting in increased numbers of Leydig cells with compromised steroidogenic capacity in the adult testis.

Another relatively simple approach involves the use of decapsulated testicular parenchyma incubated with or without LH stimulation to identify alterations in testosterone biosynthetic ability under stimulated or basal conditions, respectively. These incubations can be performed using parenchyma derived from testes exposed in vivo or in vitro. An advantage is that data can be easily obtained on a per animal basis, an important consideration when using species such as the rabbit and hamster that contain relatively few steroidogenically active Leydig cells following enzymatic dispersion. This technique has been used to identify chemical effects on both LH-stimulated and basal testosterone production. The effects of EDS on LH-stimulated testosterone production were compared in the rat and hamster [252]. Testosterone production was linear over time in the testis incubations of both species, and the results demonstrated that the hamster Leydig cell is far less sensitive than the rat Leydig cell to the cytotoxic effects of EDS. Chloroethyl methanesulfonate is an example of a toxicant that resulted in significantly reduced basal testosterone production [92].

A similar strategy has been applied in the mouse where either an entire, nicked testis or aliquot of testis parenchyma was studied on postnatal days 24 and 82, respectively [253]. Gestational exposure of mice to EDS resulted in decreased LH-stimulated testosterone production per testis at both time points. There were significantly fewer Leydig cells in the adult testis but these Leydig cells produced more testosterone per cell than control Leydig cells. In addition, there were decreased numbers of sperm in the cauda epididymis and decreases in fertility in these adults.

Epididymal Cells

Because the epididymis is the organ that confers fertilizing ability on maturing sperm, it is important to develop methods that identify epididymal toxicity following in vivo exposure and confirm any direct toxicant action on the epididymis following in vitro exposure. To establish direct toxicant action, a culture system must be used that is capable of maintaining facets of normal epididymal sperm maturation. This means that the culture system must (1) preserve the morphological integrity of the epididymal epithelial cells, that is, tight junctions between adjacent cells and polarized ultrastructure and

(2) synthesize and secrete proteins in an androgen-dependent manner. Few in vitro models meet these criteria. Several epididymal cell lines have been developed. Immortalized epithelial cells from the caput epididymidis of the mouse achieved polarized features and, based on expression of specific genes, retained some degree of differentiation but failed to express androgen receptor and other key markers of epididymal epithelial cell function [254]. Another immortalized epididymal epithelial cell line was shown to exhibit polarity, form tight junctions between adjacent cells, and express the androgen receptor but was not androgen responsive [255]. Recently, epididymal epithelial cells from both prepubertal and adult rats were cultured and maintained normal in vivo expression of both androgen and estrogen receptors but these cells were not contiguous and displayed no polarity [256].

Epididymal epithelial cells from various regions of the boar epididymis have been cultured with reasonable success. Both monolayer and tubule fragment cultures were compared with regard to their ability to support the maturation of cocultured immature boar sperm [257]. The results indicated that functionally, the epididymal epithelial cell monolayers behaved no differently than other epithelial cells, whereas the tubule fragment cultures appeared to secrete factors necessary for facets of sperm maturation. Using small intact fragments of rat epididymal epithelial cells that were cultured within a dilute extracellular matrix on top of a porous membrane, epithelial cells were well maintained and did respond to toxicant exposure, for example, EDS [258]. Not only was the synthesis and secretion of specific proteins decreased, but when caput sperm were cocultured above the underlying epithelial cells, secreted proteins failed to become associated with the sperm membrane and the progressive motility of cocultured sperm was reduced. It was concluded that EDS acts directly on epididymal epithelial cells to disrupt protein secretion and this, in turn, disrupts facets of sperm maturation. Because the biomarker of fertility (SP22) was discovered using a protocol to identify toxicity within the epididymis and is now known to be expressed in the testis around the time of round spermatid formation [208], it is likely that a protein secreted by the epididymal epithelium serves to stabilize SP22 on the sperm surface. To explore this possibility, epididymal epithelial cell–sperm cocultures will be useful. Since gestational exposures to a variety of environmental chemicals perturb reproductive development, including the development and differentiation of the Wolffian ducts, it may be worthwhile to investigate the critical events (e.g., gene/protein expression) that regulate the development of the Wolffian ducts. For this, a system for the isolation and culture of the Wolffian ducts will be required.

PATERNALLY MEDIATED EFFECTS ON OFFSPRING

The concept is well accepted that exposure of a female to toxic chemicals during gestation or lactation may produce death, birth defects, growth retardation, or postnatal functional deficits in her offspring. Sufficient data now exist with a variety of agents to conclude that male-only exposure can also produce deleterious effects in offspring [259,260]. Agents for which such adverse effects in test species have been reported include lead [261], diethylstilbestrol [262], urethane [263], cyclophosphamide [264–273], marijuana [274], and opiates [275]. The dominant lethal test is intended to detect mutagenic effects in the spermatogenic process that are lethal to the embryo or fetus. Dominant lethal protocols may utilize acute dosing (1 to 5 days) followed by serial matings with one or two females per male per week for the duration of the spermatogenic process. An alternative protocol may utilize subchronic dosing for the duration of the spermatogenic process followed by matings. Females are monitored for evidence of mating, sacrificed at approximately midgestation, and examined for incidence of pre- and/or postimplantation loss. The acute exposure protocol of the standard dominant lethal test, combined with serial mating, may allow identification of the spermatogenic cell types that are affected; however, acute dosing may not produce adverse effects at levels as low as with subchronic dosing because of factors such as bioaccumulation. Information from such studies can be useful for identifying site and potential mechanism of action and, thus, facilitate design of subsequent studies. The occurrence of pre- or postimplantation loss is often considered to provide sufficient evidence that the agent has gained access to the reproductive organs and has compromised fertilizing ability or induced mutagenic damage to the sperm, respectively. Such data were informative, for example, in the CERHR's report on acrylamide [223], which is available at http://cerhr.niehs.nih.gov/chemicals/acrylamide-eval.html.

Although a number of human studies have reported associations between a variety of paternal occupations and the occurrence of birth defects or childhood cancer [276–282], others have failed to observe such relationships [283–285]. A large proportion of the chemicals reported to cause paternally mediated effects are considered to exert this effect via transmissible genetic or epigenetic alterations [286–287]. Low doses of cyclophosphamide have resulted in induction of single-strand DNA breaks during rat spermatogenesis that, due in part to the absence of subsequent DNA repair capability, remain at fertilization. The results of such damage have been observed in F2 generation offspring [288] and result in changes evident as early as the pronuclear stage of development [289]. Indeed, paternal cyclophosphamide exposure is now known to result in alterations in both chromatin structure and basic sperm nuclear proteins [290].

Another example of epigenetic transgenerational action was provided by Anway et al. [56]. Brief gestational exposure of pregnant dams to vinclozolin was shown to result in compromised sperm production and altered sperm quality including infertility. The altered male genome was transmitted through several generations and linked to altered DNA methylation. More recently, this laboratory compared the effects of vinclozolin and another well-known antiandrogen flutamide [291]. While vinclozolin has antiandrogenic action, it appears that its ability to induce epigenetic alterations is

independent of this action; only vinclozolin produced transgenerational alterations in male offspring.

Other mechanisms of induction of paternally mediated effects also are possible. Xenobiotics present in seminal plasma or bound to the fertilizing sperm could be introduced into the female genital tract or into the oocyte directly and might also interfere with fertilization or early development. With humans, the possibility exists that a parent could transport the toxic agent from the work environment to the home (e.g., on work clothes), exposing other adults or children. Further work is needed to clarify the extent to which paternal exposures may be associated with adverse effects on offspring. Regardless, if an agent is identified in test species or in humans as causing a paternally mediated adverse effect on offspring, the effect should be considered an adverse reproductive effect.

SEXUAL BEHAVIOR

Sexual behavior is a complex process involving neural and endocrine components of the central and peripheral nervous systems and the reproductive system. For humans, interactions of personality, social, and experiential factors also influence the initiation and performance of these behaviors. Similar factors may exist in other species, but they are more controlled by standardized laboratory conditions; however, the perturbation of sexual behavior in animals suggests the potential for similar effects on humans. Consistent with this position are data on CNS-active drugs that have been shown to disrupt sexual behavior in both animals and humans [292].

Although the functional components of sexual performance can be quantified in rats [293], direct evaluation of this behavior is not typically done in most breeding studies; rather, the presence of copulatory plugs or sperm-positive vaginal lavages has been interpreted as indirect evidence of successful mating. These markers do not demonstrate that male performance necessarily resulted in adequate sexual stimulation of the female. In rats, the degree of sexual preparedness of the female partner can strongly influence the site of semen deposition and subsequent sperm transport in her genital tract [294]. Failure of the female to achieve sufficient stimulation may adversely influence these processes, thereby reducing the probability of successful impregnation. Such a mating failure would be reflected in the fertility index as reduced fertility and could erroneously be attributed to a spermatotoxic effect. Other aspects of current breeding protocols exist that may serve to mask a decline in the fertility potential of a given male.

Although the need and outcome of direct evaluation of sexual behavior routinely for all suspected reproductive toxicants is questionable in rodent studies, likely candidates may be agents reported to exert neurotoxic effects, as several neurotoxicants have also been shown to produce disruptions in copulatory behavior (e.g., trichloroethylene [295], carbon disulfide [296], acrylamide [297]). Chemicals possessing or suspected to possess androgenic or estrogenic properties (or antagonistic properties) also are potential candidates for the evaluation of copulatory behavior, separate from effects on reproductive organs (e.g., chlorinated hydrocarbon pesticides).

The limitations of evaluating sexual behavior using rodent models described earlier can be overcome by using rabbits in male reproductive toxicology studies as the teaser doe need not be sexually prepared to be receptive to a buck as the female rabbit is an induced ovulatory and is always sexually receptive and the male rabbits are easily trainable to ejaculate in an artificial vagina in the presence of a teaser doe. Thus, by timed collection of ejaculates using an artificial vagina, the copulatory behavior as well as erectile and ejaculatory functions can be methodically evaluated. Indeed, valuable information on the detrimental effects of common chemical contaminants in drinking water [71] and the antiandrogenic fungicide vinclozolin [298] on sexual behavior and functions has been obtained utilizing the rabbit as an animal model.

Follow-up studies on the brain as a target organ for the observed sexual dysfunction revealed that vinclozolin significantly increased calbindin expression in the ventral preoptic area and anterior hypothalamus and significantly decreased the number of gonadotropin-releasing hormone (GnRH) neurons selectively in the region of the organum vasculosum of the lamina terminalis [299]. This is the first documentation of a sexually dimorphic region in the rabbit brain and supports the use of this species as a model for studying the influence of vinclozolin on reproductive development with potential application to human systems. Furthermore, it was found that subacute, prenatal vinclozolin exposure is sufficient to create perdurable alterations in the GnRH neuronal network that forms an important input into the reproductive axis. Finally, the effect of vinclozolin on the GnRH neuronal network was not comparable to that of flutamide, suggesting that vinclozolin was not acting through antiandrogenic mechanisms [300].

MALE REPRODUCTIVE EPIDEMIOLOGY

The ultimate goal of the toxicologist is to provide data that might be extrapolated to human exposures. As already discussed, human males are inherently on a threshold for subfertility, and coupled with a myriad of unintended daily occupational and recreational exposures, it is reasonable to assume that environmental exposures are indeed further compromising reproductive competence. Unfortunately, most epidemiology studies are not designed and executed in a manner that allows one to support or refute toxicology data and most toxicology data are derived from studies conducted at exposures that are several orders of magnitude above relevant human exposures. The pitfalls in both scientific arenas have been recently reviewed [43].

In most epidemiology studies, exposure data are inadequate or completely lacking. Levels of a particular chemical(s) in the blood, urine, or semen need to be obtained to correlate with observed effects in semen quality. Additionally, the data typically gathered on sperm quantity and quality inconsistent across laboratories. Some laboratories report sperm

concentration, some sperm count, some both and abstinence is not consistently controlled. Equal variability exists for measures of sperm quality. Finally, usually only one ejaculate is obtained from an individual rather than repeated measures. It has been argued that the only biologically meaningful parameter of sperm production by the testis is total sperm per ejaculate [301,302] and that only by controlling abstinence to an interval of 42–60 h can meaningful data on the rate of sperm production can be gathered [303]. By extension, this is the only manner in which total sperm per ejaculate can be compared across individuals in a meaningful fashion. It is no wonder that we are still debating whether there is plausible scientific data to determine whether semen quality is on the decline, and if so, to what extent environmental exposures may play. Recently, Bonde et al. [304] stated that the fundamental problem with secular trend studies is the lack of comparability of study data across time and that we can now only change and adopt consistency to obtain meaningful data in future studies. Finally, while most epidemiology studies attempt to gather data on semen quality, measures of fertility such as time to pregnancy are rarely incorporated. Aside from irrelevant in vivo exposures in most toxicology studies, another common failing is the use of insensitive measures of fertility. The bottom line—fertility assessments come up short on both fronts.

A TDS has been described to encompass are male reproductive phenotypes that have been reported with increased incidence, namely, cryptorchidism, hypospadias, testicular cancer, and reduced semen quality [305]. Each phenotype has been associated with decreased fetal testosterone production [306]. Obviously, data on the testosterone production by the human fetal testis in males presenting with TDS phenotypes after birth cannot be gathered. Thus, the link to decreased fetal testosterone production was hypothesized based on phthalate studies in the rat that resulted in some of the same phenotypes albeit at high exposure levels. Recent data suggest that testosterone production by the human fetal testis is not decreased by phthalate exposure even at comparable high doses [307]. This clearly illustrates the need to incorporate new predictive markers of altered phenotypes in epidemiology studies.

FUTURE OF MALE REPRODUCTIVE TOXICOLOGY

The field of male reproductive toxicology and risk assessment has been evolving rapidly since reports of adverse effects of pesticides such as dibromochloropropane became evident in the 1970s [18]. Our understanding of modes of action of chemicals on male (and female) reproductive health has expanded with the application of cell and molecular approaches, including genomics and proteomics. The need to develop better interfacing between toxicology and epidemiology has been evident for some time now [308], but far too little progress has been made [43]. The importance of measuring contaminants in the environment and in accessible human tissues and fluids (i.e., blood, urine, semen) to build more precise models of exposure–effect relationships is obvious. The Centers for Disease Control and Prevention has added many reproductive toxicants and endocrine disruptors to its list of substances measured in Americans as part of their biomonitoring program. These are listed in the National Report on Human Exposure to Environmental Chemicals (see www.cdc.gov/exposurereport). While this is valuable effort, more needs to be done to attempt to estimate fetal exposures to improve the quality of prospective study data.

The importance of identifying adverse outcome pathways of male reproductive toxicity has grown in scope to include not only the relationships between exposures and semen quality in adults but also the relationship between exposures during fetal development, or prepubertal development, and adverse phenotypes such as hypospadias, testicular cancer, delayed puberty, and poor semen quality at adulthood. Realizing that there are far too many chemicals in the environment to test in multigenerational protocols, U.S. and international agencies and their industrial partners have gathered to test and implement new screening protocols such as the in vivo and in vitro tests summarized earlier for EDCs. These efforts have now given rise to systems modeling and high-throughput computational toxicology with the end goal being virtual (i.e., in silico) predictive models for toxicity in the male reproductive axis—the hypothalamic–pituitary–gonadal axis throughout reproductive development, from fetus to adult. This is a very attractive approach because it reduces the need for animals and could save much time and effort. However, before such models become an institutional reality, model validation will need to be done, particularly if the data is to be extrapolated to humans.

Although chemicals are usually listed, studied, and regulated singly, their occurrence as components of highly complex mixtures is recognized—for example, disinfection by-products in our drinking water, various products that are widely used by consumers (e.g., pharmaceuticals and personal care products), antibiotics and growth promoters (and their metabolites) used in agriculturally important species, and the rapidly growing list of nanomaterials introduced into our environment. This further complicates the challenge as relevant mixture studies are only beginning to emerge. And the predictive models alluded earlier will be even more abstract and difficult as mixtures are incorporated. Moreover, most high-throughput screening tests are based on a specific mode of action, for example, androgen receptor antagonism. It is quite unlikely that a relevant environmental mixture acts via one or two specific modes of action. It is more likely that many modes of action are involved simultaneously and the resulting adverse outcome or phenotype is dependent on the relative weight given to these multiple paths. As such, it seems prudent to continue research that can evaluate effects in a collective manner. To this end, in recent years, progress has been made in the culture of the testis. It is now possible to produce functional sperm in vitro [243,244]. But like all in vitro systems, their success limited to knowledge of the metabolite(s). So it is really inevitable that animal work continues, but it must be done in a more meaningful fashion [43].

As new adverse outcome pathways and the associated molecular targets are elucidated, we must begin to validate these biomarkers of effect, first in the animal, and then in accessible human tissues and fluids. It's conceivable that someday, we will be able to assay a mother's urine and predict whether the baby she is carrying is at increased risk for hypospadias or testicular cancer.

DISCLAIMER

This document has been reviewed in accordance with the policy of the National Health and Environmental Effects Research Laboratory, U.S. EPA, and approved for publication. Approval does not signify that the contents necessarily reflect the views or policy of the agency nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

QUESTIONS

34.1 Why is it necessary to evaluate so many different endpoints to assess adult male reproductive toxicity? Why is the harmonized multigeneration test more informative than an adult subchronic toxicity test?

34.2 What cellular and molecular mechanisms are thought to be responsible for male-mediated transmissible (transgenerational) effects?

34.3 How can histology help determine the phase of spermatogenesis implicated with toxicity to a particular chemical exposure?

34.4 What in vitro approaches provide data that best supports what might be occurring in the exposed animal and advance our understanding of path to phenotype?

34.5 Why is it important to correlate multiple endpoints on an individual animal basis?

34.6 Why is it important to assess fertility by a more sensitive means than natural mating?

34.7 How can epidemiology and toxicology studies be improved for better data linkage?

35 Test Methods for Assessing Female Reproductive and Developmental Toxicology*

Raymond G. York, Robert M. Parker, and Lynne T. Haber

CONTENTS

* We (York and Parker) have worked with and learned from Dr. Mildred Christian. We were greatly saddened with her passing and are honored to pick up her torch to revise and update this chapter on assessing female reproductive and developmental toxicology. While writing these sections, we were constantly reminded to look at all the animal data, not just the group means or statistical significances, because as Dr. Christian would say, "The animals will tell you what is happening. You just need to look."

PURPOSE

This chapter presents practical methods of testing used in performing female reproductive and developmental toxicity studies, as well as approaches for interpreting the test results in a risk assessment context. The evaluation methods presented are those used in studies conducted for regulatory use, that is, in the process of identifying the safety of both small and large (biologic) molecule pharmaceuticals, chemicals, pesticides, fungicides, direct and indirect food additives, and medical devices. The methods described in this chapter deal mainly with in vivo tests conducted for regulatory use in standard laboratory species and touch only briefly on in vitro and in vivo methods used for screening agents and identification of the mechanism or mode of action. Test methods used to evaluate reproductive toxicity in male animals, as well as in depth in vitro methods used to evaluate development, genomic methodology, and in vivo behavioral/functional parameters, are addressed elsewhere in this book.

INTRODUCTION

During ancient times, humans and animals that deviated greatly from their parents at birth were impressive events. Attitudes toward these abnormal progeny ranged from admiration and adoration to rejection and hostility, depending on the culture of the tribe or nation. Historically, human birth defects were usually considered spontaneous or hereditary events.[1,2] By 1925, the effects of maternal malnutrition were known to reduce fertility, reduce birth weight, and cause abortion or death of the conceptus, but were not thought to cause congenital malformation.[3,4] In 1941, the causal relationship between maternal exposure to German measles and congenital cataracts was the first identification of a disease to adversely affect human pregnancy.[5,6] Extreme maternal malnutrition during World War II resulted in congenital malformations, reproductive failure, amenorrhea, abortions, reduced birth weights, and postnatal survival.[7,8]

Research on animals used for food generally focused on enhancing the reproductive performance or the effects of nutrition on these animals. Studies on vitamin A deficiency in animals[9,10] were the first to demonstrate that the observed anophthalmia was associated with a maternal dietary deficiency (vitamin A). Congenital malformations in a conventional laboratory species, diet-deficient rats, were first reported in 1940.[11] Once it was proven that laboratory animals could be used to study congenital malformations, considerable research into teratogenic agents and susceptibility to these agents followed.[12,13]

The development of reproductive testing guidelines in animals followed three human tragedies resulting from in utero exposure: (1) 1961, congenital malformations from thalidomide[14,15]; (2) early 1970s, vagina cancer in young women whose mothers underwent stilbestrol therapy[16,17]; and (3) 1976, behavioral/functional alterations from methylmercury compounds. The first event, the thalidomide tragedy, completely changed the perception of concern regarding consumption of a medicine during pregnancy and potential adverse outcomes. The second event, cancer resulting from in utero exposure to diethylstilbestrol, raised additional concerns regarding adverse effects that were not evident until after sexual maturity. The third, Minamata Bay disease, resulted in additional tests for postnatal behavioral changes.

Increased public concern and regulatory requirements resulted in a large body of research associated with teratogenic insult during the first trimester of gestation.[1,18] Many continue to assume that susceptibility to teratogenesis is limited to this period of organogenesis.[19,20] It is now clearly evident that the *all or nothing* law of recovery or death does not always apply to preimplantation embryos (i.e., surviving embryos may demonstrate growth retardation, malformation, and/or functional impairment), that both the preimplantation and fetal stages of development are also susceptible to toxic insult (i.e., toxic exposure may result in death, retarded growth, malformation, and/or functional impairment), and that many systems continue to develop after birth (e.g., lungs, immune and nervous systems, reproductive organs).

Pregnancy, as well as the outcome, is dependent upon dynamic complex interactive systems. Each pregnancy is dependent upon the entire reproductive process (Figure 35.1), including the development, genetic makeup and nutritional status of the parental generation, as well as the genetic makeup, nutritional status during growth and development, and exposure of the offspring to perturbations in the macro- and microenvironments. Both sensitivity and response to a xenobiotic are sex-, age-, dose-, and tissue-dependent.

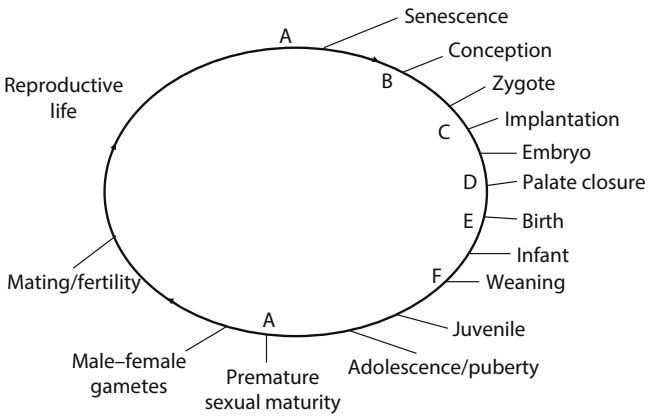

FIGURE 35.1 Reproductive and developmental effects.

NORMAL REPRODUCTION AND DEVELOPMENT

Reproduction in humans, as well as domestic, wild, and laboratory vertebrates, can occur multiple times, beginning at puberty and ending at reproductive senility. During this process, two haploid chromosomes, one from each sex, are joined to produce a diploid state in a new individual. In most mammalian species, phases of the reproductive cycle, during which development of a new individual occurs, principally take place within the uterus of the female. This development of the conceptus from the fertilized ovum to birth is a complex process during which extremely rapid cell proliferation occurs, and apoptosis is normal and required. The multiplicity of xenobiotic exposures, lesion sites, and potential reproductive disorders precludes simple screening of suspected reproductive toxicants in humans, because the effects and the agents causing reproductive dysfunctions or altered development are often impossible to predict.

Normal Reproductive Performance

A high proportion of humans have difficulty getting pregnant or staying pregnant. Infertility occurs in tens of millions married couples in the United States, with noncontraceptive sterility occurring in at least one of the partners in approximately 3 million of these couples[21,22]; ovulatory problems have been reported to be the cause of infertility in approximately 40% of all infertile couples.[23] It has been estimated[24] that as many as 50% of all fertilized ova are lost within the first 3 weeks of human development. The World Health Organization (WHO)[25] estimated that 15% of all clinically recognizable pregnancies end in a spontaneous abortion, defined as 20 weeks from the first day of the last menstrual period for a fetus weighing less than 500 g, and that 50%–60% of the spontaneously aborted fetuses have chromosomal abnormalities.[26,27] Prematurity (defined as birth before the 37th week of gestation) occurs in approximately 7% of births, and low birth weight (defined as 2.5 kg or less) is the most common developmental abnormality in humans and has often been associated with functional/neurological defects and malformations.[28,29] In the United States, of over 4.1 million liveborn infants in 2011, 5.98 per 1000 die before one year of age,[30] and 2%–3% of these liveborn infants are identified to have a congenital malformation within the first postnatal year.[31,32] Based on the current relatively crude criteria, approximately 16% of live births have major or minor malformations.[31]

Causes of Birth Defects

The cause of approximately 50% of human congenital malformations is unknown.[33] As causes for birth defects continue to be identified, this percentage can be expected to decrease. Known causes can be divided into genetic and partially genetic causes originating preconception, and those causes originating postconception, but before birth.

Most birth defects originate preconception and are due to genetic abnormalities in the chromosomes or genes. Genetic abnormalities can be inherited and thus are found in families, or they can occur as isolated events. Chromosomal abnormalities are due to changes in normal structure or in the number of chromosomes. Such abnormalities account for approximately 6% of the birth defects in industrialized nations.[33] Down's syndrome, caused by an extra chromosome 21 (Trisomy 21) or part of chromosome 21, is the most common chromosome abnormality in man and was first described clinically by John Langdon Down in 1866[34] and has an incidence rate estimated at 4.6 per 10,000 births.

Mutations, or single-gene defects, result in abnormal cell function. More than 15,000 single-gene defects had been described by 2004.[35] The first clinical description of a single-gene defect was brachydactyly (short digits) in a family in 1903.[36] All single-gene defects combined account for approximately 6% of the birth defects in industrialized nations.[33]

The concept of inheritance due to complex genetic and environmental factors (multifactorial inheritance) was first put forth by Boris Ephrussi in 1953; and F. Clarke Frazer expanded on multifactorial inheritance in the area of birth defects in 1976.[37] This category accounts for approximately 20%–30% of all birth defects, a number of which are lethal.[33] Modulating factors include, but are not limited to, placental blood flow, placental transport, site of implantation, maternal disease states, infections, drugs, chemicals, and spontaneous errors of development.

Causes of birth defects originating postconception are primarily nongenetic, caused by intrauterine environmental factor(s), and account for approximately 5%–10% of all birth defects.[38] These include teratogens that interfere with normal growth and development of the embryo or fetus, mechanical forces that deform the fetus, and vascular accidents that disrupt normal growth. Teratogens are broadly grouped into five categories: (1) physical agents like radiation; (2) environmental contaminants, such as methylmercury; (3) maternal metabolic disturbances, like diabetes mellitus; (4) maternal infections, such as rubella; and (5) drugs, both legal and illegal.[39]

Human Epidemiology Studies

Epidemiology has the potential to play central and imperative roles regarding identifying how developmental and reproductive toxicants affect human populations. Several inherent problems exist in performing human epidemiology studies.[40] First, they are time-consuming and expensive, especially when dealing with rare disease states. Second, reported findings are often based on anecdotal information, and essentially impossible to prove in the absence of an association. Third, studies may be either experimental or observational, and the more scientifically useful experimental type is precluded by ethical concerns that disallow direct testing of women of childbearing potential. Thus, epidemiology studies in the area of reproduction and development usually are observational, that is, evaluation of events in two groups without intervention or random assignment of subjects to treatments. These epidemiology studies usually involve statistical analyses of medical data to identify associations between toxic agents and adverse outcomes, resulting in identification of relative risks that may or may not identify causal relationships.

The greatest difficulty in reproductive/developmental epidemiology studies is in obtaining adequate sample sizes. To detect a 3.2-fold increase in major malformations with a rare frequency of 3%, a sample size of at least 300 live births is required.[41] Frequent outcomes, such as spontaneous abortion, which occurs at a 15% incidence, would require only a population of 50 pregnancies to detect a threefold increase.[42] Animal studies are most frequently used to detect potential adverse reproductive or developmental effects because of the difficulties and complexities associated with human clinical and epidemiological studies, and the need to prevent potential human exposures. Such studies are, for the most part, the subject of this chapter.

FEMALE REPRODUCTIVE TOXICOLOGY

Indifferent Gonad

An indifferent gonad is a gonad in an embryo that has not differentiated into a definitive testis or ovary. An indifferent gonad becomes a testis if the embryo has a Y chromosome, but if the embryo has no Y chromosome, the indifferent gonad becomes an ovary. The absence of a Y chromosome permits the indifferent gonad to become an ovary, but both X chromosomes are needed for the ovary to function normally.

Soon after gastrulation, the primordial germ cells migrate by ameboid movement to the dorsal mesentery of the hindgut, the coelomic epithelium of the genital ridge proliferates, and epithelial cells penetrate the underlying mesenchyme.[43] Here they form a number of irregularly shaped cords connected to the surface epithelium. Since these cords are impossible to differentiate between the sexes, they are known as the indifferent gonad. The indifferent gonad contains three principal types of somatic cells: supporting, stromal, and steroidogenic. Each type is able to progress in a male or female direction. The supporting cells will provide support to the Wolffian or Mullerian ducts, the steroidogenic cells will differentiate into either embryonic male Leydig cells or female ovarian theca cells, and the stromal cells become involved in forming the vasculature and extracellular matrix.[44]

Gametogenesis and Ovulation

Each sex of most multicellular animals produces specialized cells (gametes), which are joined (fertilization) to form a new individual zygote/conceptus. Gametogenesis is the production of sperm or ova and the peripubertal changes leading up to its onset. The mammalian ovulatory cycle includes multiple interrelated events involving folliculogenesis, ovulation, and preparation of the reproductive tract for fertilization and implantation leading to pregnancy. Ovulation is the central event in the ovulatory cycle.[45]

Ovulation results from interaction of multiple feedback systems, including the hypothalamic regions of the interbrain (diencephalon), anterior pituitary, and the ovary. The hypothalamus releases gonadotropin hormone-releasing hormone (GnRH) and, through this process, regulates anterior pituitary production and secretion of gonadotropin hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH released from the anterior pituitary and transported to the ovary initiate and maintain ovarian follicle growth.

The initial phase of positive feedback is that in which the hypothalamic–anterior pituitary axis component signals to initiate growth of the ovarian follicles. The mature ovarian follicle then signals to start ovulation through production and secretion of estradiol and progesterone. Estradiol and progesterone initiate a release of GnRH, which is followed by a release of the ovulating-inducing hormones, LH and FSH. These hormones provide the stimulus initiating the cascade of events in the ovary ultimately resulting in ovulation.[45]

Ovulation of a fertilizable ovum (oocyte, egg, or female gamete) requires formation of a corpus luteum, and growth, maturation, and differentiation of three cell types. Each of these three cell types, the germ cell (oocyte), granulosa cells, and thecal endocrine cells, is susceptible to toxic effects, as are the three major processes that occur during the development of the mature oocyte: (1) mitosis of oogonia and granulosa cells during follicular growth; (2) meiosis of oogonia to form oocytes; and (3) differentiation of granulosa cells and theca cells, allowing response to a surge of LH and subsequent ovulation.

The inseparability of the reproductive process and development of the conceptus is most apparent when one considers that the female germ cells and follicles are formed during prenatal life. Primordial germ cells are first detectable in the yolk sac at 3 weeks of human development. These cells undergo mitosis, migrate to the urogenital ridge, populate the indifferent gonad, and then differentiate into oogonia or prespermatogonia. Approximately 1700 germ cells migrate to the gonads in a human embryo. These increase to approximately 600,000 germ cells by 8 weeks of gestation and peak at approximately

7,000,000 germ cells by 20 weeks of gestation. Oogonia begin to enter meiosis at month 3 of gestation, with all oogonia in early prophase I by the end of month 5, at which time the oogonia are termed primary oocytes.[46] Oocyte atresia then results in decline in numbers to less than 1,000,000 by birth, another sharp decline with the onset of puberty (at around 12 years of age), and continued reductions in numbers throughout the remainder of the reproductive life of the woman until they are all gone by about 50 years of age.[45]

The meiotic stages are prophase, metaphase, anaphase, and telophase. Prophase is the first meiotic division and occurs during the fetal or neonatal period. Within 8 weeks after birth, human oocytes enter a resting phase (diakinesis), in which they stay until puberty begins.[47] Sex differentiation and ovarian germ cell development occurs at different developmental ages in various mammalian species, as shown in Table 35.1.

The majority of germ cells are lost to normal, physiological degeneration of atresia, which occurs during the oogonial and primary oocyte stages. Approximately 60% of the germ cells in a human fetus are lost between 5 months of gestation and birth, with three distinct waves of oogonial degeneration occurring. One wave affects oogonia in mitosis (final interphase), and the other two affect oocytes in the pachytene and diplotene stages of prophase I. This normal apoptosis is synchronous in oogonia connected by cytoplasmic bridges. After the meiotic prophase, simultaneous atresia no longer occurs, although individual oocytes spontaneously degenerate at all stages of development.

Folliculogenesis

Folliculogenesis is the maturation of the ovarian follicle, a densely packed shell of somatic cells that contains an immature oocyte. Granulosa cells surround the oocytes during prophase. Their initial growth is gonadotropin-independent with no LH or FSH support. Follicular growth then becomes dependent on the continuous presence of gonadotropins; follicles that do not grow remain as primary oocytes within unilamellar follicles during prepubertal and reproductive periods. This provides a pool from which groups of small follicles are recruited for further maturation, resulting in preovulatory or Graafian follicles. There are three stages to follicular growth: oocyte enlargement, transition of granulosa cells, and formation of the zona pellucida, an extracellular matrix present between the granulosa cells and oocyte. The first stage is characteristic of small follicles[48] that enter the pool of committed growing follicles. Follicle growth requires five events: continued oocyte enlargement, rapid proliferation and increase in layers of granulosa cells, formation of basal lamina, organization of endocrine thecal cells around a basal lamina, and formation of the antrum. The majority of follicles grow into the preantral stage. A large surge of gonadotropins in the cycle preceding ovulation results in selection of a few antral stage follicles from a pool of preantral follicles.

The preovulatory surge in gonadotropin stimulates conversion of progesterone to androstenedione in theca cells,[49] which is then converted to estradiol in granulosa cells. The estradiol secreted by the growing follicles, in conjunction with FSH, effects differentiation of granulosa cells. Only follicles that can produce estradiol progress to preovulatory follicles. Oocyte atresia can be induced by any agent that inhibits either the theca cell's ability to synthesize androstenedione or the granulosa cell's function to synthesize estradiol. Atresia may also be caused by agents that alter gonadotropin receptors or the functional coupling of the receptor to adenylate cyclase.[49]

Primary oocytes in preovulatory follicles continue to form secondary oocytes through the first meiotic division and remain in metaphase of the second division. The first polar body, containing half of the chromosomes, is extruded. As ovulation nears, the follicle vascularizes and swells, becoming a macroscopically visible blister-like protuberance. The secondary oocyte is ovulated at metaphase II and stays in this stage until fertilization. At fertilization, the second meiotic division is completed, the second polar body extruded, and the female pronucleus formed. Male and female pronuclei combine at fertilization to regain the diploid state.[50]

Fertilization and Implantation

Fertilization is the union of a spermatozoon and an oocyte and occurs in the female reproductive tract in mammals. This restores the diploid number of chromosomes, determines the genetic sex of the zygote, and initiates rapid mitotic division.[51] Following ovulation, vascularization of the granulosa cell layer occurs, and granulosa cells are transformed into luteal cells, which produce the progesterone required for preparation of the endometrial lining of the uterus for implantation of the conceptus.[52] In the absence of fertilization, the process by which a postovulatory ovarian follicle vascularizes and

Note: Numbers indicate days of gestation. Numbers in parentheses indicate days of postnatal age.

transforms into a corpus luteum occurs (luteinization). This process includes degeneration of the ovulated oocyte, continued LH stimulation, and luteinizing of the empty follicle into a corpus luteum (Latin for *yellow body*), which secretes progesterone. This process continues to occur throughout reproductive life until all primordial follicles are depleted or menopause occurs.

The corpus luteum is dependent on LH to function, and withdrawal leads to luteal failure, decreased estrogen and progesterone secretions, and failure to maintain the pregnancy. In a normal cycle without fertilization, corpus luteal failure occurs after approximately 10 days of functioning. This failure is associated with an increase in the activity of prostaglandins.[53] Once the oocyte is fertilized, the corpus luteum is maintained by secretion of human chorionic gonadotropin (HCG), which is an LH-like molecule synthesized by the trophoblastic tissue of the embryo. Under HCG stimulation, progesterone synthesis continues in the corpus luteum until this steroid is principally produced by the placenta. The corpus luteum is also a source for oxytocin, a mammalian hormone that acts primarily as a neuromodulator in the brain.

Ovulatory Cycles

The process of ovulation is controlled by the hypothalamus of the brain and through the release of hormones secreted in the anterior lobe of the pituitary gland, LH and FSH. Ovulatory cycles vary widely in laboratory animals, farm animals, nonhuman primates (NHP), and humans[45] and among humans.[54] Two major categories exist: (1) animals that spontaneously ovulate and (2) animals that are induced to ovulate by mating. Spontaneous ovulators include laboratory rodents, hamsters, mice, guinea pigs, sheep, pigs, rhesus monkeys, baboons, and humans. Reflex or induced ovulators include rabbits, cats, ferrets, short-tailed shrews, and voles. Mechanical or coital stimulation in these species results in a gonadotropin release of primarily LH within 1–2 h that results in ovulation of follicles that have reached maturity in the ovary. The FSH secreted in the surge may result in the development of new ovarian follicles for estradiol production, which is essential for continued corpus luteum function.

Circadian rhythms and seasonal variation are two other neuroendocrine signals that are important in regulating ovulatory cycles. Humans and guinea pigs are species least affected by circadian rhythms and seasonal variations. In rodents, the suprachiasmatic nucleus in the hypothalamus is identified as the site of signal transduction by light-dark cycles, and lesions at this site, as well as exposure to constant light, can terminate the estrous cycle. Seasonal variations associated with the duration of the photoperiod are known to affect reproduction. Most laboratory species require a minimum of 10 h of light for reproduction to occur. Diets with phytoestrogen content are also known to affect ovulatory cycles and fertility. Phytoestrogens are naturally occurring diphenols that have structural and functional similarities to 17β-estradiol.[54,55]

Oocyte maturation, folliculogenesis, ovulation, and corpus luteum formation are processes under the influence of gonadotropins and occur during each menstrual cycle in humans. Many of these events also occur in rodents, although factors other than gonadotropins appear to be involved in the initial stimulation of growth of the resting follicle. Once the follicle is committed to growth, the selection of preovulatory follicles depends on the LH surge proceeding each cycle.[42]

Ovarian Physiology and Toxicology

Ovarian weights should be recorded at necropsy close to the time of removal and trimming to avoid dehydration. Ovarian weight in the normal rat does not show significant fluctuations during the estrous cycle; however, polycystic ovaries, luteal cysts, decreases in corpus lutea or oocytes, and reproductive senescence can alter weight changes. Evaluation of follicular alterations is difficult because a sexually mature ovary contains a diverse population of resting, maturing, and mature follicles, and the female has only one cluster of follicles that is selected for maturation in each cycle. However, the oogonia enter meiosis during fetal life, and there is no mechanism to replace oocytes, so reduction of the numbers of oocytes has the potential to reduce the reproductive life span of the female. During adulthood, each of the three components of the follicle may be uniquely susceptible to specific toxicants.[56] A xenobiotic agent, for example, might increase the progesterone/estradiol or testosterone/estradiol ratios by FSH stimulation or alter steroidogenesis and androgen production in the thecal cells, thus delaying follicle maturation and ovulation.[57]

Primordial follicle counts are among the most variable reproductive endpoints measured across laboratories.[58] This is probably related to the variability in the number of animals, number of histologic sections, and selection of ovarian sections examined since they are not specified in current U.S. Environmental Protection Agency (EPA) and OECD (Organisation for Economic Co-operation and Development) guidelines.[59] There is an inherent intra- and interanimal variability in the ovarian follicle pool: 30%–40% variability in counts between ovaries taken from the same rodent and even greater variability between ovaries from different rodents of the same strain.[60]

Reproductive Endocrinology and Toxicologic Interactions

An in-depth review of endocrine disruptive chemicals and the field of endocrine disruptors will be presented in the Chapter 36.

Interaction of Reproductive Hormones and Target Tissues

Estrogens increase oviduct secretions and muscular contractions, actions antagonized by progesterone. Thus, cyclic patterns of estrogen and progesterone levels that occur during the menstrual cycle in primates and humans play important roles in regulating sperm transport, through the cervix, into the uterine

lumen and to the oviduct.[61] Of the 150–300 million sperm in an ejaculate, less than 500 (<0.001%) reach the site of fertilization, with the greatest loss of sperm at the cervix and uterotubal junction. Capacitation is the changes sperm undergo in the female reproductive tract, allowing penetration of the ovum, and is normally induced by secretions in the female genital tract that require several hours to occur. Capacitated sperm penetrate the layers of the granulosa cells and bind to a major glycoprotein in the zona pellucida, which is the main barrier to fertilization. The release of proteases and hyaluronidase from the binding sperm is essential for sperm penetration of the zona. Contact of the sperm and oocyte membrane after penetration triggers a cortical reaction in the egg, releasing enzymes that prevent further binding and entry of other sperm.[62]

The fertilized ovum divides and slowly moves down the oviduct. Decreased motility in the oviduct is associated with secretions by the corpus luteum and prevents the ovum from prematurely reaching the uterus. The *morning-after* pill accelerates ovum migration by levonorgestrel, a progestin, resulting in premature reaching of the uterus.[63] Similar effects have been observed with methoxychlor, which mimic estrogens.[64] The embryo floats free in the uterus before implantation, nourished by endometrial gland secretions under the control of progesterone. Combined estrogen and progesterone action result in the uterine endometrium preparing for implantation of the blastocyst and the embryo invading the uterine endometrium. In humans, decidualization of the uterine lining normally occurs during the luteal phase of the menstrual cycle, whether or not implantation occurs (Figure 35.2). Decidualization of the uterine lining contributes the maternal portion of the placenta.[45]

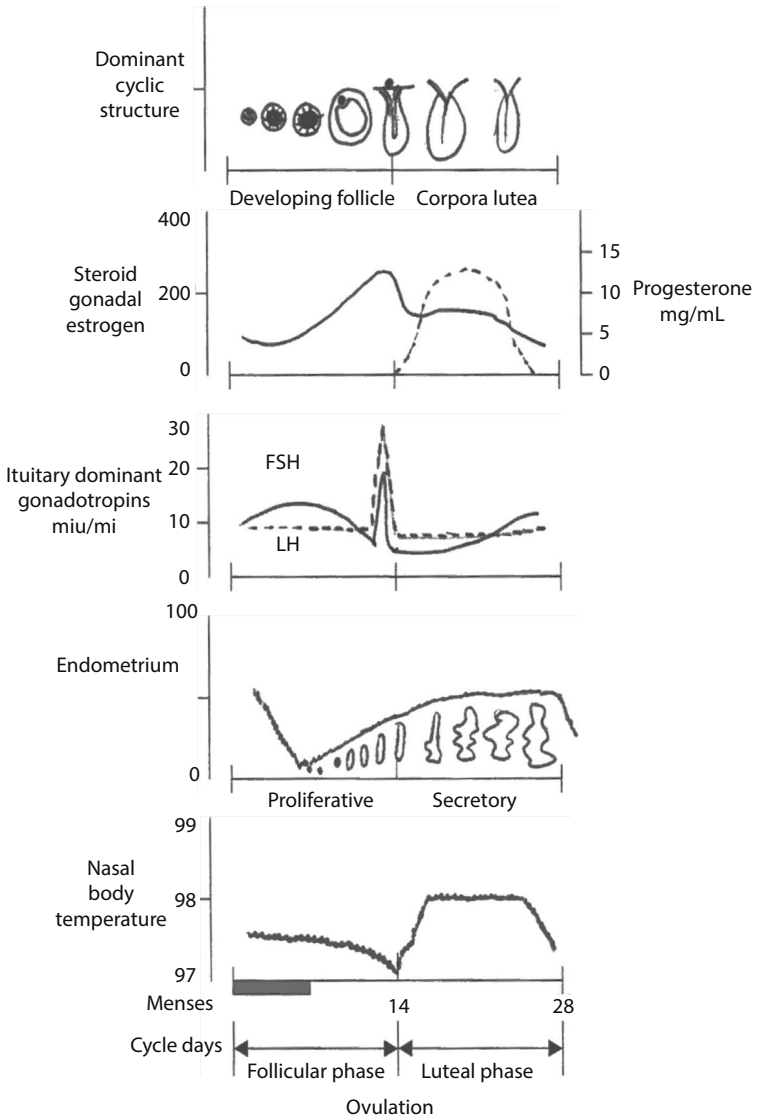

FIGURE 35.2 Progression of ovulatory cycle in humans. Development of the dominant follicle of pituitary gonadotropins, endometrial proliferation, and basal body temperature are depicted. (Adapted from Goldman, J.M. and Cooper, R.L., Normal development of the female reproductive system, in: Kapp, R.W. and Tyl, R.W. (eds.), *Reproductive Toxicology*, 3rd edn., Informa Healthcare, New York, 2010, pp. 36–50; Cohen, G.M., *Biochem. J.*, 326(1), 1, 1997.)

Estrogen and progesterone synthesis and secretion during normal human pregnancy are a cooperative effect of the mother, fetus, and placenta. Large amounts of estradiol, estrone, and estriol are produced during pregnancy, with the placenta being the primary source. A biomarker used to monitor fetal well-being is estriol because one of the precursors for its synthesis by the placenta is dehydroepiandrosterone, which is produced by the fetal adrenal gland.[65]

The placenta is the connection between fetal and maternal systems and has many functions: an endocrine organ; the exchange of gases, nutrients, and metabolic wastes; and protects the fetus from physical and potential chemical harm.[66] It also secretes human placental lactogen, a protein that is similar to human growth hormone and human prolactin, but does not appear to promote body growth. Lactogen prepares the mammary gland for lactation and usually appears in the blood approximately 2 months after fertilization, increases until parturition, and is used as a biomarker to monitor placental size and growth.[61] Prolactin is secreted by the anterior pituitary gland and controls mammary development in women. Prolactin levels continually increase during pregnancy from about 2 months after fertilization, until parturition.[67]

TABLE 35.2
Steroid Source and Mechanism of Action for Preparturition Progesterone in Several Species

Species	Source of Steroids in Late Pregnancy	Fall in Maternal Progesterone	Mechanism
Mouse	Corpus luteum	Yes	Luteolysis
Rat	Corpus luteum	Yes	Luteolysis
Rabbit	Corpus luteum	Yes	Luteolysis
Guinea pig	Placenta	No	—
Goat	Corpus luteum	Yes	P450C17/ Luteolysis
Sheep	Placenta	Yes	P450C17
Monkey	Fetoplacental unit	No	—

Note: P450C17 enzymes are induced in the placenta by an increase in fetal cortisol levels. Luteolysis is provoked by prostaglandin $F_{2\alpha}$ acting on fetoplacental receptors.

Source: Adapted from Soloff, M.S., Endocrine control of parturition, in: Wynn, R.M. and Jollie, W.P. (eds.), *Biology of the Uterus*, 2nd edn., Plenum Press, New York, 1989, pp. 559–607.

Parturition

Parturition, process of labor and delivery, represents the transition of the fetus to the neonate and occurs when the fetus and its associated membranes are expelled to the external environment. The exact mechanisms that initiate parturition in humans are not well understood; however, maturation of the fetal hypothalamic–pituitary–adrenal axis plays an important role, and most current evidence suggests that estrogen, progesterone, oxytocin, and prostaglandins may all be involved.[61] Fetal cortisol elevations activate the placental steroidogenic enzyme system, resulting in decreased progesterone and elevated estrogen prior to parturition.[68] The fall of maternal progesterone is a necessary prerequisite for parturition, but source and mechanism for the endocrine changes are not uniform across species: the source of progesterone varies (placenta or corpus luteum) and is dependent on the mechanism of action (MOA) (luteolysis, the structural and functional degradation of the corpus luteum, or P450C17 metabolism in the placenta enabling progesterone to be converted to estrogen) (Table 35.2). Luteolysis is responsible for the physiological reduction of maternal progesterone levels preceding parturition in the common laboratory species rat, mouse, and rabbit; however, P450C17 metabolism is responsible in the goat and sheep.[69] In the primate and guinea pig, there is no apparent change in maternal progesterone levels before parturition.

As labor approaches, estrogen and oxytocin stimulate uterine muscle contractility.[70] Progesterone antagonizes the effects of progesterone and oxytocin, and the decreasing progesterone levels trigger uterine contractions, although peripheral progesterone concentrations do not fall prior to the onset of labor. The decrease in levels of progesterone is thought to occur before peripheral changes, and that local prostaglandin production may also be involved in initiating labor.[70] The fall in progesterone levels following delivery is one of the triggers for milk production, since it inhibits lactation during pregnancy. Stretching of the uterine cervix and vagina stimulates reflex release of oxytocin from the posterior pituitary, resulting cyclically in increased uterine contractions and stretching, facilitating the delivery process. The increase in oxytocin receptors near term may be the cause of the increased sensitivity of the myometrial response to oxytocin.[71] Physical factors also regulate myometrial activity in the human, of which the increase in uterine volume associated with fetal and placental growth, resulting in stimulation of myometrial contractions, and the inhibition of myometrial contractions by progesterone are the most important. Estrogens, oxytocin, and PGF_2 are stimulatory hormones additionally contributing to uterine contractility and inhibited by progesterone, which blocks estrogen action, oxytocin receptor production, and prostaglandin release. Drugs, such as alcohol, can directly act on uterine smooth muscle or indirectly inhibit oxytocin release.[61]

Lactation

Lactation describes the secretion of milk from the mammary glands and the period of time that a mother lactates to feed her young. Lactogenesis is a two-stage process: (1) the enzymatic and cytologic differentiation of the mammary alveolar cells and (2) the secretion of milk, which normally begins after parturition. The first stage requires growth hormone, aldosterone, prostaglandins, insulin, estrogens, progesterone, placental lactogens, and prolactin and generally occurs in the third trimester of pregnancy. The second stage is initiated by prolactin secretion by the lactotropes located in the anterior pituitary. These hormones modulate the development and secretory capacity of the mammary gland. Prolactin is

the primary hormone responsible for increased growth and differentiation of the alveoli and influences differentiation of ductal structures. Gonadotropin hormones stimulate the ovaries to secrete estrogen that work indirectly on the mammary gland to promote prolactin synthesis.

The posterior pituitary gland secretes oxytocin as the result of stimulation of the nipple by the suckling reflex. While prolactin release from suckling does not cause the milk release at the time of nursing, it is responsible for release of milk (milk letdown) during the subsequent nonsuckling interval. The young obtain this milk at the next nursing. Normal milk secretion also requires other hormones, including ACTH, insulin, growth hormone, parathyroid hormone, and thyroid hormones.[72] Milk letdown in humans is a conditioned reflex phenomenon that can be affected as a response to the presence or crying of a baby.[72] Initiation of milk secretion will not occur until the placenta is removed by abortion or delivery because of estrogen and progesterone secreted by the placenta.[72] Most common oral contraceptives contain estrogen and progesterone and can suppress lactation; therefore, they should not be used during the nursing period.[61]

Thelarche is the onset of secondary (postnatal) breast development in humans and usually occurs at the beginning of puberty in girls 8 years and older. Estrogens are the primary ovarian hormones responsible for mammary gland development and growth, although progesterone is important for alveolar development in some animals. However, there is no evidence that progesterone is required for alveolar development in humans.[72] Initiation of lactation normally involves withdrawal of an estrogen and progesterone block to the stimulatory effect of prolactin on milk secretion.[61]

Lactating women have a diminished response to GnRH as a result of reduced LH and FSH secretion during lactation.[73] The ovaries seem to be refractory to gonadotropic stimulation during lactation, although the mechanisms resulting in lactational amenorrhea are not currently understood. Several conditions are known to result in abnormal lactation associated with increased prolactin levels: pituitary tumors can cause this observation and hypothalamic lesions, abnormal afferent neural input into the hypothalamus, and tranquilizers can also raise prolactin secretion sufficiently to result in galactorrhea, the spontaneous flow of milk from the breast unassociated with childbirth or nursing.[72]

Ovarian Cyclicity

Normal ovarian function is predicted by the appropriate interactions of the various compartments of the ovary and the changes that occur within these compartments during the cycle. In vivo adverse effects may result from active intermediates or metabolites or through modulation of hypothalamic–pituitary axis; such effects would not be identified by in vitro assays.

Distinct differences exist between ovarian cyclicity in humans and rodents that should be considered in designing toxicologic studies. For example, in most mammals, follicular growth continues through the luteal phase. Luteolysis is mediated by uterine prostaglandins in rats and NHP, whereas, in humans, follicular growth does not continue through the luteal phase, and estrogen, rather than prostaglandins, is the luteolytic agent.[74] Other differences among species include maintenance of progesterone production by the corpora lutea throughout pregnancy in the rat, while in humans and guinea pigs, placental progesterone contributes significantly to maintenance of pregnancy during mid- and late gestation.[75] Progesterone levels in rats must be reduced to induce parturition, while humans and guinea pigs have high levels of progesterone until parturition. Deciduoma formation in rats is highly dependent on a correct progesterone/estrogen ratio, and abortion occurs if the serum estrogen level is increased, while humans and guinea pigs are estrogen-resistant.[75] Prostaglandins, however, have abortifacient properties in humans and guinea pigs. Thus, hormonal similarities between guinea pigs and humans and the greater similarities in timing of fetal in utero development suggest that the guinea pig would make a better model for human risk assessment on ovarian function than the rat, although this model has not been as extensively studied.

The typical estrous cycle in rats lasts 4–5 days and varies from 5% to 30% with some rat strains, animal suppliers, and individual shipments.[76] Estrous cycle reporting is also complicated by the fact that the cycling stages are so short in duration, once daily smears may miss stages and infer an incorrect cycle or duration evaluation.[77] Estrous cycle data are generally used to complement other data and do not typically indicate an adverse effect alone.[76] However, in a collaborative study looking at known female reproductive toxicants,[78] effects on estrous cycle were apparent at lower doses than other functional endpoints. An excellent report to consult for background and methods is Goldman et al.[44,79]

Reproductive Behavior

The rat is frequently considered to provide a model system to study central nervous system (CNS) function and behavioral development based on the large amount of normal and abnormal data available. Neural and molecular mechanisms for female reproductive behaviors in the rat have been widely investigated. The components of reproductive behavior can be divided into proceptive and receptive.[80] Proceptive behaviors include the approach and solicitation by the male, followed by the pacing of the mating interaction. Receptive behavior consists of the lordosis reflex (arching of the back, elevation of the head and rump, and deflection of the tail). Although not the model most used for basic research, female monkeys show clear changes in behavior during the menstrual cycle and subsequent to injection of steroid hormones. Copulation in NHP is restricted to the periovulation period. Similar findings have not been made in women, although the absence of clear findings may reflect methodological problems inherent in the conduct of such studies.[81] Humans have sexual behaviors that are dependent on steroid hormone secretion during puberty, and perceptual and sensory behaviors vary within the menstrual cycle, as well as the susceptibility to irritability, anxiety, and depression during the premenstrual

period.[82] The early postpartum period in humans is known to be an interval with emotional alterations in many women and severe disturbances in some women.[83]

Alteration of Hypothalamic–Pituitary Axis/Ovarian Feedback

Effects on female reproduction are generally studied by evaluation of many endpoints (Table 35.3). Toxic effects may be produced by targeting the hypothalamic–pituitary axis, the ovary, or any point in the complex feedback system. Examples of some agents known to adversely affect female reproductive performance are cited in Table 35.4.

Altered hypothalamic and pituitary secretions can adversely affect fertility and estrous cyclicity in female rats.[74] A substituted triazole[84] inhibited ovarian estradiol synthesis, with resultant delay in the LH surge and ovulation. Further study of this fungicide found that pituitaries from treated rats had LH production after GnRH stimulation.[85] This chemical was later identified as an aromatase inhibitor, preventing ovarian synthesis of estradiol.[74]

Ovarian Morphometry

Ovarian endpoints that may be affected by xenobiotic exposure include oocyte number and follicular development, ovulation, estrous cycling, fertility, and maintenance of pregnancy. There are excellent reviews on ovarian follicular development[86] and follicle quantitation and morphometrics.[87] Models used to evaluate dose- and stage-dependent, as well as age-dependent, effects of xenobiotic exposures of the ovary generally utilize morphometry, which can be performed either as part of general toxicity evaluations or within the framework of reproductive toxicity studies. Histopathological evaluation of the three major compartments of the ovary (i.e., follicular, luteal, and interstitial) plus the capsule and stroma should be performed to reveal possible toxicological conditions. Original methods were extremely time-consuming and expensive (30–60 sections per ovary, resulting in 300–600 sections per group of 10 animals) to be evaluated; however, current screening methods generally are restricted to every 10th or 20th section. Even though these methods have been incorporated into some guidelines, they produce highly variable results that should not be used as the sole endpoint in a risk assessment.

Corpora Lutea Count and Preimplantation Loss

Evidence of an adverse event at the ovarian level in in vivo studies is most frequently based on reduced numbers of corpora lutea, often in combination with preimplantation loss. Preimplantation loss reflects the number of eggs ovulated, fertilized, and implanted, as well as the receptivity of the uterus. Rabbits and ferrets are reflex (induced) ovulators, requiring stimulation of the cervix, whereas humans and most laboratory animals are spontaneous ovulators. When artificial insemination procedures are used for breeding rabbits, an intravenous injection of HCG is generally administered to compensate for reduced natural cervical stimulation during mating. Artificial insemination procedures in rabbits result in greater variability in ovulation, numbers of corpora lutea and preimplantation loss values than natural mating because of several factors. First, release of ova depends on the number of mature follicles present when ovulation is induced by the stimulation of natural mating or injected HCG. One major

TABLE 35.3
Scheme for Identifying Effects on Female Rat Reproduction

Step	Treatment	Activity	Potential Adverse Effects
1	None—14 days	Identify estrous cycling.	Abnormal cycling—if incidence is high, consider environmental factors.
2	Precohabitation—up to 14 days	Identify estrous cycling.	Alterations from treatment—assume hormonal changes.
3	Cohabitation through gestation	Mate females with untreated males (1:1). Observe mating behavior (receptivity) and fertility (persistent diestrus, sperm or plug).	Reduced or absent mating behavior or irregular estrous cycling.
4	Through day before sacrifice	Sacrifice 1/2 preselected pregnant animals per group at GD 21. Observe gross lesions, corpora lutea, pregnancy, implantation numbers, resorptions, live and dead fetuses, fetal body weights, and sexes.	Reduced corpora lutea, implantation sites, live fetuses; reduced fetal body weight; altered sex ratios.
5	Through delivery and lactation	Allow remaining 1/2 of animals per group to deliver. Observe durations of gestation and parturition, maternal behavior peri-partum, pup number, viability, body weight, sex and morphology at birth, pup viability, growth, clinical signs and interaction with dam to weaning, and maternal implantation sites.	Reduced implants; altered gestation or parturition durations; reduced maternal care during lactation; reduced total litter size, live litter size, and/or pup viability; reduced or increased pup weight; altered pup sex ratio; altered pup morphology; reduced pup growth and viability; altered function.

TABLE 35.4
Examples of Agents Producing Adverse Female Reproductive Effects

Agents	General Mechanism	Potential Toxicity
Ethanol, DDT, isoflavones	Altered puberty, estrous/ menstrual cycling	Altered ovarian activity and hypothalamic–pituitary feedback
DDT, kepone	Impaired ovulation	Altered endocrine signal
β-Endorphin, naloxone	Altered mating behavior	Altered modulation
Progesterone, diethylstilbestrol, estrogens, methoxychlor	Altered gamete/embryo transport	Increased urine contractions
Estrogens, DDT, methoxychlor, kepone, EGME	Suboptimal endometrial environment	—
Alkylating agents, chemotherapeutic agents (e.g., prednisone, vincristine, vinblastine, 6-mercaptopurine, radiation, methotrexate, adriamycin), alcohol, polycyclic aromatic hydrocarbons, 4-vincyclohexene, cyclophosphamide	Ovarian toxicity/oocyte destruction/atresia	Mimic structure of naturally occurring hormones; general chemical reactivity
Aminoglutethimide, 3-methoxybenzidine, cyanoketone, estrogens, azastene, danazol, spironolactone, epostane, triazole, fungicide	Altered steroid synthesis	Inhibition of steroidogenic enzymes
Clomiphene citrate, cimetidine, spironolactone, opioid peptides	Antagonized steroid action	Inhibited steroid activity
Marijuana	Inhibition of gonadotropins	Alterations at hypothalamic level
Tranquilizers (e.g., imipramine, clomipramine, buspirone)	Altered maternal behavior/lactation	Alterations at hypothalamic level
Tranquilizers (e.g., trifluoperazine, diazepam, thioridazine, fluphenazine)	Impaired lactation	Altered prolactin levels

consequence of HCG priming of the female is the possibility of *superovulation*, that is, a large number of eggs ovulated, including ones not completely mature, and subsequent inability of these eggs to be fertilized or implanted, resulting in a large percentage of preimplantation loss.[88] Second, fertilization depends upon multiple factors, including the quality and quantity of both the eggs and the sperm, as well as the timing of priming, ovulation, and insemination. Artificial insemination is generally performed using one introduction of diluted sperm into the primed female's vagina.

Natural breeding may involve one or more intromissions and inseminations, generally increasing the number of sperm inseminated, cervical stimulation of the female, associated hormonal changes and ovulation of appropriately aged eggs, and the number of egg fertilized and implanting. A summarization of the placental, uterine, and other gestational parameters of humans and six commonly used laboratory mammals for reproductive toxicology studies is presented in Table 35.5.

DEVELOPMENTAL TOXICOLOGY

As early as 1973, Wilson[20] expressed the concept of developmental toxicology: "The unborn is not only the embryo and the fetus in utero but also the as yet unconceived individuals whose potential for future development is represented in the germ cells residing in the parental gonads. Also of interest….are those who have already been born but who are incompletely developed." Wilson also expanded the definition of teratology (study of congenital malformations) to "the study of the adverse effects of environment on developing systems, that is, on germ cells, embryos, fetuses, and immature postnatal individuals," and stated, "a more comprehensive definition is that teratology is the science dealing with the causes, mechanisms, and manifestations of developmental deviations of either structural or functional nature.[89]" Based on these definitions, developmental toxicology can be considered to be the study of the entire reproductive process, with special emphasis on the developing conceptus, but including the development and function of that conceptus throughout its entire life span.

Wilson's basic principles[20] remain valid. All investigators in the field should be familiar with their details (see the following; to comply with current usage, *teratogenesis* has been made synonymous with *developmental toxicity*):

1. Susceptibility to developmental toxicity depends on the genotype of the conceptus and the manner in which this interacts with adverse environmental factors.
2. Susceptibility to developmental toxicity varies with the developmental stage at the time of exposure to an adverse influence.
3. Developmental toxins act in specific ways (mechanisms) on developing cells and tissues to initiate sequences of abnormal developmental events (pathogenesis).

TABLE 35.5
Historical Values for Mean% Preimplantation Loss in Hra: (NZW)SPF Rabbits

Facility and Mating Procedure	Number of Studies, Time Period, Number of Does	Mean, Standard Deviation, and Range per Study
Artificially inseminated—hCG-primed rabbits		
RTI—Tyl and Marr[320]	88 does Years and number of studies Not reported	30.90% ± 2.9 (range not reported)
Charles River, Pennsylvania	98 studies (1980–1989)	17.8% (SD not reported)
Feussner[a]	1463 does	Range = 8.2% to 38.4%
Naturally mated rabbits		
RTI—Tyl and Marr[320]	117 does Years and number of studies Not reported	11.34% ± 1.49
Charles River, Pennsylvania (historical control data)[b]	30 studies June 2009–June 2011 624 does	5.8% (SD not reported) Range = (1.6% to 15.2%)

4. The access of adverse influences to developing tissues depends on the nature of the influence (agent).
5. The four manifestations of deviant development are death, malformation, growth retardation, and functional deficit.
6. Manifestations of deviant development increase in frequency and degree as dosage increases, from the no-effect to the totally lethal level.

Schmidt and Johnson[90] provided an elegant refinement of Wilson's principles, including that while "teratogenesis *per se*, has its primary focus on embryogenesis, developmental biology, and molecular genetics, the field of developmental toxicology also involves basic principles of toxicokinetics, dose-response relationships, target organ toxicity and exposure assessment."

Normal Development

The following information is provided as an overview of the complex process of normal development and also as an introduction to differences in developmental events in laboratory animal species and humans. For additional information on specific facets discussed, the reader is recommended to reviews by DeSesso,[91] Klinefelter and Gray,[74] Rogers and Kavlock,[92] and Shield and Mirkes,[93] as well as to basic texts[94] on embryology and developmental biology. Much of the following information is excerpted from these sources. For the interrelationship of the reproductive process in the maternal animal, vis-à-vis the developing conceptus, the reader is referred to the prior sections in this chapter.

As noted by Rogers and Kavlock,[92] development is characterized by changes in size, biochemistry and physiology, and form and functionality. The overall process is orchestrated by a cascade of gene transcription regulating factors, the first of which are present in the egg before fertilization. These factors activate regulatory genes in the embryonic genome, with sequential gene activation continuing throughout development.

Development of the Conceptus

Preimplantation

The development of a post-fertilization mammalian conceptus occurs within the uterine tubes and fundus of the uterus. After fertilization, there is a fusion of genetic material of haploid egg and sperm to form a diploid zygote. Sperm activate the egg's metabolism to start development. The development of the conceptus from the zygote to neonate is a complex process of extremely rapid cell proliferation and apoptosis (programmed cell death). In most laboratory species, the time from sperm penetration to first cleavage requires approximately 12 h. As the fertilized oocyte (zygote) travels down the uterine tube to the uterus, cleavage continues with growth to the morula stage. During this time, the zygote is surrounded by an acellular mucopolysaccharide layer, the zona pellucida, which previously prevented sperm penetration and now prevents premature implanting. In most mammals, the zona pellucida disappears at the blastocyst stage and the morula cavitates between 5 and 8 days of gestation. The preimplantation embryo has remarkable regulative (restorative) growth potential,[95] and it has been shown that one cell from an eight-celled rabbit embryo can produce a normal offspring.[96] The preimplantation period was generally identified historically as a period during which toxic insult generally results in embryo death or absence of effect, because of the regenerative powers of the embryo.[97] Currently, the preponderance of evidence shows all or nothing concept of *either death or recovery* does not always apply to preimplantation embryos (i.e., surviving embryos may demonstrate growth retardation, malformation, and/or functional impairment). It has been shown that preimplantation exposure to some agents affects the ultimate growth and development of the embryo, for example, actinomycin D and methotrexate, among others.[19,97,98] Therefore, the entire embryonic and fetal stages of development are susceptible to toxic insult, and because many systems continue to develop after birth (e.g., lungs, immune system, reproductive organs), the postnatal period is also susceptible to toxic insult.

Implantation and Placentation

Cavitation is followed by attachment of the blastocyst to the uterine wall (nidation) and subsequent invasion of the uterine wall (implantation) by the syncytiotrophoblast, which erodes the endometrium. Placental circulation is subsequently established.[99] Each blastocyst includes two different cell populations, the outer layer (trophoblast), which becomes the placenta and fetal membranes, and the inner cell mass (cluster of cells within the blastocyst), which becomes the embryo. Although sometimes not considered in the overall development of the embryo, the trophoblast serves an important function: the extraembryonic membranes protect the conceptus, while the placenta provides a means to supply nutrients and remove metabolic waste. There are multiple diverse mechanisms for placental transport of molecules, including both simple diffusion and carrier-mediated mechanisms (active transport, facilitated diffusion, receptor-mediated endocytosis). The placenta is clearly not a barrier, but rather a means by which a substance in the maternal system will, at some rate and by some mechanism, be transported into the embryo. Remarkable differences exist across species with respect to the layers of embryonic and maternal tissues interposed between the respective circulations, and differences in the duration and functions of the yolk sac among species, which can affect the rate and access of a test material to a conceptus. In the addendum to ICH S6 (May 2012),[100,101] these differences have been used to alter the classical design of developmental and reproductive toxicology (DART) studies in NHP.[101,102] In the NHP and human, IgG placental transfer is low during organogenesis and begins to increase in early second trimester, reaching highest levels late in the third trimester.[103] Therefore, standard embryo–fetal studies in NHPs, which are dosed from early pregnancy gestation day (GD) 20 to GD 50, might not be of value, although effects on embryo–fetal development as an indirect result of maternal effects can be evaluated. Furthermore, maternal dosing in NHP after delivery is generally without relevance as IgG is only excreted in the milk initially (i.e., in the colostrum), and not later during the lactation and nursing phase. Rodents differ from the NHPs and humans, as IgG crosses the yolk sac in rodents by neonatal Fc receptor (FcRn) transport mechanisms and exposure can occur relatively earlier in gestation than with NHPs and humans. In addition, delivery of rodents occurs at a stage of development when the pups are not as mature as the NHP or the human neonate. Therefore, rat/mouse dams should be dosed during lactation in order to expose pups via the milk up to at least day 9 of lactation when the offspring are at an equivalent stage of development as human neonates.

Embryogenesis

The rapid growth of the conceptus continues through embryonic, fetal, and neonatal stages. The duration of these stages differs in various species, as shown in Table 35.6.[104] Comparative development of organ systems (e.g., renal, lung, heart, bone, gastrointestinal tract, male and female reproductive systems, immune system, and CNS) of common laboratory species are included in *Birth Defects Research* (Part B) Volume 68.

TABLE 35.6
Timing of Early Development in Some Mammalian Species

	Times of Early Development (Days from Ovulation)			
Mammal	**Blastocyst Formation**	**Implantation**	**Organogenesis Period**	**Length of Gestation**
Mice	3–4	4–5	6–15	19
Rats	3–4	5–6	6–15	22
Rabbits	3–4	7–8	6–18	33
Sheep	6–7	17–18	14–36	150
Monkeys (rhesus)	5–7	9–11	20–45	184
Humans	5–8	8–13	21–56	267

Source: Adapted from Brinster, R.L., Teratogen testing using preimplantation mammalian embryos, in: Shepard, T.H. and Miller, J.R. (eds.), *Methods for Detection of Environmental Agents That Produce Congenital Defects*, American Elsevier, New York, 1975.

The period of embryogenesis (organogenesis) is generally identified as the interval between implantation (and formation of the neural plate in the ectoderm) and closure of the hard palate. Most organ systems are formed during this period, requiring cell proliferation, cell migration, cell–cell interactions, and morphogenetic tissue remodeling. Each forming structure has a period of maximum susceptibility, with peak susceptibility to insult coinciding with the time key developmental events occurring in these structures. Wilson's classic diagram (Figure 35.3)[105] demonstrates the pattern for the rat embryo. The varying susceptibilities in the hamster, mouse and guinea pig have been demonstrated.[106] In toto, these investigations demonstrate that peak sensitivity may not only differ for a given tissue/organ, but also with the administered dose, reverting to Wilson's concepts.[18,20,105] In addition, the same insult may affect the growth of concurrently developing

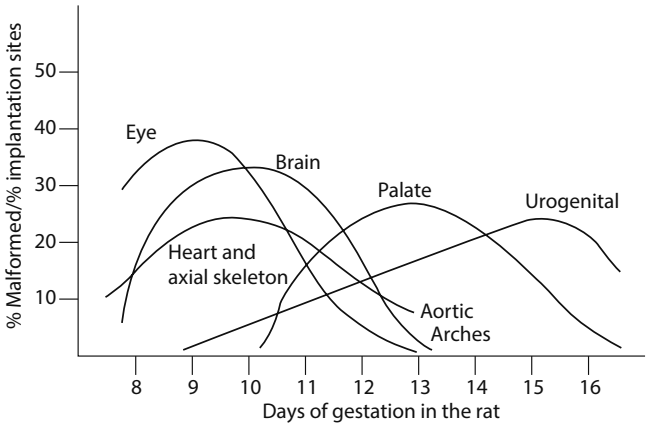

FIGURE 35.3 Hypothetical pattern of susceptibility of embryonic organs to teratogenic insult. (Adapted from Japan Ministry of Agriculture Forestry and Fisheries, *Guidelines for Screening Toxicity Testing of Chemicals*, 59 NohSan No. 4200, 209, 1985.)

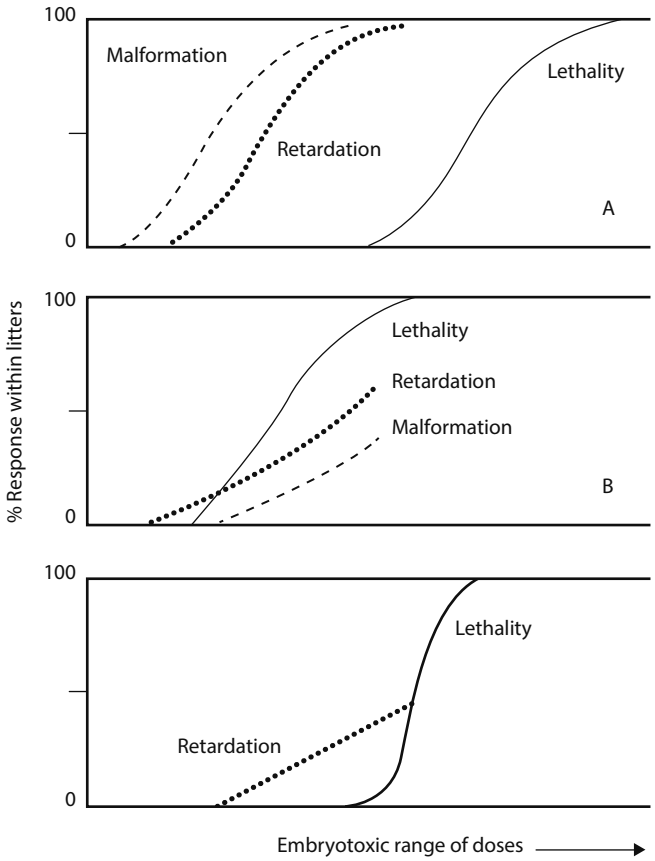

FIGURE 35.4 Dose–response patterns (A–C) for different types of developmental toxicant. (Adapted from Daston, G.P., Relationship between maternal and developmental toxicity, in: Kimmel, C.A. and Buekle-Sam, J. (eds.), *Developmental Toxicology*, 2nd edn., Raven Press, New York, 1994, pp. 189–212.)

systems. Thus, insult during the period of organogenesis is most likely to result in gross structural malformations,[20,105] although all endpoints of developmental toxicology have been shown affected, although the dose–response pattern for agents often differs (see Figure 35.4), and the interrelationships of the responses often confound apparent dose-dependency. In general, the type of agent that is of most concern is that causing malformation at doses that are less than those associated with growth retardation or lethality. As discussed later, regardless of the dose–response, current practice in risk assessment is to base the developmental toxicity effect level on the lowest dose level where any of the four potential endpoints are adversely affected, whether the effect occurs alone or in combination.

Fetogenesis

The fetal period is characterized by tissue differentiation, growth, and physiological maturation. Almost all organs are present and grossly recognizable, and further development of these organs proceeds with the fetus attaining required functions before birth. These include fine structure morphogenesis (e.g., synaptogenesis, neural outgrowth, branching morphogenesis of the bronchial tree and renal cortical tubules) and biochemical maturation (e.g., induction of tissue-specific enzymes and structural proteins). Insult during the period of fetogenesis is most likely to affect growth and functional maturation of the CNS, reproductive organs (including behavioral and motor deficits and reductions in fertility), the pulmonary system, and the immune system. Although gross structural changes can occur during the fetal period, such observations are generally secondary to deformations (changes in previously normal structures, such as clubbed or bent limbs), rather than malformations (abnormal growth).

Apoptosis

Apoptosis (controlled cell death) has been recognized for over 60 years to be as important to development of the conceptus as are cell proliferation and differentiation.[93,107–109] Apoptosis occurs in the developing embryo and in normal healthy adult tissues, as well as in many pathological settings. It is genetically directed, usually requires ongoing protein synthesis,[110] continues through life, and provides the central mechanism for removal of surplus, unwanted, damaged, or aged cells. Apoptosis occurs in almost every tissue during development,[111,112] including palate formation,[113] body sculpting (e.g., digit formation[114]) gastrointestinal development, sexual organ development and gamete formation and number,[109,110,112,115–118] and in the homeostasis of normal tissues, especially the gastrointestinal tract, immune system, and skin.[110] Establishment of normal craniofacial pattern requires apoptosis of the neural crest,[119] with apoptosis perhaps most well studied in development of the nervous system. It is critical in the development of both neuronal and nonneuronal cells in the peripheral nervous system and CNS[120,121] and occurs both pre- and postnatally. As noted by Mazarakis et al.,[118] apoptosis is seen in the developing nervous system as early as neural tube formation and persists throughout terminal differentiation of the neural network, with more than 50% of the neurons lost during development.

The mechanisms of apoptosis are highly complex and sophisticated, involving an energy-dependent cascade of molecular events. A full description is beyond the scope of this chapter. Readers are referred to two recent review articles (and the reference within) on this topic.[122,123] There are two main apoptotic pathways: the extrinsic or death receptor pathway and the intrinsic or mitochondrial pathway.[122] However, these two pathways are linked and molecules in one pathway can influence the other.[124] There is another pathway that involves T-cell-mediated cytotoxicity and perforin–granzyme-dependent killing of the cell. The perforin–granzyme pathway can induce apoptosis via either granzyme B or A. The extrinsic, intrinsic, and granzyme B apoptotic pathways all converge on the same terminal (execution) pathway.

Extrinsic pathway: Tumor necrosis factor (TNF) receptor family members share similar cysteine-rich extracellular domains and have a cytoplasmic domain of about 80 amino acids that has been called the *death domain*.[125] This death domain plays a critical role in transmitting the death signal from the cell surface to the intracellular signaling pathways involving a multistep process leading to the formation of a

death-inducing signaling complex that results in the autocatalytic activation of procaspase-8 to caspase-8, triggering the execution phase of apoptosis.[126]

Intrinsic pathway: The intrinsic apoptotic signaling pathways involve a diverse array of nonreceptor-mediated stimuli that produce intracellular signals that act directly on targets within the cell and are mitochondrial-initiated events. The stimuli that initiate the intrinsic pathway produce intracellular signals that may act in either a positive or negative fashion. Negative signals such as the absence of certain growth factors, hormones, and cytokines can lead to failure to suppress death programs, thereby triggering apoptosis. Other stimuli (e.g., radiation, toxins, hypoxia, hyperthermia, viral infections, and free radicals) can cause changes in the inner mitochondrial membrane that result in an opening of the mitochondrial permeability transition pore, loss of the mitochondrial transmembrane potential, and release of two main groups of normally sequestered proapoptotic proteins from the intermembrane space into the cytosol.[127] The control and regulation of these apoptotic mitochondrial events occurs through members of the Bcl-2 family of proteins, which govern mitochondrial membrane permeability and can be either proapoptotic or antiapoptotic.[128] The tumor suppressor protein *p53* has a critical role in regulation of the Bcl-2 family of proteins.[129] It is thought that the main MOA of the Bcl-2 family of proteins is the regulation of cytochrome *c* release from the mitochondria via alteration of mitochondrial membrane permeability.

Execution pathway: Caspases are widely expressed in an inactive proenzyme form in most cells. Activated caspases can often activate other procaspases, allowing initiation of a protease cascade, which amplifies the apoptotic signaling pathway leading to rapid cell death. Once caspases are initially activated, there appears to be an irreversible commitment toward cell death. To date, 10 major caspases have been identified and broadly categorized into inflammatory caspases (caspase-1,-4,-5), initiators (caspase-2,-8,-9,-10), and effectors or executioners (caspase-3,-6,-7).[130,131] The other identified caspases include caspase-11 (which regulates apoptosis and cytokine maturation during septic shock), caspase-12 (which mediates endoplasmic-specific apoptosis and cytotoxicity by amyloid-β), caspase-13 (probably a bovine gene), and caspase-14, which is highly expressed in embryonic tissues but not in adult tissues.[132–135]

It is the activation of the execution caspases that begins the execution phase of apoptosis. Execution caspases activate cytoplasmic endonuclease, which degrades nuclear material, and proteases that degrade the nuclear and cytoskeletal proteins. Caspase-3, caspase-6, and caspase-7 cleave various substrates that ultimately cause the morphological and biochemical changes seen in apoptotic cells.[136] Caspase-3 is considered to be the most important executioner caspase and can be activated by any of the initiator caspases (caspase-8, caspase-9, or caspase-10). In apoptotic cells, activated caspase-3 cleaves ICAD to release the endonuclease CAD,[137] which then degrades chromosomal DNA within the nuclei and causes chromatin condensation. Caspase-3 also induces cytoskeletal reorganization and disintegration of the cell into apoptotic bodies. Phagocytic uptake of apoptotic cells is the last component of apoptosis. Apoptotic cells express surface markers (e.g., annexin, calreticulin, thrombospondin-1) that result in the early phagocytic recognition by adjacent cells, permitting quick phagocytosis with minimal compromise to the surrounding tissue.[138–142] Phospholipid asymmetry and externalization of phosphatidylserine on the surface of apoptotic cells and their fragments is the hallmark of this phase. The appearance of phosphatidylserine on the outer leaflet of apoptotic cells then facilitates noninflammatory phagocytic recognition, allowing for their early uptake and disposal.[143] This process of early and efficient uptake with no release of cellular constituents results in essentially no inflammatory response.

Necrosis: Necrosis, in contrast to apoptosis, is an uncontrolled and passive process that usually affects large fields of cells while apoptosis is controlled and energy-dependent and usually affects individual or clusters of cells. Using standard histology, it is often difficult to distinguish apoptosis from necrosis.[122] Apoptosis and necrosis can occur simultaneously depending on factors such as the intensity and duration of the stimulus, the extent of adenosine triphosphate (ATP) depletion, and the availability of caspases.[144]

Changes associated with necrosis include cellular swelling, organelle dysfunction, mitochondrial collapse and ultimately cellular disintegration, release of the cellular contents in the extracellular milieu, and a marked host inflammatory reaction. Necrotic cell injury is mediated by two primary mechanisms: (1) interference with the energy supply of the cell and (2) direct damage to cell membranes. It is the loss of cell membrane integrity with the subsequent release of the cytoplasmic contents into the surrounding tissue that initiate chemotaxic signals, which eventually cause recruitment of inflammatory cells. Because apoptotic cells do not release their cellular constituents into the surrounding interstitial tissue and are quickly phagocytosed by macrophages or adjacent normal cells, there is essentially no inflammatory reaction.[145] It is also important to note that pyknosis and karyorrhexis are part of the spectrum of cytomorphological changes that occurs with apoptosis and necrosis.[146]

Endpoints of Developmental Toxicology

One or more endpoints of developmental toxicity, alone or in combination, have been identified as affected for scores of agents, despite the fact that *teratogenicity* remains the endpoint of greatest interest. Compendiums of *animal teratogens* are regularly updated[147–149] and provide overviews of effects of test agents, generally in animal studies conducted at high multiples of human exposures. Despite the concept that most, and possibly all, agents are toxic to development when administered to the appropriate species, at the required dose, during the appropriate period of sensitivity,[150] many researchers continue to perceive teratogenicity as a unique property of an agent and incorrectly categorize agents as *teratogenic* or *nonteratogenic*[151] or induced by *maternal toxicity*, when only

an association of toxicity at a given dose can be identified on the basis of the study design.[152–155] Agents that result in toxic effects in the maternal and paternal animals may be expected to result in adverse effects on the developing conceptuses from which the parents but not necessarily the conceptuses may recover, and that cross-species extrapolation of the affected developmental endpoint does not necessarily occur, because of multiple timing, exposure, and species-specific differences.

Mechanisms of Developmental Toxicity

As early as 1977, Wilson[18] identified six general categories for mechanisms resulting in developmental toxicity. These include mitotic interference, altered membrane function/signal transduction, altered energy sources, enzyme inhibition, altered nucleic acid synthesis, and mutations. The current increased knowledge regarding molecular mechanisms of normal development results in addition of perturbations in gene expression and programmed cell death to Wilson's general categories.[156] Six teratogenic mechanisms of medical drugs have been identified by van Gelder et al.[157]: (1) neural crest cell disruption, (2) endocrine disruption (sex hormones), (3) folate antagonism, (4) vascular disruption, (5) oxidative stress, and (6) specific receptor- or enzyme-mediated teratogenesis. In their review, van Gelder et al. used three methods to identify the teratogenic mechanisms of medications: first, the MEDLINE and EMBASE databases; second, two recent books on teratogenic agents; and third, a list of drugs classified as U.S. Food and Drug Administration (FDA) class D or X. Mechanisms were included only if they are associated with major structural birth defects and medications that are used relatively frequently by women of reproductive age. A brief discussion of each mechanism follows. Readers are referred to van Gelder et al.[157] (and references within) for greater detail.

Neural Crest Cell Disruption

The neural crest, a pluripotent cell population originating in the neural folds, can be divided into two major populations: the cranial and truncal neural crest. During neurulation, the neural crest cells detach from the neural folds and migrate into the embryo to give rise to numerous structures. In the craniofacial region, various cell types and structures, including intramembranous bone, cartilage, nerves, and muscles, are derived from the cranial neural crest. The cardiac neural crest, a cranial neural crest subpopulation, migrates into the cardiac outflow tract to mediate septation. Therefore, neural crest–related cardiovascular malformations include aortic arch anomalies and conotruncal defects.[158] Membranous ventricular septal defects are also neural crest–related, since the membranous part of the interventricular septum originates from the cardiac neural crest, whereas the muscular part originates from the mesenchyme.[159] The cardiac neural crest also migrates into other derivatives of the pharyngeal arches (e.g., thymus, thyroid, and parathyroids).[160] Neural crest, noncardiovascular defects include craniofacial malformations,[161] esophageal atresia,[162,163] and abnormalities of the pharyngeal glands.[164] The truncal neural crest produces important components of the peripheral nervous system.[165]

Proper induction, migration, proliferation, and differentiation of neural crest cells are tightly regulated. A variety of molecular signals and receptors are implicated in neural crest cell development. Therefore, drugs that interfere with these molecular pathways may induce neural crest–related malformations. In addition, in vivo and in vitro experiments suggested that altering levels of folate and/or homocysteine cause abnormalities of cardiac neural crest cell migration, differentiation, and cell cycle progression,[166] thereby connecting this teratogenic mechanism with folate antagonism. Retinoic acid, the biologically active form of vitamin A, is one of the most important signaling molecules in neural crest cell development. Excesses as well as shortages[167,168] of retinoic acid appear to cause neural crest–related malformations, indicating that proper retinoid homeostasis is necessary for normal development.

Endocrine Disruption: Sex Hormones

Since the 1940s, a number of drugs have been developed to mimic or inhibit the actions of hormones. These drugs include diethylstilbestrol (DES), oral contraceptives, and hormones used in fertility treatment. These drugs and other endocrine disrupting chemicals (EDCs, such as bisphenol A and phthalates) may interfere with the physiologic functions of endogenous hormones by affecting their release, binding, or metabolism. Their actions may depend not only upon the estrogen and/or androgen receptors binding affinity or specificity but also upon their ability to activate or inhibit other receptor-mediated actions. The in utero actions of EDCs have been of concern because of their possible impact on the developing reproductive systems, especially since treatment of pregnant women with the synthetic estrogen DES led to an increased risk of vaginal adenocarcinoma in their female offspring[16] and has also been associated with an increase in reproductive disorders in sons[169] and grandsons.[170,171]

In addition to drugs that influence endocrine homeostasis as their primary MOA, some oral medications (e.g., mesalamine and omeprazole) have coatings that contain phthalates, which may be a source of EDC exposure.[172] These enteric coatings may affect human male reproductive development due to their anti-androgenic properties.[172] Additionally, other products also contain phthalates as plasticizers, but it should be noted that phthalates do not bioaccumulate and are rapidly excreted in contrast to some other EDCs. The susceptibility to EDCs may also vary greatly between individuals due to genetic factors.[173] Therefore, it is questionable whether the levels of phthalates *in medications* are great enough to produce male reproductive tract anomalies in humans. In epidemiologic studies, the two medications with phthalate containing enteric coatings, omeprazole, and mesalamine have not been associated with an increased risk of major birth defects.[174,175]

Male development is more susceptible to endocrine disruption than female development because of its hormone dependence.[176] The sexual differentiation of males generally depends on a balanced androgen/estrogen ratio. In mice, estrogens impair fetal Leydig cell development and reduce

testosterone production.[177] In rats, phthalates induce male reproductive disorders through inhibition of steroidogenesis by the fetal testis.[178,179] In contrast, this does not occur in vitro with human fetal Leydig cells.[180]

However, since EDCs may affect endocrine homeostasis in multiple ways, the underlying teratogenic mechanisms are often difficult to discern. There are considerable species differences and markedly different estrogen levels in normal human pregnancy when compared with normal rodent pregnancy. Whether many of the described mechanisms elucidated in rodent and in vitro studies are applicable to humans remains debatable.[157]

Folate Antagonism

Folate is the generic term for a water-soluble B vitamin that occurs in certain natural foods (fruits, leafy green vegetables, beans, and liver) as polyglutamate, while folic acid, the synthetic form with a higher bioavailability than food folate, is used in vitamin preparations and food fortification. Folate is converted through two reduction reactions by dihydrofolate reductase (DHFR) to the naturally bioactive form tetrahydrofolate (THF), which is converted into 5-methyltetrahydrofolate, which is the main form of folate in the blood. 5-Methyltetrahydrofolate is transported into cells, and once inside the cell, 5-methyltetrahydrofolate acts as an essential coenzyme by being an acceptor or donor of one-carbon units in many biochemical reactions (e.g., purine and pyrimidine synthesis and DNA methylation reactions). Because rapidly proliferating tissues require DNA synthesis, folate-dependent reactions are essential for growth and development of the conceptus and that folate requirements increase during pregnancy. In addition, DNA methylation is known to be involved in the epigenetic control of gene expression during development.

The teratogenicity of folate antagonists in humans was first suggested by reports of women who were given aminopterin in the first trimester of pregnancy to induce abortion.[181] Some antiepileptic drugs, for example, carbamazepine and valproic acid, are generally known to increase the risk of folate-sensitive birth defects, such as neural tube defects, orofacial clefts, and limb defects. Currently, the exact mechanism by which disturbances of the folate metabolism increase the risk of neural tube defects is unclear.

Several drugs disturb the folate metabolism and may have a teratogenic effect through inhibition of the folate methylation cycle. Two general groups of drugs act as folate antagonists. The first group blocks the conversion of folate to THF by binding irreversibly to the enzyme DHFR. This group consists of competitive inhibitors of DHFR and includes methotrexate, sulfasalazine, triamterene, and trimethoprim.[182] The second group antagonizes other enzymes in the folate metabolism, impair folate absorption, or increase folate degradation. This group primarily consists of antiepileptic drugs, including valproic acid, carbamazepine, and phenytoin.

Vascular Disruption

Vascular disruption defects are structural birth defects resulting from interference with or extrinsic breakdown of an originally normal prenatal development of the arteries, veins, and capillaries (vasculature).[183] Vascular disruption refers to disturbances in the blood circulation (e.g., hyperperfusion, hypoperfusion, hypoxia, obstruction) in the uterine–placental unit, the placental–fetal unit, or the fetus itself. They may be caused by acute or chronic decreases in uterine blood flow, vascular infections, or an abnormal anatomy in the uterine–placental unit. Factors such as placental insufficiency, amnion rupture, and umbilical cord obstruction may cause failures in the vascular supply in the placental–fetal unit. In the fetus, abnormal regulation of vessel formation, premature regression of embryonic vessels, disruption of newly formed vessels, external compression, embolic events, and occlusion with venous engorgement can lead to vascular disruption.[184] Vasoconstriction of maternal and fetal vessels, hypoperfusion, and obstruction may cause a reduced supply of nutrients to the embryonic tissues, which can affect development and growth of embryonic structures or result in tissue loss. These disturbances may create a state of hypoxia, which is involved in the formation of reactive oxygen species (ROS) and oxidative stress.[185] The types of structural anomalies that may be caused by vascular disruption are determined by the timing during gestation, the location and severity of tissue damage, and the possible presence of secondary adhesion of necrotic tissue with adjacent organs or the amnion.[183] During embryogenesis, vascular disruption results in aberrant differentiation and distortion of contiguous tissues, loss of tissue, and incomplete development of structures within the same or a secondary embryonic developmental field. Anomalies resulting from vascular disruption during the fetal period are usually limited to the areas with disturbed blood supply, to which the peripheral vasculature is most susceptible.[184] Thus, the majority of defects caused by tissue damage through vascular disruption during the fetal period occur in structures supplied by the most peripheral vasculature, such as the distal limbs and the embryonic intestine. Vascular disruption–related birth defects include terminal limb reductions, hydranencephaly/porencephaly, gastroschisis, small intestinal atresia, and Poland anomaly. The majority of evidence in support of this mechanism comes from case reports with suspected vascular events such as occlusion, emboli, amnion rupture, and twin placental vessel anastomoses.[183]

During pregnancy, exposure to vasoactive substances, especially vasoconstrictives, has been hypothesized to play a causal role in vascular disruption defects. These substances could decrease placental or embryo–fetal blood flow or affect the angiogenesis, thereby altering the vasculature structure.[181] The following vasoactive therapeutic drugs have shown associations in epidemiologic studies with the vascular disruption: misoprostol, aspirin, ergotamine, and pseudoephedrine. However, all drugs with vasoconstrictive or vasodilating effects may have the potential to cause birth defects due to vascular disruption.

Oxidative Stress

In vivo, several drugs (redox cycling agents) used in the treatment of epilepsy, cardiac arrhythmias, and cancer undergo

single electron reduction reactions yielding radical species.[186] In redox cycling reactions that involve oxygen, ROS such as hydrogen oxide, alkyl peroxides, and various radicals are generated (e.g., hydroxyl and superoxide).[187] The creation of ROS is induced by internal and external agents, such as phagocytes, cytochrome P450 mono-oxygenases (CYP), irradiation, and exogenous chemicals. The generation of ROS can be decreased or reversed by various enzymes, for example, superoxide dismutase, catalase, and glutathione reductase, and by antioxidants.[188] Endogenous ROS serve as second messengers in signal transduction[189] and are thought to be important in ion transport, immunological host defense, transcription, and apoptosis of unwanted cells.[190,191] Conversely, ROS can also be harmful by either covalently or irreversibly binding to cellular macromolecules. Oxidative stress is an imbalance between ROS generation and antioxidant defense mechanisms of a cell or tissue. It can cause irreversible oxidation of DNA, proteins, and lipids, leading to inactivation of many enzymes and cell death. In addition to damaging cellular macromolecules, oxidative stress may affect gene expression by interfering with the activity of redox-sensitive transcription factors and signal transduction by oxidizing thiols.[192] During the gestational period, this may result in birth defects and growth retardation and, in severe cases, in in utero death.[189,193,194]

Because of its weak antioxidant defense, the embryo is especially susceptible to high levels of ROS; however, placental enzymes play a role in protecting the fetus against oxidative stress. Increased ROS in embryos are usually the result of embryonic metabolic changes rather than exposure to ROS of maternal origin.[183] Enzymatic bioactivation of proteratogens may cause increased embryonic ROS. However, the ontogeny and functionality of most of the CYP family occurs after birth. Those CYPs present during the embryonic period are expressed at relatively reduced levels. Only some isoforms are expressed at levels that could be significant in ROS-induced teratogenesis.[195,196] In contrast, the prostaglandin H synthases have a relatively greater expression during the embryonic and fetal period than after birth.[197,198] The peroxidase component of this enzyme can bioactivate exogenous substances, including phenytoin and related teratogens,[199] to toxic reactive intermediates that initiate ROS formation.[200] There is evidence that lipoxygenases, which oxidize proteratogens yielding free radical intermediates, are substantially expressed in embryonic tissues. Based on this information, it is inferred that bioactivation of proteratogens by embryonic prostaglandin H synthases and lipoxygenases is necessary for the formation of ROS and subsequent macromolecule damage in the developing embryo.[191] Additionally, embryonic ROS formation and subsequent oxidative stress may be induced by hypoxia. There is considerable evidence that hypoxia followed by reperfusion is teratogenic in animal studies.[201] In addition to embryonic ROS generation, maternal determinants may play an indirect role in ROS-mediated teratogenesis. Embryonic exposure to proteratogens is reduced by maternal pathways that eliminate these compounds or their metabolites before they can cross the placenta. However, deficiencies in those pathways may increase the maternal plasma concentration of proteratogens and, therefore, increase the concentration that reaches the embryo. Furthermore, maternal production of factors that interfere with embryonic ROS-mediated signal transduction or alter embryonic determinants of oxidative stress may also contribute to the risk of teratogenicity.[202]

Oxidative stress is postulated to be involved in the pathogenesis of a wide spectrum of birth defects, including neural tube defects, cleft lip/palate, cardiovascular defects, limb defects, and skeletal malformations. Several drugs are known to induce oxidative stress, which is suspected to be their main teratogenic mechanism. Among these drugs are phenytoin, class III antiarrhythmic drugs, thalidomide, iron supplements, valproic acid, and various chemotherapeutic drugs.

Specific Receptor- or Enzyme-Mediated Teratogenesis

Many medical drugs and chemicals act on a specific receptor or enzyme in the human body, leading to a particular MOA. Inhibition or stimulation of these specific receptors and enzymes can result in effects on fetal development (e.g., angiotensin-converting enzyme and angiotensin II receptors, hydroxymethylglutaryl-coenzyme A reductase, histone deacetylase, cyclooxygenase-1, *N*-methyl-D-aspartate receptors, 5-hydroxytryptamine receptors and transporters, γ-aminobutyric acid receptors, and carbonic anhydrase). A discussion of these specific receptor- and enzyme-mediated teratogens is beyond the scope of this chapter; the reader is refereed to van Gelder et al.[157] and references cited within.

Structure–Activity Relationships, In Vitro Assays, Computational Biology, and Other Considerations

Reproductive and developmental effects are caused at the molecular and/or cellular level. While some MOAs are known for some toxicants (e.g., thalidomide, phthalic acids, valproic acid), many of the mechanisms are currently unknown or only partially elucidated, and the structure–activity relationships remain weak for elucidating mechanisms of developmental toxicity.[203] Along with carcinogenicity studies, reprotoxicity studies are among the most difficult, time-consuming, and costly experimental procedures. Furthermore, reprotoxicity testing requires the highest number of test animals. For all these reasons, the development of alternative (nonanimal) methods for reprotoxicity assessment has become a high political priority. Although a detailed discussion of structure–activity relationships of reproductive and developmental toxicant agent interaction is beyond the scope of this chapter, a state-of-the-art review of available models for developmental and reproductive toxicity is available online.[204] The 2010 review by Piparo and Worth consists of three sections: (1) software (both freely available and commercial) that can be used to predict reproductive and developmental toxicity, (2) databases that can be used to build the models, and (3) literature available models.

As stated earlier, the reproductive cycle combines a highly diverse multitude of biological processes and mechanisms, each of which has its own time-related sensitivity to

xenobiotic exposures. It is therefore a significant challenge to mimic all aspects of the reproductive cycle with in vitro and in silico assays, which may be considered necessary in order that reproductive toxicity can be predicted reliably on the basis of alternative assays alone. The classical aim of *one to one* replacement of in vivo protocols by alternative tests is clearly not feasible for the complex reproductive and developmental toxicity animal study protocols. However, a *battery of assays* approach in which a limited array of sensitive endpoints are reproduced by a set of in vitro and in silico assays could provide sufficient background for hazard identification and risk assessment. A significant number of alternative in vitro and in silico assays have been developed; however, their implementation in regulatory toxicity testing has not yet been totally achieved. Although a detailed discussion of in vitro and in silico assays is beyond the scope of this chapter, a state-of-the-art review of available assays in the OECD armamentarium for developmental and reproductive toxicity is available online.[205] Details concerning these assays are available at the OECD and EPA websites.

Bioinformatics and computational biology are rooted in life sciences as well as computer and information sciences and technologies. Both of these interdisciplinary approaches draw from specific disciplines (e.g., biology, computer science, mathematics, statistics, physics, engineering, and behavioral science). Bioinformatics and computational biology each maintain close interactions with life sciences to realize their full potential. Bioinformatics involves information theory and data management. Bioinformatics apply principles of information sciences and technologies to make the vast, diverse, and complex life sciences data more understandable and useful, while computational biology uses mathematical and computational approaches to directly address biological hypotheses (theoretical and experimental). The terms *bioinformatics* and *computational biology* are often used as synonyms, but they have also been viewed as having distinct characteristics (NIH Working Definition of Bioinformatics and Computational Biology, July 17, 2000).

Computational biology involves the development and application of data-analytical and theoretical methods, mathematical modeling, and computational simulation techniques to the study of biological, behavioral, and social systems. The field is broadly defined and has as its foundations: computer science, applied mathematics, statistics, biochemistry, chemistry, biophysics, molecular biology, genetics, ecology, evolution, anatomy, neuroscience, and visualization.

Established in 2005, the U.S. EPA's National Center for Computational Toxicology (NCCT) coordinates computational toxicology research on chemical screening and prioritization, informatics, and systems modeling. NCCT is involved in the following areas: (1) applying mathematical and advanced computer models to help assess chemical hazards and risks to human health and the environment; (2) using advances in informatics, high-throughput screening technologies and system; (3) using biology to develop robust and flexible computational tools that can screen the thousands of chemicals for potential toxicity. The NCCT has several databases available, (1) ACToR (Aggregated Computational Toxicology Resource), (2) DSSTox (Distributed Structure-Searchable Toxicity Public Database Network), and (3) the ToxRefDB (Toxicity Reference Database), as well as several programs, (1) ExpoCast™ program, (2) ToxCast™ program, (3) Toxicological Priority Index (ToxPi), (4) Tox21, and (5) the Virtual Embryo Project (v-Embryo™), the one that is most important to this chapter .

Scientists in the U.S. EPA's computational toxicology research program are developing new ways to answer the question: "What role does a pregnant woman's exposure to chemicals in the environment play in disrupting the development of an embryo?" And in the process, they are helping revolutionize the field of developmental toxicology. The traditional method of exploring how chemicals affect a developing embryo is conducting controlled tests on pregnant laboratory animals. While these practices provide valuable information, they can be both costly and slow. Reliance on them is one reason why the pace of testing has not kept up with the development of commercial chemicals, leaving significant data gaps.

The v-Embryo™ is aimed at developing new methods that use high-tech computer modeling and vast collections of data and biological knowledge bases in place of traditional lab tests. As stated by Thomas B. Knudsen, an EPA systems biologist who is leading the project,

> The ultimate objective is to build a suite of screening models, a toolkit, that researchers can use to look at embryonic development and make scientifically-based predictions on how that development might be affected by different chemicals …We are building models that properly integrate all the relevant data and information known about various organ systems and birth defects.[206]

Using a selection of everyday chemicals with known health effects in animals, Knudsen and an interdisciplinary team of reproductive toxicologists, computer engineers, programmers, bioinformaticians, biologists, mathematicians, and other experts have continued to work on building computer-based virtual models of embryo development.

> Computer models can handle this complex information, and it is feasible with current math and engineering practices to use these models as a new approach for predicting the potential for environmental chemicals to affect a developing embryo.[206]

Computer models have been developed for embryonic systems that are susceptible to environmental factors, and they are simple enough that computer engineers and programmers can simulate them. Three embryonic systems developed were embryonic eye, blood vessel, and limb development. The predictive value of these embryo systems models is currently being tested using new and existing data from standardized tests conducted in embryonic stem cells (ESCs), zebrafish embryos, and ToxCast™ program. For more information on the EPA's Virtual Embryo program and the NCCT, readers

are referred to the U.S. EPA's website (www.epa.gov). For more information on the international programs, the reader is referred to the website of the *International Society of Computational Biology* (http://www.iscb.org).

Mixtures: The potential for interaction of multiple chemicals has been known to exist for developmental and other toxicities, and that such interactions may enhance or reduce general toxicity of the agents and their potential developmental toxicity, although not necessarily equally or by the same mechanism. For example, early on, it was identified that caffeine potentiates the activity of multiple agents,[207] and while initial emphasis was on the pharmacologic activity of the putative agent, in this case, the vasoconstrictive effect of caffeine,[208] studies are now investigating the interaction of the agent with gene expression. The U.S. EPA has an active program for evaluating multiple chemical combinations[209,210] that are potential water contaminants, often using modified reproductive or developmental toxicity protocols.[211–215]

METHODS USED IN REPRODUCTIVE (FEMALE) AND DEVELOPMENTAL TOXICOLOGY

Testing Procedures and Guidelines for Regulatory Use

The purpose of this section is to provide an overview of the methods used in collection and interpretation of data obtained from reproductive and developmental toxicity studies, when conducted for regulatory use. The methods described are those used in several laboratories and were developed from the literature and practical experience. Because it was not always practical to provide in-depth details, useful publications have been referenced, when possible. Multiple laboratory species are used in these types of studies. However, for practical reasons, most studies are performed using rats and rabbits and sometimes mice and hamsters. In general, the described techniques can be applied to ferrets, guinea pigs, mini-pigs, dogs, and NHP, using species-specific considerations. As previously noted, there are often special reasons to use alternative species (e.g., prolonged in utero development and comparable in utero CNS development in the guinea pig theoretically make this species ideal for evaluation of neural development). Important caveats are that studies conducted for regulatory use should provide evidence that the agent is pharmacologically active in the species, absorbed, if administered orally or topically, and, if possible, similarly handled metabolically by the test species and humans.

The Guidelines for Toxicity to Reproduction of Medicinal Products,[216] an effort of the International Conference for Harmonization (ICH), are accepted by FDA,[217,218] European Union (EU), and Japan.[219] Although the United States, the EU, and Japan have worked together to harmonize their test guidelines, the ICH Guidance M3(R2),[220] the timing of the conduct of the reproduction toxicity studies is based on two factors: (1) the population in which the clinical trials are going to be performed and (2) the ICH countries that the regulatory dossier will be submitted. Recently, a series of review articles concerning the three principle ICH DART study designs were published and have also been incorporated into the following discussion.[221–223] The Nonhuman Primate Developmental and Reproductive Toxicity study designs have significantly changed, and this topic has been thoroughly reviewed in recent publications.[224–227]

DART study guidelines have been promulgated by the FDA,[228–233] the EPA,[89,234–236] the Ministry of Agriculture, Forestry and Fisheries (MAFF),[219,237] Canada,[238,239] Great Britain,[240] WHO,[241] and the OECD.[242–246] The ICH[228,229,247] has been concerned with unifying the study guideline requirements for pharmaceutical safety assessment for the EU, Japan, and the FDA. Guideline-compliant reproductive and fertility studies must be performed in accordance with associated Good Laboratory Practice (GLP) Regulations[248–250] and biosafety[251] and animal welfare guidelines.[252,253] Comprehensive comparisons of the ICH guidelines with other guidelines have been published.[254,255] The Guidelines and Guidance for Industry documents are available on the U.S. FDA (http://www.fda.gov), U.S. EPA (http://www.epa.gov), European Medicines Agency (EMA) (http://www.emea.europa.eu), OECD (http://www.oecd.org), or ICH (http://www.ich.org) websites.

For the purpose of this chapter, the ICH guidelines were used as the reference for identifying the various stages and interrelationships of female reproductive functions and development of the offspring. These guidelines segment the reproductive cycle into six *ICH stages* (ICH stages A through F) that may be tested separately or in combination, generally using a 1-day overlap of treatment. The recommendations of ICH guidelines were often unidentified in other guidelines, including the use of (1) scientific justification of flexible study designs, (2) kinetics, (3) expanded male reproductive toxicity evaluations, (4) a requirement for mechanistic studies, and (5) essentially equal emphasis on all endpoints of developmental toxicity (death, malformation, reduced weight, functional/behavioral alterations), rather than emphasizing malformation as the most important outcome. Flexible testing strategies are to be based on (1) anticipated drug use, especially in relation to reproduction; (2) the form of the substance and route(s) of administration intended for humans; and (3) consideration of existing data on toxicity, pharmacodynamics, kinetics, and similarity to other compounds in structure/activity. In toto, the purpose of these studies is to identify any effect of an active substance on mammalian reproduction, to compare this effect with all other pharmacologic and toxicologic data for the agent, and ultimately, to determine whether the human risk for reproductive and developmental effects is the same, increased, or reduced, in comparison with the risks of other toxic effects of the agent. As should occur for all toxicologic observations, additional pertinent information should be considered before the results of the animal studies are extrapolated to humans. This information includes human exposure considerations, comparative kinetics, and the mechanism of the toxic effect.

Because this chapter emphasizes toxic effects on the female animal and its offspring (through completion of the lactation period), sections of the ICH guidelines relevant to male reproductive performance and postnatal development of the offspring are discussed only when relevant to the primary subject area. Assessments of male reproductive effects, functional/behavioral effects in the offspring, and pediatric effects are more fully described in other chapters.

General Procedures for Pharmaceuticals

The ICH stages are identified in Figure 35.1. Conduct of a study, including two full reproductive cycles, is equivalent to a two-generation study. As previously noted, rodents and rabbits are the most commonly used laboratory animals. Common protocol designs used for evaluation of these species are provided in Figures 35.5 through 35.8. The most common practice used in developing pharmaceuticals is to evaluate ICH stages A (premating to conception) and B (conception to implantation) in a fertility study, with treatment of the female animals initiated 2 weeks before cohabitation and continuing through day 7 of gestation with a pregnancy evaluation usually around GD 13/14. Embryo–fetal toxicity studies treat through ICH stage C (implantation to closure of the hard palate; rats—days 6/7 through 17 of gestation). ICH stage C is also evaluated in a nonrodent species (generally the rabbit; treatment on days 6/7 through 19 of gestation) early in product development, although depending upon the proposed use of the agent, some investigators chose to delay this test until after the early clinical trials are completed (metabolism, kinetics, safety, and efficacy). Based on the proposed use of the agent, pre- and postnatal toxicity studies are conducted that evaluate ICH stages C (implantation to closure of the hard palate), D (closure of the hard palate to parturition; rats—day 17 through 22 of gestation), E (birth to weaning; rats—day 0/1 through 21 postnatal), and F (without drug exposure—weaning to sexual maturity; rats—day 22 to 60 postnatal).

General Procedures for Indirect Food Additives

The FDA *Toxicological Principles for the Safety Assessment of Food Ingredients* (*Redbook 2000*), last updated on July 2007,[216,256] is the new name for *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food* that was originally published in 1982 (*Redbook I*) and a draft revision was published in 1993 (*Redbook II*). Major changes were made in this revised guidance (*Redbook II*). This document provides guidance to industry and other stakeholders (e.g., academia, other regulatory groups) regarding toxicological information submitted to the Center for Food Safety and Applied Nutrition (CFSAN), Office of Food Additive Safety (OFAS) regarding food ingredients. It is a guidance document that is intended to assist in (1) determining the need for toxicity studies; (2) designing, conducting, and reporting the results of toxicity studies; (3) conducting statistical analyses of data; (4) the review of histological data; and (5) the submission of this information to the FDA as part of the safety assessment of food ingredients. The toxicity studies with female reproductive toxicity evaluations included in this guidance document are located in Section IV.C.9.a. *Guidelines for Reproduction Studies*, Section IV.C.9.b. *Guidelines for Developmental Toxicity Studies*, and Section IV.C.10. *Neurotoxicity Studies*, which contains *Developmental Neurotoxicity Study Design*.

General Procedures Specific to EPA OPPTS Protocols

Developmental toxicity studies are required in two species (one rodent and one nonrodent).[257] Treatment is administered from implantation to delivery (GDs 6 through 20 in rats and 6 through 29 in rabbits), with 20 pregnant animals per group assigned to study. It is acceptable to provide treatment throughout the entire gestation period (GDs 0 through 20 in rats and 0 through 29 in rabbits).

The EPA multigeneration (two-generation) protocol[258] has multiple endpoints, incorporating many endpoints traditionally performed in pharmaceutical development, although differing from the ICH guidelines in that the protocols are set, rather than open to scientific judgment regarding design (see Figure 35.9). Treatment of the parental generation (P_0/F_0 male and female rats) is initiated 10 weeks before mating and continues through a 3-week mating period (the male rats can be terminated after the cohabitation period). Treatment of the P_0/F_0 and F_1 generation male and female rats continues until termination. Additional endpoints assessed include estrous

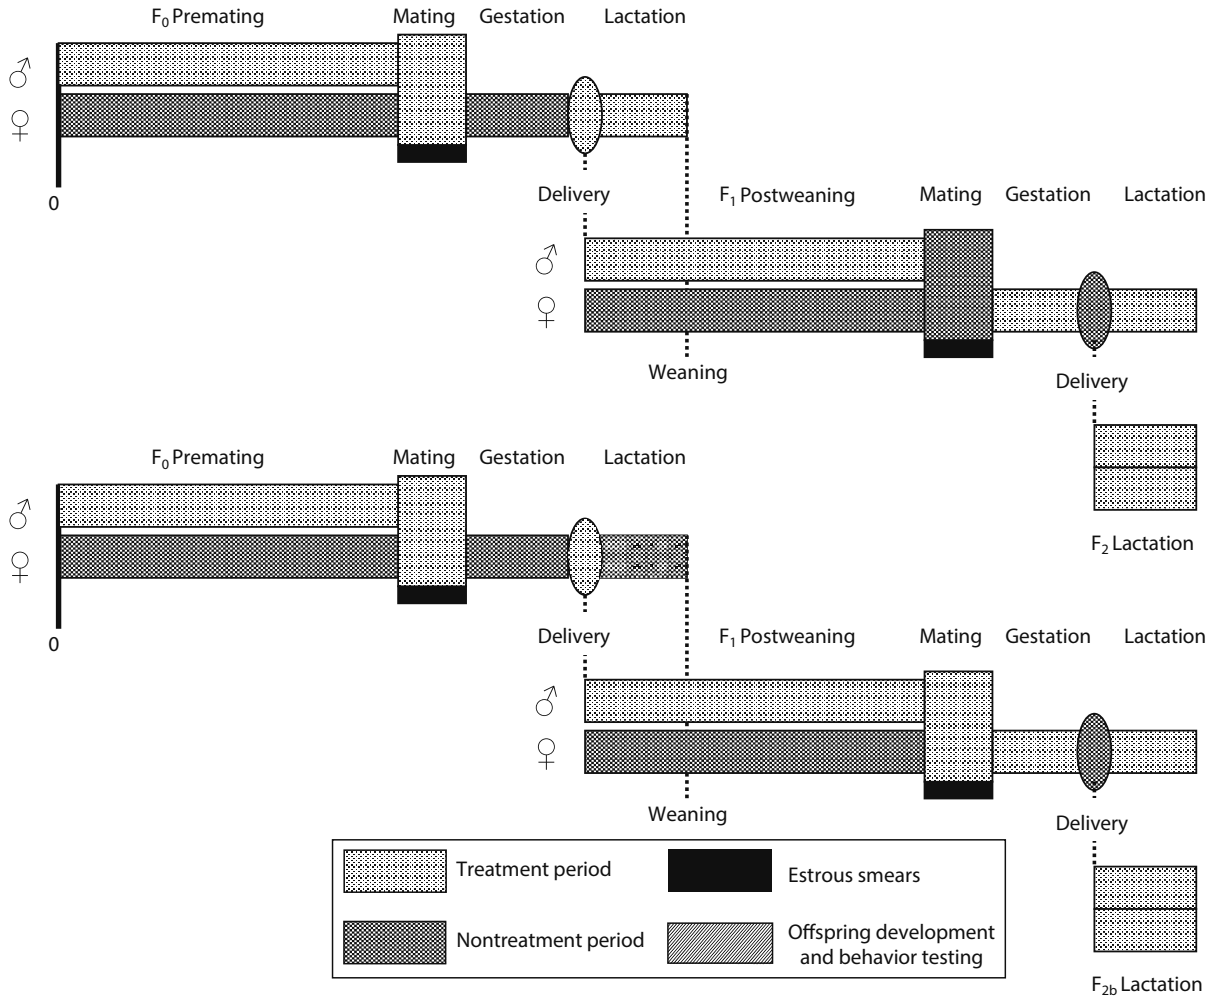

FIGURE 35.9 Two-generation reproduction study schematics (OPPTS 870.3800 and OECD 416).

cyclicity data (vaginal smears) for 3 weeks prior to mating, during mating, and at termination; sperm parameters (total number of sperm, percent of progressively motile sperm, and sperm morphology); developmental milestones (age of vaginal opening and preputial separation for the F_1 generation, anogenital distance for the F_2 generation, if triggered by a treatment-related effect on the sexual maturation of the F_1 generation); gross pathology and selected histopathology of weanlings; and adult organ weight data (uterus, ovaries, testes, one epididymis, including the total weight and cauda epididymal weight, seminal vesicles with coagulating glands and fluids, prostate, brain, liver, kidneys, adrenal glands, spleen, thymus, and all known target organs). Histologic evaluation of the ovary is to include a minimum of 10 sections, randomly selected from one completely sectioned ovary per female in the control and high-dosage groups. Examination of the intact epididymis is to include the caput, corpus, and cauda regions. For the F_1 generation, organ weight data are to be collected for one pup per sex per litter from all dose groups for the ovaries, testes, brain, liver, kidney, adrenal glands, spleen, thymus, and known target organs, with histopathology triggered by treatment-related effects in the F_1 high-dosage group histopathology.

The EPA developmental neurotoxicology protocol may be incorporated within the multigeneration study design or conducted separately. A potential schematic for this very complex study is presented as Figure 35.10. In this study, treatment occurs from implantation through postnatal development of the majority of the CNS (rats—GD 6 through lactation day 12), although treatment can be continued through lactation to day 21, when weaning occurs. Direct dosing of pups may be necessary when lactational exposure through the milk has either been documented as not occurring or is unknown.

REACH and the Extended One-Generation Study: The new European chemicals legislation REACH (Registration, Evaluation, and Authorization of Chemicals) has been estimated to require several million experimental animals until the year 2018, more than 60% of which will be necessary for reproductive and developmental toxicity testing.[259] Testing for REACH can only proceed after approval from the agency. Current OECD activities include the designing of an extended one-generation study, which is aimed at omitting the second-generation offspring whenever justified. The Agricultural Chemical Safety Assessment (ACSA) Committee of HESI (ILSI Health and Environmental Sciences Institute) protocol

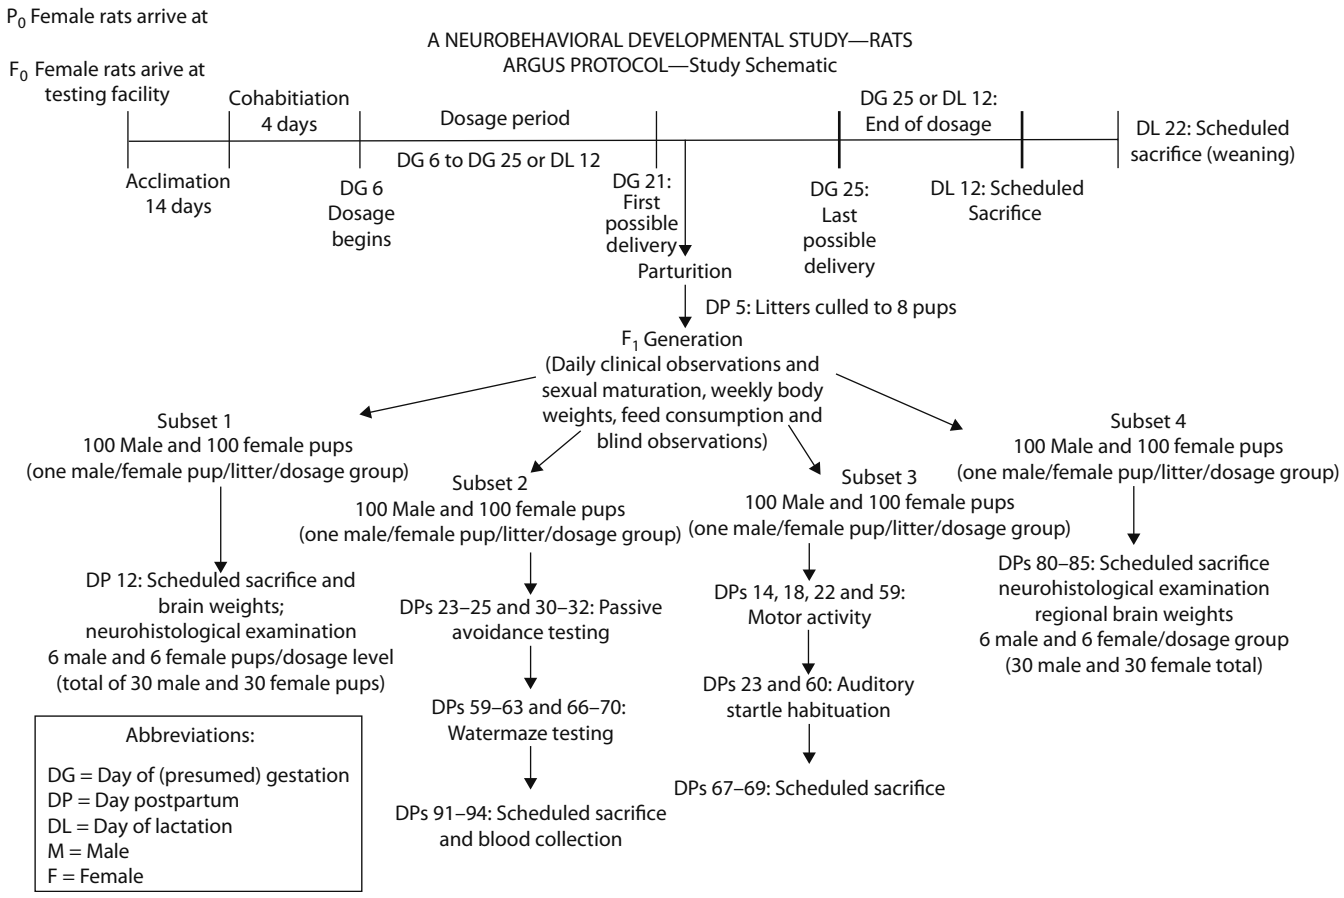

FIGURE 35.10 Neurobehavioral developmental toxicity study—rats.

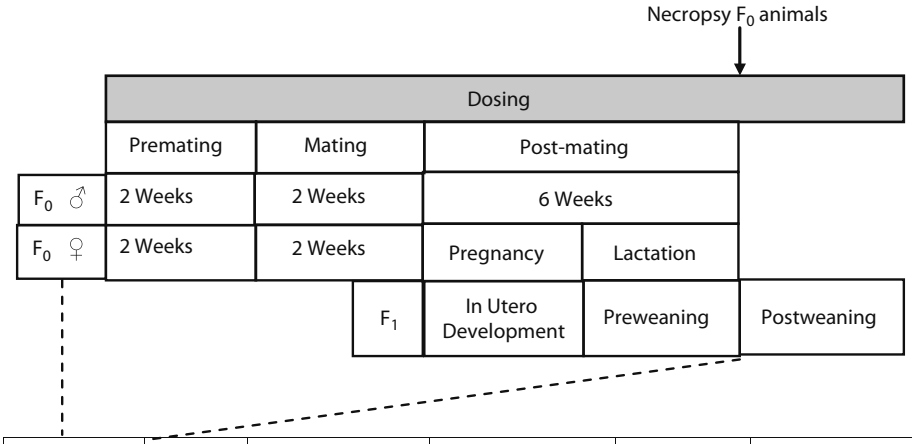
designed by Cooper et al.[260,261] was put forward as a replacement of the two-generation study. Proponents stated that it would significantly reduce animal use as well as cost and duration of the study. The Extended One-Generation Reproductive Toxicity Study Testing Guideline OECD 443 (July 2011) has been promulgated by the OECD, and it is similar to the Agricultural Chemical Safety Assessment (ASCA) protocol. The guideline could replace the current two-generation study and would not require mating of the animals of the second (F_1) generation and assessment of their reproductive performance unless triggered by study findings.

Young adult F_0 males would be treated for 2–4 weeks before pairing and young adult F_0 females treated for 2 weeks before pairing (see Figure 35.11). F_0 males are further treated at least until weaning of the F_1. They should be treated for a minimum of 10 weeks. Treatment of the F_0 females is continued during pregnancy and lactation until termination after the weaning of their litters (i.e., 8–10 weeks of treatment). Pups would be selected to form the second (F_1) generation, and these animals would be treated from weaning until 70 days of age. The F_1 Cohort 1 would be used to assess reproductive/developmental endpoints and could be extended to include an F_2 generation if the data warrant it. The F_1 Cohort 2 and 3 would be used to assess the developing nervous system and immune system, respectively. At this point, the study would be terminated unless there was a trigger to extend the study to include mating of the animals of the second (F_1) generation and assessment of their reproductive performance. There would be no routine testing of the reproductive performance of animals exposed as juveniles.

The *triggering signals* required and the importance of the assessment of the reproductive and developmental endpoints of the second (F_1) generation (as done in a two-generation study) are currently being debated.[262–264] There have been several reviews that are attempting to determine the relative importance of mating the second (F_1) generation versus the first (F_0) generation in identifying treatment-related adverse effects on reproductive performance. Decisions on whether to assess the second generation and to omit the developmental neurotoxicity cohort and/or developmental immunotoxicity cohort would also reflect existing knowledge for the chemical being evaluated, as well as the needs of various regulatory authorities. Additional information concerning this testing guideline can be found on the OECD website.[265]

General Considerations Regarding Reproductive/Developmental Toxicology Studies Conducted for Submission to Regulatory Agencies

These studies should be conducted in conformance with appropriate GLP regulations.[248–250,266,267] Whenever possible, the same species and strain of animal should be used



Parental Generation	Cohort	Designation	Animals/cohort	Sexual maturation	Approximate age at necropsy (weeks)
Target is 20 litters per group	1A	Reproductive	20 M + 20 F	Yes	13
	1B	Reproductive	20 M + 20 F	Yes	14 or 20 if assessed
	2A	Neurotoxicity	10 M + 10 F[a]	Yes	9
	2B	Neurotoxicity	10 M + 10 F[a]	No	3
	3	Immunotoxicity	10 M + 10 F[a]	Yes	8
	Surplus	Spares		No	3

[a] One per litter and representative of 20 litters in total where possible.

FIGURE 35.11 Extended one-generation toxicity study schematics.[340]

as tested in other toxicology studies and in the kinetics studies. The kinetics, pharmacological, and toxicological data should support the position that the selected species provides a model relevant for use in human safety assessment.

Reproductive toxicology studies are generally conducted in one species (usually the rat), with some subsegments (e.g., ovarian toxicity, testicular toxicity) obtained from companion subchronic studies in the same species and strain. Developmental toxicology studies are generally conducted in two species, one rodent (usually the rat) and one nonrodent (usually the rabbit). Each study usually includes a vehicle control group and three or more groups administered dosages of the test agent at arithmetic multiples of the highest clinical dosage. Ideally, the low dosage is a multiple of the highest clinical dosage, based on blood serum levels. Each group should include 16–20 animals or litters. It is axiomatic that animals should be at comparable ages, weights, and parity when assigned to a study.

Reproductive toxicology studies may be conducted by treating animals of only one sex and mating these animals with untreated animals of the opposite sex or by treating both male and female animals. A common refinement of the test is to use double-sized control and high-dosage groups during the premating period, with cross-mating of one-half of the animals in each dosage group, in order to determine whether the administration of the agent to animals of only one sex causes different effects from those observed when both sexes are administered with the agent.[244]

Positive control groups are not considered necessary when reproductive toxicology studies are conducted for regulatory use, because consistent sensitivity to xenobiotics has already been demonstrated in most laboratory species by historical experience and GLP compliance mandates training and expertise of personnel. However, historical control data of abnormalities in fertility, fecundity, fetal morphology, resorption, and consistency from study to study should be available for comparative use with any new study data. Historical data for common laboratory species are available from many published sources, as well as recent updates to the Charles River Historical Control Data (www.criver.com/sitecollection-documents/rm_rm_r_tox_studies_crlcd_br_rat.pdf) and the soon to be rolled out MARTA Historical Control Database (Personal communication with Dr. Hew (2012)), but the most relevant data are those generated at the testing facility in the same animal strains, using the same nomenclature and technical conditions.[268,269] A rule of thumb is that a positive control agent should be evaluated before conducting a new test paradigm or examining a new endpoint, to document appropriate training and expertise.

In general, regulatory studies require that the high dosage be maternally and/or developmentally toxic and that the low dosage should be a no-observable-adverse-effect level (NOAEL). In the past, depending upon the regulatory body, no more than 10% mortality and/or 10% reduction in maternal body weight gain were usually considered sufficient to identify a maternally toxic dosage. Conformance with these criteria and the associated testing of excessively high dosages resulted in both maternal toxicity and developmental toxicity.[270] In contrast, the ICH guidelines indicate that the high dosage should produce minimal maternal (adult) toxicity

and be selected on the basis of data from all available studies, including pharmacologic, acute, and subchronic toxicity and kinetic studies. These guidelines allow evidence of maternal toxicity to include reduced or increased weight gain, specific target organ toxicity, changes in hematology or clinical chemistry parameters, and exaggerated pharmacological response, which may or may not be reflected as marked clinical reactions (e.g., sedation, convulsions). Additional justification for high-dosage selection includes (1) physicochemical properties of the test substance or dosage formulation, which, in combination with the route of administration, can be additional justification for limiting the administered amount (generally 1–1.5 g/kg/day provides an adequate limit dosage); (2) kinetics, which can be very useful in determining exposure; and (3) a marked increase in embryo–fetal lethality in preliminary studies. Although often contested and infrequently pursued, the author's experience is that good science can also be used successfully to justify dosage selection and as a negotiating point with regulatory bodies.

Methods for Testing Reproductive/ Developmental Toxicity

According to the ICH S5(R2) document revised in November 2005, *Guideline for Industry, Detection of Toxicity to Reproduction for Medicinal Products*,[231] a reproductive and developmental toxicity testing regimen should be selected that would "allow exposure of mature adults and all stages of development from conception to sexual maturity. To allow detection of immediate and latent effects of exposure, observations should be continued through one complete life cycle, i.e., from conception in one generation through conception in the following generation." The document further suggests that an integrated test sequence can be subdivided into the following stages (see Figure 35.1):

- (Stage A): Premating to conception (adult male and female reproductive functions, development and maturation of gametes, mating behavior, fertilization)
- (Stage B): Conception to implantation (adult female reproductive functions, preimplantation development, implantation)
- (Stage C): Implantation to closure of the hard palate (adult female reproductive functions, embryonic development, major organ formation)
- (Stage D): Closure of the hard palate to the end of pregnancy (adult female reproductive functions, fetal development and growth, organ development and growth)
- (Stage E): Birth to weaning (adult female reproductive functions, neonate adaptation to extrauterine life, preweaning development and growth)
- (Stage F): Weaning to sexual maturity (postweaning development and growth, adaptation to independent life, attainment of full sexual function)

Nevertheless, in most cases, these six stages are assessed by means of just three studies: ICH 4.1.1. The Fertility and General Reproductive Performance Study (*Segment I*; Stages A to B); ICH 4.1.2. The Prenatal and Postnatal Study (*Segment III*; Stages C to F); and ICH 4.1.3. The Developmental Toxicity or Embryotoxicity Study (*Segment II*; Stages C to D). In addition, in recent years, increased emphasis has been placed on direct toxicity studies in juvenile animals[271,272] and developmental immunotoxicity.[273] All of these study types are discussed in some detail in other chapters in this book. Common protocols for use in evaluation of the various ICH segments are identified in Figures 35.5 through 35.8.

ICH Stage A

Premating to conception (reproductive functions in adult animals, including development and maturation of gametes, mating behavior, and fertilization).

Evaluation of the Ovary

Numerous articles,[274,275] chapters,[276–278] reviews,[86,279] and books[87,280] have been written concerning the ovary and ovulation, and a detailed description of ovarian histology and ovulation is beyond the scope of this chapter. The ovary serves a number of functions that are critical to reproductive activity, including ovulation of oocytes and production of hormones. The developing ovarian follicles produce estrogen, while the corpora lutea formed after ovulation produce progesterone. Delayed ovulation can alter oocyte viability and cause trisomy and polyploidy in the conceptus.[281–283] Altered follicular development, ovulation failure, or altered corpus luteum formation or function can result in disruption of cyclicity and reduced fertility. Therefore, significant increases in follicular atresia, evidence of oocyte toxicity, interference with ovulation, or altered corpus luteum formation or function should be considered adverse reproductive effects.

Ovarian Weight

Ovarian weights are recorded using the same techniques as those generally used for recording organ weights. The tissue should be trimmed and weighed close to the time removed from the animal, to avoid dehydration. An alternate method is to weigh the ovaries after trimming and fixation. Ovarian weight in the normal rat does not show significant fluctuations throughout the estrous cycle. However, persistent pathologies such as polycystic ovaries, oocyte depletion, decreased corpus lutea formation, luteal cysts, and altered pituitary–hypothalamic function, as well as reproductive senescence, may be associated with ovarian weight changes. Ovarian gross morphology and histology should be examined to detect alterations associated with ovarian weight changes.[284]

Follicle Number and Size

Methods described in the following can be used to quantify ovarian follicular development. Histopathological evaluation of the three major compartments of the ovary (i.e., follicular, luteal, and interstitial) plus the capsule and stroma should be performed to reveal possible toxic effects.[285–287] The U.S.

EPA OTTPS 870.3800 *Reproductive and Fertility Effects Guideline* and the Female Pubertal Assay[288] require a quantitative evaluation of the primordial follicle population of the ovary. A postlactational ovary should contain primordial and growing follicles, as well as the large corpora lutea of lactation. Ovarian histology, oocyte quantitation, and differential follicle count methodology have been described.[289] Ovarian follicles have been classified into 10 categories,[48] and these categories have been reduced into three classes for the purposes of quantification: (1) primordial follicles, (2) growing follicles, and (3) antral follicles. The primordial follicles can be described as early with the oocyte having no surrounding granulosa cells or late with the oocyte having a single layer of surrounding granulosa cells. The growing follicle can be described as early with the oocyte that is starting to enlarge and the surrounding cells having formed two layers (granulosa and theca) or late with the enlarging oocyte and multiple layers of granulosa and thecal cells but with no evidence of antral formation. The antral follicle can be described as early with a large oocyte, multiple cell layers, and a developing cavity (antrum), while the late antral (Graafian) follicle has mature multiple layers of granulosa and thecal cells and a large antrum.

Routine histopathological examination should detect qualitative depletion of the primordial follicle population; however, current reproductive study guidelines require a quantitative evaluation of primordial follicles of the F_1 females. The number of animals, ovarian section selection method, and section sample size should be statistically appropriate for the evaluation procedure used. The guidelines cite ovarian follicular-counting methodologies[60,290,291] that use a differential count of the primordial follicles, growing follicles, and antral follicles. The current EPA Multigeneration Protocol modification[235] requires ovaries from 10 randomly selected females from highest dosage and control groups. Five 5-µm ovarian sections are made from the inner third of each ovary, at least 100 µm apart. The number of primordial follicles, growing follicles, antral follicles, and corpora lutea is counted from the highest treatment and control groups' ovaries. If statistically significant differences are found, the next lower treatment group is evaluated.

The Female Pubertal Assay[288] requires ovarian histology following hematoxylin and eosin (H&E) staining that includes an evaluation of follicular development (including presence/absence of tertiary/antral follicles, presence/absence of corpora lutea, changes in corpus luteum development, and changes in the number of both primary and atretic follicles) in addition to any abnormalities/lesions, such as ovarian atrophy. Five random sections are evaluated, using the method of Smith et al.[292]

The Society of Toxicological Pathology's Position Paper (2005)[59] on ovarian follicular counting stated that the publications by Bolon et al.[290] and Bucci et al.[60] provided the most thorough comparisons of follicle-counting techniques in mice. These follicular-counting methods have been adopted and/or modified for use as first-tier screening methods in some regulatory guidelines for reproductive toxicity studies. A current proposal for assessing the ovarian histology and counting ovarian follicles (D. Creasy, personal communication, 2011) is as follows:

1. One ovary is fixed in 10% neutral buffered formalin.
2. The middle third of the ovary is sampled and embedded in paraffin.
3. Five-step serial sections at least 100 microns apart are mounted on a slide and stained with proliferating cell nuclear antigen (PCNA) (to visualize the primordial follicles).[293] PCNA is preferred over routine H&E stain.
4. The ovarian sections are qualitatively evaluated for follicular development (including presence/absence of tertiary/antral follicles, presence/absence of or changes in corpora lutea development) in addition to any abnormalities/lesions, such as ovarian atrophy.
5. Quantitative analysis of the number of primordial and primary follicles (follicles with intact oocytes surrounded by a single layer of granulosa cells) are made and recorded.

Differential follicular counts are associated with age, number of animals evaluated, number and location of the ovarian sections, number of sections per ovary, section thickness, differences between evaluators, and the criteria for defining primordial follicles. Ovarian follicle count appears to be a more sensitive endpoint than ovarian weight. In 18 Reproductive Assessment by Continuous Breeding studies using Sprague-Dawley rats,[292] the number of small follicles counted had a remarkably wide variation, ranging from 147 ± 57 to 556 ± 144, and another investigator reported 301 ± 13 small follicles.[87] A review of follicle count historical control data in rats[294] suggests that (1) with a large number of animals, there is relatively good replication within a generation (*when evaluated by the same person*); (2) there is great variability within individual ovaries and sections; (3) random selection of ovarian sections has a high probability of biasing effects; (4) ovarian follicle counts do not appear to be correlated with either ovarian weight or body weight at termination; and (5) ovarian follicle counts should not be the sole endpoint used in risk assessment. However, notwithstanding the great variability between reported values, a detectable decrease in follicle count in a treated group when compared to the control group is considered an adverse effect, because no recovery is possible.

Corpora Lutea Number

The corpus luteum is a transitory endocrine organ formed from the thecal and granulosa cells of the postovulatory follicle.[295] Progesterone is the major hormone produced by the corpus luteum and is necessary for implantation and the maintenance of pregnancy. Each corpus luteum appears as a round, slightly pink, discrete swelling on the surface of the ovary. Corpora lutea can be counted with the naked eye or under a dissecting microscope to determine the number of eggs ovulated. The number of corpora lutea should be

recorded for each ovary. In a litter with no obvious signs of resorption, the number of corpora lutea should be equal to or exceed the number of total implantation sites. For partially resorbed litters, the number of corpora lutea may actually be less than the total number of implantations. When some of the corpora lutea are no longer required to support the remaining conceptuses, some of the corpora lutea involute to become corpora albicantia. However, the concordance between the number of corpora lutea that involute and the number of resorbed implants is not precise. Corpora lutea count either can be discounted (excluded), when the count made is less than the number of implants, or be set to correspond to the number of implants to correct for involuting corpora lutea in partially resorbed litters. The method of handling this issue should be described in the Standard Operating Procedure.

The number of corpora lutea can be affected by many factors, including enhanced ovarian atresia, injection of hormones, a procedure common in mating rabbits; handling, especially in reflex ovulators; and litter size and hormonal feedback mechanisms, some of which are species-specific.[296,297] The corpora lutea count is used in determining pre- and postimplantation losses. Identification of preimplantation loss on the basis of comparison of the number of implants at Caesarean sectioning of the dams is often quite imprecise, especially in mice and rabbits. Generally, in these types of studies, comparison of litter sizes is a more representative indicator of preimplantation loss. As regression of the corpora lutea occurs during lactation, inclusion of this parameter in postlactational evaluations is unnecessary. Even though imprecise, a reduction in the number of corpora lutea or an increase in the pre- and/or postimplantation loss should be considered an adverse reproductive effect.

Hormone Integrity and Function

Sexual maturation begins in the hypothalamic–pituitary–ovarian (HPO) axis, leading to the development of female secondary sex characteristics and fertility. A complete discussion of hormones involved with ovarian function is beyond the scope of this chapter. However, several review articles[298–300] are available. The interrelationships within the HPO axis are already functional during gestation. The basic mechanisms involved in the progression of sexual maturation are conserved across most species. Many of the endocrine-mediated events that are involved in this progression in the rat are similar to those of other mammalian species, including humans. For example, the control of GnRH, the release of gonadotropins from the pituitary, and the steroid positive and negative feedbacks are relatively consistent.[301]

The three primary controllers in the HPO axis are as follows: (1) the neurosecretory neurons within the hypothalamic arcuate nucleus that produce GnRH, (2) the pituitary gonadotropes (which secrete LH and FSH) and lactotropes (which secrete prolactin [PRL]), and (3) the ovarian tissue secreting estradiol and inhibin (granulosa cells of the follicle) and progesterone (the corpora lutea). Germ cells and gonadotropins are not necessary for the development of the female genital tract. Puberty coincides with the maturation of the HPO–uterine axis, as does the onset of vaginal opening (described earlier), ovulation, and estrous cycles. Vaginal opening and vaginal cornification are dependent on increased estrogen levels. Ovulation and estrous cyclicity are dependent on increasing estrogen but are also a function of the developing HPO axis.

Female reproductive cycles are a manifestation of complicated endocrine, paracrine, and autocrine hormonal positive and negative interactions between and within the hypothalamus, pituitary, ovary, and uterus. Sampling of blood for female hormone level determinations must take into account the pulsatile nature (within hours), the diurnal nature (within the day), and the cyclical nature (usually over 3–5 days in rodents) of the female reproductive hormones. A detailed description of the hormonal activity during the estrous cycle is beyond the scope of this chapter [302]; however, there are numerous reviews.[76,303–305]

While numerous hormones and other factors are involved with the HPO axis, few preclinical toxicology studies require the evaluation of hormones. Direct measurements of hormone levels are usually second-level evaluations. These can most effectively be performed using commercially available antibody kits or by sending samples to contract analytical laboratories for evaluation.

Evaluation of the Uterus

Uterine Weight

Uterine weight measurements are a historic method of measuring potential estrogenicity of a test material. Uterine weight fluctuates throughout the estrous cycle, peaking at proestrus when the uterus is distended with watery fluid (sometimes misdiagnosed as hydrometra) in response to increased estrogen secretion. Compounds that inhibit steroidogenesis and cyclicity can cause the uterus to become small and atrophic, thereby decreasing the uterine weight. Uterine weight change has been used as a basis for comparing relative potency of estrogenic compounds in bioassays.[306] Both juvenile[289] and ovariectimized[307] models are used, with the intact model demonstrating both primary and secondary effects and the ovariectimized model identifying uterine-specific effects. The text within the uterotrophic assay guideline fully describes the methodology for the dissection and measurement of uterine weight.

Regardless of the duration of the treatment period, responses can vary with the strain, source, and specific population and age tested, requiring characterization of historical data at the testing laboratory. The common use of limited numbers of animals (10 and 6 animals per group in repeated-dose toxicity and uterotrophic studies, respectively) often results in statistical significance between groups when outlier values (increased and reduced uterine weights) are included, with inappropriate identification of false positives and negatives.[308] However, because of the sensitivity of the assay, the screen is a good predictor of absence of effect. When a positive effect is observed, it should be further characterized. When uterine weights are evaluated in animals in subchronic or chronic tests, it is helpful to identify the estrous cycle stage shortly before sacrifice, as cyclicity greatly affects uterine

weight. The estrous stage identified from a vaginal lavage and the uterine estrous stage identified by histopathology will differ by approximately 1/2 day.

Note: The oviducts and vagina are not routinely weighed in reproductive toxicity studies. The oviductal weight fluctuates depending upon the stage of the estrous cycle. The oviductal lumen contains a variable amount of fluid, which is greatest at metestrus, the period of ovulation.[309] Gross evaluations can be of value in detecting morphologic anomalies, such as agenesis and segmental aplasia. Vaginal weight changes usually parallel uterine weight changes during the estrous cycle, although the magnitude is less. The vaginal and cervical epithelia show cyclic changes in morphology and thickness associated with stages of the estrous cycle.

Evaluation of Estrous Cycling

Reprotoxicity screening studies are usually performed in rodent species, with the female animals treated for the first 14 days before cohabitation and then until mating occurs. Ideally, sexually mature female rodents are evaluated for estrous cycling[77] for 14 days before treatment, to establish a baseline for regularity of cycling, and animals that irregularly cycle should be excluded from evaluation before the treatment phase. Animals housed in the same room tend to have synchronous estrous cycles, with resultant cyclic matings.

Vaginal lavage for the determination of the stage of estrous can be performed at any time of the day; however, it is important that the samples be collected at approximately the same time each day over the course of a study. A pre- and post-check of the saline should be made. (*Note*: If glass pipettes are used, the rubber bulbs can be saved and washed for future use, while the glass stems should be discarded after each sampling. If plastic pipettes are used, the pipettes should be discarded following each sampling. Dropping pipettes should be held with the tip pointing down whenever they contain a vaginal lavage or saline sample, to avoid contaminating the bulb. Contaminated bulbs should be discarded.)

The female rat is removed from the cage, and her identification is verified. One or two drops (approximately 0.25 mL) of physiological saline are drawn into a new, clean dropping pipette, and the tip of the pipette is gently inserted into the vaginal canal. The pipette bulb is firmly but gently depressed to expel the saline into the vagina. The saline is gently drawn back into the dropping pipette, and the pipette is removed from the vaginal canal. If the flush is very clear, the lavage should be repeated. As previously mentioned, care must be taken not to insert the tip too far into the vaginal canal, which can result in pseudopregnancy. The animal is returned to its cage. The contents of the pipette are then delivered onto either (1) a clean glass slide or (2) a ring slide containing designated areas for the placement of each sample (vaginal smear). Each slide should be numbered, the top and bottom of each slide clearly identified, and a corresponding record made, indicating the animal number and location for each vaginal smear. Technicians should record the date, the start and end times of sample collection, and their initials on appropriate forms. All slides should be handled carefully to avoid mixing vaginal lavage samples from different animals. If samples become mixed, they are discarded, and the sampling procedure is repeated for those animals. The smear of the vaginal contents is then examined (wet and unstained) by using a microscope at 100–200×.

The cellular characteristics of vaginal smears reflect structural changes of vaginal epithelium and follow a predictable course during the estrous cycle. The stage of the estrous cycle is determined by recognition of the predominant cell type present in the smear at each daily evaluation. An estrous cycle in rats and mice is typically 4–5 days and may be influenced by multiple factors, including light, temperature, humidity, noise, nutrition, and social relationship. In general, cycles are more easily influenced in mice than in rats.

Cycling changes are usually divided into four stages: estrus, metestrus, diestrus, and proestrus (Figure 35.12). Estrus lasts approximately 10–15 h in rats and approximately 21 h in mice; it is the only stage in the cycle when the female will copulate with the male. As shown in Figure 35.12A, cornified squamous epithelial cells are the dominant cell type in the vaginal smear and are few in number or absent. The squamous epithelial cells vary from flat (occurring singly during early estrus) to curled (occurring in large sheets in late estrus). Metestrus lasts from 6 to 14 h in rats and approximately 22 h in mice. It is characterized by the presence of numerous cornified epithelial cells together with irregularly shaped nucleated epithelial cells. Leukocytes are present in considerable numbers (Figure 35.12B). Diestrus lasts 60–70 h (approximately 1/2 of entire cycle) in rats and 22–33 h in mice. It is dominated by leukocytes, although some nucleated epithelial cells may be present. In late diestrus, the nucleated epithelial cells become more spherical, and occasional cornified cells and erythrocytes are present (Figure 35.12C). Proestrus has a 12–18 h duration in rats and approximately 21 h in mice and denotes the beginning of the next cycle. The vaginal smear is dominated by numerous nucleated epithelial cells, usually arranged in grape-like clusters (Figure 35.12D).

Measurement of estrous cycle length is done by selecting a particular stage and counting until the recurrence of the same stage (usually day of first estrus, day of first diestrus, or day of proestrus). The estrous cycle lengths should be calculated for each female. It is often easier to visualize the estrous cycle by plotting the data (e.g., Figure 35.12E). The group mean estrous cycle length should be calculated, and the number of females with a cycle length of 6 days or greater should be calculated. There is a general consensus that a single cycle with a diestrus period of 4 days or longer or an estrus period of 3 days or longer is aberrant. Cycles that have three or more days of estrus during most of the cycles are classified as showing *persistent* estrus. Cycles that have four or more days of diestrus during most of the cycles are classified as showing *persistent* or prolonged diestrus. Pseudopregnancy is a persistent diestrus (approximately 14 days in duration). Constant estrus and diestrus, if observed, should be reported. Persistent diestrus indicates at least temporary and possibly permanent cessation of follicular development and ovulation,

and thus at least temporary infertility. Anestrus or persistent diestrus may be indicative of toxicants that interfere with follicular development, that deplete the pool of primordial follicles, or that perturb gonadotropin support of the ovary. The ovaries of anestrous females are atrophic, with few primary follicles and an unstimulated uterus. As expected, serum estradiol and progesterone are abnormally low. The presence of regular estrous cycles after treatment does not necessarily indicate that ovulation occurred, because luteal tissue may form in follicles that have not ruptured. However, that effect should be reflected in reduced fertility. Altered estrous cyclicity or complete cessation of vaginal cycling in response to toxicants should be considered an adverse reproductive effect. Subtle changes of cyclicity can occur at doses below those that alter fertility. However, subtle changes in cyclicity without associated changes in reproductive or hormonal endpoints would not be considered adverse.

Evaluation of Mating Behavior and Fertilization

Techniques for evaluating mating performance and fertility are used both for impregnating animals for use in developmental toxicity studies and when mating performance is evaluated in a reproductive toxicology evaluation. In the latter case, treatment is usually begun in the female animal at least 2 weeks before cohabitation and continued until necropsy. The timing of necropsy is dependent on the endpoint(s) to be evaluated, occurring at some interval within the gestation period. If the purpose of the screen is to observe mating behavior and any associated impairment of fertility or implantation, necropsy is usually performed at 13–15 days of presumed gestation. For alternate uses, treatment continues to the day before termination, either approximately 1 day before expected parturition, with Caesarean sectioning and evaluation of uterine contents, or at completion of a 21 day lactation period, with evaluation of uterine contents and litter sizes and viability.

In general, mating ratios of one male per female are ideal for use in rodents, because it allows easy identification of the sire and dam, history of reproductive performance, and excludes potential reductions in performance associated with excess use of the same male. The most effective way to produce pregnancies is to pair the animals when the female is in proestrus (usually late in the afternoon, dependent upon the light cycle used), as it will soon enter estrus and be receptive. However, assuming a large population of animals is available (approximately 125 breeder males and 125 virgin females), sufficient numbers (approximately 100 mated females) can be obtained within 4–5 days by simply cohabiting the entire

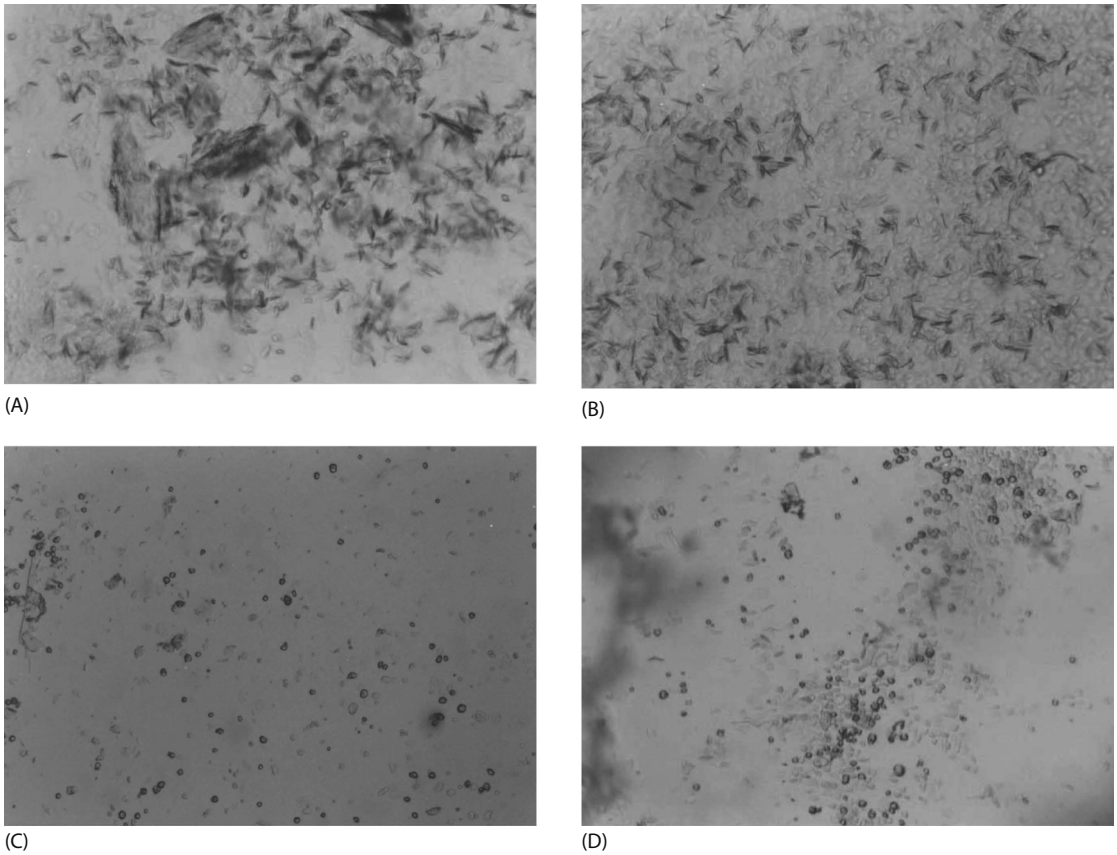


FIGURE 35.12 (A) Estrus cycle stage 1: estrus. (B) Estrus cycle stage 2: metestrus (C) Estrus cycle stage 3: diestrus. (D) Estrus cycle stage 4: proestrus.

(*continued*)

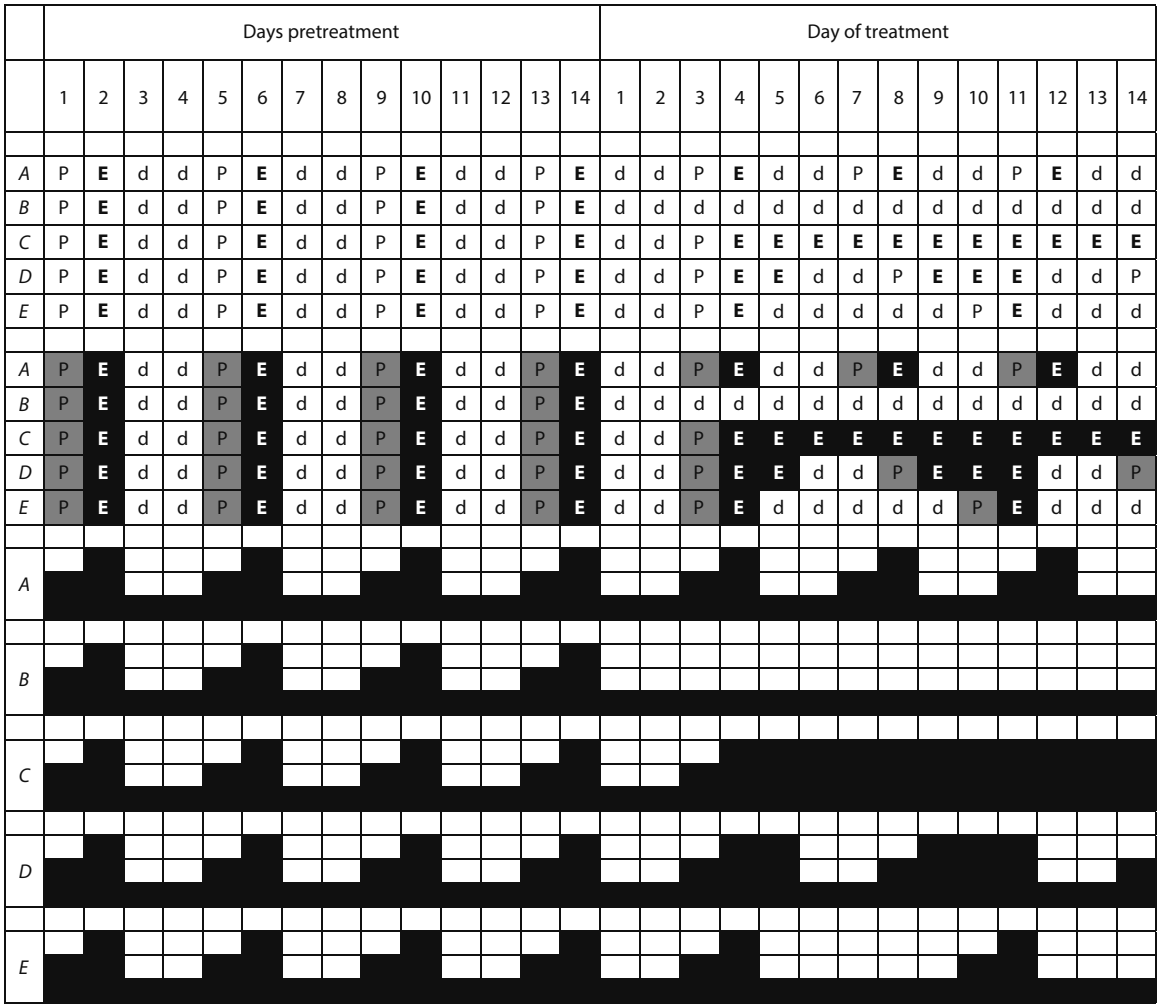

FIGURE 35.12 (continued) (E) Graphical display of vaginal smear data. Three methods of depicting the estrus cycle data are presented in the following. The first method is presenting the data on a spreadsheet with the estrus in bold letter. The second method is shading the estrus and proestrus. The third method is using stacked bars (estrus, 3 bars; proestrus, 2 bars; and diestrus, 1 bar). Cycle A represents a normal cycle. Cycle B shows the pattern in constant diestrus or pseudopregnancy. Cycle C shows constant estrus. Cycle D shows persistent or prolonged estrus. Cycle E shows persistent or prolonged diestrus. (From Parker, R.M., Testing for reproductive toxicity, in: Hood, R.D. (ed.), *Handbook of Reproductive Toxicology*, 3rd edn., CRC Press, Boca Raton, FL, 2011.)

population simultaneously. Timed-mated female rats can also be purchased from animal vendors. The pregnancy rate for timed-mated females is greater than 95%, which is similar to in-house breeding colonies.

Although estrous cycling is not usually evaluated when animals are bred for use in developmental toxicity studies, this parameter is very helpful in identifying potential effects in female animals in reproductive toxicity evaluations, when perturbations in estrous cycling may predict reduced female receptivity and fertility. Male mating performance should be considered in evaluation of any observed effects, as altered estrous cycling during cohabitation and reduced female fertility may reflect male-mediated effects (e.g., naivete, general health, altered/reduced mating performance, testicular lesions, and abnormal sperm characteristics).

Rats and mice generally have multiple intromissions in one copulatory interval. If there is an indication that aberrant copulatory behavior may be present, the animals can be observed (videotaped) and graded for the number of copulations, number of intromissions, duration of intromission, as well as expected female receptivity (lordosis). Mating (copulation) is confirmed by the presence of spermatozoa in the contents of the vaginal smear and/or the observation of a copulatory plug in situ; these findings designate day 0 of presumed gestation. It is prudent to note when less than 10 sperm are present in a smear, because this information can assist in interpreting mating and fertility data. For mice, the presence of an expelled copulatory plug in the pan is often considered an adequate proof of mating, although only approximately 85% of the mice identified in this fashion actually become pregnant.

Female mating performance can be measured by several endpoints. These include identifying the number of days in cohabitation before mating (this value can be adjusted to the number of days after the first estrus), the number of mated (inseminated) female animals per group, and pregnancy

incidences based on the total population per group (% pregnant/number cohabited) and on the inseminated population per group (% pregnant/number inseminated). These formulas can be found in several textbooks.[94,285] The number of females assigned to an alternate male and the duration of cohabitation (routinely 7 days) with the second male should always be identified. Care must be taken to ensure that all parameters based on group values are calculated on the basis of observations for the initial cohort pair, and data regarding any subsequent matings should be identified as such.

Vendor-Supplied Timed-Pregnant Rabbits

Vendors (e.g., Covance Research Products, Denver, PA) offer timed-mated rabbits and have done extensive studies with numerous laboratories that show the fertility rate based on gestational day of shipment. Unless the facility doing the study is in close proximity to the vendor, it is not possible to measure food consumption from GD 0. The advantage of purchasing timed-mated rabbits is eliminating the upkeep of a large number of bucks and the technical time expended for mating procedures and recordkeeping, but there is no on-site quarantine period prior to GD 0 with these animals. Usually, the period between the arrival of the purchased timed-mated does on GD 1, 2, or 3 and the first data collection (GD 4) is considered the stabilization (quarantine) period. During this period, technicians monitor the does for viability and observe feed consumption. Body weights and clinical observations as well as beginning food consumption measurements occur on GD 4.

Artificial Insemination Procedures (Rabbits)

Artificial insemination is an alternate method of mating rabbits. It has the advantages of better control over fewer male breeders (up to five females may be inseminated with one sample) and reductions in possible cross-infection and technical time requirements. Another advantage of artificial insemination is that the semen sample can be evaluated for sperm count, viability, and motility before insemination to ensure that an optimal sample is introduced into the female. However, the downside is a slightly reduced pregnancy rate and limited genetic background of the sires, although this can prove a benefit, should a malformation be traceable to the sire. The methodology of semen collection and evaluation is not a subject for this chapter and can be found in the literature. The standard sperm concentration used for insemination is 6.0×10^6 spermatozoa per 0.25 mL. Saline is then used to dilute the semen sample.

Before insemination, each doe is given an intravenous injection (ear vein) of HCG (20–25 U.S.P. units/kg HCG), to induce ovulation (larger dosages tend to result in superovulation and do not increase fertility or litter sizes). At this concentration, each injection volume is 0.10 mL/kg of body weight (e.g., a rabbit weighing 5.0 kg is administered 0.50 mL for a dosage of 20 U.S.P. units/kg, which is a total dose of 100 U.S.P. units/animal).

Approximately 3–6 h after HCG-induced ovulation of the female rabbits, each doe is inseminated with approximately 0.25 mL of diluted semen. The technician gently restrains the doe with the head downward and facing away from the technician. A glass insemination tube (with an inside diameter of 4 mm, length of 7.5 in.) that is bent at a 45° angle 1.5 in. from one end is used; a rubber bulb covers the opposite end. The tube is filled to the bend with the diluted semen (approximately 0.25 mL). The tail is pulled, exposing the vulva, which should appear pink and glistening (evidence of receptivity). The semen-filled glass tube is held with the short end of the glass tube parallel to the rabbit's spine and guided into the vagina to the depth of the bend (at the pelvic brim). The tube is inserted until resistance is no longer felt, because the tube has passed into the cervix. The tube bulb is squeezed, depositing the dilute semen, and the tube is then gently rotated 90°–180° (stimulating the cervix) and subsequently removed (continued squeezing of the bulb occurs during removal). If the doe urinates during insemination, another semen sample is injected approximately 30 min later. The day of artificial insemination is usually designated GD 0. One major consequence of hormonally priming the female (necessary for artificial insemination) is the possibility of *superovulation*. A large number of eggs can be ovulated, but many are not implanted, resulting in a large percentage of preimplantation loss for this animal.

ICH Stage B

Conception to implantation (reproductive functions in the adult female, preimplantation, and implantation stages of the conceptus).

Evaluation of Preimplantation Loss and Impaired Implantation

This process is based on comparison of the number of corpora lutea with the number of uterine implantation sites identified at Caesarean sectioning of the dams. As previously described, this parameter is highly variable and tends to be of minimal value in mice, rabbits, and guinea pigs and is highly associated with fetal survival and hormonal feedback in rats.

ICH Stages B, C, and D

- B: Conception to implantation—reproductive functions in the adult female and preimplantation and implantation stages of the conceptus
- C: Implantation to closure of the hard palate—adult female reproductive functions and development of the embryo through major organ formation
- D: Closure of the hard palate to the end of pregnancy—adult female reproductive function, fetal development and growth, and organ development and growth

Caesarean-Sectioning Procedures

When the purpose of the reproductive or developmental toxicity study is to screen for preimplantation loss and early implantation, the animals are killed near the beginning of the fetal period, as this allows easy identification of viability,

based on a beating heart. In a full developmental toxicity screen, the animals are killed on the day before or the day parturition is expected, to preclude effects associated with delivery complications (e.g., prolonged gestation and associated pup mortality and maternal cannibalization of stillborn or malformed pups). Regardless of the day of gestation, balanced termination of animals across groups should occur, to preclude differences associated with gestational ages. Termination of large populations of animals on the day parturition is expected tends to result in some dams delivering litters. This is particularly common in mice and hamsters and occurs occasionally in rabbits. Such events produce complications in data capture because the animals can be included in some analyses (e.g., pregnancy incidence, implantation numbers), but should be excluded from others (e.g., fetal body weights, fetal ossification site observations). One benefit of termination of the dam on the day parturition is expected is that there is less variability in the degree of skeletal ossification. General practice is to terminate mice, rats, rabbits, and hamsters on days 18, 20 or 21, 29, and 15 of gestation, respectively.

Gross Necropsy of Maternal Animals

Euthanasia of the rodent dams is easily accomplished by asphyxiation with carbon dioxide gas, and animals are terminated at intervals, ensuring that the time between death and necropsy is no more than 20 min. After external examination, the animal is placed on its dorsal surface and an incision made through the skin and/or musculature, extending from the inguinal area to the anterior portion of the neck. The abdominal viscera are exposed by making an incision through the abdominal muscles and peritoneum up to the sternum. The thoracic viscera are exposed by making an incision along one or both sides of the sternum up to the level of the clavicles.

Gross examination of the thoracic, abdominal, and pelvic viscera of the dam and retention of gross lesions in neutral buffered 10% formalin is a standard procedure that often provides evidence of maternal effects. When required, the brain may also be examined. In some cases, target organs, for example, liver, kidneys, and brain, are weighed and retained for further evaluation. It is also common to collect maternal blood, placentas, and embryos or fetuses for use in pharmacokinetics evaluations at Caesarean sectioning. Obviously, data from nonpregnant animals should be excluded in the pharmacokinetics studies relevant to pregnancy. According to present ICH guidelines, pharmacokinetic studies should be conducted in pregnant animals to determine if pharmacokinetic differences occur in the pregnant state versus the nonpregnant state and whether the fetus is exposed to appreciable amounts of the test material. These studies are usually conducted twice (first and last dosage) during pregnancy in rats and rabbits and are frequently performed in satellite animals or as separate studies, in order to preclude the occurrence of developmental abnormalities that may be associated with the stress of multiple blood collections and/or unusually high dosages of test material in the dams assigned to full reproduction or developmental toxicity studies. Although it is occasionally appropriate to perform detailed kinetics studies, such is not usually done. Common practice in the toxicokinetics animals is to identify only pregnancy (presence of live conceptuses), to avoid potential legal or liability actions based on the identification of possible fetal malformations associated with nondrug-related manipulations of the dam.

Evaluation of Ovaries and Uterus

Evaluation of the uterus and its contents can be performed at any time during the gestation period, depending upon the purpose of the evaluation. The uterus with attached ovaries is removed from the abdominal cavity and placed on a dissection blotting paper. The number of corpora lutea in each ovary is counted (with ovaries attached to oviduct), and the number is compared with the number of implantation sites, which can be identified through the uterine wall. Figure 35.13A and B show rat and rabbit ovaries with corpora lutea, respectively. The uterus of female rodents that do not appear pregnant can be examined effectively by pressing the uterus between glass plates and examining it for the presence of implantation sites or by staining it with ammonium sulfide.[310]

Evaluation of Uterine Weight

When a uterine weight is desired, the right ovary is removed, and the left ovary remains on the oviduct of the uterine horn (for identification of right and left uterine horns). An alternate method is to remove both ovaries and attach a hemostat (weight tared before weighing) to the right uterine horn for identification. Care is taken throughout the process to not cut the uterus or express any fluid. The same procedure can be used to evaluate nonpregnant uterine weights of rats or mice used in assays for estrogenicity, as described previously.

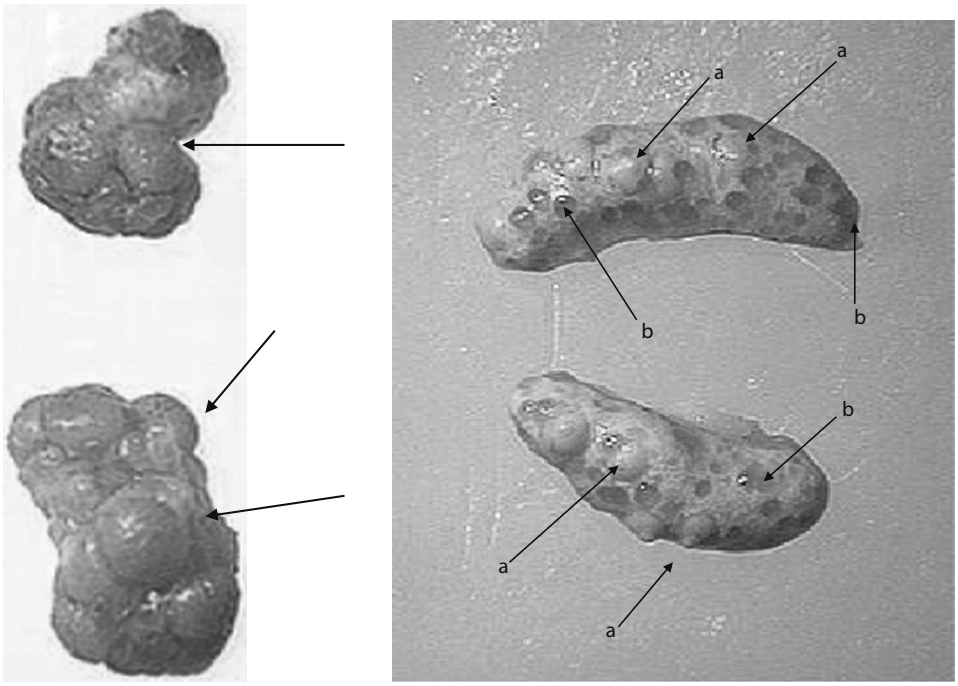
Evaluation of Uterine Contents

After weighing, the uterine horns are opened along the greater curvature, and the number and distribution of implantation sites are recorded (see Figure 35.14A and B). Each implantation site is consecutively numbered in both uterine horns, beginning with the ovarian end of the right horn and counting toward the cervix, and continuing with the ovarian end of the left uterine horn and again counting toward the cervix. Each implantation site is described as follows.

Early or Late Resorption

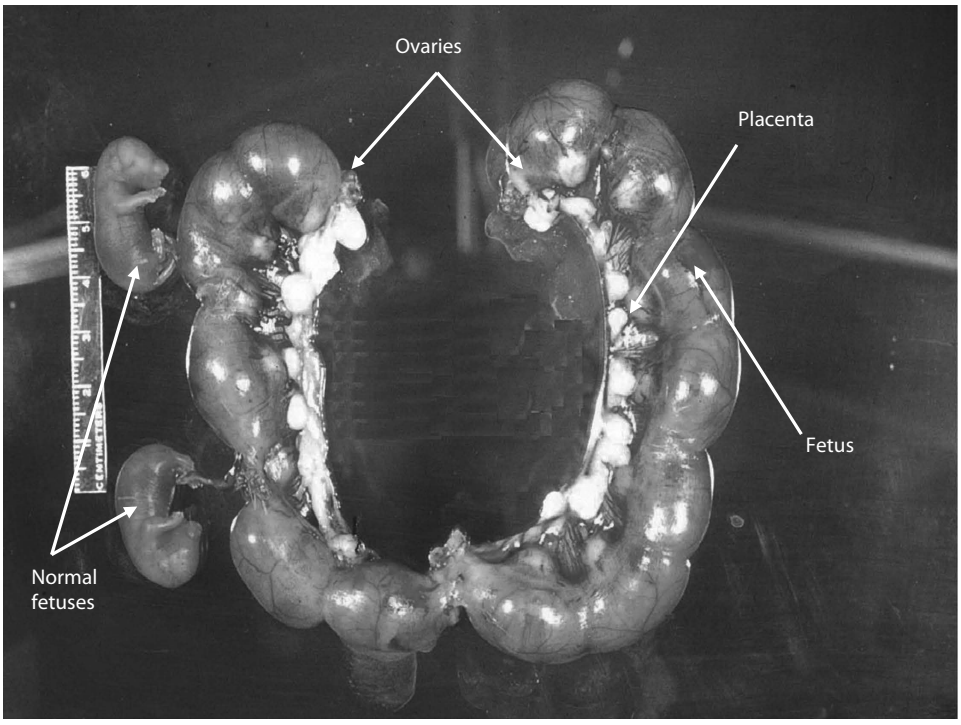
An implanted conceptus that is undergoing autolysis is termed a resorption.

- An *early resorption* is defined as a conceptus that has implanted but has no recognizable embryonic characteristics evident upon examination. An early resorption is usually visualized by ammonium sulfate staining or by observation through pressed glass plates.



(A) (B)

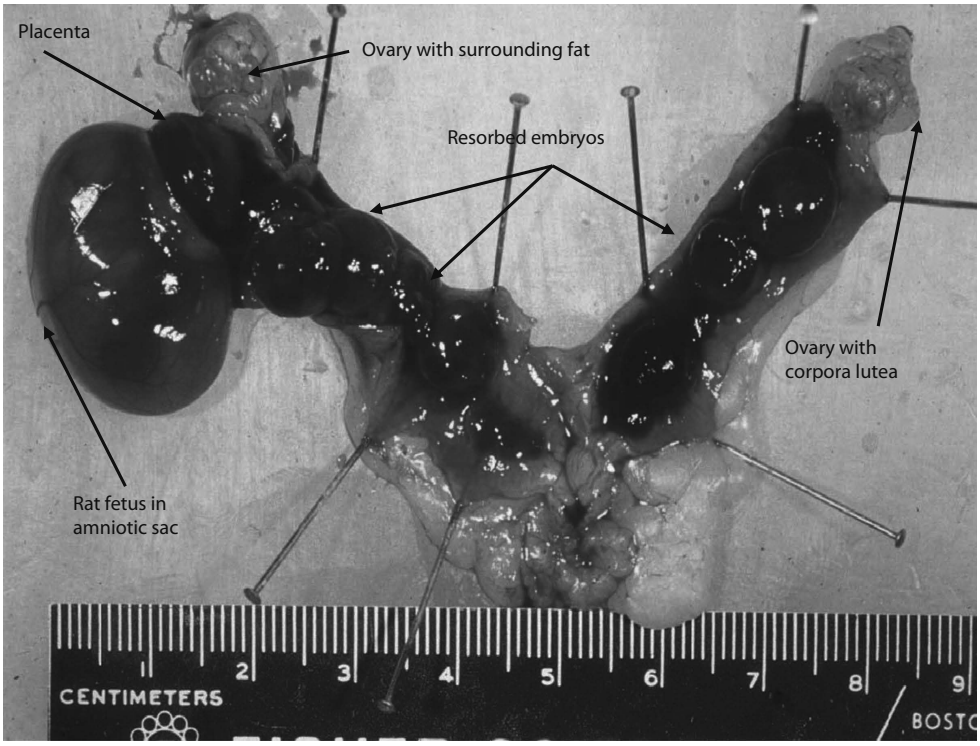
FIGURE 35.13 (A) Rat ovaries—corpora lutea. (B) Rabbit ovaries—(a) corpora lutea; (b) empty follicles.



(A)

FIGURE 35.14 (A) Rat uterus—day 20 of gestation.

(*continued*)



(B)

FIGURE 35.14 (continued) (B) Rat uterine contents—day 20 of gestation.

- A *late resorption* is defined as fetal remains or tissues that have recognizable fetal characteristics (such as limb buds with no discernable digits present) and are undergoing autolysis. Fetuses with marked to extreme autolysis are considered to be late resorptions.
- A *live fetus* is defined as one that has a beating heart or a fetus that responds to stimuli.
- A *dead fetus* is defined as one that has tissues with recognizable fetal characteristics (such as limb buds with no discernable digits present) and usually undergoing autolysis. A dead fetus is defined as a term fetus not demonstrating marked to extreme autolysis.

In some fertility studies, in which the necropsy is performed near term, fetuses are classified as live (fetus exhibits normal appearance, spontaneous movement, heartbeat, etc.) or dead (nonliving full-sized fetus with discernable digits, with a body weight greater than 0.8 g for rats).

Viable or Nonviable Embryos (Day 10, 13/14/15 of Gestation for Rats)

In fertility studies in which the pregnant female rodents are necropsied around day 10–15 of gestation, the conceptuses are categorized as live (normal appearance, heartbeat, etc.) or dead (discolored, undergoing autolysis). The dead classification in these studies is analogous to a resorption. The numbers and uterine positions of any early and late resorptions and viable and dead fetuses are recorded:

- A viable embryo is oval or crescent shaped, pink, firm, and enclosed in an amniotic sac filled with clear fluid.
- A nonviable embryo is amorphous, small, pale pink to tan or deep red to black, soft, and enclosed in an amniotic sac filled with clear or cloudy fluid; it is unnecessary to open the uterine horns to determine viability of day 10 or day 13 rat embryos.

Assessment of Implantation in *Apparently Nonpregnant* Dams

When dams appear to not be pregnant at necropsy, a thorough examination of the uterus must be performed. If no implantation sites are observed, the opened uterus is stained with a 10% aqueous solution of ammonium sulfide.[310] The results will be recorded (under maternal gross findings) that the uterus was placed in stain, and if implantation sites are found after staining, the pregnancy status must be updated.

Gross Examination and Weight of Placenta

The placenta and attached amniotic sac containing the fetus are removed from the uterine horn. The placenta is separated from the amniotic sac, and the placenta and fetus are placed in the compartmentalized box for the litter. Each placenta is observed for gross changes (e.g., white spots, areas of necrosis, abnormal size). Individual placental weights are often recorded. Altered placental weights might reflect an estrogenic effect, although the relatively high variability in placental weight associated with fetal size and blood status at maternal death makes this endpoint relatively variable.

Fetal Evaluations

The following description is a representation of the activities involved in the evaluation of the fetus but should not be construed as the only acceptable methodology. During the fetal examinations, all unusual (notable) observations for each individual fetus are recorded or described by the examining technician. The general considerations for designation of a finding as an "**M**" or a "**V**" are imprecise, may vary from teratologist to teratologist and study to study, may be relatively arbitrary, and are not always generally accepted. This lack of consistency was noted in the Terminology of Developmental Abnormalities in Common Laboratory Mammals,[311] which does not attempt to differentiate between malformations and variations. However, the observations are often coded by many laboratories as malformations or variations based on previously established criteria and designations (usually defined by the study director and laboratory supervisor).

Fetal alterations are generally considered *malformations* when

- The alteration is incompatible with or severely detrimental to postnatal survival (e.g., exencephaly, anencephaly, ventricular septal defect [VSD], diaphragmatic hernia, spina bifida, and cleft palate)
- The alteration is irreversible without intervention (e.g., hydroureter, hydronephrosis, VSD). Although, if small, VSDs may resolve postnatally in children
- The alterations result from partial or complete failure of cellular migration, closure, or fusion (e.g., cleft palate, cleft lip, spina bifida, facial clefts, renal agenesis, and ectopic organs)
- The alteration involves replication, reduction (if extreme), or absence of essential organs or structures (e.g., brain region(s), appendages, major blood vessels, heart chambers or valves, lungs)
- The alteration exhibits a concentration- or dose-dependent increased incidence with a qualitative and/or quantitative increase in severity across dose groups (e.g., missing distal limb bones/missing distal and some proximal limb bones/amelia (missing limb)
- Several alterations occur together comprising a recognized syndrome of otherwise minor anomalies

An alteration is considered a *variation* when

- The alteration is nonlethal and not detrimental to postnatal survival
- The alterations are generally transitory and/or reversible (e.g., wavy ribs or the reduced ossification in a cephalocaudal sequence that is frequently seen associated with immaturity or delayed development due to toxicity)
- The alteration may occur with a measurable frequency in controls and/or not always exhibit a dose-related increased incidence in treated litters
- The alteration is a small detectable change in size of specific structures

Experience and expertise are pivotal requirements for accurate evaluations of fetus specimens. Technical training should include evaluation of a positive control group (e.g., aspirin or vitamin A), as well as evaluation of several untreated control group litters (co-evaluation of two or three studies, with an experienced investigator), particularly for soft tissue and skeletal evaluations, to ensure comparable levels of expertise, when multiple technicians perform these evaluations in the same laboratory. It is also recommended that identified alterations be confirmed by a senior level investigator, to ensure comparable evaluation within a study, as well as across studies.

The UK Industrial Reproductive Toxicology Discussion Group (UK IRDG) and the Society of Biology have established an International Register of Fetal Morphologists. There are excellent teaching images of external, visceral, and skeletal evaluation of the rat and rabbit on the UK IRDG website (http://www.irdg.co.uk).

Gross External Fetal Examination

After removing the fetus from the uterus, excess blood and amniotic fluid are removed from the fetus by rinsing and/or blotting on absorbent paper. Individual fetuses are deposited in multicompartmented boxes, each compartment of which contains a tag that will ultimately be tied to the fetus and will remain with the fetus throughout processing, evaluation, and archiving. The tag cites the study number, dam number, uterine placement of the fetus, and appropriate fixative to be used for further processing, if required. When evaluations are to be made without the investigator's knowledge of the dosage group of the fetus (i.e., *blind*), the box containing the fetuses is given a white label bearing only the study number and animal number and with a Caesarean-sectioning processing tag. Although some investigators believe that *blind* evaluations enhance the quality of the data, this procedure is not always valid. In many cases, knowledge regarding the specimen evaluated enhances the ability of an experienced investigator to identify alterations associated with treatment. In addition, conducting evaluations under blinded conditions increases the probability of error in data processing and storage of the specimens. It also increases the difficulties of data collection, should an automated data collection system not be available.

To the extent possible, observations made during gross external examination of the fetus should be confirmed in soft tissue and skeletal examinations and the related changes described. Because the degree of ossification increases very rapidly shortly before birth, any errors regarding day 0 of gestation for the dam should result in exclusion of the litter from summarizations of delays in ossification.

Examples of typical externally identifiable abnormalities in rat fetuses are provided in Figure 35.15A through F. All fetuses are examined for gross external alterations, externally sexed, weighed, and tagged. Each fetus is euthanized by intraperitoneal injection of pentobarbital or euthanasia solution (preferred method of euthanasia for fetuses assigned to skeletal evaluation). Hypothermia is no longer an acceptable method of euthanasia for fetuses.[312] Decapitation may

be used for fetuses assigned to evaluation using Wilson's free-hand sectioning technique[105] for the head and visceral dissection of the body. After completion of the gross external fetal examinations, a fresh visceral examination can be performed.

The general practice for rabbits and other large mammals with relatively small litter sizes is to evaluate all fetuses for gross external, soft tissue, and skeletal alterations; for small rodents (rats, mice, hamsters, relatively large litter sizes), the usual practice is to evaluate half of the fetuses in each litter for soft tissue alterations and the remaining fetuses for skeletal alterations. If all fetuses must be evaluated for both soft tissue and skeletal examinations, dissection procedures, such as those described by Staples[313] and Stuckhardt and Poppe,[314] are performed before fixation of tissues and processing for skeletal examination.

Although some investigators recommend random assignment of fetuses to either evaluation, this procedure complicates an already technically difficult process. The most common practice is to assign fetuses to skeletal or soft tissue evaluation on an every-other-fetus basis, beginning with the first fetus at the ovarian position of the right uterine horn and ending with the last fetus at the vaginal position of the left uterine horn. The first fetus is assigned to skeletal evaluation, although the use of the reverse procedure would not affect the overall outcome of the evaluation. Occasionally, it may be desirable to evaluate a fetus with a specific gross external alteration to the alternate fixative, in order to achieve a more meaningful evaluation.

Soft Tissue Evaluation

All nonrodent fetuses are evaluated for soft tissue alterations by using gross dissection techniques. Soft tissue evaluation in rodents can be performed by using either Wilson's free-hand cross-sectioning,[105] or gross dissection.[313] Examples of normal sections and a few abnormalities in rat fetuses are provided as Figure 35.16A through J. As noted previously, approximately half of the rodent fetuses in each litter are generally assigned to soft tissue evaluation after gross external evaluation. Fixation of these specimens in Bouin's solution and subsequent evaluation by Wilson's method,[105] rather than dissection of the fetuses directly after Caesarean delivery, allow the use of fewer personnel and reduce the time required to perform all observations associated with Caesarean sectioning. Evaluation of the modified Davidson's- or Bouin's-fixed fetuses can occur at any time after hardening and decalcification of the specimens (a process usually requiring approximately 1–2 weeks). In the absence of high incidences of multiple abnormalities in the fetuses, an experienced individual can generally evaluate all specimens (approximately 1000 fetuses) from a study over five working days. The cross sections are easily preserved and are ready for processing for histopathological evaluation, if required. The disadvantages of this method are that it tends to require more intensive training and experience than fresh dissection. This is because the evaluator must have an extensive knowledge of normal appearance of each cross section and be aware of potential artifacts associated with fixation (e.g., potential shrinkage, tracks from slicing), biased slicing, and small differences in the thickness of the slices and the tissue present, events associated with individual fetal size.

In contrast, the Staples' gross dissection[315] allows identification of both gross external and soft tissue alterations on the same day Caesarean delivery occurs, shortening study time by approximately 1–2 weeks. It requires less training, because the viscera are evaluated in situ, an aspect that is relatively easy to conceptualize. Gross dissection provides an overall view of the major organs, blood vessels, and the heart, as well as a relatively easy identification of most common cardiac and great vessel alterations. It also eliminates

artifacts associated with fixation and allowed processing of all fetuses for skeletal examination. The disadvantage of this method is increased personnel requirements (generally four technicians are required to simultaneously evaluate the fetuses, in order to complete all Caesarean-sectioning deliveries and evaluations within approximately 5 h, which greatly reduces inter-litter variability).

Wilson's Cross-Sectioning Technique

After the fetuses have been fixed in modified Davidson's or Bouin's solution long enough to harden soft tissues and decalcify the bones, but before sectioning, the fetus is reexamined for external abnormalities. Any previously noted abnormality is confirmed and any additional findings are recorded. The fetal identification tag and the limbs and tail of the fetus are then removed, and the fetus is cross-sectioned. The actual number of cross sections made is dependent on the size of the fetus when using the Wilson's cross-sectioning technique.[105] Keeping the sections moist with Bouin's solution, each section is examined with the aid of a stereo microscope at 7× to 40× magnification. Because so many diagrams and photographs of Wilson's procedure are available for brevity, only a few representative sections (Figure 35.16A through I) are provided here, along with a description of expected observations.

The initial sections are made through the nasal passages, which should be open and unblocked throughout. The roof of the mouth should be continuous (Figure 35.16A) and separate the oral cavity from the nasal passages. The nasal septum should completely divide the nasal passage in anterior sections, but loses its connection ventrally in more posterior sections. The cross section through the eyes should demonstrate the presence of two eyes of equal size (Figure 35.16B). The retina should be in one piece, without separation of the layers.

Cross sections through the cerebral hemispheres should demonstrate the presence of cranial nerves and minimal dilation of the lateral and third ventricles in the brain (Figure 35.16C through F). Both lobes of the pituitary should be identifiable, with minimal space between the lobes. The section through the inner ears should allow identification of the presence of the lumina of the cochlea, sacculus, and utriculus and absence of obstruction of the lumina of the semicircular canals.

Cross section through the upper neck should demonstrate that the esophagus is dorsal to the trachea, and that both are unobstructed. The thyroid should be present on each side of the trachea, with lobes of equivalent and appropriate sizes. The cross section through the lower neck should reveal the presence and size of the thymus, absence of obstruction of the esophagus and trachea, and presence of the trachea to the right of the esophagus. Subsequent cross sections through the upper thorax and great vessels should allow identification of the size and orientation of the great vessels, the size of the atria (they should not be enlarged), separation of the left and right atria (the atria are not separated at the level of the foramen ovale), absence of obstruction of the esophagus and bronchi, and the presence of four lobes in the right lung and one in the left lung. The three cusps of the aortic valve, separation of the left atrium and left ventricle by the mitral valve, and the tricuspid valve, separating the right atrium and right ventricle, should be identifiable. More posterior, the intact interventricular septum should be evident (Figure 35.16G).

The cross section at the level of the diaphragm should allow inspection of the surface of the diaphragm for any ruptures or herniations of abdominal viscera into the thoracic cavity. More posterior, the lobation of the liver should be evident, as well as the entry of the esophagus into the stomach. The mid-abdominal cross section should be evaluated for any unusual patches or raised areas in the mucosa of the stomach. More posterior, it should be noted that the right kidney is slightly anterior to the left kidney; the size and shape of the kidneys and each pelvis should be checked for enlargement and papillary development and the spleen evaluated for size, shape, and texture. Should the adrenal glands not be transected, they should be examined separately and sectioned; normal adrenal glands appear as a single solid mass of tissue.

The pelvic area should be examined for the ureters, located in the connective tissue of the lower back, and any deviations in the course or diameter noted. The sex of each fetus should be confirmed internally (Figure 35.16H and I), and any discrepancy in the externally identified sex noted. Bilateral testes and ovaries should be present, with the testes descended.

Staples' Dissection Technique

Unless also assigned to skeletal examination, the head of the rodent fetus is removed and stored in Bouin's solution for subsequent examination after cross sectioning, as described by Wilson[105,315] or Barrow and Taylor.[316] The fetus is placed on a board, and the limbs are restrained with elastic bands or dissection pins. Visceral examinations may be made using a binocular microscope or a magnifying lens and light, when necessary (for the larger nonrodent fetuses, a microscope is not generally required). A longitudinal cut is made, extending from below the umbilicus through the midline of the trunk. The diaphragm is examined for intactness, after which the cut is continued along one side of sternum exposing the thoracic viscera. The trachea is detached from the surrounding tissues, and the supporting ligaments are separated from viscera, after which the trachea, esophagus, and thymus are examined. The thymus is removed, and the heart and great vessels are examined for shape and position. The main arterial branches above the heart are examined, but subbranches of these major vessels are not explored, because of the extensive variability present in normal fetuses (Figure 35.17A). At the anterior portion of the heart, the semilunar values are present at the base of the pulmonary truncus. Also present are the ascending arch of the aorta, the innominate artery, the right carotid artery, the right subclavian artery, the left carotid artery, and the left subclavian artery. The heart is

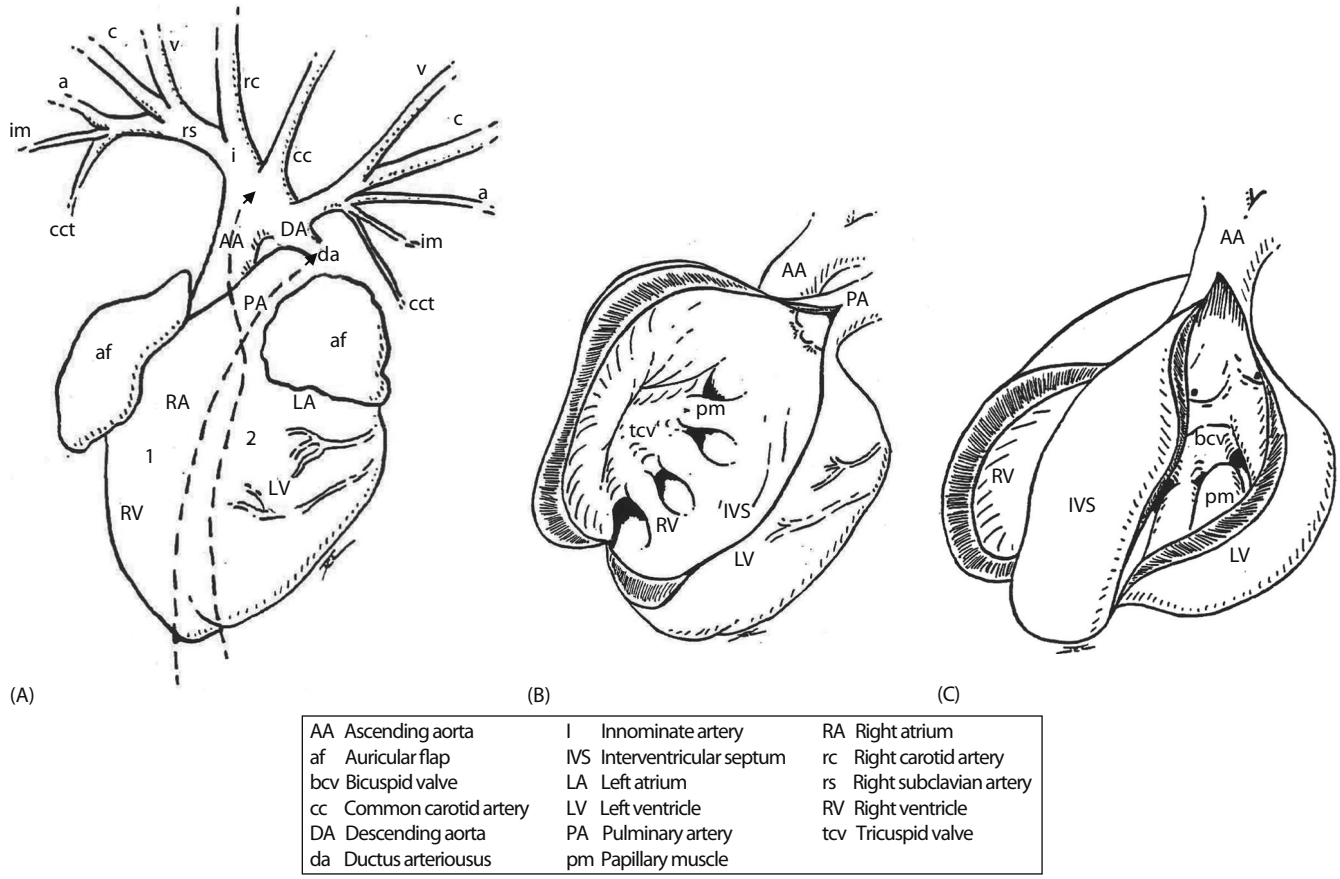

FIGURE 35.17 (A) Major arteries above the heart. (B) First heart cut. (C) Second heart cut.

then pulled over to the right, revealing the pulmonary arteries leading to the lungs and the ductus arteriosus.

The heart is cut and examined for internal alterations (Figure 35.17B and C), as follows. The first cut is made anteriorly from the apex of the heart, entering the right ventricle and exiting from the pulmonary truncus, without cutting the dorsal musculature of the heart. This cut reveals the papillary muscles, the tricuspid valve, and the three semilunar valves. In a beating heart preparation, a functional septal defect could be easily detected because blood would spurt through the septum. A second cut is made through the left ventricle, which will cross over the first incision and enter the ascending aorta. This cut will reveal the bicuspid valve, the papillary muscles, and the three semilunar valves.

The lungs, liver, stomach, pancreas, spleen, and gallbladder (when appropriate) are examined for color, size, shape, position, and appropriate lobation. The color, size, and position of adrenals, kidneys, ureters, intestines, bladder, and genitalia are then evaluated (the rectum should contain meconium) (Figure 35.16J). Particular attention is given to evaluation of the reproductive organs for gross integrity, size, shape, and position. During this procedure, gender (sex) is confirmed for rodent species and identified for rabbits (ferrets can be sexed either as fresh or fixed specimens). The ureters are observed for hydroureter, tortuousness, and obstruction, and it is noted whether urine is present in the urinary bladder. The kidneys are sectioned for a detailed examination of infrastructures (size of each renal pelvis, size and appearance of the renal papilla). The patency of the anus can be checked by the use of a hair.

When the head is examined for skeletal alterations, the skull and brain may be sectioned at the level of the frontal–parietal suture and the brain examined in situ. Alternatively, the head and/or brain may be retained in Bouin's solution for later sectioning, as previously described. The eyes are removed and examined for color, size, and shape (nonrodent species).

Evisceration of Fetuses

Fetuses are eviscerated to aid in clearing and staining of the skeleton. It is helpful to also remove the skin from nonrodent fetuses. Small scissors are used to make a longitudinal cut in rodent fetuses. This cut extends from below the umbilicus through the midline of the trunk and along one side of the sternum, severing costal cartilage, but not ribs, and avoiding the clavicle. Before further processing, the externally identified fetal sex is confirmed internally (evidence of testicles or uterine horns and ovaries). Similar procedures are then used to evaluate both rodent and nonrodent specimens, although small forceps are used for the rodent fetuses and

blunt forceps may be used for the larger nonrodent fetuses. Evisceration is performed by inserting the forceps into the thoracic cavity and pulling downward on the trachea and esophagus, removing these organs and the lungs and heart (thoracic viscera) as a unit. The diaphragm is gripped and pulled downward, and abdominal viscera (liver, kidneys, and intestines) are removed. Any remaining viscera in the abdomen or pelvis are then removed. Throughout this process, care must be taken to prevent damage to the skeleton.

For nonrodent fetuses, blunt forceps are used to remove as much of the skin and subcutaneous fat as possible, although skin can remain on the paws, tail, and snout, to prevent damage to the underlying bones. Any damage occurring during processing should be noted, to prevent the artifact from being potentially incorrectly identified as a skeletal anomaly. After checking that the fetal identification tag remains secure, that the eyes have been removed, and that the head was sectioned, the eviscerated, skinned fetus is returned to the holding tray, containing 95%–99% isopropyl alcohol or 70%–95% ethanol.

Clearing the Carcass

A 1% KOH solution is recommended for clearing rodent fetuses and a 1%–2% KOH solution for nonrodent fetuses. Although higher concentrations may be used, the speed of maceration is associated with fetal size, temperature and lighting conditions, and agitation; and small specimens can be easily and inadvertently dissolved. For optimal skeletal processing, minor changes should be made in any maceration/staining process, depending upon individual specimens. Inspection should be ongoing, and the speed of the process modified depending upon the observed degree of completion of the maceration and staining of the individual specimen. KOH is generally prepared or obtained in 1 gallon units, and alizarin red S is added (50.0 mg/1 gallon of 1% KOH solution) to stain the skeletons.

Several concentrations of glycerin are needed to clear and preserve the stained skeletal preparations during storage. As supplied by the manufacture, glycerol is 99.5% pure. This should be diluted to 20%, 40%, 60%, and finally 80% concentrations, so that for use as the macerated, stained fetuses can be gradually brought up to the 80% glycerin or 99.5% glycerol concentration used for storage. Too rapid an increase of the glycerin concentration will result in compression of the fetal skull.

Processing can be performed using compartmentalized polystyrene utility boxes, or alternate containers that do not react with the KOH or alizarin. Several commercial units are now available, although they are not recommended for use in staining very small fetuses, which should be observed during the processing, to prevent inadvertent damage.

The procedure described is a modification of the method of Staples and Schnell,[317] in which eviscerated, skinned (if appropriate) fetuses are fixed in plastic bottles filled with 99% isopropanol or 95% ethanol. Fixation of rodent fetuses generally requires at least 7 days, while nonrodent fetuses may require at least 14 days. After the alcohol fixation period, the fetuses are placed into individual compartmentalized plastic boxes and any remaining alcohol drained away. Each compartment is then filled with 1% (rodent) or 2% (nonrodent) KOH solution, and the fetuses are allowed to macerate for approximately 24 h. The KOH solution is then drained and replaced with 1% KOH solution containing the alizarin red S stain, and the fetuses are allowed to remain in the stain for approximately 24 h, after which this solution is drained and replaced with a fresh 1% KOH solution, in which the specimens remain for another 24 h. The KOH solution is again drained, and the rodent fetuses are cleared with progressively higher concentrations of glycerin (20%, 40%, 60%, and 80% for rodents; 20%, 40%, and 80% for nonrodents). After completion of this process, the fetuses are stored, ultimately for archiving, in plastic jars to which 80% glycerin and a few crystals of thymol, a preservative, have been added.

Staining of Fetal Skeletons

While there has been some emphasis on the use of double staining (alizarin red and alcian blue) to identify changes in cartilage in term fetuses during the last few decades, in practice, this procedure has not been widely utilized. In a double-stained skeleton, the ossified bone stains purple to red and the cartilage stains blue. The staining of the cartilage allows the examiner to ascertain the bone merely not yet ossified, while the cartilage anlage is present, or is the underlying cartilage absent. As stated by Tyl and Marr,[318] "…a cleft in the cartilage plate of the sternum explains bipartite ossification sites of the sternebrae, and a misalignment of the sternebrae may be seen by the abnormal fusion of the cartilage plate. The normalcy of the cervical vertebrae can only be determined in a double-stained specimen, as these are not normally ossified in the term fetal skeletal preparation. The visualization of the cartilaginous anlagen may allow distinction between a delay in a normal process (i.e., a variation; ossification is delayed, but the underlying cartilage is normal) versus a frank malformation (ossification may be delayed, abnormal or normal, but the underlying cartilaginous skeleton is abnormal)."

Technical training is critical. The technician must be familiar with the normal appearance of bone and cartilaginous structures in the fetus and with the degree of ossification that should be evident on different sacrifice dates. Double staining may be especially useful in pathogenesis studies of skeletal development. Although not described here, several references are available for double staining[319,320] and in an atlas by Menegola et al.[321,322] A description of age-related fetal observations in the rat skeleton can be found in Marr et al.[323]

Examination of Fetal Skeletons

The skeletal system consists of axial and appendicular sections. The axial skeleton includes the skull, vertebral column, sternum, and ribs. The skull (Figure 35.18A through C) consists of the paired bones of the face and the upper jaw (premaxillae, maxillae, zygomatics, and squamosals). The zygomatic arch is formed by the zygomatic bone, squamosal

bone, and zygomatic process of the maxilla. The mandibles form the lower jaw. The exoccipital and supraoccipital bones form the cranial cavity's posterior wall, while the cranial roof's posterior portion formed by the interparietal bones and the anterior portion is formed by the parietal bones that also form the sides of the cranial cavity. The anterior portion of the cranial vault is formed by the paired frontal and nasal bones.

The vertebral column consists of the vertebrae, hyoid, ribs, and sternum. Each vertebra consists of three parts (the centrum and two arches). The vertebral column articulates anteriorly with the exoccipital bones of the skull. The vertebrae are divided into the following groups: cervical vertebrae (7; C1 through C7) (Figure 35.18D and E); thoracic vertebrae (rat, 13 or 14 [T1 through T13 or 14]; rabbit, 12 or 13 [T1 through T12 or 13]) (Figure 35.18F and G); lumbar vertebrae (rat, 5 or 6 [L1 through L5 or 6]; rabbit, 6 or 7 [L1 through L6 or 7]) (Figure 35.18H and I); sacral vertebrae (3 [S1 through S3; the vertebrae present between the

limits of the ilia are counted]) (Figure 35.18J); and caudal vertebrae (the number varies [CA1 through CA*x*]) (Figure 35.18K). Each vertebra consists of three parts (the centrum and two arches). The centrum consists of an ossified center surrounded by cartilage (the caudal centra are entirely cartilage). The atlas (C1) and the axis (C2) are the two most anterior cervical vertebrae. Each thoracic vertebra articulates dorsally with a pair of ribs. Rodents usually have 13 pairs of ribs while rabbits usually have 12 pairs. Rat and rabbits often have a full rib, rudimentary rib, or an ossification site at L1. In rodents, this may be unilateral, but in rabbits, it is usually bilateral. Each rib normally consists of a cartilage tip proximal to the vertebral arch, an ossified middle portion, and a distal cartilaginous portion. The distal cartilages of ribs 1 through 7 are attached to the sternum, while ribs 8 through 11 curve upward with their tips in close proximity. Ribs 12 and 13 are free distally.

The hyoid bone (Figure 35.18C) is a U-shaped bone consisting of three named parts: the body and paired great and lesser horns. The hyoid bone is considered a lingual bone because of the tongue musculature attached to it. It also serves, however, as an attachment for the larynx, specifically the thyroid cartilage via the thyrohyoid membrane and the extrinsic muscles of the larynx. Embryologically, the hyoid bone is derived from mesodermal cells that form cartilaginous masses in the second and third branchial arches.

The sternum (Figure 35.18L) usually consists of six or seven ossification sites (the manubrium, the body or corpus consisting of four or five sternal centers, and the xiphoid). Sternal ossification is nonsequential, with centra 2 and 3

normally ossifying before centra 1. Incomplete ossification of the last (3rd, 4th, or 5th) centrum between the manubrium and xiphoid is considered normal and identified as a delay based on the number of ossified sites present (i.e., 2, 3, or 4).

The appendicular skeleton includes the pelvic and pectoral girdles and the appendages. The pectoral girdle is composed of paired scapulae and clavicles. The scapulae are flat, trapezoidal bones with anterior-dorsal projections; the clavicles are elongated, curving, slender bones that articulate laterally with the scapulae and medially with the sternum. The forelimb skeleton consists (from proximal to distal) of the humerus, the radius and ulna, and carpals, metacarpals, and phalanges of the forefoot. In GD 20 rodents, the only bones of the forefoot that have ossified are the metacarpals. By GD 21 in rodents, the phalanges have ossified. In term mice, usually only the second through fourth metacarpals are ossified, while in term rats, the second through fifth metacarpals are normally ossified. The pelvic girdle consists of three pairs of bones (ilium, ischium, and pubis). The hindlimb skeleton consists (from proximal to distal) of the femur (thigh) patella, the tibia, and fibula with hindfoot (tarsals, metatarsals, and phalanges). The five metatarsals ossify first. The hindfoot of the rabbit has only four digits.

When the sacrifice day is GD 21 (rats) or GD 18 (mice), there is less variability in the skeletal development; however, there is an increased risk of delivery prior to scheduled sacrifice.

Procedures

To perform a skeletal examination, each fetus is removed from the container holding the processed litter, checked for identification, and then placed in a petri dish and examined using a light source and magnification (5× to 10×). Rat, mouse, hamster, and ferret fetuses are examined using a binocular microscope. It is recommended that all nonrodent fetuses (except ferrets) be examined using a magnifying light.

Each skeletal examination proceeds systematically from head to tail. The skull is examined for size, shape, and extent of ossification; each skull bone is examined for ossification appropriate to the specimen's gestational age. The paired bones of the skull must be identified during the skeletal examination. When the fetus has a domed skull associated with marked or extreme dilation of the lateral ventricles in the brain or when the fetal skull is small and has retarded ossification, the anterior and posterior fontanelles are often enlarged and the parietals frequently contain holes. In such cases, the affected fontanelle and degree of dilation should be noted. When holes are present (Figure 35.20A), the number, location, and approximate size of each hole should be noted, as also should be intra- and interossification sites (Figure 35.20B).

The hyoid bone (Figure 35.18C) is observed to be present or not ossified. Rabbit fetuses frequently have angulation of the hyoid alae (Figure 35.20D); the hyoid is not ossified (cartilage is present) in rat fetuses at 20 or 21 days of gestation (Figure 35.18C). Appropriate alignment and closure of the upper and lower jaws (mandibles and maxillae) should be present (teeth should be present in rabbit fetuses). The size and shape of each eye socket should be checked and correlated with reported findings of microphthalmia or apparent anophthalmia.

The vertebral column is next examined (Figure 35.18D through K). The vertebral column articulates anteriorly with the exoccipital bones of the skull. As described earlier, each vertebra consists of three parts (the centrum and two arches) and should be evaluated to determine whether areas, other than those expected to have minor developmental alterations, demonstrate changes. The centrum consists of an ossified center surrounded by cartilage. The caudal centra are entirely cartilage. The examiner should record all unossified, asymmetric or small (Figure 35.19E and J), misaligned, bipartite (Figures 35.19D and 35.20I), dumbbell, or unilateral (Figures 35.19F, 35.20F and G) ossified centra and/or arch. In a normal GD 20 rat, all lumbar and sacral centra should be ossified, while thoracic centra T1 through T7 are normally unossified. The ossified portion of the centra may or may not be bipartite or dumbbell when the cartilage portion is bipartite or dumbbell. The centra must be examined for fusion of the cartilage between centra. A small arch(es), open arches, and fused centra and/or arches of vertebrae (Figures 35.19E, J and 35.20G) should be recorded. If the cartilage anlage is affected, it should be recorded along with any findings for the ossified portion. The vertebral arch is almost completely ossified except for a cartilage tip, which may or may not be present on the transverse process, depending on the relative maturity of the fetus. The spinous process is normally entirely cartilaginous and can be examined only from the dorsal side. The cartilage of the transverse processes of sacral centra (S1 through S3) is normally fused, providing extra support for the pelvis. The atlas (C1) and the axis (C2) are the two most anterior cervical vertebrae. Each thoracic vertebra articulates dorsally with a pair of ribs. Rodents usually have 13 pairs of ribs while rabbits usually have 12 pairs. Rats and rabbits often have a full rib, rudimentary rib, or an ossification site at lumbar 1. In rodents, this may be unilateral, but in rabbits, it is usually bilateral. Additional rib structures are typically classified as extra, full, or supernumerary ribs if they are at least one-half or greater than the length of rib 1 or 13. Ribs that are less than one-half the length of rib 1 or 13 are classified as rudimentary ribs. If the additional rib structures appear as small, round *dots*, they are classified as ossification sites. Extra ribs may also be found on seventh cervical arch (C7) and in rats are sometimes found only as cartilage (Figure 35.19C); this extra cartilage is sometimes found to be fused to rib 1 of the same side. Any alterations in rib ossification are noted, such as a thickened area of ossification (Figure 35.20E), waviness (Figure 35.19I), splitting (branching), fusion, or misalignment (Figures 35.19K, M, and 35.20H). To the extent possible, interrelated vertebral-rib malformations are identified and this malformation counted as one finding (Figure 35.20F and G). Abnormal rib numbers (unilaterally increased or decreased) associated with increased or absent ribs and the presence of a hemivertebra are excluded from the litter average. Altered ribs are noted by number (T1 through T13), affected area of ossification (proximal, beside the vertebral column; medial, middle of

the ossified area; distal, near costochondral junction), and whether the alteration is unilateral (left or right) or bilateral.

The sternum is next to be evaluated (Figures 35.18L, 35.19N, 35.20N, and O). The adult sternum usually consists of six or seven ossification sites (manubrium, four or five sternal centers and xiphoid). For the fetal examination, the degree or lack of ossification of the manubrium and xiphoid is recorded followed by the intermediate sternal ossification sites, which may have degrees of delayed ossification (incompletely ossified or not ossified). Any alterations in sternal ossification are noted.

The pectoral girdle consists of two claviculae and two scapulae (Figure 35.18M and N). Any alterations in ossification, such as an irregular shape, waviness, bending, or small size, are noted. Each forelimb (Figure 35.18O and P) consists of long bones (humerus, radius, and ulna), the carpals, and the bones of the forepaws (metacarpals and phalanges). The carpals, metacarpals, and phalanges in each digit are evaluated for ossification. Each paw is evaluated separately and between-paw differences noted. The carpals are usually not ossified, while there are normally four or five metacarpals present in each forepaw. Because the preaxial metacarpal is often not ossified in fetuses, the presence of only four metacarpals indicates delayed ossification of the preaxial metacarpal, unless the finding is associated with the absence of the pollex (first preaxial digit), a relatively common finding in some rabbit strains. Each forepaw has five digits in most rodent and nonrodent species. The digit count begins at the preaxial digit, after which the phalanges in each digit are counted, including the distal phalanx (claw). Day 20 rat fetuses normally have 1, 1, 1, 1, and 1 ossified phalanges, and

day 29 rabbit fetuses normally have 2, 3, 3, 3, and 3 ossified phalanges in the five respective digits. Counts excluded from the ossification site averages are noted, for example, fused or absent digits and short, twisted, thick, bent, absent, or incompletely ossified long bones.

The pelvic girdle (pelvis) consists of two ilia, two ischia, and two pubes (Figure 35.18Q). Any alterations in ossification are recorded, including incomplete, absent, or abnormal ossification (Figure 35.19O). Each hindlimb (Figure 35.18R and S) consists of long bones (tibia and fibula) and the bones of the hindpaws (tarsals, metatarsals, and phalanges). Using the methods described to count the bones in the forepaws, the numbers of tarsals, metatarsals, phalanges in each digit are counted. Normally four metatarsals are observable. Rat fetuses have five hindpaw digits, and when four metatarsals are present, the finding indicates delayed ossification of the preaxial metacarpal. Rabbit fetuses have only four hindpaw digits and four metacarpal bones. Beginning with the preaxial digit, the hindpaw phalanges are counted across. Normal day 20 rat fetuses have 1, 1, 1, 1, and 1 phalanges, and normal day 29 rabbit fetuses have 3, 3, 3, and 3 phalanges, including the distal phalanx, or claw. Examples of reasons for exclusion of count values from averages include fused or absent digits, short, thick, and bent or absent long bones (Figure 35.19Q).

Some laboratories calculate the ossification site averages for each litter per group for the hyoid (body), vertebrae (cervical, thoracic, lumbar, sacral, and caudal), ribs (pairs), sternum (manubrium, xiphoid, and sternal centra between these sites), forepaws (carpals, metacarpals, phalanges), and hindpaws (tarsals, metatarsals, and phalanges) as a method for identifying delays in ossification. Separate averages for the manubrium, four or five sternebrae, and xiphoid better identify reduced ossification than citing retarded sternal ossification by site, to the exclusion of the interrelationship of the biological pattern of sternal development. Delays in ossification identified by using this method should be correlated with other evidence of retarded ossification that may be observed (e.g., a reduction in the average for the litter average number of ossified sternebrae per fetus should be compared with nonsequential sternal ossification). This method also allows association of increases in rib numbers (supernumerary ribs) with increases in thoracic vertebrae and reductions in lumbar vertebrae, thus eliminating identification of supernumerary thoracic ribs as rudimentary, full, unilateral, or bilateral, which often obscures an increase in supernumerary ribs because the counts are recorded as separate findings, rather than an overall response.

Interpretation of Fetal Findings

The interpretation of fetal findings requires a *weight of evidence* (WOE) approach. If there is a dose-related increase in the incidence of fetal malformations, then the finding(s) is considered adverse. Often, however, the incidence of fetal malformations is increased at the middle dose but not at the high dose. In this case, further examination of the data may reveal that there was increased in utero embryo–fetal mortality, which was greatest at the high dose. It is likely that the most affected conceptuses at the high dose had died and were not evaluated for malformations. In this case, the *lack of a dose–response* pattern is spurious. The *true dose–response* pattern will be indicated by evaluating the affected implants (nonlive plus malformed). When there are reduced fetal body weights, it is common to observe increased incidences of reduced ossification, especially in those skeletal areas that undergo ossification last. Reduced fetal body weights are also commonly associated with visceral growth retardation (e.g., dilatation of the renal pelvis (a delay in growth of the renal papilla), dilated (enlarged) lateral ventricles of the cerebrum without compression of the cerebral walls). Conversely, an increase in the incidence of an ossification site, partial or full rib on L1 (e.g., a 14th rib in rodents or a 13th rib in rabbits) may indicate an alteration in developmental patterning, genetic drift over time, and/or may predict possible greater effects at higher doses. When using the WOE approach, the biological plausibility must also be considered.

ICH Stage E—Birth to Weaning

E: adult female reproduction function, adaptation of the neonate to extrauterine life, including preweaning development and growth (postnatal age optimally based on postcoital age).

Observation and Timing of Parturition

Parturition, lactation, maternal–pup interaction, and pup growth and development until weaning are monitored during ICH stage E. Female rats should be housed to litter in boxes with bedding material no later than day 20 of presumed gestation (2 days prior to the day of expected delivery; earlier if required by protocol). The dams are observed periodically throughout the day (every few hours) for signs of parturition (e.g., stretching, visible uterine contractions, vaginal bleeding, and/or placentas in the nesting box). These signs are strong indicators of parturition onset and indicate that dams should be monitored closely for delivery of the first pup.

As soon as a pup is found, parturition is considered initiated. If required by protocol, the time should be recorded. To indicate that a delivery is *in progress*, a marker (e.g., a tape *flag*) may be placed on the outside of the nesting box. Once delivery has begun, the dams are checked periodically during the day for evidence of difficulty in labor or delivery (e.g., a pup only partially delivered, a dam cold to the touch and pale). Any apparent difficulty is recorded, and a supervisor should be notified if the difficulty seems extreme or unusual.

The calendar date on which delivery of a litter appears to be completed is defined as lactation day 0 (LD 0) for the dam and postnatal day 0 (PND 0) for the pup. The following maternal behaviors offer evidence that parturition is complete: (1) removal of amniotic sacs, placentas, and umbilical cords, and grooming of the pups by the dam; (2) self-grooming by the dam; (3) nesting behavior by the dam; and (4) nursing. However, parturition may be complete without all of these behaviors being observed. Individual pup observations (e.g., appearance and viability) should not be recorded until delivery is complete. Apparently, dead pups should be carefully removed from the nesting box during parturition to

preclude cannibalization by the dam. Care should be taken not to disturb the dam. The dead pups should be retained in a container, such as a weigh boat (labeled with the dam number), until pup statuses are recorded following the completion of parturition. Pups observed as delivered but not present at the end of parturition because of cannibalization should be recorded as *Undetermined Sex, Undetermined Viability.*

In order to preclude disruption of delivery and/or maternal care, dams in the process of delivering pups should not be administered the test substance. If a dam has completed parturition by the time the last additional animal in the normal sequence has been dosed, this dam can be administered the test substance. If the dam continues to actively deliver after daily test substance administration is completed, the dam's daily administration can be skipped for that day. A delayed or missed daily test substance administration and the reason for its occurrence should be recorded on the appropriate form.

The day on which delivery is completed is functionally defined as day 0 or 1 postpartum, based upon the laboratory's historical use. Because most deliveries occur overnight and the litter has been first observed at the morning viability check, the LD 0 was considered to have occurred the previous day, and the morning of discovery of the litter is designated as LD 1. If parturition begins overnight but is completed in the morning, that day is designated LD 0. To keep the data consistent, maternal and litter body weights are routinely recorded on LD 1 and PND 1, respectively. Appropriate maternal behavior is determined on the basis of examinations for maternal and pup nesting behavior. Criteria evaluated include pup appearance (clean and warm), presence of a nest in which the pups are grouped together, and evidence of nursing activity and/or milk in the pup stomach. When a dam with a litter dies before her scheduled sacrifice, the pups are sacrificed and necropsied. The sacrifice and necropsy observations are recorded. When all the pups in a litter die, the dam may remain on study until her scheduled sacrifice date, or the dam may be sacrificed at the discretion of the study director.

Occasionally, additional pups are born to a litter that has already been weighed and observed on PND 1. These pups are handled as follows:

- If delivery of a litter has been marked as completed, and it is within the same day, the additional pup(s) and dam are weighed on *PND 1 and LD 1* (e.g., a Monday).
- If an additional pup(s) is found when this litter was counted during the day after the litter was marked as completed (on PND 1 (e.g., Tuesday), the following comment (or a comment that conveys the same information) should be entered on the litter observation form for PND 1. "One additional (sex) pup present that was delivered after completion of weighing and recording of litter observations, for all pups delivered on PND 1." The additional pup(s) is not weighed until PND 4 (the next scheduled weighing interval for that litter). The pup(s) is tattooed if required by protocol.

Edits to the database will be required to change the number of pups in the litter. The date of the dam's DL 0 remains the same (it is not changed to the date that the additional pup was found). Pups are weighed on the days specified in the protocol. On those days when pup body weights are recorded, bedding is usually changed, and each litter is evaluated for maternal and pup nesting behavior. Each litter should be checked for viability and counted every day, with the number and status of the pups recorded.

Evaluation of Pups at Birth

The pups are further evaluated after removal from the nesting box. Gender is identified on the basis of observed anogenital distance (longer in male than in female pups). For studies in which endocrine perturbations are expected, these observations are made using calipers. Any gross physical alterations are identified and the viability and weight of each pup is identified. Dead pups are necropsied and a section of the lung placed in a container of water. Pups with lungs that float are assumed to have breathed and are considered liveborn. Pups with lungs that sink are identified as stillborn. Each pup is examined for the general shape of the head and features, bruises, lesions, number of digits, length and shape of the limbs and tail, presence of an anus, presence of milk in the stomach, and any injury inflicted by the dam.

Culling

Whether to cull is an area of debate.[324,325] Its appropriateness depends upon the purpose of the study and the degree of control required for evaluation of the endpoint in question. Although culling is a common practice, and required in some guidelines, this practice does increase the variability in litter values for viability and weight gain and has the potential to obscure late occurring effects because pups are removed from evaluation.

Cross-Fostering

Parturition observations begin three times daily on day 20 of gestation. If the beginning of parturition is observed, that is, the birth of the first pup, this is deemed postnatal/lactation day 0. If an animal delivers overnight and delivery is observed as complete at the morning parturition observation, then parturition is considered to have begun prior to midnight and the day of observed completion is deemed as postnatal/lactation day 1. When animals have completed delivering their litters, this information is recorded on the parturition observations sheet. After the morning parturition observation is completed and a list of litters to be cross-fostered on that day is finalized, the pups in each *birth* litter are separated by sex and counted. This information is entered on the deliveries sheet together with details of any pups that were excluded from the cross-fostering (e.g., runts, deformed pups), and the pups are returned to their mothers.

When the deliveries sheet has been completed, the cross-fostering plan is developed. The details of the birth litters

with the pups available for cross-fostering are entered into a spreadsheet entitled *Birth Litters*. This information is then verified. The *Birth Litters* information is then transferred to a spreadsheet entitled *Cross-Fostered Litters* where the pups are arranged into foster litters with no pup remaining with its birth mother and no same sex siblings in each litter. Ideally, no siblings at all will be in each litter. The *Cross-Fostered Litters* sheet is then verified and approved by the study director prior to use.

The physical cross-fostering is then performed. The litters are removed from their home cage and placed in containers by sex labeled with the birth dam's number and the sex of the pups. Using a partitioned box labeled with the foster dam's number and with each partition labeled with the pup number within the foster litter and using the Cross-Fostered Litters sheet, the required pups are removed from the birth litter containers and placed in the appropriate space in the foster litter box. Once the entire foster litter is filled, the pups are tattooed, weighed, sexed, and placed in their foster mother's cage. The placing of the foster litter in the foster dam's cage is achieved by removing the foster dam, placing the foster pups in the cage, rolling the pups in the bedding to acquire some of the scent of the foster dam/home cage, and then returning the foster dam to the cage. This process requires the ordering of approximately 20% more presumed pregnant females than litters required due to some of the dams being nonpregnant, or having litters with insufficient numbers and/or abnormal sex ratios. Cross-fostering of more than 30 litters per day is labor-intensive and difficult.

ICH Stages E (Postnatal Development to Weaning) and F (Postweaning Development of Reproductive Organs to Puberty)

E: adult female reproduction function, adaptation of the neonate to extrauterine life, including preweaning development and growth (postnatal age optimally based on postcoital age).

F: pediatric evaluation when treated; postweaning development and growth, adaptation to independent life, and attainment of full sexual development.

Anogenital Distance

With the event of enhanced concern regarding estrogenic agents, many investigators have incorporated determination of anogenital distance at Caesarean delivery or birth of fetuses and pups, respectively.[326] Anogenital distance is the length between the anus and the genital tubercle. In rodents and primates, the anogenital distance is greater for males than for females. For rodents, this differential begins on GD 17 and continues through PND 21. Mean anogenital distances at birth for males and females are approximately 3.5 and 1.4 mm, respectively. The increased growth of this region occurs in response to testosterone. The genders of rabbit fetuses or neonates cannot be reliably determined using anogenital distance but can be determined by examining the gonads during the visceral evaluation.

Anogenital distances for rat fetuses (GD 20 or 21) or pups on PNDs 0 to 3 are measured with a micrometer and a stereomicroscope. Measurements taken on pups on PND 4 or later should be done using a caliper. The fetus or the PNDs 0 to 3 pup is held in the technician's hand, and the tail is raised with the other hand to an 80°–90° angle from the horizontal, exposing the anus. (*Note*: Be careful not to pull the tail, as this stretches the anogenital distance.) The anogenital area is brought into focus with a calibrated stereomicroscope. The anogenital distance is measured from the cranial (or anterior) edge of the anus, which comes to a point, to the base (or posterior edge) of the genital tubercle. The base of the tubercle is not clearly differentiated as it slopes into the anogenital area. A base line between the distinct edges of the genital tubercle is visually estimated. It is very important that the anus and the base of the genital tubercle be kept in the same focal plane. The length from the base of the genital tubercle to the cranial edge of the anus is recorded.

Hold the PND 4 or older pup by its tail, keeping the tail at an 80°–90° angle from the horizontal. The arms of the caliper should be aligned as follows: for males, the anogenital distance is measured from the cranial (or anterior) edge of the anus to the base (or posterior edge) of the anogenital aperture; for females, the anogenital distance is measured from the cranial edge of the anus to the base of the urinary aperture (*not* the base of the vulva). The anogenital distance is recorded in millimeters.

The comparison of the anogenital distance between groups (especially for males) is confounded when the groups have different fetal or pup weights. The anogenital distance data can be normalized (when group body weight differences are not too severe) by using some other linear measurement (e.g., crown-rump) or by using the cube root of the body weight to simulate a linear measurement.

Balanopreputial (Male Rodents) and Vaginal (Female Rodents) Opening (Sexual Maturation)

Sexual maturation landmarks (preputial separation and vaginal patency) are required or recommended in perinatal/postnatal studies, multigenerational studies, and developmental neurotoxicity studies, where the offspring are raised to adulthood. The most appropriate way to perform these evaluations is to observe all animals daily until all animals (by sex) in the litter meet the appropriate criterion. Therefore, when differences occur on the basis of individual animal evaluations, litter analyses should be made. Evaluations are performed while the male or female rodent is held in a supine position.

Males: Evaluation of male rodents for balanopreputial separation is begun on day 22 (mouse), day 27 (hamster), or day 35–40 (usually 39) (rat) postpartum (Figure 35.21). In rats, balanopreputial separation is considered to result from balanopreputial membrane cornification, which leads to the detachment of the prepuce from the glans penis in the rat. Preputial separation occurs dorsolaterally and then ventrally on the penis and down the shaft of the penis. The prepuce remains attached to the glans penis on its ventral surface by the frenulum. (*Note*: The process of development of the prepuce in humans is different from that of the rat.) Published

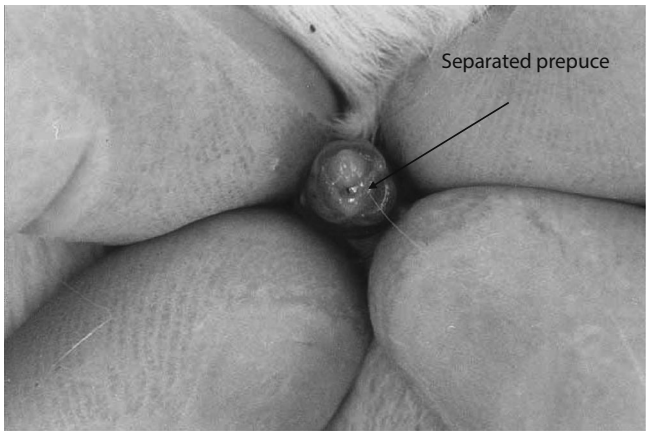

FIGURE 35.21 Rat pup—preputial separation.

preputial separation age range from PND 41 to 46,[327,328] depending on the observation criterion. Each male rodent is removed from its cage and held in a supine position. Because manipulation of the prepuce can accelerate the process of preputial separation, the males must be examined gently. Gentle digital pressure is applied to the sides of the prepuce, and the criterion is met when the prepuce completely retracts from the head of the penis (see previous discussions for alternate criterion). The foreskin can be attached along the shaft of the penis, but it cannot be attached to the opening of the urethra. Each male rodent is examined daily until acquisition or until PND 55, whichever is earlier. Body weight should be recorded on the day the criterion is met.

Females: Evaluation of female rodents for vaginal patency is begun on day 21 (mouse) or day 28 (rat) postpartum. The vaginal opening remains covered by a septum or membrane after canalization of the vagina has occurred in rats. The age when the septum is broken or no longer evident is described as the age of vaginal patency, and vaginal patency is the most readily determined marker for puberty in rats. Published Sprague-Dawley rat vaginal patency values range from PND 30.8 to 38.4.[320,329] Female rats are examined beginning a few days prior to the expected age of maturation (e.g., PNDs 25 to 28), continuing until the criterion for patency has been achieved or until PND 43, whichever comes first. The female is removed from the cage and held in a supine position, exposing the genital area. Pressure is gently applied to the side of the vaginal opening to see if the septum or membrane remains. When the membrane is present, the area has a slight *puckered* appearance; however, when the membrane has broken, the vaginal opening is about the size of a pinhead. The criterion has been met when the vagina is completely open. Body weight should be recorded on the day the criterion is met.

Additional Developmental Landmarks

Additional developmental landmarks can be assessed, including pinna detachment, hair growth (pilation), incisor eruption, eye opening (pups are born blind with eyelids closed), nipple development, and testis descent. The examinations must begin prior to the landmarks' historical day of onset and continue daily until each animal in the litter meets the criterion.[330] Data for each day's testing should be expressed as the number of pups that have achieved the criterion for each developmental landmark, divided by the total number of pups tested in the litter. Forelimb grip test and pupillary constriction tests are conducted on PND 21 only. Data for the forelimb grip test and pupillary constriction tests should be expressed as the number of pups that have achieved the criterion, divided by the total number of pups tested in the litter. The PNDs listed in Table 35.7 for each developmental landmark were compiled from several sources and are subject to variability between laboratories and subtle differences in assessment of the criteria.[330–332]

TABLE 35.7
Developmental Landmarks, Methodology, Initiation, and Acquisition Range

Developmental Landmark	Methodology	Evaluation Initiation	Acquisition Range	References
Day of first estrus	Daily vaginal smears to confirm estrus	Vaginal opening (PND 30)	PND 40 to 45	333
Pinna unfolding	Point of a pinna (ear flap) examined to determine detachment from a head	PND 1	PND 2 to 3	327,332
Hair growth	Pups examined until bristles appear on the dorsal surface of all pups in the litter	PND 1	PNDs 1 to 5	332
Incisor eruption	Eruption through the gum of either an upper or lower incisor	PND 7	PND 8 to 16, mean PND 11	327,332
Eye opening	Pups examined for break in the membrane connecting the upper and lower eyelids	PND 10	PNDs 11 to 18, mean PND 13 or 14	327,332
Nipple retention	Males in each litter examined for the presence of areolae and/or nipples by brushing the hair coat against the nap	PNDs 11	PNDs 12 to 13	327,332
Testes descent	Male examined for the presence of one or both testes in the scrotum	PND 19	PNDs 20 to 29, mean between PND 18 and 25	327,329,332,333

Behavioral or Reflex Ontogeny

Behavioral or reflex ontogeny is a component of developmental neurotoxicity testing that is often included in the preweaning period (e.g., air righting, surface righting, inclined plane (negative geotaxis), limb placing, cliff avoidance, and swimming ontogeny).

Surface-Righting Reflex

The surface-righting reflex is evaluated beginning on PND 1 for rat pups. Surface righting is regaining the normal position after the pup is placed on its back. This is a complex coordinated action requiring many different muscles in the neck, trunk, and limbs. Pups are placed on their backs on a flat surface and quickly released. The criterion is met when the pup regains its normal position on four paws on the floor within 5 s. This usually occurs between PNDs 1 and 9[330,331] in Sprague-Dawley rats, with the average acquisition around PND 6 or 7.[332]

Cliff Avoidance

Cliff avoidance is evaluated beginning on PND 1 for all pups. Cliff avoidance is the behavior of crawling away from an edge of a flat surface edge (cliff). Pups are placed on a table or platform, with their front paws over the edge. The criterion is met when the pup attempts to crawl away from the edge within a 10 s period. This usually occurs between PNDs 2[330] and 12[331] in Sprague-Dawley rats, with the average acquisition around PND 8 or 9.[332]

Forelimb Placing

Beginning on PND 7, rodent pups are tested for forelimb placing or lifting in response to tactile stimulus on the dorsal surface of the foot. The pup is suspended by holding the scruff of the neck so that one forelimb is in contact with a stainless-steel plate (e.g., cage tag holder) held horizontal to the working surface by a clamp and ring stand. The dorsum of the suspended foot is gently touched with a thin (approximately 2–3 mm in diameter) metal rod. The pup must immediately raise and place the suspended foot on the rod to meet the criterion. This usually occurs around PNDs 9 to 10.[323]

Negative Geotaxis Test

Beginning on PND 7, rodent pups are tested for the ability to change from a downward to an upward orientation on an inclined plane of approximately 30°. Each pup is placed facing *downhill* on a platform tilted at a 30° angle. The pup must turn 180° to face *uphill* within a 60 s interval to meet the criterion (a pup with its body positioned sideways and its head facing *uphill* does not meet the criterion). This usually occurs between PNDs 7 and 14[331] in Sprague-Dawley rats, with the average acquisition around PND 7 or 8.[332]

Pinna Reflex

The pinna reflex tests the somatomotor component of the seventh cranial nerve in rats. The presence of the pinna reflex is evaluated daily, beginning on PND 13. The inner surface (near the concha) of the pinna is lightly touched with a filament or the tip of an artist's brush. The criterion is met with the presence of any movement of the pinna (sudden twitch or flattening of the ear) made in response to the applied stimulus. If the first ear tested does not respond to the stimulus, the opposite ear is tested. This reflex usually occurs around PND 14[331] in Sprague-Dawley rats.

Auditory Startle Reflex

Beginning on PND 10, all pups are examined daily for the auditory startle reflex. The auditory startle reflex is noted as a sudden flinch or cessation of ongoing movement following the auditory stimulus. Each nesting box is removed from the study room and placed in a quiet room. Littermates remain outside the testing room in order to mitigate habituation to the auditory stimulus. The pup is placed into a container, such as a beaker, with approximately 600 mL of bedding material and taken into the testing room. A clicker is held directly above the beaker, but not touching it, and the clicker stimulus is delivered. Any observable whole body response (e.g., flinching, jumping, and freezing of activity) meets the criterion for the startle response. This usually occurs between PNDs 12 and 13[330,331] in Sprague-Dawley rats.

Hindlimb Placing

Beginning on PND 14, rodent pups are tested for hindlimb placing in response to a tactile stimulus on the dorsal surface of the foot. Each pup is held so that one hindlimb is in contact with the metal plate. The dorsum of the suspended foot is gently touched with a thin rod. The pup must immediately raise and place the suspended foot on the rod to meet the criterion. This usually occurs around PND 16.[331]

Air-Righting Reflex

The air-righting reflex is the ability of pups to land on all four paws when dropped from an inverted position. All pups in each litter are tested once each day beginning on PND 14 until all pups in the litter demonstrate the reflex. The pup is held in a supine position above a well-padded surface and then released. Rat and hamster pups are held approximately 38 cm above the surface; mouse pups are held 17–20 cm above the surface. The pups must land on all four limbs to meet the criterion. This usually occurs between PNDs 8[330,331] and 18 in Sprague-Dawley rats, with the average acquisition around PND 16 or 17.[332] The use of videotape to record the response will allow more information to be obtained, such as response speed, character, and progression.[334,335]

Forelimb Grip Test (Categorical)

Each pup is tested for forelimb grip on PND 21. A thin rod (approximately 2–3 mm in diameter) is supported by a ring stand suspended horizontally above the padded surface. The pup is held so it can grasp the thin rod with its forepaws and is then released. It must remain suspended for at least 1 s to meet the criterion. The number of pups that met the criterion, divided by the total number of pups tested, is recorded.

Pupil Constriction Reflex

All pups in each litter are examined once on PND 21 for direct and consensual pupillary constriction of both eyes in response to the beam from a penlight. This test evaluates the autonomic component of cranial nerve reflexes. Each nesting box is transferred from the study room to a quiet, isolated testing room, sufficiently dim to dilate the pupils of the eyes of the pups. Each pup is tested individually, with the following requirements to meet the criterion:

- The pup is removed from the nesting box, and the penlight is directed into one eye. Immediate constriction of the pupil of the eye being tested is the initial requirement.
- Without turning the light off, it is immediately directed into the contralateral eye, the pupil of which should already be constricted.

The light is turned off for a minimum of 5 s. This sequence is then repeated for the remaining eye. Reponses should be identical to meet the criterion.

OVERVIEW OF RISK ASSESSMENT

The National Research Council (NRC)[336] defined risk assessment as consisting of *hazard identification*, *dose–response assessment*, *exposure assessment*, and *risk characterization*. This general paradigm is used for risk assessment by many different agencies worldwide. These elements of the risk assessment paradigm are introduced briefly here, and then described in the following sections.

Hazard characterization is the qualitative evaluation of all available data, including laboratory animal data, in vitro studies, and human studies and case reports, to determine the nature of the effects observed and relevance to humans. In the context of the topic of this chapter, the focus is on whether and under what conditions reproductive toxicity and developmental toxicity occur.

Dose–response assessment is the quantitative evaluation between dose level and the response, with the aim of identifying a dose that would be safe for human exposure.

Exposure assessment involves determining who is exposed and the magnitude, duration, frequency, and route(s) of the actual or potential exposure.

Risk characterization integrates the result of the hazard characterization, quantitative dose–response analysis, and human exposure estimates to describe the risk to the exposed population under the scenario of interest, along with a characterization of uncertainty.

The recent NRC (2009) report on Science and Decisions: Advancing Risk Assessment[337] noted the importance of problem formulation and added it to the general risk assessment framework. Building on concepts from the ecological risk assessment field,[338] the process puts additional emphasis on the initial planning, on the *signal* that initiated the risk assessment, and on the options for managing the problem. The risk assessment might be initiated by *signals* such as a positive result for a chemical in an epidemiology study or animal bioassay, a finding of a disease cluster, evidence of high exposure, or the need to evaluate a drug before it enters the market. Note that exposure scenario often plays a key role in the problem formulation. The problem formulation determines the scope, nature, and depth of the risk assessment.

Hazard Characterization

The purpose of the hazard characterization is to conduct an overall WOE evaluation of all relevant available data in order to determine the effects caused by the agent of interest and relevance of those effects to humans. This evaluation requires consideration of both chemical-specific data and other data that may help to inform the WOE evaluation. For example, as described further in the following in the context of MOA evaluation, general biological information, and information on related chemicals may play key roles in the hazard characterization.

In conducting the hazard characterization, the assessor considers the quality and relevance of the available studies. For animal toxicology studies, important considerations include the appropriateness of route, dosing regimen, adequacy of sample size, and endpoints evaluated. Test guidelines for pharmaceuticals and industrial chemicals developed by the ICH[339] and the OECD,[340] respectively, aid in both the conduct of studies and the evaluation of study quality; EPA guidelines have been harmonized with those of the OECD.[89,235] In evaluating whether the data are indicative of an effect occurring in the animal study, a key consideration is whether a dose–response relationship is present.[341] However, one needs to evaluate the data holistically in considering the presence of a dose–response. For example, the incidence of malformations might decrease at high doses, due to the occurrence of a high incidence of resorptions or embryo lethality at those doses. In this case, there is insufficient survival for the malformations to develop.

Guidelines have been developed to aid in the interpretation of reproductive and developmental toxicity data in a risk assessment context and illustrate the critical thinking needed to integrate the data.[236,342] As discussed further later in this section, recent risk assessment approaches emphasize the use of chemical-specific and chemical-related data. However, when such data are not available, guidelines lay out some default assumptions to aid in addressing data gaps. As described by the EPA, the general assumptions used in the absence of data to the contrary include the following[236,342]:

- A chemical that causes an adverse reproductive or developmental effect in animal studies poses a potential adverse reproductive or developmental effect to human if sufficiently exposed at the critical stage.

- Effects of a chemical on male or female reproductive processes or developmental outcome are assumed to be predictive of similar effects in humans.
- With sufficient information, the most appropriate species for estimating risk to humans should be used for hazard characterization. In the absence of these data, the most sensitive species should be used.
- It is assumed that a chemical that affects the reproductive function or development of the offspring of one sex may also affect the reproductive function or development of the other sex.
- When the MOA and pharmacokinetics data are available, they should be used for low-dose extrapolation. In the absence of these data, a threshold is assumed for chemicals that produce reproductive or developmental toxicity.[343]
- Effects of xenobiotics on male and female reproductive processes are assumed to be generally similar unless demonstrated otherwise.
- All four types of developmental toxicity effects (death, structural abnormalities, growth alterations, functional deficits) are of potential concern.
- Developmental effects seen in animals are not necessarily the same as those that may occur in humans.

As noted, these default assumptions apply when data are not otherwise available, but it is the risk assessor's responsibility to consider all of the available data before resorting to defaults. These data include not only the toxicology data on the chemical and any available human data. Other information can come from in vitro studies or knowledge of molecular structure–activity relationships.[344] These latter types of data sources can be particularly important in contributing to an understanding of a chemical's MOA. The MOA can be thought of as a general description of how the chemical causes toxicity[345] and is distinguished from the detailed description at the molecular level that comprises a description of a chemical's MOA. The MOA is defined in terms of *key events*, empirically observable precursor steps (or markers for such steps) that are necessary for the development of the toxic endpoint of interest. Both chemical-specific information and general understanding of the relevant biology can be used in defining an MOA.

An important shift in the thinking about risk assessment is reflected in the transition from hazard identification (determining effects occurring in animal studies) to hazard characterization. Hazard characterization is a holistic WOE evaluation of the data, including evaluation of the relevance of the observed effects to the exposure scenario of interest and relevance to humans, based on such factors as the dose at which the effect occurred, the chemical's MOA, and interspecies differences. In conducting this integrative evaluation, the risk assessor considers any differences in patterns of effects, any differences seen between studies, and the potential reasons for the observed differences. These reasons could include first-pass metabolism, and differences between rat strains in endocrine regulation, or differences in study design. Rather than simply adding positive and negative results, the WOE evaluation includes a critical evaluation of all of these.

MOA is a key concept that plays several roles in the hazard characterization. It can aid in the development of a full description and an integrated understanding of the effects caused by the chemical. MOA is also used in evaluation of the human relevance of effects observed in animals and in prioritization and screening applications, where structural similarities and an understanding of the chemical and physical properties are used to reach some general predictions of a chemical's expected effects and relative potency. Some key MOAs relevant to developmental and reproductive effects include cytotoxicity, changes in cell fate regulation, and hormonal perturbations, which can result from the chemical acting as a hormone mimic, changes in hormone metabolism, effects on hormone-producing or regulatory tissue, or other mechanisms.

The data regarding a hypothesized MOA are evaluated using the modified Hill criteria.[346] These criteria include the following:

- Dose–response relationship
- Temporal relationship
- Consistency—reproducibility across database, related endpoints
- Coherence—biological plausibility of MOA
- Strength—magnitude of association
- Specificity—apical effect seen only following the occurrence of key event

Of these criteria, evaluating data on the dose–response relationship and temporal relationship between key events and the effect of interest is particularly important. If the key event is part of the MOA, the key event should occur at lower (or comparable) doses and earlier (or comparable) times compared with the endpoint of interest.

Once the MOA has been established in the experimental animal species, the data can be used to evaluate the human relevance of that MOA. This is done using the framework developed by the Internationale Programme on Chemical Safety (IPCS) and International Life Sciences Institute (ILSI).[345,346] This approach is presented in Figure 35.22. If the MOA in animals cannot be determined, the endpoint is assumed to be relevant to humans, and the dose–response implications of toxicokinetic and toxicodynamic differences are evaluated. If the MOA is established in the experimental animal species, the human relevance framework goes on to ask whether (1) human relevance of the MOA can be reasonably excluded on the basis of fundamental, qualitative differences in key events between animals and humans and (2) human relevance of the MOA can be reasonably excluded on the basis of quantitative differences in either kinetic or dynamic factors between animals and humans. If the answer to either of these questions is yes, then the MOA is determined to not be relevant to humans. If the answer to both questions is no, implications of toxicokinetic

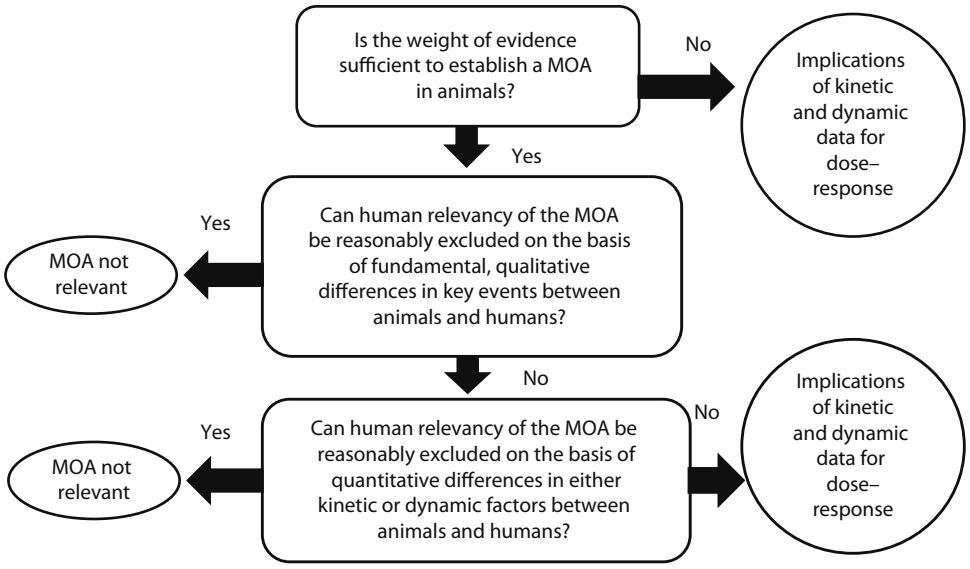

FIGURE 35.22 IPCS/ILSI mode of action framework.

and toxicodynamic differences on the dose–response are evaluated. Both chemical-specific information and a general understanding of biology and physiology are used in addressing the questions.

The result of the hazard characterization is a determination of which endpoints should be carried forward into the dose–response assessment. As discussed in the following, the hazard characterization for pharmaceuticals also includes a risk–benefit evaluation, weighing the risk of adverse effects against the benefit from the intended use of the drug.

Dose–Response Assessment

Dose–response assessment is the quantitative evaluation between dose level and the response, with the aim of identifying a dose that would be safe for human exposure. The same general approach is used for multiple regulatory agencies, including agencies that regulate industrial chemicals, food additives, and pesticides. Dose–response assessment for pharmaceuticals typically follows a comparative approach, comparing the doses at which the pharmaceutical would be administered with those projected to cause adverse reproductive or developmental side effects. Fewer extrapolations tend to be needed for the assessment of pharmaceuticals, although reproductive or developmental data are usually not available in humans.

General Quantitative Approach

Many different regulatory organizations use similar approaches for calculating safe doses, or health-based guidance values (HBGVs) although the name used to describe that value varies. These include International Programme on Chemical Safety's Tolerable Intake (TI),[347] U.S. EPA's Reference Dose (RfD)[348] or Reference Concentration (RfC),[349] or the WHO's Acceptable Daily Intake (ADI), which is also used by WHO agencies for food additives and pesticides. The general safe dose approach is designed to protect sensitive populations from lifetime exposure to the chemical of interest. HBGVs are calculated by dividing a point of departure, such as a NOAEL, lowest-observed-adverse-effect level (LOAEL), or NOAEL surrogate, such as a benchmark dose/concentration (BMD/BMC), by uncertainty factors that account for areas of uncertainty and extrapolations needed to calculate the HBGV from the available data. The goal for the point of departure is to identify the dose boundary for the onset of the effect from the most relevant species, or the most sensitive species, if the most relevant is not known.

The approaches used by different organizations in determining uncertainty factors (UFs) share many commonalities, although there are some differences. All organizations include UFs for extrapolation from animal data to humans (interspecies factor) and for considering human variability and protection of sensitive populations (intraspecies factor). These factors reflect variability that is inherent to the population; additional data can characterize that variability, but not remove it. For these areas of uncertainty, the state of the science is to develop a *chemical-specific* (also called *data derived*) adjustment factor to quantify the interspecies differences or human variability, if data are available. If such data are not available, then a default uncertainty factor of 10 is generally used. IPCS has developed guidelines for the data needed to develop chemical-specific adjustment factors (CSAFs) based on chemical-specific or chemical-related data as the basis for adjustments to the point of departure instead of default uncertainty factors.[350]

The U.S. EPA is perhaps the most explicit in considering the areas of uncertainty, an approach that is followed by some other agencies. The EPA considers five areas of uncertainty in the development of its HBGV (the RfD/RfC). In the absence of data, a default factor of 10 is used for each

area; rules for combining uncertainty factors reflect the overlap that exists between factors.[351] In addition to the two uncertainty factors noted earlier (addressing interspecies differences and intraspecies variability), EPA uses three uncertainty factors to address database deficiencies. These factors address true uncertainty and can be replaced by data. These areas of uncertainty are for LOAEL to NOAEL extrapolation, subchronic to chronic extrapolation, and (other) deficiencies in the database.

Two of the uncertainty factors are of particular importance for issues related to DART endpoints, including potential systemic and developmental effects in children. The first is the factor addressing human variability, including variability resulting from such factors as genetic differences and age-related differences. Increased sensitivity in children could result, for example, because many enzyme systems have low activity during the first year of life, resulting in increased sensitivity if the parent chemical is the active form, but decreased sensitivity if the metabolite is the active form. Other physiological differences, including the potential for increased sensitivity in the growing organism, may also make children more sensitive than adults. Several risk assessment frameworks or guidance documents are available on issues to consider in conducting risk assessment for different life stages or developmental stages.[352–354]

The second uncertainty factor of particular importance to DART endpoints is the factor addressing deficiencies in the database. This uncertainty factor addresses the question of whether the correct critical effect has been identified, or whether a different critical effect at a lower dose would be identified if an additional study were conducted. In the absence of adequate human data, U.S. EPA considers that the minimum database for development of a high-confidence RfD or RfC, sometimes referred to as a *complete* database for calculating an RfD/RfC, includes the following studies[349,351]:

- Two adequate mammalian chronic toxicity studies by the appropriate route in different species
- One adequate mammalian multigenerational reproductive toxicity study by an appropriate route
- Two adequate mammalian developmental toxicity studies by an appropriate route in different species

Because the minimal database for calculating an RfD/RfC is a subchronic systemic toxicity study, the data gaps often include reproductive and/or developmental toxicity studies. In an analysis of pesticide data (for which all five study types were available), Dourson et al.[355] found that the systemic toxicity and reproductive toxicity studies were most likely to identify the critical effect. For most chemicals, developmental effects occurred at higher doses.

For pesticides, the Food Quality Protection Act (FQPA) factor addresses specific concerns about the potential for greater sensitivity of children. However, EPA has stated that an additional factor addressing hazard considerations for children is not needed if "appropriate care has been taken in accounting for all deficiencies and uncertainties in the database using the currently available uncertainty/variability factors."[356] The FQPA factor also incorporates exposure considerations that result in age-dependent sensitivity and are not addressed with the standard uncertainty factors.

EPA guidelines for developmental toxicity risk assessment[236] also describe the approach for setting RfDs specific for developmental toxicity (RfD_{DT}s). The approach is similar to that used for general RfDs, except that the point of departure is based on the most sensitive *developmental* effect. The interspecies and intraspecies uncertainty factors and the factor for LOAEL to NOAEL extrapolation would be applied as for general RfDs. However, the factors for subchronic to chronic extrapolation and (other) deficiencies in the database would generally not be applied in developing an RfD_{DT}. Although the RfD_{DT} is noted in EPA guidance, relatively few have been developed; the RfD for lifetime exposure is intended to protect from developmental effects and may be lower than the RfD_{DT}.

State of the Science Methods

The BMD or its lower confidence limit (the BMDL) can be used as a point of departure instead of an NOAEL or LOAEL.[357–360] The BMD is determined by fitting a flexible mathematical model to the data and determining a dose corresponding to a defined response level. BMD modeling has several advantages over the NOAEL method: (1) the BMD is not limited to the tested doses, (2) a BMD can be calculated even when the study does not identify an NOAEL, and (3) unlike the NOAEL approach, the BMD approach accounts for the statistical power of the study. The EPA has developed user-friendly software for conducting benchmark dose modeling (BMDS)[361]; functionally similar software is available from Netherlands National Institute for Public Health and the Environment (RIVM).[362] Of particular interest in the context of this chapter are the specialized BMD modules for modeling the nested data available for developmental toxicity studies when data are available at the level of the individual pup within each litter. These models can account for the fact that measurements are made on pups, but the litter is the unit of measurement, due to the impact of the mother's biology and toxicokinetics. The models can include both intralitter correlations and litter-specific covariates, such as litter size. Based on the results of a series of studies comparing BMDLs associated with different definitions of the benchmark response (BMR) and NOAELs,[363–366] the standard BMR used as the point of departure for developmental toxicity studies when quantal nested data are available is 0.05.[364] Modeling of reproductive endpoints is conducted in the same manner as for systemic endpoints, using the standard BMDS models. The default BMR for reproductive endpoints is 0.1 for quantal endpoints, or a 1 standard deviation change in the mean for continuous endpoints, if information on the degree of change that is considered adverse is not available.[360]

Physiologically based pharmacokinetic (PBPK) models can be used to improve the extrapolations needed in developing an HBGV. PBPK models describe the flow and transformation of the chemical by the body (toxicokinetics) using

species-relevant organ and tissue volumes, blood flows, and kinetic transformation parameters (reviewed by Clewell[367]). This allows the estimation of the biologically important dose delivered to the target organ(s), based on the relevant dose metric. When selecting the PBPK models compartments to be represented for reproductive and developmental endpoints, consideration must be given to the target site (e.g., fetus, sperm) and portal of entry (e.g., lung, placenta). A challenge unique to PBPK models for developmental toxicity is the need to capture the rapidly changing growth dynamics of the maternal and fetal tissue.[368] Since the metabolism in reproductive organs is often limited in terms of their overall impact, these organs are not routinely represented as separate compartments and are frequently lumped together. PBPK models have been used to replace the default UF for interspecies differences based on a characterization of the relationship between exposure and tissue dose.[369]

A key concept for both interpreting developmental toxicity studies and applying the results in a risk assessment is the idea of a window of susceptibility. It is assumed that a single exposure at a sensitive developmental stage can produce an adverse effect. Thus, even though standard developmental toxicity studies involve exposures for all of the gestational period, or during major organogenesis, it is assumed that a single exposure could cause an effect if it happened during the window of susceptibility to the effect. The relevant window should be considered in interpreting the results of toxicity studies, particularly if exposure did not include the entire gestational period. Similarly, human exposures that are compared with an HBGV should not be adjusted for the duration of exposure or pattern of exposure.

A particularly challenging issue in interpreting developmental toxicity data is the interpretation of developmental effects that occur in the presence of maternal toxicity, and determining whether the effects reflect true developmental toxicity or are secondary to the maternal toxicity. Fetal endpoints commonly associated with maternal toxicity include rib malformations, cleft palate, decreased fetal body weight, and fetal death.[370] This issue has been addressed in several review articles and guidance documents,[370–372] which provide information on approaches to use in considering the issue. The relative severity and dose–response for the maternal and fetal effects are important for this evaluation. For example, the observation of mild fetal effects (e.g., mild decrease in body weight) only in the presence of frank maternal toxicity is consistent with the effect being secondary to maternal toxicity, while fetal effects seen only in the presence of more mild maternal toxicity should be considered as evidence of potential developmental toxicity. Mechanistic studies and pair-feeding studies can also aid in determining whether the developmental effects reflect a direct effect of the chemical or are secondary to maternal toxicity.

Exposure Assessment

The exposure assessment includes characterizing the exposed population, and the magnitude, duration, frequency, and route(s) of the actual or potential exposure. Several considerations are of particular interest in the context of developmental and reproductive toxicity. Exposure of the fetus or neonate can occur via placental transfer or breast milk, and so these exposures are dependent on maternal absorption, distribution, metabolism, and excretion. Direct exposure of neonates and children may also occur via the environment (water, air, soil) and therefore may require estimates of exposure from multiple sources. Duration and timing of exposure must be related to the stage of development (first, second, or third trimester; infancy; childhood; or adolescence).

EPA's Guidelines for Exposure Assessment[373] discuss various approaches for monitoring actual exposures or modeling various exposure scenarios. Exposure factors have been published for adults and children of various ages to aid in estimating exposure from a variety of sources, including food and water consumption, respiration, activity patterns, body weight, soil ingestion in children, and respiration rates in children and adults.[374,375] These data can be used to estimate exposure from various sources, or as input into exposure modeling.

Risk Characterization

The risk characterization integrates the result of the hazard characterization, quantitative dose–response analysis, and human exposure estimates to describe the risk to the exposed population under the scenario of interest, along with a characterization of uncertainty. The characterization includes the strengths and weaknesses of each component of the risk assessment, as well as major assumptions, relevancy to humans, scientific judgments, level of confidence, and when possible, qualitative descriptions and quantitative estimates of uncertainties. Key risk characterization principles are transparency, clarity, consistency, and resonableness.[376] Key aspects specific to reproductive and developmental toxicity include ensuring that the exposure assessment and dose–response assessment were consistent in terms of the problem formulation, particularly the population exposed and the exposure scenario.

Drug Safety Studies

There are two key differences between risk assessment for chemicals and for pharmaceuticals. The first is that pharmaceuticals are used to treat specific diseases, and so risk is considered on a risk-benefit basis; that is, the beneficial uses of the agent are compared with the risk of its use. The second is that pharmaceuticals are provided to a targeted population, and so developmental and reproductive risks can be managed by not administering the drugs to certain populations (e.g., pregnant women).

These issues are addressed in the labeling of the pharmaceutical, published, for example, as the official FDA-approved package insert of a drug or biologic. This system was established by law in 1979 to assist physicians prescribing drugs to pregnant women and categorizes risk by assigning a pregnancy label category to drugs and biologics (Table 35.8). Category A is the safest, having proven safety

TABLE 35.8
FDA Labeling Requirements: Pregnancy Categories

Category	Effects	Criteria
A	Animal studies and well-controlled studies in pregnant women failed to demonstrate a risk to the fetus.	Most stringent criteria
B	Animal studies have failed to demonstrate risk to fetus; no adequate and well-controlled studies in pregnant women.	Less stringent criteria
C	Animal studies showed adverse effect on fetus; no well-controlled human studies.	Assumes risk without data
D	Positive evidence of human fetal risk based upon human data, but potential drug benefit outweighs risk.	Expect effects on humans
X	Studies show fetal abnormalities in animals and humans; drug is contraindicated in pregnant women.	Indicates high adverse risk

Source: Adapted from Collins, T.F.X. et al. Principles of risk assessment—FDA perspective, In: *Developmental and Reproductive Toxicology—A Practical Approach*, Hood, R.D., ed., 2nd edn., CRC Press, Boca Raton, FL, 2006, pp. 877–909.

in humans. Category X drugs are the most hazardous, having proven adverse developmental or reproductive effects in humans or animals and thus are contraindicated during pregnancy. Precautionary statements, regardless of animal study findings, are often included in product labels, since there are limitations in predicting human risk from animal data. An example of such a statement is as follows: "There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction and developmental studies are not always predictive of human response, 'the drug' should be used during pregnancy only if clearly needed."

The categories may mislead healthcare providers (and the women they counsel) to believe that risk increases from category A to B to C to D to X. In fact, that is not the case, because Categories C, D, and X are based not just on risk, but reflect risk weighed against benefit. That means that a drug in categories C or D may pose risks similar to a drug in Category X.

FDA Guidance[372] provides an approach for integrating nonclinical reproductive and developmental toxicity data, in order to determine the appropriate wording for labeling. The overall approach is conceptually consistent with the concepts discussed earlier for hazard characterization. According to this approach, *positive signals* are broadly classified as reproductive or developmental toxicities. Reproductive toxicity is broken into three subclasses: male fertility, female fertility, parturition, and lactation; these endpoints include both structural and functional changes affecting the reproductive competence of male and/or female animals in the parental (F_0) generation. Developmental toxicity has four subclasses: developmental mortality, dysmorphogenesis, alterations to growth, and functional toxicity. The decision process described in Figures 35.23 through 35.25 applies to any reproductive or developmental endpoint. Human data are considered separately from nonclinical findings but carry considerable weight in the overall evaluation.

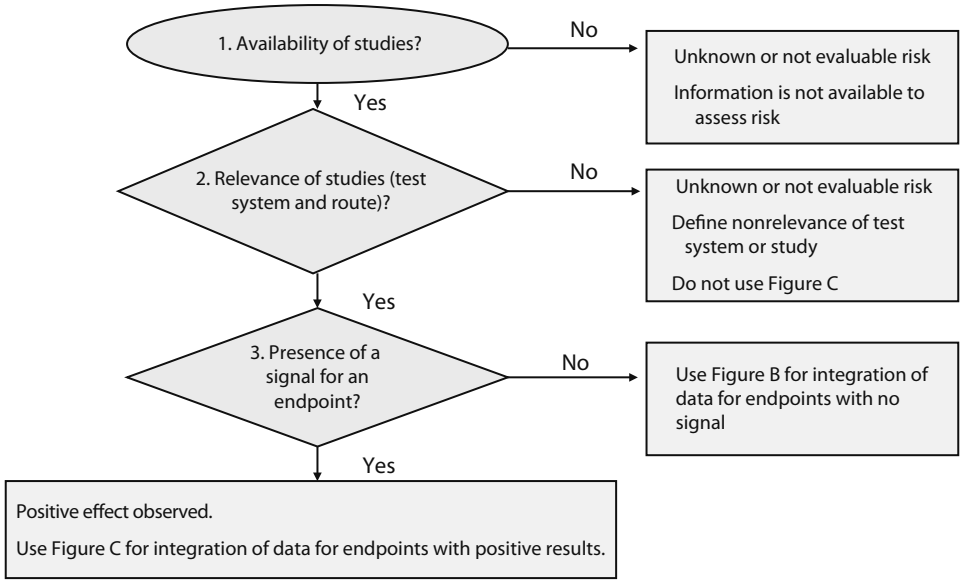

FIGURE 35.23 FDA Flowchart A: Overall decision tree for evaluation of reproductive/developmental toxicities.

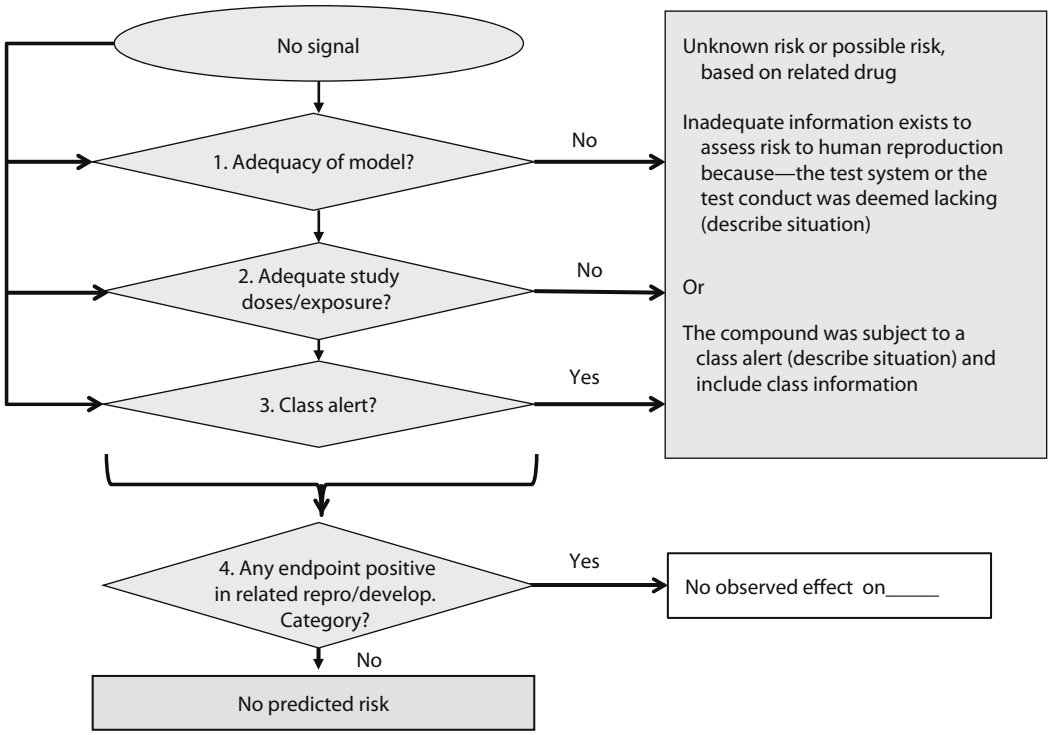

FIGURE 35.24 FDA Flowchart B: Decision tree for endpoints with no signal.

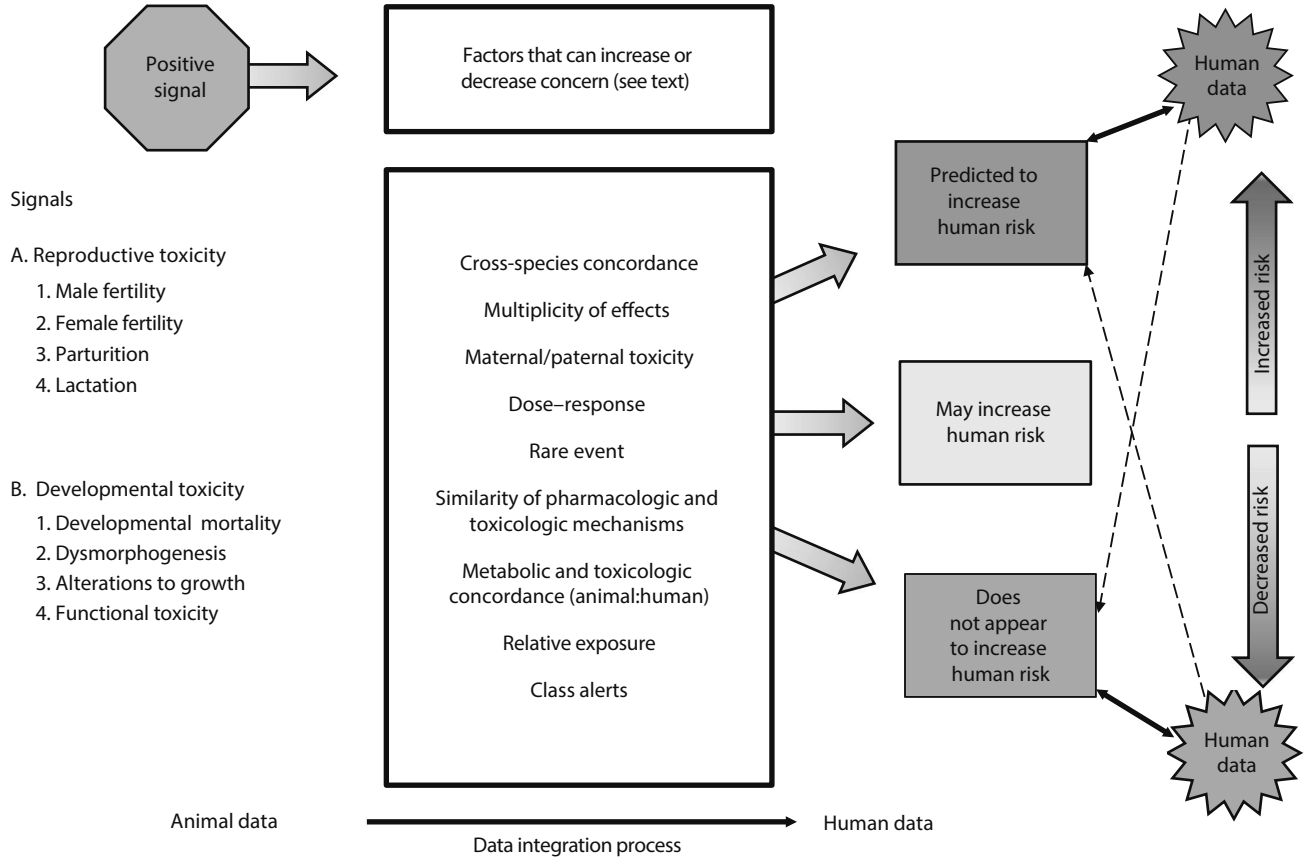

FIGURE 35.25 FDA Flowchart C: Integration of reproductive or developmental toxicities with a positive signal.

Flowchart A (Figure 35.23) is used to evaluate the available studies and determine the next steps in the evaluation. If relevant studies conducted via a relevant route are available, the presence of a positive signal for an endpoint is evaluated. If there are no positive signals in any of the studies addressing a particular reproductive or developmental endpoint, the evaluation continues with Flowchart B (Figure 35.24). This flowchart includes further evaluation of the test adequacy and consideration of other potential reasons for concern, such as findings for related chemicals or for related endpoints. When positive signals exist for reproductive or developmental endpoints, factors that can increase or decrease the level of concern are evaluated for class of toxicity (see Flowchart C, Figure 35.25).

Flowchart C illustrates a number of key factors that contribute to the overall evaluation by increasing or decreasing the level of concern for adverse effects in humans. Scientific judgment is critical in integrating the data for a final conclusion; other factors may also contribute. The factors in the flowchart are as follows:

- Cross-species concordance—observation of the same *or related* types of toxicity in multiple species increases the concern
- Multiplicity of effects—observation of two or more positive signals in a single species within the general categories (reproductive or developmental toxicity) increases concern
- Maternal or paternal (in fertility studies) toxicity—signal in the absence of maternal toxicity increases concern; signal only in the presence of frank maternal toxicity may decrease concern if attributed to maternal toxicity
- Dose–response—concern is increased when the incidence or severity of effect increases with dose
- Rare event—an increased incidence of rare events increases the concern, even though small increases may not be statistically significant
- Similarity of pharmacologic and toxicologic mechanisms—concern is increased if the observed effect is related to the drug's intended pharmacologic MOA
- Metabolic and toxicologic concordance between animals and humans—concern is increased by this concordance and decreased by lack of concordance, as illustrated in the MOA discussion earlier
- Relative exposure—the appropriate dose metric (e.g., area under the [concentration × time] curve [AUC], Cmax) is identified and used to evaluate relative exposure in animals versus humans, with ratios <10 increasing concern and ratios >25 decreasing concern
- Class alerts—concern is increased when the drug belongs to a class known to produce adverse reproductive/developmental effects in humans and animals and is decreased only where a class of compounds has produced no adverse effects on human reproduction, despite adverse effects in animals

Based on these factors, a WOE approach is used to reach an overall conclusion regarding the drug's potential for reproductive or developmental toxicity in humans.

Timing of Preclinical Developmental and Female Reproductive Toxicity Studies

The timing of the conduct of preclinical reproductive toxicity studies is based on the population in which the clinical trials are going to be performed and on the ICH countries that the investigational new drug and/new drug application (IND/NDA) will be submitted.[377,378]

Women Not of Childbearing Potential

Women who do not have childbearing potential (i.e., permanently sterilized, postmenopausal) can be included in clinical trials without reproductive toxicity studies if the relevant repeated-dose toxicity studies (which include an evaluation of the female reproductive organs as described earlier) have been conducted.

Women of Childbearing Potential

A high level of concern exists for the unintentional exposure of an embryo or fetus of the women of childbearing potential (WOCBP). When WOCBP are included in clinical trials, the risk to the embryo or fetus should be minimized. Minimizing the risk can be achieved by conducting preclinical reproductive toxicity studies to understand the inherent risk of a drug. Alternatively or in addition, the risk can be limited by taking precautions to prevent pregnancy during clinical trials. Informed consent should be based on any known pertinent information related to reproductive toxicity, such as a general assessment of the potential toxicity of pharmaceuticals with related structures or pharmacological effects. If no relevant reproductive information is available, the potential for risks should be communicated.

Timing of Clinical Trials[379]

The recommendations on timing of reproductive and developmental toxicity studies to support the inclusion of WOCBP in clinical trials are similar in all ICH regions (the United States, EU, and Japan). WOCBP can be included in clinical trials without nonclinical developmental toxicity studies (e.g., embryotoxicity studies) in certain circumstances. WOCBP can be enrolled in clinical trials of short duration (such as 2 weeks) with intensive control of pregnancy risk.[380] WOCBP can also be enrolled in longer duration clinical trials when the objectives of the clinical trial cannot be effectively met without their inclusion, when the disease occurs predominantly in women, and when pregnancy risk can be adequately controlled. WOCBP can also be considered for inclusion in early clinical studies without the nonclinical developmental toxicity studies, based on the knowledge of the type of pharmaceutical agent (e.g., an antibody), its MOA, its absorption, distribution, metabolism, and excretion (ADME) characteristics (such as half-life, AUC, Cmax), and difficulty of conducting developmental toxicity studies in an appropriate animal model.

Generally, where appropriate preliminary developmental toxicity data are available from two species but the definitive reproductive toxicity testing has not been completed, and where adequate birth control methods are used, WOCBP can be included in clinical trials for a relatively short duration (up to 3 months), and a relatively small size (consisting of 150 subjects) can be used. An appropriate preliminary embryo–fetal study is defined as a study with adequate dose levels with a minimum of six dams per group that are treated over the period of organogenesis: assessment of fetal survival, body weight, and external and visceral examinations. The timing of the conduct of the reproductive and developmental toxicity studies varies by region:

- In the United States, assessment of embryo–fetal development can be deferred until prior to phase III for WOCBP using highly effective contraceptive methods.
- In the EU and Japan, definitive nonclinical developmental toxicity studies should be completed prior to exposure to WOCBP.
- In all ICH regions, nonclinical studies that specifically address female fertility should be completed to support inclusion of WOCBP in phase III trials.
- In all ICH regions, the pre- and postnatal development study should be submitted for marketing approval or earlier if there is a cause of concern.

Pregnant Women

All of the reproductive toxicity studies and the standard battery of genotoxicity tests should be conducted prior to the inclusion of pregnant women in clinical trials. In addition, safety data from previous human exposure should be evaluated.

Pediatric Populations

Reproductive toxicity studies relevant to the age and gender of the pediatric patient populations under study can also be important to provide information on direct toxic or developmental risks (e.g., fertility and prenatal and postnatal developmental studies). Embryotoxicity studies are not critical to support clinical studies for males or prepubescent females. Results from repeated-dose toxicity studies of appropriate duration in adult animals, the core safety pharmacology package, and the standard battery of genotoxicity tests should be available prior to the initiation of trials in pediatric populations. Juvenile animal toxicity studies are designed on a case-by-case basis.[225]

Labeling Approaches

Proposition 65 (California)

As described on the California EPA website,[381] Proposition 65 was an initiative approved by California voters in 1986 to address their growing concerns about exposure to toxic chemicals. That initiative became the Safe Drinking Water and Toxic Enforcement Act of 1986, better known by its original name of Proposition 65. Proposition 65 requires the State of California to publish a list of chemicals known to cause cancer or birth defects or other reproductive harm. This list has grown to include approximately 800 chemicals since it was first published in 1987. Proposition 65 also requires businesses to notify Californians about significant amounts of chemicals in the products they purchase, in their homes or workplaces, or that are released into the environment. For example, labeling of products is required if exposure to a chemical listed based on reproductive or developmental toxicity is greater than the no observable effect level (NOEL) divided by 1000. As illustrated by this program, the ability to assess and characterize the reproductive and developmental health of a community is often limited by a lack of data and a lack of consensus as to the adverse effects of a specific chemical. Evidence cited by Mattison[382] indicates that of the estimated 90,000 chemicals in commerce in the United States, only 4000 have been tested in animals for reproductive or developmental toxicity, and up to one third of the tested substances may be reproductive or developmental toxicants. A study by the NRC[383] also concluded that only a small fraction of the chemicals tested contained enough toxicity information for reproductive and developmental hazard identification. The growing field of high-throughput screening, alternative test systems, and in silico (computer analysis) evaluation of structure–activity relationships is likely to help address this data gap, although numerous challenges remain.[384–386] These approaches, combined with a thoughtful approach to consideration of MOA, can help focus resources on the chemicals most likely to have reproductive or developmental effects.

Globally Harmonized System (GHS); REACH

Labeling of developmental and reproductive toxicants is also required under both the GHS and REACH. GHS is a harmonized system of classification and labeling of chemicals under the UN.[387] REACH is an EU regulation addressing the production and use of chemicals and their effect on human health and the environment. Both labeling systems follow IPCS guidelines for chemical evaluation and are based on WOE approaches.

CONCLUSION

The goal of this chapter is to familiarize the reader with the basic anatomy and physiology of the female reproduction system and embryo/fetal/neonatal development, methods used to assess the impact of chemical exposure on these endpoints, and how to apply those concepts in a risk assessment context. The importance of these topics is reflected in the reports of barren women and malformations in babies dating back to ancient times. Exposure to biotoxins, chemical toxicants, radiation, malnutrition, disease, hyperthermia, or stress in the environment, home, or workplace can lead to infertility, adverse pregnancy outcome, and poor childhood development. Appreciating how these exposures can adversely affect reproduction and development requires understanding of the sequence of events involved. The continuous biological changes that occur in the mother, placenta, fetus, and neonate follow a tightly controlled series of events, complicating the evaluation of the effects of chemical exposures.

Even with current experimental paradigms and international harmonization of DART testing guidelines, animal

studies will still provide the vast majority of information needed for regulatory risk assessment for humans for at least the immediate future. The future of DART testing will likely focus on three major areas: (1) advances in new real-time technologies to examine the fetus in utero, such as ultrasound, positron emission tomography (PET) imaging, and microcomputer tomography (micro-CT); (2) continued application of receptor-mediated developmental toxicity and intercellular signaling pathway analyses; and (3) refinement of current in vitro and in silico models to better identify and predict potential reproductive hazards and risks, including the use of human ESCs and induced pluripotent stem cells (iPSCs) that provide an unprecedented window to examine reproductive and developmental toxicants. Genomic technologies are developing new reproductive and developmental screening strategies, biomarkers for toxicity, mechanisms of cellular toxicity and molecular perturbations, and monitoring alterations in key biochemical pathways.[388] Together, these new developments will help improve the speed and predictivity of nonanimal testing methods, leading to cheaper, faster, and more accurate assessments.

ACKNOWLEDGMENTS

The authors wish to thank all of the people in our lives and career who have contributed to our understanding of reproductive and developmental toxicology. We especially want to express our appreciation to our mentors Mildred Christian, Jeanne Manson, Bill Scott, Jim Schardein, Andy Hendrickx, Alan Hoberman, Andrew Maier, and Michael Dourson. And a special thanks to Alan Hoberman for agreeing to review this manuscript.

KEYWORDS

Developmental and reproductive toxicology, Gametogenesis, Fertilization, Ovarian and placental toxicity, Estrous, Implantation, Parturition, Lactation, Birth defects, Perinatal mortality, Behavior, Testing guidelines, Risk assessment

QUESTIONS

35.1 A new carbamate (AChE inhibitor) insecticide needs approval. What developmental and reproductive testing needs to be conducted?

35.2 A new biologic (polypeptide) drug for diabetes is being developed. Would going straight to the nonhuman primate to conduct the developmental toxicity testing instead of the standard rat and rabbit developmental toxicity studies be appropriate? When would using transgenic animal models be better for this testing?

35.3 A new drug is being developed for breast cancer. What maternal, fetal, and developmental landmark endpoints may be of particular interest and why?

35.4 What in vitro or in silico tests have been developed to screen for potential female reproductive toxicity?

35.5 How would you use MOA information to address the implications of data gaps for the choice of uncertainty factors for an industrial chemical?

36 Hormone Assays and Endocrine Function

Robert M. Parker and Raymond G. York

CONTENTS

INTRODUCTION

All physiological responses are essentially controlled by two primary monitoring/control systems: (1) the nervous system, which is electrical in nature and controls processes requiring immediate attention, such as breathing, skeletal muscular movements, and heartbeat, and (2) the endocrine system, which is chemical in nature and controls slower processes, such as cell growth and development, metabolism, and sexual function. Both systems are critical to the body's function, and they frequently work together to allow the body to function at its most optimal level.

The purpose of this chapter is to examine the endocrine system of physiological control. The endocrine system basically consists of ductless glands or cells that secrete chemical messengers that are released into the bloodstream or local cellular fluid. Hormone receptors strategically placed throughout the body recognize and ultimately react to the presence of the hormone and affect a biological change. Hormones are usually very specific in nature, binding to a specific receptor in much the same way a key fits into a lock. There may be many keys present at the location of the locks, but only one fits and creates a hormonally activated receptor; therefore, even though hormones reach all parts of the body, only target cells with compatible receptors are equipped to fully respond. When a receptor and a hormone bind, the receptor carries out the instructions of the hormone by either altering the existing proteins of the cell or building new proteins. These actions create hormonally mediated chemical reactions throughout the body.

In conjunction with the nervous system, the endocrine system integrates many different processes that allow multicellular organisms to maintain homeostasis. It is estimated that there may be at least 50 hormones in mammals.[1] Several drugs and chemicals are known to affect the endocrine system.[2] Perturbation of endocrine homeostasis often produces consequences that can lead to metabolic derangements, developmental abnormalities, and sexual or reproductive dysfunction. Endocrine disruptors, including environmental estrogens, is a contemporary term used to describe such effects. Endocrine toxicology involves the study of chemicals and drugs that disrupt endocrine processes, leading to either augmentation or inhibition of a physiologic response.[3] In a broad sense, endocrine toxicology encompasses reproductive toxicology (see Chapters 33 and 34).[4] In addition, endocrine toxicology can also include metabolic derangements that result from toxic injury to nonendocrine systems; for example, renal or hepatic toxicity may alter the rate of hormone catabolism. This chapter reviews endocrine physiology, morphology, and endocrine function as it relates to toxicology. Another area of interest is endocrine pharmacology, which involves the therapeutic and diagnostic use of hormones and other nonhormonally related agents. It can also encompass endocrine toxicology, as many nonhormonal medicinal products possess side effects that can alter the biochemical activity of the organs of internal secretion.[5] Importantly, molecular biology continues to provide a number of techniques that are very useful in endocrinology.[6]

Although some endocrine organs appear to be more sensitive or vulnerable to toxicologic agents than others, hormone–target organ interrelations often lead to a substance causing multiple disruptions in the hormonal balance of the organism. It is not uncommon to witness chemically induced changes in gonadal function along with alterations in thyroid gland activity. In some species, chemically induced changes in sex steroids can affect pancreatic secretion of insulin. Chemically induced stress leading to increased secretion of glucocorticoids (GCs) can also affect insulin secretion but more importantly can affect adrenocorticotropin hormone (ACTH) levels and hence alter the pituitary–adrenal axis.

The thalidomide tragedy of the 1960s led to the formulation of toxicologic testing guidelines for the field of teratology beginning as early as 1962. No such guidelines have been invoked for the endocrine system. Pesticide-induced sterility (e.g., dibromochloropropane [DBCP]) first reported in 1977[7] eventually led to concern about the deleterious actions of such substances in both male and female reproductive systems.[8,9] The inherent estrogenicity of *o,p′*-dichlorodi phenyldichloroethane (*o,p*-DDD) can affect the reproductive

system, and concern has been expressed about the possible relation between diethylstilbestrol (DES) and the incidence of vaginal and cervical cancers[10]; thus, numerous examples of chemically induced changes in the endocrine system have been reported. Because many of these agents represent reproductive hazards in the workplace, the endocrine system falls prey to many such agents. Polyhalogenated biphenyls, dibenzodioxins, and dibenzofurans can interfere with thyroid hormone metabolism. Certain insecticides and pesticides can be toxic to the pancreatic β cell.

Agents toxic to the endocrine system reach a relatively small number of individuals at the site of manufacture, which can be controlled, but they gain access to entire communities when, for example, toxic wastes are released into the environment. Large geographic regions are exposed to natural goitrogens, such as resorcinol, that are derived from regional coal and shale deposits. Likewise, radioisotopes of iodine released during atmospheric nuclear weapons testing or reactor accidents can be disseminated over very large areas in detectable, if not clearly toxic, concentrations throughout the world.[11]

Conceptually, the endocrine system is vulnerable to chemical toxicity at multiple points. Most, if not all, tissues are target organs of one or more hormones and are influenced in some fashion by endocrine substances. A vast number of critical biological processes, for example, are regulated by the endocrine system, including brain and nervous system development, development of the reproductive system and secondary sex characteristics at puberty, metabolism, and blood sugar maintenance. In fact, major physiological events from conception and infancy through adolescence to old age are generally mediated by large numbers of various hormones working together with the nervous system to achieve this immensely complex task. Because of structural similarity to certain hormones, some toxic substances interfere with hormone metabolism or subsequent actions at the receptor site. Still other toxic agents interfere directly with the glands that synthesize and secrete hormones. Compounding the chemical vulnerability of the endocrine system are the tier and feedback systems of many hormones.

The effects of thyroid hormone on a target organ are dependent on the quantity of thyroid hormone secreted by the thyroid. Thyroid secretion is regulated by the serum concentration of the tropic hormone, thyroid-stimulating hormone (TSH), which is secreted by the pituitary thyrotroph cell. The function of the thyrotroph cell is likewise influenced by another tropic hormone, thyrotropin-releasing hormone (TRH). Multilevel regulatory systems for thyroid and other hormones are counterregulated in a negative system by the serum concentration of the hormone. A transient excess of circulating thyroid hormone would, for example, feed back upon the hypothalamus and pituitary thyrotroph to bring about a corrective reduction in levels of TRH and TSH secretion.

In effect, the glands producing the regulatory hormones are also target organs of the primary hormone; hence, every cell in the endocrine system is chemically linked to every other cell within the sphere of influence. Given this complexity of the endocrine system, it is not difficult to understand how the similar endocrine toxicities of relatively diverse compounds may, in fact, represent common manifestations of interventions of the compound at very different points in a hormone's pathways of production, regulation, and action. The effects can be widespread and can be life-threatening if they do not function in synchrony.

Interestingly, chemically induced changes in the endocrine system are not always considered undesirable. Indeed, with what is now a very common type of birth control, synthetic steroids are therapeutically directed to inhibit pituitary gonadotropins, thereby providing a chemical method of birth control for millions of women. Chemical (or drug) suppression of target organ hormone secretion can also be therapeutically useful in such organs as the thyroid gland and the adrenal gland.

HISTORICAL PERSPECTIVE

Claude Bernard first broached the subject of internal secretions as early as 1855 in his research on the pancreas. His concept of a stable *milieu intérieur*, or the internal environment, in spite of the constantly changing exterior environment was critical in the understanding of maintenance of body functions.[12] Ivan Pavlov's early experiments on classical conditioning in dogs provided additional groundwork for the concept of internal control of bodily functions; however, the digestive processes described by Pavlov were thought to be controlled solely by the nervous system. In 1902, William Bayliss and Ernest Starling were able to identify secretin in experiments in which they were able to chemically increase pancreatic secretions in dogs. They were first to use the term *hormone* (from the Greek word *horman*, meaning "to set in motion") to describe secretin as a chemical messenger.[13] Their experiments revealed that secretin could cause changes in physiology at a distant site from the site of entry after being transported through the circulatory system.

In 1915, Walter Cannon revealed the connection between the endocrine glands and emotions such as fear, pain, hunger, and rage.[14] Later that year, Edward Kendall isolated thyroxin, which is the active component of the thyroid and for which he was awarded the Nobel Prize in 1950.[15] Frederick Banting, J.J. McLeod, and Charles Best were awarded the Nobel Prize in 1923 for their work in 1921 on isolating insulin in the control of carbohydrate metabolism.[16] In 1953, Vincent du Vigneaud synthesized oxytocin and other posterior pituitary hormones for which he was awarded the Nobel Prize in 1955. [17–19] In 1959, Rosalyn Yalow and Solomon Berson first published a method to detect minute amounts of hormones in humans with the radioimmunoassay (RIA).[20] They were awarded the Nobel Prize in 1977 for their work on the development and application of RIAs for peptide hormones.[19] Köhler and Milstein published work in 1975[21] on theories concerning the specificity in development and control of the immune system and the discovery of the principle for the production of monoclonal antibodies (mAbs) and were awarded the Nobel Prize for this groundbreaking work in 1984.[19] The nervous and chemical control of bodily functions works

intimately in concert with the immune system to maintain a delicate internal balance that is collectively termed *homeostasis*. Momentous events in scientific history have led to our current understanding of this field. The importance of these findings to mankind cannot be minimized in light of this worldwide recognition of their importance to the health and welfare of humans. A focus of this chapter will be to review testing assays in an effort to understand the chemical control exerted by the endocrine system.

GENERAL PRINCIPLES

The basic foundations of the endocrine system include glands, the hormones they produce, and the receptors at the site of action. The fundamental concept of the endocrine system is that endocrine cells release a hormone that is transported to a receptor site in the target tissue, where the hormone binds and subsequently exerts its biological effect. In a traditional sense, endocrine systems have been portrayed as encompassing those tissues that release a hormone that is transported through the bloodstream to a target tissue, resulting in an effect at some point distant from the original tissue. This has been found to be a simplistic definition, as many variations have been discovered. New techniques in tissue cell culture and molecular biology have permitted the identification of several intercellular signaling pathways that do not export hormones in the traditional way via the general circulation to target tissue; for example, paracrine effects are produced when an effector cell releases a hormone that acts on adjacent target cells to produce a local effect. Many examples of paracrine systems can be found among various growth factors and inflammatory mediators (such as arachadonic acid metabolites, complement factors, cytokines, clotting factors, and somatostatin). Autocrine systems occur when a particular cell type releases a hormone that can act on the same cell to augment a particular response. Examples of autocrine systems include the cytokine interleukin-1 in monocytes and peripheral membrane protein in T-cells.

Several classification schemes have been developed for hormones. One classifies hormones according to their source, another classifies them according to their solubility characteristics in water or fat, and yet another classifies them according to their chemical composition.[22,23] Examining hormones based on their chemical composition also leads to several sets of data. One grouping that is routinely utilized in the endocrine literature divides hormones into one of six general chemical categories (Table 36.1). These include biogenic amine hormones, polypeptide hormones, protein hormones, steroid/sterol hormones, thyroid hormones, and fatty-acid-derived hormones.

Amine hormones include catecholamines (notably, epinephrine, norepinephrine, and dopamine) as well as serotonin and derivatives of tryptophan, tyrosine, or glutamic acid. They are hydrophilic in nature and are related to compounds found in the nervous system that can exert local effects in tissues such as the gastrointestinal tract. Biogenic amines are small, biologically active, modified, single amino acids that are stored in vesicles prior to their release into the circulation. They act primarily as neurotransmitters and are capable of affecting mental functioning. In contrast to most polypeptide hormones, stores of biogenic amines can be quickly restored by rapid synthesis.

TABLE 36.1
Categories of Hormones

Biogenic amines (e.g., epinephrine)
Polypeptides (e.g., thyroid-releasing hormone)
Proteins (e.g., insulin, growth hormone)
Steroids (e.g., estrogens, androgens)
Thyroid hormones (e.g., thyroxine)
Fatty acids (e.g., prostaglandins)

Source: Adapted from Gardner, D.G. and Nissenson, R.A., in *Basic and Clinical Endocrinology*, 7th edn., Greenspan, F.S. and Gardner, D.G., eds., McGraw-Hill, New York, pp. 61–84, 2004; Porterfield, S.P., ed., *Endocrine Physiology*, 2nd edn., Mosby, St. Louis, MO, 2001.

Polypeptide hormones are composed of short amino acid chains; protein hormones are composed of many amino acids and polypeptides together in a single molecule and are generally hydrophilic in nature. These types of hormones can range in length from three amino acids (as in the case of TRH) to several hundred amino acids (e.g., growth hormone [GH]). They can be composed of two or more subunits (e.g., gonadotropins) or may be linked by disulfide bonds (e.g., insulin). These hormones are synthesized in the endoplasmic reticulum and subsequently transferred to the Golgi apparatus for inclusion in secretory vesicles. Other post-translational modifications, such as glycosylation, may occur that can affect biological activity. Following synthesis in an endocrine cell, hormones may be stored in vesicles prior to stimulation of the endocrine system. Patterns of peptide and protein hormone secretion can be either pulsatile (regulated) or basal (constitutive).

Steroid and sterol hormones are derived from cholesterol, contain a cyclopentanoperhydrophenanthrene ring (four ring) structure, and are hydrophobic in nature. Steroid hormones are generally synthesized in the adrenal cortex, placenta, and gonads and are further characterized by being immediately secreted by these glands. Because they are fat soluble, these hormones can readily cross cell membranes and have intracellular receptors. When they have entered the cytoplasm, these steroid hormones bind to a specific receptor (e.g., alpha (α) and beta (β) estrogen receptors [ERs]), a large metalloprotein. Further binding occurs that permits the steroid to enter the nucleus. In the nucleus, the steroid–receptor ligand complex binds to specific DNA sequences and induces transcription of its target genes. Examples of steroid hormones include the sex steroid hormones (e.g., testosterone, estrogen, and progesterone), corticosteroids, mineralocorticoids, vitamin D, and retinoic acid. Recent evidence suggests that megalin, a member of the low-density lipoprotein

receptor superfamily of endocytic proteins, is an important facilitator of steroid entry into cells.[25]

Thyroid hormones are an intermediate-molecular-sized group of compounds that fall in between biogenic amines and short polypeptides. Thyroxine is produced by attaching iodine atoms to the ring structures of tyrosine molecules. Thyroxine contains four iodine atoms. They are composed of two iodinated tyrosine residues, which are converted to triiodothyronine by deiodinases to enhance biological activity.

Fatty acid hormones or eicosanoids are generally derived from polyunsaturated fatty acids such as linoleic acid and phospholipids, with the most prominent of these being arachadonic acid. They are synthesized throughout the body, and their primary effects are paracrine and autocrine in nature through both surface and nuclear receptors.[23] These hormones are effective at minute concentrations and are typically active for 5–10 s. These hormones include prostaglandins, prostacyclin, leukotrienes and thromboxanes, lipoxins, isoprostanoids, and hydroxylated fatty acids.

Transport of hormones from endocrine tissues to target tissues frequently involves carrier plasma proteins (e.g., sex-hormone-binding protein [SHBP]) that bind the hormones with high affinity and specificity while the hormones are transported within the circulatory system. Although many of the carrier proteins possess high specificity and affinity, they often possess low capacity, so the availability of binding sites is limited. Other nonspecific carrier proteins, such as albumin, can bind hormones with a high capacity but possess low specificity and characteristics unlike biogenic amines, steroid, thyroid, and some polypeptide hormones, which have specific binding proteins. Some hormones such as protein hormones are transported free in the blood, while steroid and thyroid hormones are transported bound to plasma proteins.

After a hormone is transported to the target tissue, it must then interact with a receptor within the target tissue to exert a biological effect. An important concept of hormone action is that only the free, unbound hormone can interact with its receptor to exert a biological effect in the particular target tissue; therefore, the hormone must become unbound from any carrier protein before it can interact with a receptor. Hormonal signal transduction occurs when the hormone interacts with the target tissue receptor, which in turn produces an intracellular change in the target tissue. Mechanisms of signal transduction depend on whether the target tissue receptor is bound to the cell membrane surface or is present in the cytoplasm.

To permit the exposure of the required amount of hormone, a delicate equilibrium exists among the bound hormone (*B*), the plasma protein (*P*), and unbound or free hormone (*F*), which is expressed in the following equation[23]:

$$F \times P = \left[B\right] = \frac{\left(\left[F\right] \times \left[P\right]\right)}{\left[B\right]}.$$

Not only is the free hormone the critical moiety for activation, but it is also critical for deactivation in feedback control. Signal transduction by cell-membrane-bound receptors is usually either via intracellular second messengers (e.g., cyclic adenosine monophosphate [cAMP], calcium, or phosphatidylinositol metabolites) or through mechanisms such as phosphorylation of serine, threonine, or tyrosine residues of intracellular kinases and other enzymes.[26] Most polypeptide hormones interact with cell membrane surface receptors, although there is some evidence to suggest that hormonal receptor internalization may play a role in some processes. In contrast, steroid and thyroid hormones interact with intracellular receptors. Transport into the cell may be aided by cell membrane transporters (e.g., megalin), and once inside the cell, the steroid or thyroid hormone receptor complex is transported to the nucleus, where it may modulate gene expression by binding to certain DNA regulatory sequences.

CONTROL OF ENDOCRINE ACTIVITY

Regulation of hormonal activity is critical to all biological systems in their quest for biological homeostasis. Overall, the endocrine system utilizes two major control systems to respond to physiological changes: (1) automatic internal controls from the various concentrations of the hormones themselves and (2) nervous system override of the self-regulating chemical system. The primary function of the nervous system override is to respond to stimuli (i.e., fight or flight situations) and produce a hormonal readjustment. The automatic and continuous self-regulation is a complex physiologic hierarchy of chemically mediated controls that modulates the homeostasis of the endocrine system through a series of feedback loops.

The maintenance of biological systems involves negative feedback loops where the output of a hormone controls the input in a simple inverse relationship. As the concentration of the hormone increases in the system, the amount of input into the system is decreased, in much the same way as a thermostat regulates room temperature. As the temperature increases, the thermostat turns off the heating unit until the temperature drops to a predetermined point, whereupon the signal is sent to the heating unit to increase heat once again. Such would be an example of simple hormonal regulation where the involvement includes a single endocrine gland. Complex hormonal regulation is another level of control involving the anterior pituitary (adenohypophysis) as well as the target receptors. The anterior pituitary is frequently referred to as the *master gland* because of its control over a number of other glands and target cells. In this case, one endocrine gland controls the hormone release of another, which ultimately regulates another distant target. An example of this type of control is the mechanism involving the pituitary gland, the adrenal cortex, and the gonads. The anterior pituitary releases hormones that stimulate the adrenal cortex, which, in turn, releases hormones that effect a change at the gonads. The secretory releases of both the adrenal cortex and the gonads feed back to decrease the hormonal secretion of the anterior pituitary. The overall effect of negative feedback loops is that hormone

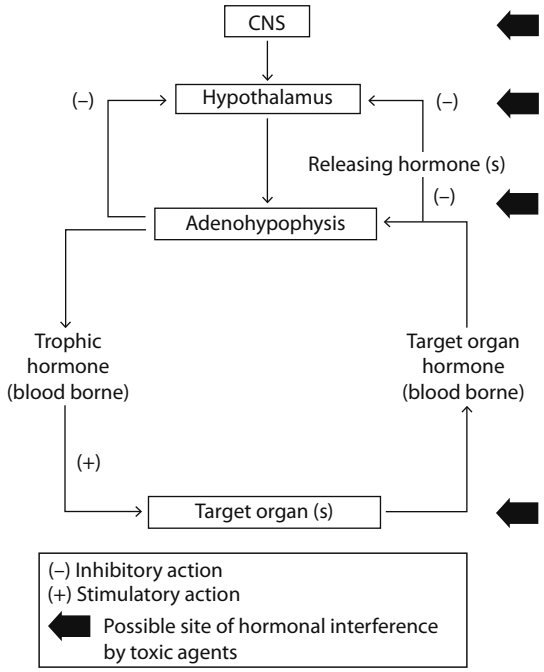

FIGURE 36.1 Relationship between adenohypophyseal–hypothalmic axis and hormone target organs.

levels are maintained within the narrow range the body needs to maintain normal homeostasis. A negative feedback loop inhibits an endocrine pathway, whereas a positive feedback loop enhances or augments an endocrine response (Figure 36.1). Positive feedback relationships, where hormone levels are actually increased by elevating levels of a hormone (i.e., ovulation), are also operants.

The concentration of a hormone at the target cells is generally determined by three factors: (1) the rate of hormone production, (2) the rate of hormone delivery, and (3) the rate of hormone elimination. The rate of hormone production is affected by many factors and is primarily controlled by feedback loops. Feedback loops can be further modulated by other endocrine systems that are pulsatile, cyclical, or stimulated through other mechanisms. The integration of various feedback loops gives rise to a complex cascade of endocrine responses to particular stimuli. The rate of hormone delivery is affected by the rate of blood flow to the target receptor. The rate of elimination is affected by two factors: (1) the body's ability to metabolize and excrete the hormone from the bloodstream and through renal elimination and (2) the physiological rate of degradation of the hormone. Some hormones have short biological half-lives, and others have long biological half-lives. Protein binding can affect a hormone residence time in the blood.

ENDOCRINE DISRUPTION

Several drugs and chemicals are known to affect the endocrine system.[2,27] Perturbation of endocrine homeostasis often produces consequences that can lead to metabolic derangements, developmental abnormalities, and sexual or reproductive dysfunction. The U.S. Environmental Protection Agency (EPA) has defined an endocrine disruptor as "an exogenous agent that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones in the body responsible for the maintenance of homeostasis and the regulation of developmental processes."[28,29] Endocrine disruption has become a subject of intense scientific research, in large part due to the publication of *Our Stolen Future* in 1996.[30] The book and its findings became sensationalized and politicized, which may or may not have been warranted; however, with the recognition of the effects of estrogen-like environmental contaminants, logically, the concern extends to many types of contaminants that might in some way effect unwanted changes to the endocrine system. Such exposures might result in ill-timed maturation, development, growth, or regulation, resulting in the reduced ability of an organism to cope with external changes or birth defects if the changes occurred during gestation. Indeed, the EPA has indicated that at least four categories of adverse effects might be linked to endocrine disruptors, including cancer, immunological effects, neurological effects, and reproductive and developmental effects involving the adrenals, thyroid, pituitary, and gonads.[31]

Evidence indicates that a number of chemicals can perturb the endocrine systems of animals in a laboratory setting, where one can precisely measure the changes in a controlled environment. There is also substantial evidence that birds,[32] dolphins,[33] alligators,[34] and other wildlife[35–37] exposed to high levels of various environmental contaminants manifest adverse developmental and reproductive effects. Although the logical extension of this concept is that it could produce similar effects in humans, the data are not clear and are scientifically controversial.[28,38]

Endocrine Disruptor Screening Program

Based on this and other evidence, Congress passed the Food Quality Protection Act and the Safe Drinking Water Act (SDWA) Amendments in 1996 requiring that EPA screen pesticide chemicals for their potential to produce effects similar to those produced by the female hormones (estrogen) in humans and giving EPA the authority to screen certain other chemicals and to include other endocrine effects. Based on recommendations from an Advisory Committee, EPA has expanded the Endocrine Disruptor Screening Program (EDSP) to include male hormones (androgens) and the thyroid system and to include effects on fish and wildlife.

An Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC) was charged with developing "a screening program, using appropriate validated test systems and other scientifically relevant information, to determine whether certain substances may have an effect in humans that is similar to an effect produced by a naturally occurring estrogen, or other such endocrine effect as the administrator may designate."[29,38,39]

The EPA announced the initial list of chemicals to be screened for their potential effects on the endocrine system (or Tier I testing) on April 15, 2009, and the first test orders were issued on October 29, 2009. Test orders are requests for data. Testing will eventually be expanded to cover all pesticide chemicals, as well as substances that may occur in the sources of drinking water to which a substantial population may be exposed. Now that screening is underway, EPA is reviewing test order responses and making available the status or test order responses and/or any decisions regarding testing requirements.

EPA has developed a second list of chemicals for screening and draft policies and procedures that the agency will use to require testing of chemicals for Tier 1 screening. EPA has also developed the EDSP Comprehensive Management Plan[40] that provides strategic guidance for agency personnel and outlines the critical activities that are planned for the EDSP over the next 5 years. The plan describes the technical review processes that will be used in implementing this program and how the agency intends to factor technology advancements into the program. The plan is flexible to allow opportunities to streamline and promote efficient processes. This EDSP Comprehensive Management Plan was developed as an internal EPA document; however, it is currently being made publically available consistent with the EPA's transparency objectives.

Developed in response to recommendations from the Office of Inspector General, "The EDSP Universe of Chemicals and General Validation Principles" document[41] provides an overview of the general validation principles that will be used to evaluate computational toxicological methods for chemical prioritization. EPA has also presented the "List of EDSP Universe of Chemicals"[42] as a separate document, which will be updated as new information becomes available. The List of the EDSP Universe of Chemicals contains approximately 10,000 chemicals as defined under the Federal Food, Drug, and Cosmetic Act (FD&C Act)[43] and SDWA[44] 1996 amendments, although not all of the chemicals are expected to undergo EDSP Tier 1 screening. The agency plans to prioritize these chemicals for screening by considering physical chemical properties, exposure, and an effect-based approach using advanced computational toxicological methods. These methods and tools will be evaluated using Organization for Economic Cooperation and Development (OECD) validation principles for their utilization in chemical prioritization, and this topic will be the focus of the upcoming planned Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) Science Advisory Panel review on January 29, 2013.

Series 890—Endocrine Disruptor Screening Program Test Guidelines

The purpose of the EDSP Tier 1 battery of screening assays is to identify chemicals that have the potential to interact with the estrogen, androgen, or thyroid (E, A, or T) hormonal pathways. Currently, the battery consists of 11 assays that have been developed and validated through a collaborative effort involving EPA program and research offices and published as harmonized test guidelines by the Office of Chemical Safety Pollution and Prevention. EPA intends to evaluate the results of the Tier 1 screening assays using a weight-of-evidence (WoE) approach to determine whether or not a chemical has the potential to interact with E, A, or T hormonal pathways and to assess the need for Tier 2 testing.

The purpose of Tier 2 testing is to further characterize the effects on E, A, or T identified through Tier 1 screening by using Tier 2 in vivo studies that establish dose–response relationships for any potential adverse effects for risk assessment. EPA refers to the WoE approach as "a collective evaluation of all pertinent information so that the full impact of biological plausibility and coherence is adequately considered" (U.S. EPA, 1999). In its recommendations to EPA, the EDSTAC referred to the WoE approach as "a process by which trained professionals judge the strengths and weaknesses of a collection of information to render an overall conclusion that may not be evident from consideration of the individual data" (EDSTAC, 1998).

EPA's EDSP uses a tiered approach for determining whether a substance may have an effect in humans that is similar to an effect produced by naturally occurring estrogen, androgen, or thyroid hormones. The core elements of the EDSP are setting priorities for chemicals to be screened and tested: Tier 1 screening, Tier 2 testing, and hazard assessment. The final guidelines are part of a series of test guidelines that have been developed by the Office of Chemical Safety and Pollution Prevention (OCSPP) for use in the testing of pesticides and toxic substances, and the development of test data for submission to the agency. Various factors contributed to selecting the Tier 1 screening that generally included the following:

- The potential of the assays to evaluate E, A, or T hormonal pathway effects in different taxa
- Estrogen- and androgen-mediated effects via receptor binding (agonism and antagonism)
- Estrogen-mediated gene transactivation
- Enzyme inhibition involving the reproductive steroidogenesis pathway
- Interactions with gonadal estrogen and androgen production that may alter feedback mechanisms involving the hypothalamic–pituitary–gonadal (HPG) axis
- Androgen- and estrogen-influenced endpoints within an assay that are complementary among the assays
- Interactions with thyroid hormone production or function and associated alterations in feedback relationships involving the hypothalamic–pituitary–thyroid (HPT) axis

Assays Included in the Tier 1 Screening Battery

The Tier 1 battery's suite of in vitro and in vivo screening assays covers several modes of action (Table 36.2). The Tier 1

TABLE 36.2
Endocrine Disruption Screening Program—Tier 1 Screening Battery

battery's suite of in vitro and in vivo screening assays (Table 36.2) includes the following:

In vitro

OPPTS 890.1150 Androgen receptor (AR) binding—rat prostate cytosol
OPPTS 890.1200 Aromatase—human recombinant microsomes
OPPTS 890.1250 ER binding—rat uterine cytosol
OPPTS 890.1300 ER—(hERα) transcriptional activation—human cell line (HeLa-9903)
OPPTS 890.1550 Steroidogenesis—human cell line (H295R)

OPPTS 890.1150 Androgen Receptor Binding (Rat Prostate Cytosol)

Purpose: The AR binding assay is a sensitive in vitro test to detect chemicals that may affect the endocrine system by binding to the AR isolated from the rat prostate. It will give added confidence that positive results seen in the Hershberger assay are truly due to an AR binding mechanism.

Design: Cytosol isolated from the rat prostate provides the source of the AR. Test chemical and R1881, a strong ligand, compete for binding with the AR when incubated together overnight. The assay measures the binding of [^{3}H]-R1881 in the presence of eight test chemical concentrations. Unlabeled R1881 serves as a strong positive control producing the standard curve. Dexamethosone is run with each block of test chemicals as a weak positive control. Solvent is run as the negative control.

Endpoints: The disintegrations per minute (DPM) of [^{3}H]-R1881 are measured by liquid scintillation counter. Data for the standard curve and each test chemical will be plotted as the percent [^{3}H] R1881 bound versus the molar concentration through the use of a four-parameter nonlinear regression program.

Interpretation: Performance criteria have been set for the top, bottom, and slope for R1881 and the weak positive, dexamethasone.

- If the binding curve crosses 50% (competes to displace the standard ligand by 50%), the test chemical is considered to be a binder.
- Chemicals for which the binding curve crosses 75%, but not 50%, are considered to be equivocal.
- Chemicals that do not fit the model or for which the binding curve does not cross 75% are considered to be nonbinders.

Strengths:

- Sensitive, rapid, and inexpensive
- Uses relatively few animals
- Specific for identifying an interaction with the AR receptor providing mechanistic information

Weaknesses:

- It cannot distinguish the consequences of binding (*i.e., functional response*).
- It does not account for potential metabolic activation or deactivation of test chemical.
- Other steroids that are not natural ligands for the AR may bind at high concentrations.
- Chemicals that denature the receptor may be identified as false positives.

OPPTS 890.1200 Aromatase (Human Recombinant)

Purpose: The aromatase assay detects chemicals that inhibit aromatase activity. Aromatase is the enzyme that metabolizes androgens such as testosterone to estrogens.

Design: Androstenedione (AND) and [1β-^{3}H]-androstenedione (ASDN) serve as substrate for human recombinant microsomal aromatase. Full activity control (ASDN in medium, no inhibitor), background activity control (no nicotinamide adenine dinucleotide phosphate [NADPH]), positive control (4-hydroxyandrostenedione at eight concentrations), and test chemical (eight concentrations) are run in the reaction for 15 min, and the reaction products produced are measured and plotted as percent enzyme activity (inhibition curve) through the use of a nonlinear regression program.

Endpoints: The formation of ^3H_2O, one of the coreaction products along with estrone, is measured by liquid scintillation counter per unit reaction time.

Interpretation: Chemicals that reduce enzyme activity levels by 50% or more (as determined by the inhibition curve calculated by a four-parameter nonlinear regression program) are considered to be inhibitors of aromatase. Chemicals that fit the inhibition curve but allow 50%–75% activity, that is, reduce activity by 25%–50%, are considered equivocal. Chemicals that do not fit the model or that fit the model but reduce inhibition by 25% are considered to be noninhibitors of aromatase.

Strengths:

- Highly specific to inhibition of aromatase activity providing mechanistic information
- More sensitive than typical in vivo assays
- Rapid and inexpensive
- Capable of high throughput (HTP)
- Provides useful information for the interpretation of in vivo assays

Weaknesses:

- Cannot detect chemicals that induce aromatase activity.
- False positives could result from chemicals that denature the enzyme.
- Limited/no ability to metabolize xenobiotics.

OPPTS 890.1250 Estrogen Receptor Binding Assay Using Rat Uterine Cytosol

Purpose: The purpose of the ER binding assay is to identify test chemicals that can bind to the ER isolated from the rat uterus.

Design: A saturation radioligand binding experiment is conducted to demonstrate that the ER binding assay is working under optimal conditions within a given laboratory. This assay is conducted by measuring the equilibrium binding of increasing concentrations of ^{3}H-estradiol to rat cytosolic or human recombinant ERα. Nonlinear regression analysis of the data provides estimates of the affinity of the receptor for 17β-estradiol (K_d) and the concentration of receptors (B_{max}).

A competitive ER binding assay is conducted by measuring the equilibrium binding of a single concentration of ^{3}H-17β-estradiol at various concentrations (over a range of at least six orders of magnitude) of a test chemical in rat cytosolic or human recombinant ER. After equilibration, the amount of radioactivity bound to the ER is measured as an indicator of how much was displaced by the test compound at each concentration. Data analysis provides an estimate of the potency of the test chemical for binding to the ER relative to 17β-estradiol. 17β-estradiol is run as a reference standard with each run, as are a weak positive and a nonbinder.

In each portion of the study, three replicate data points are collected at each concentration in one run, and three independent runs are performed to constitute one assay.

Endpoint: Binding curve fit to a four-parameter Hill equation, where the parameters are top, bottom, slope, and log(IC_{50}) (i.e., base-10 log of the molar concentration of test chemical that inhibits 50% of binding by the radioligand).

Interpretation: Performance criteria have been set for the top, bottom, and slope for 17β-estradiol and the weak positive, norethynodrel, for the competitive ER binding portion of the assay. Within-run variability is also subject to a performance criterion.

Classification of test chemicals:

- *Positive:* A log(IC_{50}) value can be obtained from an unconstrained curve fitted to the Hill equation that has a slope of approximately −1.0.
- *Equivocal:* Acceptable binding curve reaches 25% displacement of radioligand but not 50% at the highest concentration. Also applied if slope is unusually steep or shallow.
- *Negative:* Acceptable binding curve does not reach 25% displacement of the radioligand, or curve cannot be fit and no data point shows displacement of more than 25%.

Strengths:

- Quick (2 days)
- Uses relatively few animals
- Specific for identifying an interaction with ER (i.e., provides mechanism-related information)

Weaknesses:

- It cannot distinguish the consequences of binding (i.e., functional response).
- Does not account for potential metabolic activation or deactivation of test chemical.

OPPTS 890.1300 Estrogen Receptor Transcriptional Activation (Human Cell Line [HeLa-9903])

Purpose: In vitro transcriptional activation (TA) assays are based upon the production of a reporter gene product induced by a chemical, following the binding of the chemical to a specific receptor and subsequent downstream TA. TA assays using activation of reporter genes are screening assays that have long been used to evaluate the specific gene expression

regulated by specific nuclear receptors, such as the ERs.[45–48] They have been proposed for the detection of estrogenic transactivation regulated by the ER.[47,49,50] The nuclear ERs exist as at least two subtypes, termed α and β encoded by distinct genes and with different tissue distribution, relative ligand binding affinities, and biological functions. Nuclear ERα mediates the classic estrogenic response; therefore, models currently being developed to measure ER activation mainly relate to ERα. The aim of this TA assay is to evaluate the ability of a chemical to function as an ERα ligand and activate an agonist response, for screening and prioritization purposes, but can also provide mechanistic information that can be used in a WoE approach.

Initial considerations and limitations: Estrogen agonists act as ligands for ERs and may activate the transcription of estrogen responsive genes. This interaction may have the potential to trigger adverse health effects by disrupting estrogen-regulated systems. This Test Guideline describes an assay that evaluates TA mediated by the hERα. This process is considered to be one of the key mechanisms of possible endocrine disruption–related health hazards, although there are also other important endocrine disruption mechanisms. These include the following:

- Actions mediated via other nuclear receptors linked to the endocrine system and interactions with steroidogenic enzymes
- Metabolic activation or deactivation of hormones
- Distribution of hormones to target tissues
- Clearance of hormones from the body

This Test Guideline exclusively addresses TA of an estrogen-regulated reporter gene by agonist binding to the hERα, and therefore, it should not be directly extrapolated to the complex in vivo situation of estrogen regulation of cellular processes. Furthermore, this Test Guideline does not address antagonist interaction with the hERβ and subsequent effect on transcription.

This test method is specifically designed to detect hERα-mediated TA by measuring chemiluminescence as the endpoint. However, nonreceptor-mediated luminescence signals have been reported at phytoestrogen concentrations higher than 1 μM due to the overactivation of the luciferase reporter gene.[51,52] While the dose–response curve indicates that true activation of the ER system occurs at lower concentrations, luciferase expression obtained at high concentrations of phytoestrogens or similar compounds suspected of producing phytoestrogen-like overactivation of the luciferase reporter gene needs to be examined carefully in stably transfected ER TA assay systems.

Principle of the test: The TA assay using a reporter gene technique is an in vitro tool that provides mechanistic data. The assay is used to signal binding of the ER with a ligand. Following ligand binding, the receptor-ligand complex translocates to the nucleus where it binds specific DNA response elements and transactivates a firefly luciferase reporter gene, resulting in increased cellular expression of luciferase enzyme. Luciferin is a substrate that is transformed by the luciferase enzyme to a bioluminescence product that can be quantitatively measured with a luminometer. Luciferase activity can be evaluated quickly and inexpensively with a number of commercially available test kits.

The test system provided in this guideline utilizes the hERα-HeLa-9903 cell line, which is derived from a human cervical tumor, with two stably inserted constructs:

- The hERα expression construct (encoding the full-length human receptor)
- A firefly luciferase reporter construct bearing five tandem repeats of a vitellogenin estrogen-responsive element (ERE) driven by a mouse metallothionein (MT) promoter TATA element

The mouse MT TATA gene construct has been shown to have the best performance, and so is commonly used. Consequently, this hERα-HeLa-9903 cell line can measure the ability of a test chemical to induce hERα-mediated transactivation of luciferase gene expression. Investigators must use the stably transfected hERα-HeLa-9903 cell line for the assay. The cell line can be obtained from the Japanese Collection of Research Bioresources (JCRB) Cell Bank.[53] Investigators must use only cells characterized as mycoplasma-free in testing. Real-time polymerase chain reaction (RT PCR) is the method of choice for a sensitive detection of mycoplasm infection.[54–56]

Data interpretation: Based upon whether the maximum response level induced by a test chemical equals or exceeds an agonist response equal to 10% of that induced by a maximally inducing (1 nM) concentration of the positive control (PC) 17β-estradiol (E2) (i.e., the PC_{10}).

Strengths:

- Specific for identifying an interaction with the ER receptor providing mechanistic information
- Sensitive, rapid, and inexpensive
- Confirms a functional response (TA) of ER activation

Weaknesses:

- Does not account for potential metabolic activation or deactivation of test chemical

OPPTS 890.1550 Steroidogenesis (Human Cell Line—H295R)

Purpose: The H295R steroidogenesis assay is intended to identify xenobiotics that affect the steroidogenic pathway beginning with the sequence of reactions occurring after the gonatotropin hormone receptors (follicle-stimulating hormone receptor [FSHR] and leutinizing hormone receptor [LHR]) through the production of testosterone and estradiol/estrone. The steroidogenic assay is not intended to identify substances that affect steroidogenesis due to effects on the hypothalamus or pituitary gland.

Principle of the test: H295R cells (ATCC CLR-2128) are plated in a 24-well plate setup and are exposed to test

chemicals. The guideline provides detailed information regarding the handling of samples including the extraction of hormones from medium, storage of samples and extracts, and references having detailed standard operating procedures (SOPs) or protocols for the analysis of testosterone (T) and 17 β-estradiol (E2). The protocol also describes the procedure for the Live/Death® cytotoxicity test to evaluate any possible effects of the test chemicals on cell viability.

The Guideline also provides a complete list of required reagents and solvents and describes the preparation of all solutions and reagents used during the exposure experiments with the cells as well as during the subsequent extraction, hormone analyses, and cell viability measurements. It also provides descriptions of quality assurance/quality control (QA/QC) procedures that must be performed prior to initiating chemical testing and the analysis of positive controls with each run to verify proper performance of the cells. Cell culturing procedures (including initiating cell cultures from frozen stock, cultivation and splitting of the growing cells, the freezing of cells for storage in liquid nitrogen, and the maintenance of a proper cell culture diagram to track the progress of a cell line) are also described.

Performance of hormone measurement system: Each laboratory may use a hormone measurement system of its choice for the analysis of the production of T and E2 by H295R cells. Prior to the initiation of cell culture and any subsequent test runs, it is expected that each laboratory demonstrates the conformance of its hormone measurement system (e.g., enzyme-linked immunosorbent assay [ELISA], RIA, liquid chromatography–mass spectrometry [LC–MS]) with the QC criteria by analyzing supplemented medium spiked with an internal hormone control. Due to the cross-reactivity of some of the antibody-based hormone ELISAs and RIAs with hormone metabolites/conjugates produced by the H295R cells, an extraction of the medium is required prior to the measurement of hormones if an assay is used that employs antibodies.

Chemical hormone assay interference test: If antibody-based hormone measurement assays are to be used, prior to initiation of testing, it is recommended that each chemical be tested for potential interference with the hormone measurement system being utilized. It has been previously shown that some chemicals can interfere with antibody-based assays such as ELISAs and RIAs.[57] This *chemical interference test* will be conducted as described for the analysis of medium samples within the Guideline (Subsection (h)(5)).

Test results: The following results must provide raw hormone concentration data for each well for control and test substances (each replicate measure in the form of the original data provided by the instrument utilized to measure hormone production [e.g., optical density (OD), fluorescence units, counts per minute (CPM), and so on]); validation of normality or explanation of data transformation; and mean responses ±1 SD for each well measured.

Interpretation: A chemical is judged to be positive if the fold induction is statistically different from the solvent control at doses that fall within the increasing or decreasing portion of the dose–response curve. Statistically significant increases in fold induction indicate the chemical is an inducer of one or more enzymes in the steroid synthesis pathway. Statistically significant decreases in fold induction indicate the chemical is an inhibitor of one or more enzymes in the steroid synthesis pathway. Statistically significant differences at concentrations that do not follow a dose–response curve may be due to random effects; such results are considered to be equivocal. Results exceeding the limits of solubility or at cytotoxic concentrations are not included in interpreting results.

Strengths:

- Only in vitro assay that can evaluate effects on the entire steroidogenesis pathway—cells have all of the enzymes necessary for steroidogenesis
- Rapid and inexpensive
- Detects chemicals that inhibit and induce steroidogenesis
- Can effectively distinguish strong, moderate, and weak inducers and inhibitors

Weaknesses:

- Limited account for potential metabolic activation or deactivation of test chemical

In vivo

OPPTS 890.1100 Amphibian metamorphosis (frog)
OPPTS 890.1350 Fish short-term reproduction
OPPTS 890.1400 Hershberger (rat)
OPPTS 890.1450 Pubertal female (rat)
OPPTS 890.1500 Pubertal male (rat)
OPPTS 890.1600 Uterotrophic (rat)

OPPTS 890.1100 Amphibian Metamorphosis (Frog) [AMA]
Purpose: The amphibian metamorphosis assay (AMA) is a screening assay intended to empirically identify substances that may interfere with the normal function of the HPT axis. The AMA represents a generalized vertebrate model to the extent that it is based on the conserved structure and functions of thyroid systems. It is not intended to quantify or confirm endocrine disruption, or to provide a quantitative assessment of risk, but only to provide evidence that thyroid-regulated processes may be sufficiently perturbed to warrant more definitive testing.

Design: The general experimental design entails exposing *Xenopus laevis* tadpoles at NF stage 51 to a minimum of three different aqueous concentrations of a test chemical and a dilution water control for 21 days. There are four replicate tanks at each test substance concentration or treatment. Larval density at test initiation is 20 tadpoles per test tank for all treatment groups.

Endpoints: Daily mortality.

Morphological endpoints: Whole-body length/snout–vent length (d 7 and 21); hind limb length (d 7 and 21); wet weight (d 7 and 21); developmental stage (d 7 and 21); histology thyroid gland (d 21).

Interpretation: Results are evaluated for evidence of interaction of the test chemical with the HPT axis as follows.

If necessary, test concentrations with overt toxicities are removed from the data set. Significant histological findings in thyroid tissue deem the assay positive. If no thyroid gland histopathology is observed, then developmental landmarks are evaluated. If development is accelerated or asynchronous, the test is deemed positive. The assay is considered negative if no effects are detected in thyroid gland histology or morphological landmarks of development.

Strengths:

- Intact in vivo system on an animal undergoing morphological development.
- Effects on metamorphic development are relatively specific indicators of HPT axis perturbation.
- HPT axis is conserved for other vertebrate classes.
- Redundant endpoints, maximizing chance for detection while minimizing false negatives.
- Provides toxicological data in a taxon (amphibians) underrepresented.
- Well-established relationship between endpoints and endocrine system.
- Endpoints easy to measure.

Weaknesses:

- Inherent difficulties in testing some substances not amenable to aquatic systems.
- Sensitivity of the assay has not been fully characterized.
- Nonthyroidal toxicities have the potential to affect some of the morphological endpoints of the assay.

OPPTS 890.1350 Fish Short-Term Reproduction

Purpose: The fish short-term reproduction assay (FSTRA) is a screening assay intended to identify changes in morphology, histopathology, spawning, and specific biochemical endpoints, which may reflect interference with the normal function of the HPG axis. It is not intended to quantify or confirm endocrine disruption, or to provide a quantitative assessment of risk, but rather to provide suggestive evidence that endocrine-regulated processes may be sufficiently perturbed to warrant more definitive testing.

Design: The FSTRA entails exposing reproductively mature fathead minnows (*Pimephales promelas*) to a minimum of three concentrations of a test chemical and appropriate control(s) for 21 days. Successful spawning is established during a preexposure period of at least 14 days. Each of the four replicate tanks in each treatment level contains four females and two males.

Endpoints (= key endpoints):* Survival; behavior; body length; body weight; fecundity* (# of spawns; # of eggs/female reproductive day); fertilization success* (# fertile eggs/female reproductive day; % fertile eggs); gonadal histopathology*; gonadosomatic index (GSI)*; appearance and secondary sex characteristics* (overall body coloration, vertical banding; fatpad [weight, score, and index]; tubercles [count and score]; ovipositor size).

Biochemical measures:* Vitellogenin; estradiol; testosterone.

Interpretation: The FSTRA as presented is intended to serve in a screening capacity to provide an indication of potential endocrine activity, not to confirm any specific mechanism, mode of action, or adverse effect. Therefore, a significant effect in one or more of the key endpoints of this assay (fecundity, fertilization success, histopathology, GSI, biochemical measures, and secondary sex characteristics) should be considered indicative of possible endocrine system disturbance. The suite of endpoints included is necessary to provide a fully comprehensive assessment of the disrupting potential to the HPG axis in a representative fish.

It is important to note, however, that if a given exposure level results in substantial mortality or other overt signs of toxicity, responses in other endpoints may be due to general toxicity, not necessarily mediated primarily via interaction with the endocrine system. The lower treatment level(s) should be examined for effects outside of the range of general toxicity. If all test concentrations exhibit mortality, then the assay would need repeating before an inference on possible endocrine activity can be made.

It is recognized that some endpoints may be responsive to nonendocrine stresses in addition to endocrine-mediated pathways, particularly fecundity. Although reductions in fecundity indicate adverse organismal and, potentially, population level effects (i.e., reproductive toxicity), these cannot be definitively distinguished from direct endocrine-mediated effects by this assay when changes in other core endpoints are not present. Nevertheless, reductions in fecundity are considered a positive effect in this assay because they may be endocrine-mediated and should be considered in concert with results of the other assays in the Tier 1 battery. Results that would be considered equivocal for this single assay should be considered indications of potential endocrine activity and evaluated in light of the WoE from the other assays in the Tier 1 battery of assays for the EDSP.

Strengths:

- Incorporates a standard, easily acquired laboratory model species
- Straightforward, cost-effective, reasonably short-term assay
- Detects (anti-)estrogen and (anti-)androgen perturbations in addition to disruptors of the entire HPG axis
- Employs an intact HPG axis and hence is relevant to other taxa when conserved elements of the HPG axis are considered

Weaknesses:

- Inherent technical difficulties in testing substances that are poorly soluble in water in aquatic systems, and methods for delivering such substances to the test system.
- Some measurements (e.g., plasma steroids) will require specialized technical expertise.

OPPTS 890.1400 Hershberger (Rat)

Purpose: A short-term in vivo assay to detect androgenic or antiandrogenic chemicals or chemicals that inhibit 5α-reductase, based on the changes in the weight of five androgen-dependent tissues in the castrated male rat.

Design: There are two versions of the Hershberger assay: an immature version and a peripubertal version employing castrated rats. In addition, each version can be run to detect AR agonists or antagonists. When screening for potential androgenic activity, the test substance is administered daily by oral gavage or subcutaneous injection for a period of 10 consecutive days. Test substances are administered to a minimum of two treatment groups of experimental animals using one dose level per group. When screening for potential antiandrogenic activity, the test substance is administered daily by oral gavage or subcutaneous injection for a period of 10 consecutive days in concert with daily TP doses (0.2 or 0.4 mg/kg/day) by subcutaneous injection. Graduated test substance doses are administered to a minimum of two treatment groups of experimental animals using one dose level per group. In both the agonist and antagonist procedures, the animals are necropsied approximately 24 h after the last dose.

Endpoints: The assay is based on statistically significant changes in weight in androgen-dependent tissues. The five tissues weighed in the castrated male are ventral prostate, seminal vesicle (plus fluids and coagulating glands), levator ani-bulbocavernosus muscle, paired Cowper's glands, and the glans penis (GP). In the immature version, the GP cannot be detached and measured, but the testes and epidimydes are weighed in the intact weanling.

Interpretation: A positive result is a statistically significant change in the weight of two of the tissues.

Strengths:

- Relatively rapid screen that is quite specific to androgenic effects.
- In vivo procedure incorporates metabolism; thus, it can detect chemicals that need activation.
- Oral administration will model a primary exposure route and incorporates ADME.

Weakness:

- The growth response of the individual androgen-dependent tissues is not entirely of androgenic origin, that is, compounds other than androgen agonists can alter the weight of certain tissues. However, the growth response of several tissues concomitantly substantiates a more androgen-specific mechanism.

OPPTS 890.1450 Female Pubertal (Rat)

Purpose: This assay is capable of detecting chemicals with estrogenic/anti estrogenic activity, or agents which alter pubertal development via changes in steroidogenesis, or hypothalamic–pituitary regulation of the ovary and thyroid homeostasis (Table 36.3).

Design: Test chemical is administered daily by gavage from post natal day (PND) 22 to PND 42 (21 days) to 15 females per dose. Two doses plus vehicle control are employed. The animals are weighed daily, and examined for vaginal opening from PND 22 until opening is complete. After vaginal opening, vaginal smears are taken daily. Additional measures are taken at necropsy.

Endpoints: Growth (daily body weight); Age and weight at vaginal opening; Organ weights [Uterus (blotted), Ovaries (paired), Thyroid, Liver, Kidneys (paired), Pituitary, Adrenals (paired)]; Histology [Uterus, Ovary, Thyroid (colloid area and follicular cell height), Kidney]; Blood Chemistry (standard panel); Hormones [Serum or plasma thyroxine (T_4), total serum or plasma TSH]: Estrus cyclicity; Age at first estrus after vaginal opening; Length of cycle; Percent of animals cycling; Percent of animals cycling regularly.

Interpretation: Results are evaluated for evidence of interaction of the test chemical with the endocrine system, primarily estrogen- and thyroid-related. Body weight, organ weight, and hormone values for the control animals are subject to performance criteria for mean and coefficient of variation. Thyroid endpoints are generally interpreted separately from the sex-hormone-related endpoints.

TABLE 36.3
Potential Changes Indicative of Different Modes of Action in Female Pubertal Assay

Estrogen Agonist	Steroidogenesis Inhibition	Disruption of HPT Axis	Thyrotoxicants
Early VO, pseudoprecocious puberty	Delayed VO	Alterations in VO	↓ T_4
↓ BW at VO	Delayed first estrus	Alterations in cyclicity	Alterations in TSH
Early first estrus	Persistent diestrus	Altered ovarian, uterine, or pituitary wts	Changes in thyroid histology
Altered organ histology	↓ Uterine wt	Altered organ histology	Changes in thyroid wt
Persistent estrus	Altered organ histology		Changes in liver wt/enzyme profile
↓ Ovarian wt			
↑ Uterine wt			

Notes: Changes in hypothalamic–pituitary function may advance or delay puberty, modify ovarian cycling by inducing early cycles, alter the regular cycles, and alter tissue weight depending on whether the agent activates or inhibits pubertal development.

Strengths:

- Intact mammalian in vivo system, and thus addresses ADME concerns
- Apical assay covering several modes of interaction, including ones not covered by other assays in battery
- Redundant endpoints, maximizing chance for detection while minimizing false negatives
- Covers pubertal period of development
- Well-established relationship between endpoints and endocrine system

Weakness:

- Protocol is not as diagnostic for specific MOAs as other assays in the battery such as uterotrophic for ER agonist.

OPPTS 890.1500 Male Pubertal (Rat)

Purpose: Provide information obtained from an in vivo mammalian system that is useful in determining the potential of chemicals or mixtures to interact with the endocrine system. Detect chemicals with antithyroid, androgenic, or antiandrogenic [AR or steroid-enzyme-mediated] activity or agents which alter pubertal development via changes in gonadotropins, prolactin, or hypothalamic function (Table 36.4).

Design: Test chemical is administered daily by gavage from PND 23 to PND 53 (31 days) to 15 males per dose level at two dose levels plus vehicle control. The animals are weighed daily, and examined for preputial separation from PND 30 until separation is complete. The other measurements are taken at necropsy.

Endpoints: Growth (daily body weight); Age and weight at preputial separation; Organ weights (seminal vesicle plus coagulating gland, ventral prostate, dorsolateral prostate, levator ani plus bulbocavernosus muscle complex, epididymis, testis, thyroid, liver, kidney, adrenal, pituitary); Blood Chemistry (standard panel); Hormone levels (serum testosterone, total serum thyroxine, total serum thyroid stimulating hormone); and Histology (epididymis, testis, thyroid, kidney.

Interpretation: Results are evaluated for evidence of interaction of the test chemical with the endocrine system, primarily androgen- and thyroid-related. Body weight, organ weight, and hormone values for the control animals are subject to performance criteria for mean and coefficient of variation. Thyroid endpoints are generally interpreted separately from the androgen-related endpoints.

Strengths:

- Intact mammalian in vivo system and thus addresses ADME concerns
- Apical assay covering several modes of interaction, including ones not covered elsewhere
- Redundant endpoints, maximizing chance for detection while minimizing false negatives
- Covers pubertal period of development
- Well-established relationship between endpoints and endocrine system
- Endpoints easy to measure

Weaknesses:

- Variability of hormone measurements, particularly testosterone
- Relatively long duration

OPPTS 890.1600 Uterotrophic (Rat)

Purpose: To detect estrogenic chemicals through a simple in vivo assay based on uterotrophic response (increase in uterine weight).

Design: There are two versions of the uterotrophic assay an immature version and an ovariectomized adult version. In both versions, two concentrations of test substance are administered orally or sc to ovariectomized or immature female rats for a minimum of 3 consecutive days. Estrogenic substances cause a uterotrophic response that is due to the imbibition of water and the growth of cells.

Endpoints: Uterine weight is measured and compared with controls.

TABLE 36.4
Potential Changes Indicative of Different Modes of Action in Male Pubertal Assay

Androgen Antagonist	Steroidogenesis Inhibitor or HPG Suppression	Hypothyroidism
↑ Age at puberty	↑ Age at puberty	↓ T_4
↓ Wts ventral prostate, seminal vesicles, LABC, epididymis	↓ Wts ventral prostate, seminal vesicles, LABC, epididymis	↑ TSH
↑ Testosterone	↓ Testosterone or no effect	↑ Follicular cell height
		↓ Colloid area
		↑ Liver wt for agents that induce hepatic clearance of thyroxine or no effect

Notes: Results are evaluated by weight-of-evidence. Redundancy of endpoints must be incorporated into evaluation. Thyroid endpoints are generally interpreted separately.

Interpretation: A statistical increase in uterine weight compared with controls is a positive result.

Strengths:

- Relatively rapid screen that is quite specific to estrogenic effects.
- In vivo procedure incorporates metabolism; thus, it can detect chemicals that need activation.

Weakness:

- Uterotrophic response is not due exclusively to estrogenic chemicals, so a uterotrophic response should be confirmed by corroborating information such as ER binding or TA.

Tier 2 Testing

The three goals of Tier 2 assays include the following:

1. Determining whether a substance may cause endocrine-mediated effects through or involving estrogen, androgen, or thyroid hormone systems
2. Determining the consequences to the organism of the activities observed in Tier 1
3. Establishing the relationship between doses of an endocrine-active substance administered in the test and the effects observed

The Tier 2 tests are longer in duration than Tier 1 tests, are designed to encompass critical life stages and processes as well as a broad range of doses, and are intended to be administrated by a relevant route of exposure. Effects associated with endocrine disruption may not be expressed until later in the test subject's life or may not appear until the reproductive period is reached. Therefore, Tier 2 tests usually encompass two generations and include effects on fertility and mating, embryonic development, sensitive neonatal growth and development, and transformation from the juvenile life stage to sexual maturity. The two-generation reproduction study or the extended one-generation reproduction test (refer to Chapter 34 for a discussion of these study designs) is the mammalian multigeneration test that will enable EPA to obtain a more comprehensive profile of the biological consequences of a chemical exposure and identify the dose or exposure that caused the consequences. The proposed Tier 2 nonmammalian ecotoxicology tests include Amphibian 2-Generation, Avian 2-Generation, Fish Life cycle, and the Invertebrate (Mysid) Life cycle. The validation of these tests is underway. Discussions of the endocrine systems of these species, study designs, endpoints, and validation methods are contained in the respective Draft Detailed Review Papers located on the EDSP website[58–60] and will not be discussed further in this chapter.

Hazard Assessment

According to the EPA, Tier 1 screening and Tier 2 testing data collected as part of EDSP will help to identify and characterize the hazard (the potential to cause harm). When EPA integrates and interprets all of the endocrine disruptor–related hazard data in consideration with other available hazard information, the EPA will perform a hazard assessment and then conduct an exposure assessment by looking at the amount of chemical to which wildlife or humans are likely to be exposed. The final step in the process is the risk assessment, through which EPA integrates the information about the potential harm of a chemical with the likelihood that someone or something will be exposed. Based on scientifically sound risk assessment, the agency can make risk management decisions regulating the chemical(s). For more information about how EPA conducts health risk assessments, read EPA's Office of Pesticide Programs' fact sheet entitled "Assessing Health Risks from Pesticides."[61]

WoE: A WoE approach is an interpretive process that considers all scientifically relevant information in an integrative analysis.[62,63] This process takes into account various kinds of available evidence, quality and quantity of that evidence, and strengths and limitations associated with each type of evidence and explains how the various types of evidence fit together to support a conclusion. EPA's Science Policy Council[64] recommended the use of five general assessment factors: (1) soundness, (2) applicability and utility, (3) clarity and completeness, (4) uncertainty and variability, and (5) evaluation and review.

Soundness: Scientific and technical procedures, measures, methods, or models employed to generate the information are reasonable for, and consistent with, the intended purpose. The following should be considered: (1) adequacy of the test methods to detect the effect of interest; (2) conduct of studies according to the scientific method of hypothesis development and testing through observation, experimentation, and verification; (3) ability to distinguish between a specific versus a nonspecific outcome according to the intended purpose of the study; and (4) interpretation of results and conclusions that are statistically significant, biologically plausible, and consistent with the data.

Applicability and utility: The information is relevant for the agency's intended use. The following should be considered: (1) appropriateness of test materials and methods, study design, and endpoints based on rationale, objectives, and hypotheses related to the intended purpose of the study; (2) evidence of competence in collection, analysis, presentation, and interpretation of data and conclusions; and (3) reliability of information from traditional as well as new methodologies.

Clarity and completeness: The degree of clarity and completeness with which the data, assumptions, methods, QA, sponsoring organizations, and analyses employed to generate the information is documented. The following should be considered: (1) transparency of authors, coauthors, contributors, and acknowledgement of respective institutions or organizations as well as sponsors; (2) background information or rationale, study objectives, hypotheses that are being tested, and experimental design, including controls and the number of observations/groups related to the intended purpose of the study; (3) degree of standardization or scientifically valid methodology that supports repeatability with accuracy and precision; (4) availability of raw data; (5) statistical analysis

approach; and (6) interpretation of statistical significance, plausibility of biological outcomes, and scientifically sound conclusions.

Uncertainty and variability: The uncertainty and variability (quantitative and qualitative) in the information or the procedures, measures, methods, or models are evaluated and characterized. The following should be considered: (1) citation of references pertaining to the specificity and sensitivity of test methods or models, experimental designs, or endpoints; (2) evidence of reproducibility or repeatability of the QA; (3) performance criteria and QC or assurance measures that may include historical or reference control information, coefficients of variation, good laboratory practice (GLP) compliance, or independent peer review; and (4) the number of animals or observations/groups and statistical analysis approach to sufficiently and adequately detect differences between or among groups.

Evaluation and review: The information or the procedures, measures, methods, or models are independently verified, validated, and peer-reviewed. The following should be considered: (1) explanation or reference of the process for verification or validation to evaluate relevance and reliability of test methods and endpoints as specific and sensitive units of measure; (2) general acceptance of the method in the peer-reviewed literature; (3) availability of validation results; and (4) availability of performance or evaluation criteria.

Future EDSP Plans

In 2010 and 2011, EPA's Office of the Inspector General (OIG) evaluated the EDSP and concluded that, without a better defined universe of chemicals, the agency will not be able to estimate longer-term resource needs for completion of milestones for the program. Therefore, the OIG recommended that the agency first define and identify the universe of chemicals for EDSP screening and testing. In response, the agency has decided to incorporate a discussion of the universe of chemicals into both the EDSP21 Work Plan[65] and the EDSP Comprehensive Management Plan.[40] Both documents are intended to provide primary guidance regarding the strategic direction and management of the EDSP for a period of at least 5 years. The EDSP21 Work Plan describes an approach for using computational or in silico models and molecular-based in vitro HTP assays to prioritize and screen chemicals to determine their potential to interact with the estrogen, androgen, or thyroid (E, A, or T) hormonal systems. There are two important drivers for this work plan. First, EPA is statutorily required to complete a first round of registration review of previously registered pesticides by October 1, 2022. Each review takes about 5–6 years, and currently, the agency initiates the review of approximately 70–80 active ingredients each year. So far, only a small percentage of the pesticide-active ingredients under review have received test orders for screening under the EDSP. Also, Tier 1 screening has yet to begin for a large number of active ingredients. Second, the president's proposed fiscal year 2012 budget for the agency states as follows: "In FY 2012, EPA will begin a multiyear transition from the EDSP to validate and more efficiently use computational toxicology methods and high throughput screens that will allow the agency to more quickly and cost-effectively assess potential chemical toxicity" (President's Budget FY2012).

OECD Conceptual Framework for Testing and Assessment of Endocrine Disrupting Chemicals

The OECD-proposed approach is more complex in terms of the number of levels employed. However, in the OECD scheme, it is possible to enter and exit at any test level depending on the outcome of evaluations. The OECD "Guidance Document on the Assessment of Chemicals for Endocrine Disruption"[66] describes the testing guidelines used in the endocrine disruptor framework. The OECD conceptual framework can be summarized as follows:

Level 1 (sorting and prioritization) is based upon existing information such as the following:

- Physical and chemical properties, for example, molecular weight (MW), reactivity, volatility, and biodegradability
- Human and environmental exposure, for example, production volume, release, and use patterns
- Hazard, for example, available toxicological data

Level 2 (in vitro assays) provides mechanistic data such as the following:

- ER binding assay (U.S. EPA OPPTS 890.1250)
- AR binding assay (U.S. EPA OPPTS 890.1150)
- Performance-based test guideline (PBTG) for stably transfected transactivation in vitro assays to detect *estrogen receptor agonists* (TG455)
- Aromatase assay (U.S. EPA OPPTS 890.1200)
- H295R steroidogenesis assay (draft OECD TG, U.S. EPA OPPTS 890.1550)
- Stably transfected human AR transcriptional activation assay (AR STTA)
- TR binding affinity (guidance not written)
- Aryl hydrocarbon receptor (AhR) binding affinity (guidance not written)
- Thyroid function in vitro (guidance not written)
- Fish hepatocyte Vitellogenin (VTG) assay (guidance not written)
- Yeast transactivation assays (YES and YAS) (guidance not written)

Level 3 (in vivo assays) provide data about single endocrine mechanisms and effects, utilizing the following:

- Mammalian in vivo assays
  - Hershberger bioassay in rodents (TG441) (androgenic related)
  - Uterotropic bioassay in rodents (TG440) (estrogenic related)
- Nonmammalian in vivo assays
  - FSTRA (TG229)
  - AMA (TG231)

Level 4 (in vivo assays) provides data about multiple endocrine mechanisms and effects, utilizing the following:

- Mammalian in vivo assays
  - Enhanced repeated dose 28-day oral toxicity study in rodents (TG407)[67] (endpoints based on endocrine mechanisms)
  - Pubertal development and thyroid function assay in peripubertal male rats (PP male assay) (U.S. EPA OPPTS 890.1500)
  - Pubertal development and thyroid function assay in peripubertal female rats (PP female assay) (U.S. EPA OPPTS 890.1450)
  - Adult intact male assay
  - Nonmammalian in vivo assay
  - twenty-one-day fish assay (TG 230) (estrogenic related)
  - FSTRA (TG 229)
  - Androgenized female stickleback screen (AFSS) (draft OECD TG)
  - Fish sexual development test (FSDT) (TG234)

Level 5 (in vivo assays) provides data on effects from endocrine and other mechanisms

- Mammalian in vivo assays
  - One-generation reproduction toxicity (TG415 enhanced)[68]
  - Two-generation reproduction toxicity (TG416 enhanced)[69]
  - Reproduction/developmental toxicity screening test (TG421 enhanced)[70]
  - Combined repeated dose toxicity study with the reproduction/developmental toxicity screening test (TG 422 enhanced)[71]
- Nonmammalian in vivo assays
  - Fish life cycle toxicity test (FLCTT) (see similar design in U.S. EPA OPPTS 885.4700)
  - Avian reproduction test (TG206)
  - Medaka multigeneration test (MMGT) (draft OECD TG)
  - Amphibian development, growth, and reproduction assay (ADGRA) (draft OECD TG)
  - Avian two-generation test (ATGT) (draft OECD TG)
  - Invertebrate development and reproduction assays

The framework should not be considered as all inclusive at the present time. At levels 3, 4, and 5, the framework includes assays that are either available or for which validation is under way. With respect to the latter, these have been provisionally included. Once developed and validated, they will be formally added to the framework. Level 5 should not be considered as including definitive tests only. Tests included at that level are considered to contribute to general hazard and risk assessment. Level 5 ecotoxicology tests should include endpoints that indicate mechanisms of adverse effects and potential population damage.

The assessment of each chemical should be based on a case-by-case basis, taking into account all available information, bearing in mind the function of the framework levels. Entering at all levels and exiting at all levels is possible in the OECD framework and depends upon the nature of existing information needs for hazard and risk assessment purposes. For example, when a multimodal model has been performed and it covers several of the single endpoint assays of a lessor level, then that model would replace the use of those single endpoint assays.

In Vitro Assays

Performance-Based Test Guideline for Stably Transfected Transactivation In Vitro Assays to Detect Estrogen Receptor Agonists (TG455)[72] This performance-based test guideline (PBTG) describes in vitro assays, which provides the methodology of stably transfected transactivation to detect ER agonists. It comprises mechanistically and functionally similar test methods for the identification of ER agonists and should facilitate the development of new similar or modified test methods. The two reference test methods that provide the basis for this PBTG are the stably transfected TA (STTA) assay using the ERα-HeLa-9903 cell line, derived from a human cervical tumor, and the BG1Luc ER TA assay using the BG1Luc-4E2 cell line, derived from a human ovarian adenocarcinoma. The cell lines used in these assays express ER and have been stably transfected with an ER responsive luciferase reporter gene. The assays are used to identify chemicals that activate the ER following ligand binding, after which the receptor-ligand complex binds to specific DNA response elements and transactivates the reporter gene, resulting in increased cellular expression of a marker enzyme (e.g., luciferase in luciferase-based systems). The enzyme then transforms the substrate to a bioluminescent product that can be quantitatively measured with a luminometer. These test methods are being proposed for screening and prioritization purposes but also provide mechanistic information that can be used in a WoE approach.

H295R Steroidogenesis Assay (TG456)[73] This Test Guideline describes an in vitro screen for chemical effects on steroidogenesis, specifically the production of 17β-estradiol (E2) and testosterone (T). The human H295R adrenocarcinoma cell line, used for the assay, expresses genes that encode for all the key enzymes for steroidogenesis. After an acclimation period of 24 h in multi well plates, cells are exposed for 48 h to seven concentrations of the test chemical in at least triplicate. Solvent and a known inhibitor and inducer of hormone production (see Guideline) are run at a fixed concentration as negative and positive controls. At the end of the exposure period, cell viability in each well is analyzed. Concentrations of hormones in the medium can be measured using a variety of methods including commercially available hormone measurement kits and/or instrumental techniques such as LC–MS. Data are expressed as fold change relative to the solvent control and the lowest-observed-effect-concentration. If the assay is negative, the highest concentration tested is reported as the no-observed-effect-concentration.

BG1Luc Estrogen Receptor Transactivation Test Method for Identifying Estrogen Receptor Agonists and Antagonists (TG457)[74] This Test Guideline describes an in vitro assay that provides concentration–response data for substances with in vitro ER agonist and antagonist activity. The test system utilizes the BG1Luc4E2 cell line derived from a human ovarian adenocarcinoma and stably transfected with an ER responsive luciferase reporter gene. This cell line can evaluate TA mediated by ERα and ERβ. The cells are plated into 96-well plate and exposed to 7 (range finder tests) and 11 (comprehensive test) noncytotoxic concentrations of the test chemical for 19–24 h to induce the reporter gene product (luciferase). Its activity is measured in a luminometer. Acceptance or rejection of a test is based on the evaluation of reference standard and control results from each experiment conducted on a 96-well plate. A positive response is identified by a concentration–response curve containing at least three points with nonoverlapping error bars, as well as a change in amplitude (normalized relative light unit) of at least 20% of the maximal value for the reference substance (17β-estradiol for the agonist assay and raloxifene HCL/17β-estradiol for the antagonist assay).

In Vivo Tests—Mammalian

Hershberger Bioassay in Rats (TG441)[75]

The Hershberger bioassay is an in vivo short-term screening test. It evaluates the ability of a chemical to elicit biological activities consistent with androgen agonists, antagonists, or 5α-reductase inhibitors. The current bioassay is based on the changes in the weight of five androgen-dependent tissues in the castrate-peripubertal male rat: the ventral prostate, seminal vesicle (plus fluids and coagulating glands), levator ani-bulbocavernosus muscle, paired Cowper's glands, and the GP. In order to establish whether a test substance can have androgenic or antiandrogenic action, two—respectively three—dose groups of the test substance, plus positive and vehicle (negative) controls, are normally sufficient. The test substance is administered by gavage or subcutaneous injection daily for 10 consecutive days. To test for antiandrogens, the test substance is administered together with a reference androgen agonist. Each treated and control group should include a minimum of six animals. The animals are necropsied approximately 24 h after the last administration of the test substance. The tissues are excised and their fresh weights determined. A statistically significant increase (androgenic) or decrease (antiandrogenic) in the weights of two of the five tissues indicates a positive response in this assay.

Uterotrophic Bioassay in Rodents (TG440)[76] The uterotrophic bioassay is an in vivo short-term screening test. It is based on the increase in uterine weight or uterotrophic response. The uterotrophic bioassay relies for its sensitivity on an animal test system in which the hypothalamic–pituitary–ovarian axis is not functional. Two estrogen-sensitive states in the female rodent meet this requirement: (1) immature females after weaning and prior to puberty and (2) young adult females after ovariectomy with adequate time for uterine tissues to regress. The test substance is administered daily by oral gavage or subcutaneous injection. Each treated and control group should include at least six animals. Graduated test substance doses are administered to a minimum of two treatment groups of experimental animals using one dose level per group and an administration period of 3 consecutive days for immature female method and a minimum administration period of 3 consecutive days for ovx-adult method. The animals are necropsied approximately 24 h after the last dose. For estrogen agonists, the mean uterine weight of the treated animal groups relative to the vehicle group is assessed for a statistically significant increase. A statistically significant increase in the mean uterine weight of a test group indicates a positive response in this bioassay. The report should include daily body weights, daily record of the status of animal, wet and blotted uterine weight, and daily food consumption values.

Repeated Dose 28-Day Oral Toxicity Study in Rodents (TG407)[70] This method provides information on health hazard likely to arise from exposure to test substance via oral administration. The method is based on the repeated oral administration of the substance of interest during one limited period (one dose level daily during 28 days). This guideline is intended primarily for use with rodents (rat preferably). At least 10 animals (5 females and 5 males) should be used for each dose level. Three tests groups, at least, should be used. The test compound is administered by gavage or via the diet or drinking water. A limit test may be performed if no effects would be expected at a dose of 1000 mg/kg bw/day. The report of this study will include results from clinical and functional observations, body weight and food/water consumption measurements, hematology, and clinical biochemistry, as well as gross necropsy and histopathology.

One-Generation Reproduction Toxicity Study (TG415)[71] This test guideline for reproduction testing is designed to provide general information concerning the effects of a test substance (solid, liquid, gas, or vapor) on male and female reproductive performance. The test substance is administered orally in graduated doses to several groups of males and females.

Males should be dosed during growth and for at least one complete spermatogenic cycle; females of the parent generation should be dosed for at least two complete estrous cycles. The animals are then mated. The test substance is administered to both sexes during the mating period and thereafter only to females during pregnancy and for the duration of the nursing period. This test guideline is intended primarily for use with the rat or mouse. Each test and control group should contain a sufficient number of animals to yield about 20 pregnant females at or near term. Three test groups, at least, should be used. It is recommended that the test substance be administered in the diet or drinking water. A limit test may be performed if no effects would be expected at a

dose of 1000 mg/kg bw/day. The results of this study include measurements (weighing and food consumption) and daily and detailed observations, each day preferably at the same time, as well as gross necropsy and histopathology. The findings of a reproduction toxicity study should be evaluated in terms of the observed effects, necropsy, and microscopic findings. A properly conducted reproduction test should provide a satisfactory estimation of a no-effect level and an understanding of adverse effects on reproduction, parturition, lactation, and postnatal growth.

Two-Generation Reproduction Toxicity (TG416)[72] This test guideline for two-generation reproduction testing is designed to provide general information concerning the effects of a test substance on the integrity and performance of the male and female reproductive systems, and on the growth and development of the offspring. The test substance is administered daily in graduated doses to several groups of males and females.

Males and females of the parent generation (5–9 weeks old) should be dosed during growth, during their mating, during the resulting pregnancies, and through the weaning of their first-generation offspring. The administration of the substance is continued to first-generation offspring during their growth into adulthood, mating, and production of a second generation (until the weaning). The rat is the preferred species for testing. Each test and control group should contain a sufficient number of animals to yield preferably not less than 20 pregnant females at or near parturition. At least three dose levels and a concurrent control shall be used. It is recommended that the test substance be administered orally (by diet, drinking water, or gavage). A limit test may be performed if no effects would be expected at a dose of 1000 mg/kg bw/day. The results of this study include measurements (weighing, sperm parameters, estrous cycle parameters, and offspring parameters) and clinical daily observations, as well as gross necropsy and histopathology. The findings of this two-generation reproduction toxicity study should be evaluated in terms of the observed effects, including necropsy and microscopic findings. A properly conducted reproductive toxicity test should provide a satisfactory estimation of a no-effect level and an understanding of adverse effects on reproduction, parturition, lactation, and postnatal development including growth and sexual development.

Reproduction/Developmental Toxicity Screening Test (TG421)[73] The test substance is administered in graduated doses to several groups of males and females. Males should be dosed for a minimum of 4 weeks. Females should be dosed throughout the study, so approximately 54 days. This test guideline is designed for use with the rat. It is recommended that each group be started with at least 10 animals of each sex. Generally, at least three test groups and a control group should be used. Dose levels may be based on information from acute toxicity tests or on results from repeated dose studies. The test substance is administered orally and daily. The limit test corresponds to one dose level of at least 1000 mg/kg bw. The results of this study include measurements (weighing and food/water consumption) and daily and detailed observations, preferably each day at the same time, as well as gross necropsy and histopathology. The findings of this toxicity study should be evaluated in terms of the observed effects, necropsy, and microscopic findings. Because of the short period of treatment of the male, the histopathology of the testis and epididymus must be considered along with the fertility data, when assessing male reproductive effects.

Combined Repeated Dose Toxicity Study with the Reproduction/Developmental Toxicity Screening Test (TG422)[74] The test substance is administered in graduated doses to several groups of males and females. Males should be dosed for a minimum of 4 weeks; females should be dosed throughout the study (approximately 54 days). Normally, matings of *one male to one female* should be used in this study.

This test guideline is designed for use with the rat. It is recommended that the test substance be administered orally by gavage. This should be done in a single dose daily to the animals using a stomach tube or a suitable intubation cannula. Each group should be started with at least 10 animals of each sex. Generally, at least three test groups and a control group should be used. Dose levels should be selected taking into account any existing toxicity and (toxico-) kinetic data available. The limit test corresponds to one dose level of at least 1000 mg/kg bw. The results of this study include measurements (weighing and food/water consumption) and daily detailed observations (including sensory reactivity to stimuli), preferably each day at the same time, as well as gross necropsy and histopathology. The findings of this toxicity study should be evaluated in terms of the observed effects, necropsy, and microscopic findings. The evaluation will include the relationship between the dose of the test substance and the presence or absence of observations. Because of the short period of treatment of the male, the histopathology of the testis and epididymus must be considered along with the fertility data, when assessing male reproduction effects.

In Vivo Tests—Nonmammalian

Amphibian Metamorphosis Assay (TG231)[77] This test guideline describes an AMA intended to screen substances that may interfere with the normal functioning of the HPT axis. The assay was validated with the species *Xenopus laevis*, which is recommended for use in the guideline. The assay uses three test chemical concentrations and the necessary controls, including a carrier control if necessary. The assay starts with tadpoles at the development stage 51 on the Nieuwkoop and Faber scale and is extended for a duration of 21 days. Four replicate test vessels are used for each treatment level and control(s). After 7 days of exposure, a subset of tadpoles from each treatment level is sampled for the measurement of the length of the hind limb. At termination of 21-day exposure period, developmental stage, snout–vent length, and hind limb length are measured on all remaining tadpoles. A subset of tadpoles from each treatment level is fixed (whole-body or dissected) for histopathology of the thyroid gland.

Short-Term Screening for Estrogenic and Androgenic Activity, and Aromatase Inhibition (TG230)[78] This test guideline describes an in vivo screening assay for certain endocrine active substances where sexually mature male and spawning female fish are held together and exposed to a chemical during a limited part of their life cycle (21 days). This assay covers the screening of estrogenic and androgenic activities, and aromatase inhibition. The assay was validated on the fathead minnow (*Pimephales promelas*), the Japanese medaka (*Oryzias latipes*), and the zebrafish (*Danio rerio*); however, zebrafish does not allow the detection of androgenic activities. At termination of the 21-day exposure period, depending on the species used, one or two biomarker endpoint(s) are measured in males and females as indicators of estrogenic, aromatase inhibition or androgenic activity of the test chemical; these endpoints are vitellogenin and secondary sexual characteristics. Vitellogenin is measured in fathead minnow, Japanese medaka, and zebrafish, whereas secondary sex characteristics are measured in fathead minnow and Japanese medaka only.

Fish Short-Term Reproduction Assay (TG229)[79] This test guideline describes an in vivo screening assay for fish reproduction where sexually mature male and spawning female fish are held together and exposed to a chemical during a limited part of their life cycle (21 days). The short-term reproduction assay was validated in the fathead minnow (*Pimephales promelas*), and this is the recommended species. The assay is run with three test chemical concentrations and the necessary controls, including a carrier control if necessary. For the fathead minnow, four replicate test vessels are used for each treatment level and control(s). During the conduct of the assay, the egg production is measured quantitatively daily in each test vessel. At termination of the 21-day exposure period, two biomarker endpoints are measured in males and females separately as indicators of endocrine activity of the test chemical; these endpoints are vitellogenin and secondary sexual characteristics. Gonads of both sexes are also preserved, and histopathology may be evaluated to assess the reproductive fitness of the test animals and to add to the WoE of other endpoints.

Fish Sexual Development Test (TG234)[80] This test guideline describes an assay that assesses early life-stage effects and potential adverse consequences of putative endocrine disrupting chemicals (EDCs) (e.g., estrogens, androgens, and steroidogenesis inhibitors) on fish sexual development. In the test, fish are exposed, from newly fertilized egg until the completion of sexual differentiation at about 60 days posthatch, to at least three concentrations of the test substance dissolved in water. In each treatment level and control(s) group(s), a minimum of four replicates are recommended. At termination of the test, two core endpoints are measured in each fish: vitellogenin concentration from head and tail or from blood sampling, and proportion of males, females, intersex, and undifferentiated fish through gonadal histology. In fish species possessing a genetic sex marker, the genetic sex is identified to determine sex reversal in individual fish. The combination of the two core endocrine endpoints, vitellogenin concentration and phenotypic (and possibly genotypic) sex ratio, enables the test to indicate the mode of action of the test chemical.

Fish Life Cycle Toxicity Test (OPPTS 885.4700)[81] The basic FLCTT as described by Benoit,[82] the U.S. EPA, and others does not contain endpoints that solely respond to endocrine disrupters. However, many of the endpoints in this apical test are nevertheless affected by estrogen, androgen, thyroid, steroidogenesis endocrine disruptors (EATS EDs). Of particular interest in the context of estrogens, androgens, and steroidogenesis disrupters are time to sexual maturity, sex ratio of adults, fecundity, and fertility, but other endpoints may also be responsive to some EDs (e.g., growth may respond to some thyroid disrupters).

This assay is designed primarily as an apical test for chemicals with suspected reproductive or long-term toxicity. It has not been validated for publication as a test guideline but has been widely used for several decades by regulatory agencies for assessing possible chronic effects in fish. The endpoints are all apical measures of development, growth, or reproduction. Exposure of the test organisms (fathead minnow *Pimephales promelas*,[82] but other species can also be successfully used with minor changes in the protocol, including sheepshead minnow *Cyprinodon variegatus*, zebrafish *Danio rerio*, and medaka *Oryzias latipes*) usually continues from the freshly fertilized eggs of the F_0 generation to the fry or young fish of the F_1 generation (4–8 weeks posthatch in the case of fathead minnow).[82,83]

The purpose of this test guideline is to determine the effects on the reproduction of a substance administered with food to birds. Birds are fed a diet containing the test substance in various concentrations for a period of not less than 20 weeks. A minimum of three dietary concentrations of the test substance is required. The maximum recommended test concentration is 1000 ppm. Birds may be kept in pens as pairs (at least 12 pens per test group) or as groups of one male and two or three females (at least 8–12 pens per group). Birds are induced, by photoperiod manipulation, to lay eggs. Eggs are collected over a 10-week period, artificially incubated and hatched, and the young maintained for 14 days. Suitable facilities for rearing birds, preferably indoors, are necessary. Mortality of adults, egg production, cracked eggs, egg shell thickness (at least two eggs from each pen), viability, hatchability, and effects on young birds are observed during the study.

Technical Questions and Answers Concerning the Tier 1 Tests

The U.S. EPA has issued clarifications about technical aspects of the conduct of Tier 1 assays for the EDSP in response to questions raised by Test Order recipients and others. In some cases, these questions pointed out simple but significant errors in test guidelines (e.g., incorrect references to tables and misplaced decimal points). In other cases, questions pointed out ambiguous language that required clarification; and in yet other cases, questions were raised about whether alternative

techniques had been considered by the EPA and rejected, or whether they might be acceptable to use. These items must be reviewed prior to following any of the published guidelines. The following documents are available on the U.S. EPA website's EDSP[84] and review the EPA's response to questions.

- Clarifications on Technical Aspects of the EDSP Tier 1 Assays[85]
- Responses to EDSP Tier 1 Technical Questions Received from CeeTox Contract Laboratory—Generic Technical Questions Regarding the Conduct of In Vitro EDSP Tier 1 Assays[86]
- Responses to EDSP Tier 1 Technical Questions Received from Integrated Laboratory Systems—Conducting In Vivo Mammalian Studies[87]
- Responses to EDSP Tier 1 Technical Questions Received from Huntingdon Life Sciences—Conducting the EDSP Aromatase Assay Using Guideline 890.1200[88]
- Responses to EDSP Tier 1 Technical Questions Received from Huntingdon Life Sciences—Regarding the Estrogen Receptor Binding Assay[89]
- Responses to EDSP Tier 1 Technical Questions Received from CeeTox Contract Laboratory—Assessing False Positives in the Estrogen Receptor Transcriptional Activation (ERTA) Assay[90]

Standard Evaluation Procedures and Data Entry Spreadsheet Templates for EDSP Tier 1 Assays

EPA's OCSPP has developed a set of standard evaluation procedures (SEPs),[91] which provide guidance for the review and evaluation of environmental and human health effects data submitted in response to Test Orders for the 890 Guideline Series for the EDSP Tier 1 battery. There is an individual SEP for each of the eleven 890 Guideline Series EDSP Tier 1 assays that comprise the battery. The objective of the SEPs is to assist EPA reviewers and support comprehensive and consistent evaluations of major scientific topics; the SEPs also provide interpretive scientific and policy guidance where appropriate. The SEPs provide a venue for standardizing data organization and evaluation procedures with the goal of increasing the efficiency, thoroughness, and consistency with which individual study evaluations are prepared and assist the scientists to reach clear, reasonable, and concise conclusions that are scientifically robust.

Using the guidance within the relevant SEP, EPA reviewers will develop data evaluation records (DERs) for each of the submitted assays. The DERs reflect how well the assay conforms to the Series 890 EDSP Test Guidelines and document basic study information such as materials, methods, results, and significant deviations from the study protocol or guideline recommendations as well as their potential impacts. The DER also provides the registrant's conclusions, the EPA reviewer's conclusions, and any other information about the performance of the study that affects the interpretation of the data within the context of the EDSP.

The SEPs do not provide guidance for making the determination that a chemical that has been screened using the EDSP Tier 1 assays should move on to Tier 2 testing. The EPA has submitted a separate draft guidance document[92] of the WoE.

OCSPP has also developed a set of data entry spreadsheet templates (DESTs) that Test Order recipients may choose to use as a method for reporting all raw data in electronic format for the 890 Guideline Series for the EDSP Tier 1 battery. There is a DEST for each of the eleven 890 Guideline Series EDSP Tier 1 assays that comprise the battery. EPA encourages Test Order recipients to use the DEST as a method for standardizing raw data reporting and to assist EPA reviewers in the comprehensive and consistent evaluations of the raw data.

BIOCHEMICAL ASSESSMENT

The diagnosis of endocrine disorders as well as an understanding of the mechanisms of hormonal action was significantly advanced when methods became available to measure hormones in the blood.[93] Until about the 1960s, the measurement of hormones usually involved in vivo bioassays. The discovery of mAb techniques revolutionized the measurement of hormones. Subsequently, antibody-based competitive protein-binding assays (i.e., RIAs) were perfected with the availability of radioactive, or tracer, hormones.

Evaluation of endocrine function is an important aspect in determining the mechanism of endocrine toxicity.[22] Measurement of hormone and hormonal metabolite levels in the blood or urine can reveal important information regarding the site of endocrine toxicity. These sites can include the endocrine tissue itself (e.g., the site of hormone synthesis and release), the endocrine target tissue (e.g., the hormone receptor and intracellular signaling pathways), and the mechanism of transport from the endocrine tissue to the target cell receptor to exert an endocrine effect (e.g., the hormone carrier proteins). Furthermore, toxic actions on feedback control mechanisms can augment or inhibit endocrine responses.

There are limitations to the biochemical assessment of the endocrine system. For example, factors that may have modulatory effects on endocrine target cells cannot always be identified by simple evaluation of blood hormone levels. For this reason, biochemical assessment of the endocrine system frequently offers a macroscopic survey of toxicology mechanisms. Determination of pathophysiology and molecular endocrine toxicity is limited due to the complex interplay of the numerous and frequently redundant regulatory and counterregulatory feedback loops.[94] Biochemical assessment of physiologic conditions can be confounded by several external factors, such as stress, extreme temperatures, or changes in the diurnal variation of sleep patterns. Similarly, the biochemical assessment can be confounded by internal factors such as the female menstrual cycle in both the reproductive and nonreproductive organs. Finally, the sensitivity and specificity of hormonal testing vary greatly among different hormonal systems.

In Vivo Bioassays

An in vivo bioassay determines the biological activity of a hormone by noting its effect on a live animal or isolated organ preparation compared to a known standard preparation. Bioassays provide a means of assessing endocrine status, and although more accurate measurement of hormonal levels can now be achieved with RIA, bioassays are sometimes useful when RIA is unable to distinguish active from inactive hormonal metabolites or precursors.[95] Historically, bioassays have used hypoglycemia to measure insulin, bone growth to measure GH, and ovarian weight change to measure gonadotropins. The main drawbacks to in vivo bioassays are that they are frequently insensitive and nonspecific, and comparisons to the dose–response curve for a standard preparation are imprecise. Some of these in vivo bioassays but definitely not all of these assays were earlier discussed in the Endocrine Disruptor Screening Program section.

In Vitro Bioassays

In vitro bioassays employ endocrine-responsive tissue cell culture lines that can assess the amount of biologically active hormone in sera or other fluids such as urine. The hormonal activity can be determined by measuring a cellular response to a hormone. Classically, hormonally induced changes in adenylate cyclase activity (with changes in cAMP levels) have been used, but more recently, changes in intracellular calcium levels, phosphoinositol metabolites, and protein phosphorylation have been used to assess hormonal activity. Other in vitro bioassays can examine changes more distal to the receptor and signal transduction mechanisms and note changes in enzymatic activity or steroidogenesis. Finally, some in vitro bioassays can assess the mitogenic responses to a given hormone. A shortcoming to in vitro bioassays is that there may be coexisting stimulatory or inhibitory substances in the matrix that can confound the observed response.

Cell Culture Systems

Examination of dispersed or cultured cells from any level of the hypothalamus–pituitary–adrenocortical (HPA) axis can provide better information than simple biochemical assays because an intact cell is much more complicated than an isolated reaction and, hence, one step closer to examining the intact organism.

Corticotropes

Mammalian corticotropes[96–98] have been used to study the actions of corticotropin-releasing hormone (CRH) and/or arginine vasopressin (AVP), also known as vasopressin, argipressin, or antidiuretic hormone (ADH), as well as the effects of other agents on the synthesis/release of ACTH (or corticotropin), into the culture medium, or on changes in messenger ribonucleic acid (mRNA) levels. These in vitro systems must be carefully examined since many additional factors can alter the responsiveness of the corticotrope in vivo (e.g., cortisol levels, CRH and/or AVP receptor levels, and other circulating or local factors such as pituitary adenylate cyclase–activating polypeptide [PACAP]).

Adrenal Cortical Cells

Mouse models of cultured adrenal cells also may be used to develop EDC screening assays. However, mouse adrenal models often differ markedly from results seen in humans.[99] A human adenocarcinoma cell line (H295R) has been developed as a screening assay for chemical factors that interfere with steroidogenesis using production of progesterone, testosterone, and E2 as end products (OPPTS 890.1550 steroidogenesis—human cell line [H295R]), and this system possibly could be validated for measuring GC growth-hormone-releasing hormone (GHRH) as well. An in vitro method for assessing pesticide effects on adrenal cells of rainbow trout has been reported recently[100] and could provide the basis for a simple screening assay for specifically directed at fish.

Glucocorticoid Growth-Hormone-Releasing Hormone Target Cells

Some in vitro systems have been described for looking at metabolic actions of GCs on mammalian uterine cells,[101] liver cells,[102–105] or adipose cells.[106,107] Additional in vitro systems have been explored in fish liver.[108,109]

Gene Activation Assays

Following the exposure of a cell to a GC, GC antagonist, or GC agonist, expression of genes can be monitored by isolating mRNA, forming the corresponding cDNA, and identifying the specific genes involved using DNA microarrays. DNA technology has resulted in the development of DNA microarrays for various species for whom the genome has been cataloged (e.g., human, *Xenopus*, zebrafish). These microarrays are available from commercial sources. However, many of the genes activated in these arrays have yet to be linked to a known GC function.

Radioimmunoassay

Measurement of endocrine values was revolutionized in 1959 when Yalow and Berson published their work on the RIA to detect nanomolar concentrations of hormones in human subjects.[20] Immunoassays are based on the fact that specific proteins can distinguish three-dimensional structures at the molecular level. When specific proteins are produced by a biological organism, their specificity can be discriminated and tightly bound to those molecules in a highly complex mixture providing a means to measure these proteins in a controlled situation. RIAs use radioactive isotopes to identify these specific proteins. Classic bioassays were vastly surpassed in sensitivity, specificity, and facilitation by RIA. In addition, RIA allows measurement of biological materials not previously detectable by chromatographic or spectrophotometric techniques.[110] RIAs can be used to measure hormones that cannot be radiolabeled to detectable levels in vivo. They are also used for hormones that cannot fix complement when bound to antibodies, or they can be used to identify cross-reacting antigens that compete and bind with the antibody.

Generally, immunoassays can be divided into two categories: competitive inhibition and noncompetitive inhibition. Competitive assays use a single specific antibody type that is fixed to a surface and a corresponding analog of the protein to carry the label. The protein in the sample competes with the labeled analog for binding positions on the antibody. Once the unbound analog is separated, the amount of label remaining is inversely related to the amount of bound protein. Competitive inhibition of radiolabeled hormone antibody binding by unlabeled hormone (either as a standard or an unknown mixture) is the principle of most RIAs. A standard curve for measuring antigen (hormone) binding to antibody is constructed by placing known amounts of radiolabeled antigen and the antibody into a set of test tubes. Varying amounts of unlabeled antigen are added to the test tubes. Antigen–antibody complexes are separated from the antigen, and the amount of radioactivity from each sample is measured to detect how much unlabeled antigen is bound to the antibody. Smaller amounts of radiolabeled antigen–antibody complexes are present in the fractions containing higher amounts of unlabeled antigen. Usually, a standard curve is constructed that measures the percent of radiolabeled antigen bound with the concentration of unlabeled antigen present.

Noncompetitive assays utilize two specific antibodies to sandwich the protein being examined. One antibody (termed the *capture protein*) is immobilized to a surface and a second (termed the *label protein*) carries the label. In the assay, the protein being examined is bound simultaneously by both the capture and label proteins. At completion of the assay, the unbound label protein is separated and measured; the remaining label is measured and is directly proportional to the protein concentration in the sample. Sandwich assays are generally limited to those proteins of sufficient size to be able to bind two materials simultaneously, typically proteins and microorganisms. Competitive assays are compatible with a wide variety of proteins and are used for the majority of low-molecular-weight proteins. Although several methods exist for the separation of antigen–antibody complexes, two methods are most commonly employed in RIAs. The first, the double-antibody technique, precipitates antigen–antibody complexes out of solution by utilizing a second antibody, which binds to the first antibody. Although other means of antigen–antibody precipitation exist, they can sometimes chemically alter antigen–antibody binding properties. The drawback to the double-antibody technique is its expense, which makes this technique uneconomical for RIA screening procedures.

Another commonly used method is the dextran-coated activated charcoal technique. Addition of dextran-coated activated charcoal to the sample followed by immediate centrifugation absorbs free antigen and leaves antigen–antibody complexes in the supernatant fraction. Although it is economical, a drawback to this technique is that it works best only when the molecular weight of the antigen is 30 kDa or less. Also, sufficient carrier protein must be present to prevent adsorption of unbound antibody.

Once a standard curve has been constructed, the RIA can determine the concentration of hormone in a sample (usually plasma or urine). The values of hormone levels are usually accurate when the RIA is used, but certain factors (e.g., pH or ionic strength) can affect antigen binding to the antibody; thus, controlled and similar conditions must be used when assessing the standard and the sample.

Difficulties with RIAs include a lack of specificity. This problem is usually due to nonspecific cross-reactivity of the antibody. Another complication is that, because the assays require the use of radioactive materials by definition, the laboratory must be regulated by the Nuclear Regulatory Commission (NRC). Despite the more complex and involved RIA and mAb methodologies, they are of immense value for measuring various tropic hormones. RIA represents an analytical approach of great sensitivity, and such techniques have been applied to numerous biological substances, many of which cannot be assessed by other techniques. Unlike bioassays that often require large amounts of tissue (or blood), the greater sensitivity of the RIAs or mAb techniques allows the use of smaller samples of biological fluids. Some of these RIA methodologies are more useful than others, and their usefulness to some extent depends on the degree of hormonal cross-reactions or, in the case of mAb methods, their degree of sensitivity.

Although the RIA technique requires specialized equipment, it is extremely sensitive and extremely specific. It remains the least expensive method to perform such tests. Today, it has been supplanted by the ELISA method, where the antigen–antibody reaction is measured using colorimetric signals instead of a radioactive signal. However, because of its robustness, consistent results, and low price per test, RIA methods are again becoming popular.

Enzyme-Linked Immunosorbent Assay

The ELISA is comparable to the immunoradiometric assay (IRMA) except that an enzyme tag is attached to the antibody instead of a radioactive label. ELISAs produce an end product that can be assessed with a spectrophotometer. The hormone is bound to the enzyme-labeled antibody, and the excess antibody is removed for IRMAs. After excess antibody has been removed or the second antibody containing the enzyme has been added (two-site assay), the substrate and cofactors necessary are added to visualize and record enzyme activity. The level of hormone present is directly related to the level of enzymatic activity. The sensitivity of the ELISAs can be enhanced by increasing the incubation time for producing substrate. Sometimes, the substrate formed may yield a color change so that detection of the hormone being measured can be determined visually.

Indirect ELISA

Indirect ELISA adopts the following mechanism:

1. A buffered solution of the antigen to be tested for is added to each well of a microtiterplate, where it is given time to adhere to the plastic through charge interactions.
2. A solution of nonreacting protein, such as bovine serum albumin or casein, is added to block any uncoated plastic surface in the well.

3. The primary antibody is added, which binds specifically to the test antigen coating the well.
4. A secondary antibody is added, which will bind the primary antibody. This secondary antibody often has an enzyme attached to it.
5. A substrate for this enzyme is then added. Often, this substrate changes color upon reaction with the enzyme. The color change shows the secondary antibody has bound to primary antibody, which strongly implies the donor has had an immune reaction to the test antigen. This can be helpful in a clinical setting, and in research.
6. The higher the concentration of the primary antibody present in the serum, the stronger the color change. Often, a spectrometer is used to give quantitative values for color strength.

The enzyme acts as an amplifier; even if only few enzyme-linked antibodies remain bound, the enzyme molecules will produce many signal molecules. Within common-sense limitations, the enzyme can go on producing color indefinitely, but the more primary antibody is present in the donor serum, the more secondary antibody + enzyme will bind, and the faster the color will develop. A major disadvantage of the indirect ELISA is the method of antigen immobilization is not specific; when serum is used as the source of test antigen, all proteins in the sample may stick to the microtiter plate well, so small concentrations of analyte in serum must compete with other serum proteins when binding to the well surface. The sandwich or direct ELISA provides a solution to this problem, by using a *capture* antibody specific for the test antigen to pull it out of the serum's molecular mixture.

ELISA may be run in a qualitative or quantitative format. Qualitative results provide a simple positive or negative result (yes or no) for a sample. The cutoff between positive and negative is determined by the analyst and may be statistical. Two or three times the standard deviation is often used to distinguish positive from negative samples. In quantitative ELISA, the OD of the sample is compared to a standard curve, which is typically a serial dilution of a known-concentration solution of the target molecule. For example, if a test sample returns an OD of 1.0, the point on the standard curve that gave OD = 1.0 must be of the same analyte concentration as the sample.

Sandwich or Direct ELISA

A sandwich ELISA adopts the following mechanism:

1. Plate is coated with a capture antibody.
2. Sample is added, and any antigen present binds to capture antibody.
3. Detecting antibody is added and binds to antigen.
4. Enzyme-linked secondary antibody is added and binds to detecting antibody.
5. Substrate is added and is converted by enzyme to detectable form.

A less-common variant of this technique, a *sandwich* ELISA, is used to detect sample antigen. The steps are as follows:

1. A surface is prepared to which a known quantity of capture antibody is bound.
2. Any nonspecific binding sites on the surface are blocked.
3. The antigen-containing sample is applied to the plate.
4. The plate is washed to remove unbound antigen.
5. A specific antibody is added and binds to antigen (hence the *sandwich*: the Ag is stuck between two antibodies).
6. Enzyme-linked secondary antibodies are applied as detection antibodies that also bind specifically to the antibody's Fc (fragment, crystallizable) region (nonspecific).
7. The plate is washed to remove the unbound antibody–enzyme conjugates.
8. A chemical is added to be converted by the enzyme into a color or fluorescent or electrochemical signal.
9. The absorbency or fluorescence or electrochemical signal (e.g., current) of the plate wells is measured to determine the presence and quantity of antigen.

Competitive ELISA

A third use of ELISA is through competitive binding. The steps for this ELISA are somewhat different from the first two examples:

1. Unlabeled antibody is incubated in the presence of its antigen (sample).
2. These bound antibody/antigen complexes are then added to an antigen-coated well.
3. The plate is washed, so unbound antibody is removed. The more antigen in the sample, the less antibody will be able to bind to the antigen in the well, hence *competition*.
4. The secondary antibody, specific to the primary antibody, is added. This second antibody is coupled to the enzyme.
5. A substrate is added, and remaining enzymes elicit a chromogenic or fluorescent signal.
6. The reaction is stopped to prevent the eventual saturation of the signal.

Some competitive ELISA kits include enzyme-linked antigen rather than enzyme-linked antibody. The labeled antigen competes for primary antibody binding sites with the sample antigen (unlabeled). The more antigen in the sample, the less labeled antigen is retained in the well and the weaker the signal. For example, for the detection of HIV antibodies, the wells of microtiter plate are coated with the HIV antigen. Two specific antibodies are used, one conjugated with enzyme and the other present in serum (if serum is positive for the antibody). Competition occurs between the two antibodies for the same antigen. Sera to be tested are added to these wells

and incubated at 37°C and then washed. If antibodies are present, the antigen–antibody reaction occurs. No antigen is left for the enzyme-labeled specific HIV antibodies. These antibodies remain free upon addition and are washed off during washing. Substrate is added, but there is no enzyme to act on it, so positive result shows no color change.

Multiple and Portable ELISA

A new technique[111] uses a solid phase made up of an immunosorbent polystyrene rod with 8–12 protruding ogives, the roundly tapered end of a two- or three-dimensional object. The entire device is immersed in a test tube containing the collected sample, and the following steps (washing, incubation in conjugate, and incubation in chromogens) are carried out by dipping the ogives in the microwells of standard microplates filled with reagents.

The advantages of this technique are as follows:

1. The ogives can each be sensitized to a different reagent, allowing the simultaneous detection of different antibodies and/or different antigens for multiple-target assays.
2. The sample volume can be increased to improve the test sensitivity in clinical (blood, saliva, and urine), food (bulk milk, and pooled eggs), and environmental (water) samples.
3. One ogive is left unsensitized to measure the nonspecific reactions of the sample.
4. The use of laboratory supplies for dispensing sample aliquots, washing solution, and reagents in microwells is not required, facilitating the development of ready-to-use lab kits and on-site testing.

Issues with ELISAs

ELISAs are very good at detecting single analytes within a fairly narrow concentration range.

- If the concentration of analyte is very high or low, then many dilutions of the sample may need to be made in order to read off a standard curve. This can mean an assay must be repeated to get accurate results.
- Each substrate used in ELISA reaches a certain color intensity after which it is not possible to determine differences; this means that usually ELISAs only have a limited *range*, for example, 1–1000 μg/mL. These ranges may be too narrow for all applications.
- ELISAs are quite lengthy assays, taking anything up to 1 day to run. This means that repeat samples, whether you have 1 repeat or 50 repeat samples, require the same time to run repeat assays.
- ELISAs only measure one analyte; it is rarely possible to *multiplex*, that is, to measure many analytes in the same sample. This means separate assays must be established in order to measure many analytes.
- There are many washing steps in ELISA that wash away unbound analyte. Antibodies bind with varying affinity (strength of binding) and avidity (numbers of binding sites). There is a risk that antibodies with low binding affinity will be washed away and false negatives or lower than true results will be obtained.
- ELISAs typically require reasonably large sample volumes for testing. This may mean that for smaller animal species, satellite animals are required in order to collect enough samples for testing.

Immunoradiometric Assays

IRMAs are like RIAs in that a radiolabeled substance is used in an antibody–antigen reaction. The radioactive label, however, is attached to the antibody instead of the hormone. This assay is based upon the reversible and noncovalent binding of an antigen by a specific antibody labeled with a radioisotope. Further, excess of antibody, rather than limited quantity, is present in the assay. All of the unknown antigen becomes bound in IRMA, rather than just a portion as in RIA. IRMAs are more sensitive. In the one-site assay, the excess antibody that is not bound to the sample is removed by the addition of a precipitating binder. In the two-site assay (i.e., sandwich technique), a hormone with at least two antibody-binding sites is adsorbed onto a solid phase, to which one of the antibodies is firmly attached (either the walls of the assay tube itself or beads that are added to the patient sample in assay buffer). After binding to the antibody is completed, a second antibody labeled with ^{125}I is added to the assay. This antibody reacts with the second antibody-binding site to form the sandwich, which is composed of antibody-hormone-labeled antibody. In contrast to RIA and similar competitive protein-binding assays, the amount of hormone present is directly proportional to the amount of radioactivity measured in the assay.[112]

Enzyme-Multiplied Immunoassay Technique

Using enzyme-multiplied immunoassay technique (EMIT) assays, enzyme tags replace the radiolabels; however, the antibody binding alters the enzyme characteristics, allowing for measurement of hormone without separating the bound and free components (i.e., homogeneous assay). EMIT assays are used to monitor urine for drugs, but because of a lack of sensitivity, they have not been used to assess hormones. No extraction is required, and the assay can be completed within a few minutes.[113] The enzyme is attached to the hormone or drug being tested. This enzyme-labeled antigen is incubated with the sample and with antibody to the hormone or drug. Binding of the antibody to the enzyme-linked hormone either physically blocks the active site of the enzyme or changes the protein conformation so the enzyme is no longer active. When antibody binding has occurred, the enzyme substrate and cofactor are added, and the enzyme activity can be measured. If the sample contains hormone or drug, it will compete with enzyme-linked hormones for antibody binding. The enzyme will not be blocked by the antibody, and more enzyme activity will be measurable.

Enzyme-Linked Immunosorbent Spot Assay

The enzyme-linked immunosorbent spot (ELISPOT) assay is a common method for monitoring immune responses in humans and animals. It was developed by Cecil Czerkinsky in 1983. The ELISPOT assay is based on, and was developed from, a modified version of the ELISA. ELISPOT assays were originally developed to enumerate B cells secreting antigen-specific antibodies and have subsequently been adapted for various tasks, especially the identification and enumeration of cytokine-producing cells at the single-cell level. At appropriate conditions, the ELISPOT assay allows visualization of the secretory product of individual activated or responding cells. Each spot that develops in the assay represents a single reactive cell. Thus, the ELISPOT assay provides both qualitative (type of immune protein) and quantitative (number of responding cells) information.

By virtue of exquisite sensitivity of the ELISPOT assay, frequency analysis of rare cell populations (e.g., antigen-specific responses), which were not possible before, are now relatively easy. This exceptional sensitivity is, in part, because the product is rapidly captured around the secreting cell: before it is either diluted in the supernatant, captured by receptors of adjacent cells, or degraded. This makes ELISPOT assays much more sensitive than conventional ELISA measurements. Limits of detection are below 1/100,000 rendering enumerate the actively producing cells. This allows much of the analysis process to be automated and permits a greater level of accuracy than what can be achieved using manual inspection.

Procedure: As noted earlier, the ELISPOT assays employ a technique very similar to the sandwich ELISA technique. Either a monoclonal (preferred for greater specificity) or polyclonal capture antibody that is coated aseptically onto a polyvinylidenefluoride (PVDF)-backed microplate. These antibodies are chosen for their specificity for the analyte in question. The plate is blocked, usually with a serum protein that is nonreactive with any of the antibodies in the assay. After this, cells of interest are plated out at varying densities, along with antigen or mitogen, and then placed in a humidified 37°C CO_2 incubator for a specified period of time (Figure 36.2).

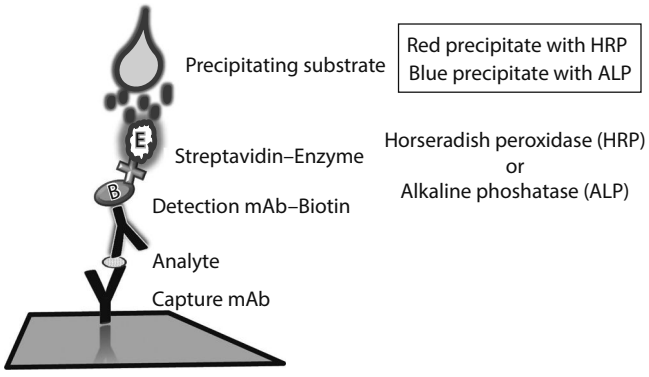

FIGURE 36.2 ELISPOT.

Cytokine (or other cell product of interest) secreted by activated cells is captured locally by the coated antibody on the high surface area PVDF membrane. After washing the wells to remove cells, debris, and media components, a biotinylated polyclonal antibody specific for the chosen analyte is added to the wells. This antibody is reactive with a distinct epitope of the target cytokine and thus is employed to detect the captured cytokine. Following a wash to remove any unbound biotinylated antibody, the detected cytokine is then visualized using an avidin-horseradish peroxidase (HRP), and a precipitating substrate (e.g., 3-amino-9-ethylcarbazole (AEC), 5-bromo-4-chloro-3-indolylphosphate/nitro blue tetrazolium (BCIP/NBT). The colored end product (a spot, usually a blackish blue) typically represents an individual cytokine-producing cell. The spots can be counted manually (e.g., with a dissecting microscope) or using an automated reader to capture the microwell images and to analyze spot number and size.

FluoroSpot Assay

The FluoroSpot assay is a modification of the ELISPOT assay and is based on using multiple fluorescent anticytokines, which makes it possible to spot two cytokines in the same assay.

Monoclonal Antibodies

All of the major hormones can be assessed using mAb techniques. In 1975, Köhler and Milstein[21] first discovered mAbs and devised an immunological method for producing large quantities of mAbs that could be targeted to specific proteins. Once mAbs for a given substance have been produced, they can be used to detect the presence of this substance. The western blot test and immuno dot blot tests detect the protein on a membrane. They are also very useful in immunohistochemistry, which detect antigen in fixed tissue sections and immunofluorescence test, which detect the substance in a frozen tissue section or in live cells. mAb techniques do provide a means of producing a specific antibody for binding antigen; this technique is useful for studying protein structure relations (or alterations) and has been used for devising specific RIAs. The advantages and disadvantages of mAbs compared to polyclonal antisera are listed in Table 36.5.

TABLE 36.5
Advantages and Disadvantages of Monoclonal Antibodies Compared to Polyclonal Antisera

Advantages	Disadvantages
Sensitivity	Overly specific
Quantities available	Decreased affinity
Immunologically defined	Diminished complement fixation
Detection of neoantigens on cell membrane	Labor intense; high cost

Polymerase Chain Reaction

Polymerase chain reaction (PCR) is a sensitive technique to amplify a piece of DNA, generating thousands to millions of copies of a particular DNA sequence. The method relies on thermal cycling, consisting of repeated cycles of heating and cooling of the reaction for DNA melting and enzymatic replication of the DNA. Two (one for each strand of DNA in a DNA double helix) sequence-specific primers (short DNA fragments) are designed to selectively target the DNA sequence of interest; these along with a DNA polymerase are key components to enable selective and repeated amplification. As PCR progresses, the DNA generated is itself used as a template for subsequent replication, setting in motion a chain reaction in which the DNA template is exponentially amplified. PCR is used for a wide range of applications.

PCR uses a heat-stable DNA polymerase (Taq polymerase, an enzyme originally isolated from the bacterium *Thermus aquaticus*). This DNA polymerase enzymatically assembles a new DNA strand from DNA building blocks, the nucleotides, by using single-stranded DNA as a template and DNA oligonucleotides (also called DNA primers), which are required for initiation of DNA synthesis. The vast majority of PCR methods use thermal cycling, that is, alternately heating and cooling the PCR sample to a defined series of temperature steps. These thermal cycling steps are necessary first to physically separate the two strands of a DNA double helix at a high temperature, to two single strands, in a process called DNA melting. At a lower temperature, the DNA primers will selectively bind each strand of their target sequence, and this event then *primes* the synthesis of the complement strand by DNA polymerase, using the original strand as a template (Figure 36.3).

The selectivity of PCR results from the use of primers that are complementary to the DNA region targeted for amplification under specific thermal cycling conditions. PCR can be combined with reverse transcription, to detect RNA in a reaction termed reverse transcriptase polymerase chain reaction (RT-PCR).

Because the target DNA sequence is of a specific size, the DNA fragment can be run on an agarose gel, separated, and sized against a predefined DNA ladder by a process called gel electrophoresis (Figure 36.4). Because DNA is negatively charged, using agarose as a molecular sieve, and applying a current across the gel, the DNA will migrate towards the positive electrode. The agarose will separate DNA fragments of different sizes as smaller molecules find it easier to migrate through this matrix. Using an intercalating dye that specifically binds DNA, the fragments can be visualized, and a band of specific size, under ultraviolet (UV) light.

Applications for PCR include DNA cloning for sequencing, DNA-based phylogeny, or functional analysis of genes; the diagnosis of hereditary diseases; the identification of genetic fingerprints (used in forensic sciences and paternity testing); and the detection and diagnosis of infectious diseases. PCR can be employed to detect mRNA for hormones, growth factors, polypeptides, receptors, and other proteins involved with the endocrine system.

Quantitative Polymerase Chain Reaction

Quantitative polymerase chain reaction (qPCR) is the use of PCR to determine the quantities of starting amounts of the target DNA. The simplest way to achieve this is by using RT PCR, or kinetic PCR, which is a technique based on PCR, and is used to amplify and simultaneously quantify a targeted DNA molecule. It enables both detection and quantification of one or more specific sequences in a DNA sample, in real time, within the reaction tube. Although standard PCR can be semi quantitative, the term "qPCR" is now synonymously used to refer to RT PCR.

The procedure follows the general principle of PCR; its key feature is that the amplified DNA is detected as the reaction progresses, in real time, a fairly new approach compared to standard PCR, where the product of the reaction is detected at its end. Two common methods for detection of products in RT PCR are: non specific fluorescent dyes that intercolate with any double-stranded DNA, and also sequence-specific DNA probes consisting of oligonucleotides that are labeled with a fluorescent reporter, which permits detection only after hybridization of the probe with its complementary DNA (cDNA) target sequence (Figure 36.5).

Frequently, RT PCR is combined with reverse transcription to quantify RNA in a reaction termed RT-qPCR. Because the term "RT" is originally designated to mean "reverse transcription" in RT-PCR, the use of "RT" to mean "real time" PCR is an incorrect abbreviation. Sometimes, the term "quantitative real-time PCR (qRT-PCR)" is used to specify the use of real-time for qPCR, as opposed to qPCR done by standard endpoint PCR. It is important to clarify what the client means by the term "RT."

TaqMan Probes

TaqMan[114] probes are hydrolysis probes that are designed to increase the specificity of RT-PCR assays. The method was first described by researchers in 1991,[115] and the technology was subsequently developed for diagnostic assays and for research applications. TaqMan probe–based assays are widely used in RT-PCR in research and medical laboratories for gene expression assays, pharmacogenomics, human leukocyte antigen (HLA) genotyping, determination of the viral load in clinical specimens (HIV, tuberculosis, and hepatitis), bacterial identification[116] assays, DNA quantification, single-nucleotide polymorphism (SNP) genotyping, and verification of microarray results.

The TaqMan probe principle relies on the 5′–3′ exonuclease activity of Taq polymerase to cleave a dual-labeled probe during hybridization to the complementary target sequence and fluorophore-based detection.[117] As in other RT-PCR methods, the resulting fluorescence signal permits quantitative measurements of the accumulation of the product during the exponential stages of the PCR; however, the TaqMan probe significantly increases the specificity of the detection.

TaqMan probes consist of a fluorophore covalently attached to the 5′-end of the oligonucleotide probe and a quencher at the 3′-end.[118] Several different fluorophores

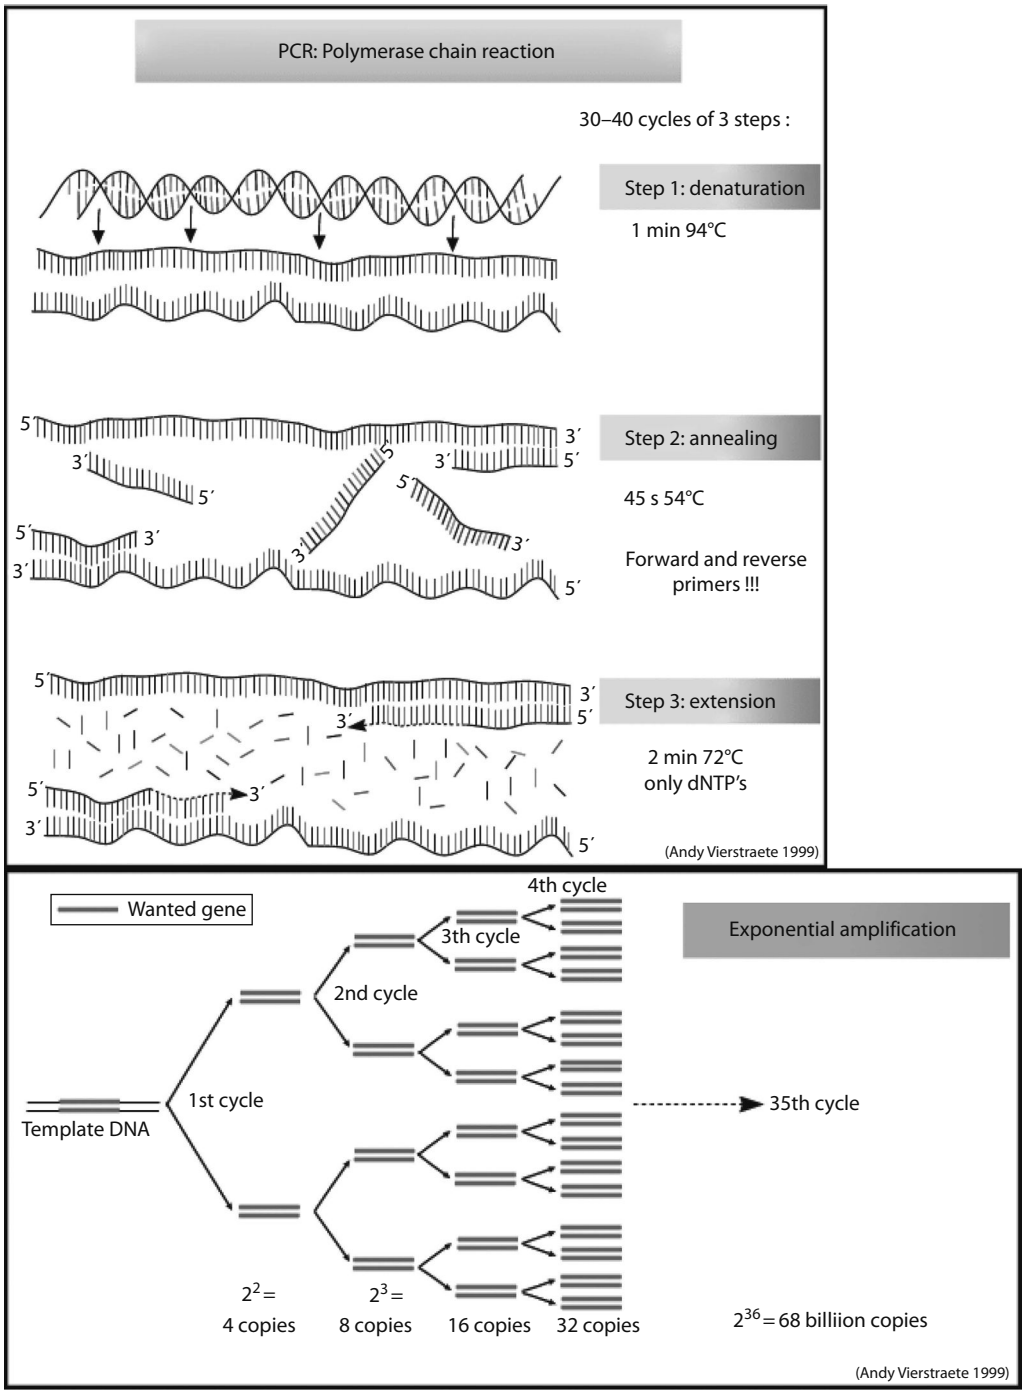

FIGURE 36.3 Polymerase chain reaction. Because both strands are copied during PCR, there is an *exponential* increase in the number of copies of the gene. Suppose there is only one copy of the wanted gene before the cycling starts, after one cycle, there will be two copies; after two cycles, there will be four copies; three cycles will result in eight copies; and so on. (From Vierstraete, A., *Principle of the PCR*, University of Ghent, revised May 20, 2012. http://users.ugent.be/~avierstr/principles/pcr.html.)

(e.g., 6-carboxyfluorescein or tetrachlorofluorescein) and quenchers (e.g., tetramethylrhodamine or dihydrocyclopyrroloindole tripeptide minor groove binder) are available.[119] The quencher molecule quenches the fluorescence emitted by the fluorophore when excited by the cycler's light source via fluorescence resonance energy transfer.[120] As long as the fluorophore and the quencher are in proximity, quenching inhibits any fluorescence signals.

TaqMan probes are designed such that they anneal within a DNA region amplified by a specific set of primers. As the Taq polymerase extends the primer and synthesizes the nascent strand, the 5′–3′ exonuclease activity of the polymerase degrades the probe that has annealed to the template. Degradation of the probe releases the fluorophore from it and breaks the close proximity to the quencher, thus relieving the quenching effect and allowing fluorescence of the fluorophore.

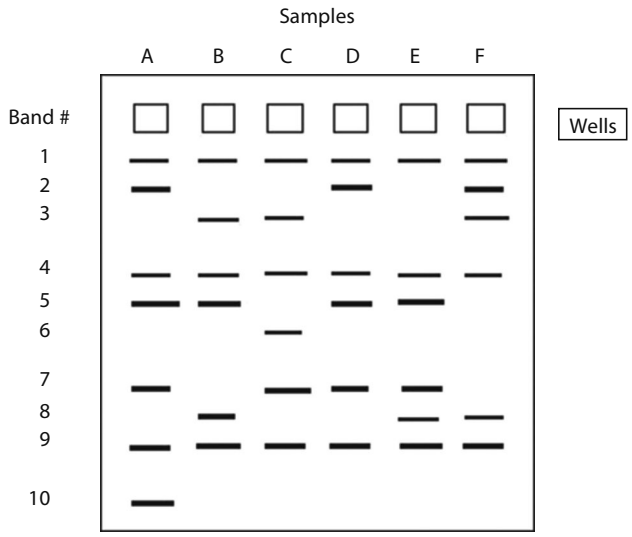

FIGURE 36.4 Gel electrophoresis. The agarose gel provides a matrix with pores to allow molecules to travel through and be sorted by size. The DNA molecules are loaded into the wells. The negative pole is located closest to the wells. The positive pole is located at the other end of the gel. An electric current causes the negatively charged DNA molecules to move toward the positive pole. Longer DNA fragments take longer to work their way through the pores of the gel matrix; they do not travel as far through the gel as the shorter fragments in the same amount of time. Each band in the drawing of the agarose gel represents many DNA fragments that are the same size. The bands nearest the wells (containing the longest DNA fragments) traveled the slowest (Band #1). The bands farthest from the wells (containing the shortest DNA fragments) traveled the fastest (Bands #10).

Hence, fluorescence detected in the RT-PCR thermal cycler is directly proportional to the fluorophore released and the amount of DNA template present in the PCR.

Gene Expression

Gene expression is the process by which information from a gene is used in the synthesis of a functional gene product. These products are often proteins, but the product is a functional RNA in nonprotein coding genes such as ribosomal RNA (rRNA), transfer RNA (tRNA), or small nuclear RNA (snRNA) genes. Several steps in the gene expression process, including the transcription, RNA splicing, translation, and posttranslational modification of a protein,, may be modulated. Gene regulation gives the cell control over structure and function and is the basis for cellular differentiation, morphogenesis, and the versatility and adaptability of any organism.

The effect of an endocrine modulator or disruptor can influence gene expression via transcriptional control. By increasing or decreasing the rate of gene transcription, one can effectively modify gene expression. By quantitating the amount of mRNA for a given gene, it is possible to measure the effect on transcriptional gene expression.[121] Because mRNA represents a relatively small fraction of RNAs in the cell, methods have been developed that are sensitive and specific for detecting changes in mRNA levels and can distinguish between tRNA and rRNA. The following experimental techniques are used to measure gene expression and are listed in roughly chronological order, starting with the older, more established technologies. They are divided into two groups based on their degree of multiplexity. Low-to-mid-plex techniques include reporter gene, northern blot, western blot, fluorescent in situ hybridization, and RT-PCR while higher-plex techniques include SOLiD-SAGE assay (serial analysis of gene expression), DNA microarray, tiling array, and RNA-sequencing (RNA-Seq).

Reporter genes can also be used to assay for the expression of the gene of interest, which may produce a protein that has little obvious or immediate effect on the cell culture or organism. In these cases, the reporter is directly attached to the gene of interest to create a gene fusion. The two genes are under the same promoter elements and are transcribed into a single mRNA molecule. The mRNA is then translated into protein. In these cases, it is important that both proteins be able to properly fold into their active conformations and interact with their substrates despite being fused. In building the DNA construct, a segment of DNA coding for a flexible polypeptide linker region is usually included so that the reporter and the gene product will only minimally interfere with one another.

Reporter genes can be used to assay for the activity of a particular promoter in a cell or organism. In this case, there is no separate *gene of interest*; the reporter gene is simply placed under the control of the target promoter, and the reporter gene product's activity is quantitatively measured. The results are normally reported relative to the activity under a *consensus* promoter known to induce strong gene expression.

A northern blot is a general blotting procedure[122] that starts with extraction of total RNA from a homogenized tissue sample or from cells. Eukaryotic mRNA can then be isolated through the use of oligo (dT) cellulose chromatography to isolate only those RNAs with a poly(A)tail.[123,124] RNA samples are then separated by gel electrophoresis. The RNA samples, now separated by size, are transferred to a nylon membrane through a capillary or vacuum blotting system. Once the RNA has been transferred to the membrane, it is immobilized through covalent linkage to the membrane by UV light or heat. After a probe has been labeled, it is hybridized to the RNA on the membrane. The membrane is washed to ensure that the probe has bound specifically and to avoid background signals from arising. The hybrid signals are then detected by x-ray film and can be quantified by densitometry. To create controls for comparison in a northern blot, samples not displaying the gene product of interest can be used after determination by microarrays or RT-PCR.[125]

The western blot (sometimes called the protein immunoblot) is a widely accepted analytical technique used to detect specific proteins in the given sample of tissue homogenate or extract. It uses gel electrophoresis to separate native proteins by 3-D structure or denatured proteins by the length of the polypeptide. The proteins are then transferred to a membrane (typically nitrocellulose or PVDF), where they are stained with antibodies specific to the target protein.[126,127]

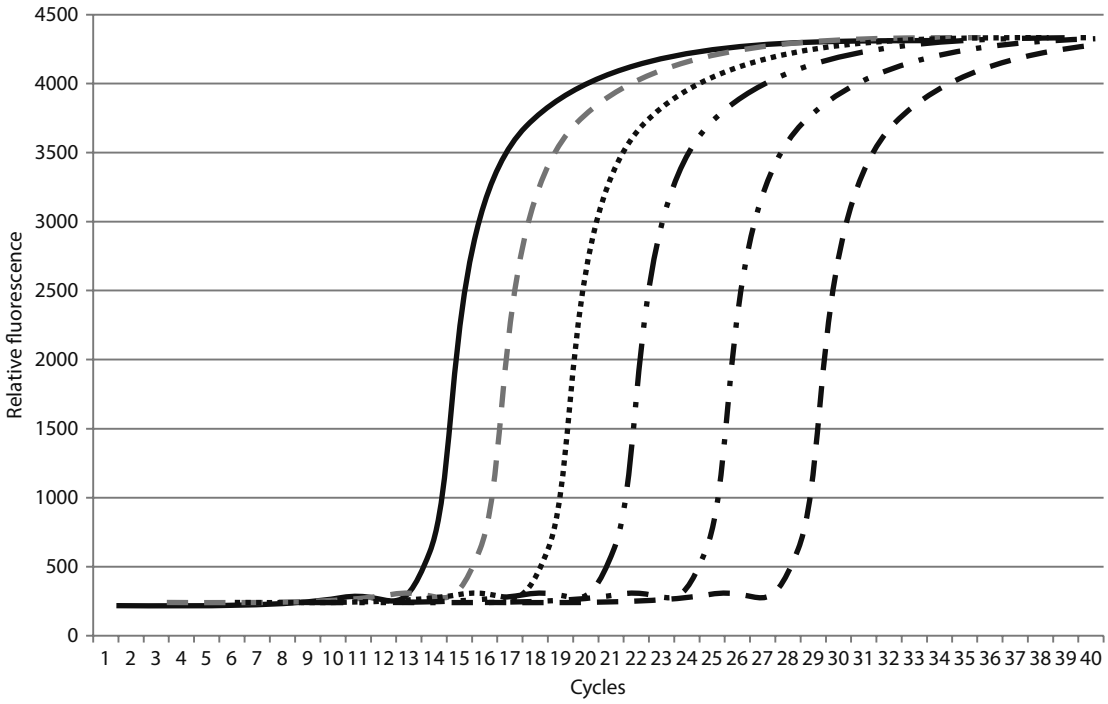

FIGURE 36.5 Concentration curves.

There are now numerous companies that specialize in providing antibodies (both monoclonal and polyclonal antibodies) against thousands of different proteins.[128] Commercial antibodies can be expensive, although the unbound antibody can be reused between experiments. This method can be used for hormone gene expression.

Fluorescence in situ hybridization (FISH) is a cytogenetic technique developed by biomedical researchers in the early 1980s[129] that is used to detect and localize the presence or absence of specific DNA sequences on chromosomes. FISH uses fluorescent probes that bind to only those parts of the chromosome with which they show a high degree of sequence complementarity. Fluorescence microscopy can be used to find out where the fluorescent probe is bound to the chromosomes. FISH is often used for finding specific features in DNA for use in genetic counseling, medicine, and species identification. FISH can also be used to detect and localize specific RNA targets (mRNA, Inc [Incompatibility] RNA [a natural antisense RNA with 72 nucleotides forming a stem-loop structure], and micro-RNA) in cells, circulating tumor cells, and tissue samples. In this context, it can help define the spatial-temporal patterns of gene expression within cells and tissues.

RT-PCR is one of many variants of PCR that is commonly used in molecular biology to detect RNA expression levels.[130] RT-PCR is often confused with real-time polymerase chain reaction (qPCR).[131] However, they are separate and distinct techniques. While RT-PCR is used to qualitatively detect gene expression through creation of cDNA transcripts from RNA, qPCR is used to quantitatively measure the amplification of DNA using fluorescent probes. qPCR is also referred to as quantitative PCR, quantitative real-time PCR,[132] and real-time quantitative PCR.[133]

Although RT-PCR and the traditional PCR both produce multiple copies of particular DNA isolates through amplification, the applications of the two techniques are fundamentally different. The traditional PCR is simply used to exponentially amplify given DNA sequences. RT-PCR is used to clone expressed genes by reverse transcribing the RNA of interest into its DNA complement through the use of reverse transcriptase. Subsequently, the newly synthesized cDNA is amplified using traditional PCR.

In addition to qualitative study of gene expression, RT-PCR can be utilized for quantification of RNA[134] by incorporating qPCR into the technique. The combined technique, described as quantitative RT-PCR[135] or real-time RT-PCR[136] (sometimes even quantitative real-time RT-PCR[137]), is often abbreviated as qRT-PCR,[138] RT-qPCR,[139] or RRT-PCR.[140] Compared to other RNA quantification methods, such as northern blot, qRT-PCR is considered to be the most powerful, sensitive, and quantitative assay for the detection of RNA levels. It is frequently used in the expression analysis of single or multiple genes and expression patterns for identifying infections and diseases.

SAGE is a technique used by molecular biologists to produce a snapshot of the mRNA population in a sample of interest in the form of small tags that correspond to fragments of those transcripts. The original technique was developed by Dr. Victor Velculescu in 1995.[141] Several variants have been developed since, most notably a more robust version,

LongSAGE,[142] Robust LongSAGE,[143] and the most recent SuperSAGE.[144] Many of these have improved the technique with the capture of longer tags, enabling more confident identification of a source gene.

A DNA microarray[145] (also known as a biochip or DNA chip) is a collection of microscopic DNA spots attached to a solid surface. DNA microarrays are used to measure the expression levels of large numbers of genes simultaneously. Each DNA spot contains picomoles of a specific DNA sequence, known as *probes* (or *reporters or oligos*). These can be a short section of a gene or other DNA element that are used to hybridize a cDNA or cRNA (also called antisense RNA) sample (called *target*) under high-stringency conditions. Probe–target hybridization is usually detected and quantified by the detection of fluorophore-, silver-, or chemiluminescence-labeled targets to determine relative abundance of nucleic acid sequences in the target.

Tiling arrays[146] are a subtype of microarray chips. Like traditional microarrays, they function by hybridizing labeled DNA or RNA target molecules to probes fixed onto a solid surface. Tiling arrays differ from traditional microarrays in the nature of the probes. Instead of probing for sequences of known or predicted genes that may be dispersed throughout the genome, tiling arrays probe intensively for sequences that are known to exist in a contiguous region. This is useful for characterizing regions that are sequenced, but whose local functions are largely unknown. Tiling arrays aid in transcriptome mapping as well as in discovering sites of DNA/protein interaction, of DNA methylation, and of sensitivity to DNase.[147] In addition to detecting previously unidentified genes and regulatory sequences, improved quantification of transcription products is possible. Specific probes are present in millions of copies (as opposed to only several in traditional arrays) within an array unit called a feature, with anywhere from 10,000 to more than 6,000,000 different features per array. Variable mapping resolutions are obtainable by adjusting the amount of sequence overlap between probes, or the amount of known base pairs between probe sequences, as well as probe length. Tiling arrays are a useful tool in genome-wide association studies.

RNA-seq,[148] also called whole transcriptome shotgun sequencing[149] (WTSS), refers to the use of HTP sequencing technologies to sequence cDNA in order to get information about a sample's RNA content. The technique has been rapidly adopted in studies of diseases like cancer. With deep coverage and base-level resolution, next-generation sequencing provides information on differential expression of genes, including gene alleles and differently spliced transcripts; non coding RNAs; posttranscriptional mutations or editing; and gene fusions.[150] The technique has been dubbed *a revolutionary tool for transcriptomics*.[151]

In Situ Hybridization and Immunohistochemistry

In situ hybridization is a type of hybridization that utilizes labeled nucleic acid probes (either DNA or RNA), which permits the detection and localization of mRNA in tissue samples with labeled nucleic acid probes (DNA or RNA). Tissue samples (or cultured cells) are treated to increase permeability, thus allowing the desired probe to enter the cell. The samples are fixed, embedded, and thinly sectioned prior to hybridization. Hybridization is permitted at elevated temperatures, and the excess probe is then removed. A complementary probe is labeled with an antigenic, fluorescent, or radioactive tag to precisely locate and quantify the probe remaining in the tissue. Radiolabeled probes work well for abundant mRNAs and can be detected using autoradiography. Other methods of signal detection include fluorescence, such as FISH, which is a cytogenetic technique used to detect and localize specific DNA sequences on chromosomes. Fluorescence microscopy is used to localize specific DNA sequences on chromosomes. For example, a probe is constructed and tagged with fluorophores for specific targets. A chromosome preparation is done with the chromosomes fixed to a glass substrate whereupon the probe is applied to the DNA of the chromosome and allowed to hybridize. Unbound probe is removed. If a very limited amount of probe remains, fluorescent-tagged antibodies or streptavidin is bound to the tagged molecules, resulting in amplified fluorescence. This preparation is embedded and subsequently examined under the fluoroscence microscope. Low-abundance mRNAs can be detected by in situ PCR, which amplifies the amount of nucleic acid target in the tissue. This technique is particularly useful for detecting hormone or receptor subtypes that are biologically unique by combining immunogenic features with related biological molecules. Generally, probe specificity parameters are first tested by northern blot analysis.

Immunochemistry refers to a process of detecting and localizing gene products (e.g., proteins) in cells of a tissue section utilizing antibodies.[152] The antibody is tagged with a color-producing tag, which can include such materials as alkaline phosphatase or HRP. Primary monoclonal or polyclonal antibodies can be used to bind specific epitopes of a hormone or receptor, which can then be visualized with a secondary marker, such as fluorochrome-conjugated secondary antibody or streptavidin–biotin labels. Selection of a fluorochrome depends on microscopy wavelength and filters, the stability of the signal, the type of the tissue being examined, and whether or not double-labeling is necessary. Nonfluorescent markers, such as immunoperoxidase or immunogold conjugates, are suitable for bright-field microscopy and offer increased stability over fluorochrome conjugates. The technique is widely used in basic research to help characterize the distribution and localization of biomarkers in different parts of a tissue. Some specific markers are known for specific cancers, such as carcinoembryonic antigen, a marker for colon cancer; CD15 and CD30, markers for Hodgkin's disease (cluster of differentiation [CD] molecules are recognized by specific sets of antibodies, used to identify the cell type, stage of differentiation, and activity of a cell); and prostate-specific antigen, a marker for prostate cancer; and CD117, a marker for gastrointestinal stromal tumors.[13]

Immunohistochemistry is a powerful complement to in situ hybridization, but limitations include the lack of antibody

specificity, denaturation of the antigen during fixation, and cell membrane permeabilization, which refers to the changes that must occur in the plasma membrane to allow for the entry of impermeable fluorescent probes and the binding of antibodies to their respective antigens.

PITUITARY GLAND

Overview

The pituitary gland, which includes the neurohypophysis and the adenohypophysis, is located at the base of the brain in a small cavity called the *sella turcica* (Turkish saddle), which is a saddle-shaped depression in the sphenoid bone at the base of the human skull (see Figure 36.6).[153] The pituitary secretes several tropic hormones that regulate the activities of cells within distant endocrine glands. The hypothalamic–pituitary axis is the union formed by the interaction between the hypothalamus and pituitary gland. It exerts control over many parts of the endocrine system. This axis functions by interacting between the nervous and endocrine systems; the nervous system regulates the endocrine system, and endocrine activity modulates the activity of the central nervous system (CNS). The pituitary is physically attached to the brain by the hypophyseal stalk connected through the median eminence. The median eminence is integral to the hypophyseal portal system, which connects the hypothalamus with the anterior lobe of the pituitary gland. The anterior lobe of the pituitary (i.e., adenohypophysis) receives releasing and inhibitory hormones on their way to the medium eminence, where they collect before entering the portal system. The hypothalamus and the anterior pituitary secrete a number of important hormones (Table 36.6). The posterior pituitary (i.e., neurohypophysis) is primarily a conduit for the hypothalamus. It does not produce its own hormones; instead, it stores and releases the hormones oxytocin and vasopressin into the blood stream.

Pituitary and Target Organ Relationships

To understand the toxicology of the endocrine system, it is necessary to grasp the concept of hormonal feedback systems (see Figure 36.1). Although measurement of specific hormone levels might not be feasible or economical for the general toxicologic screening of a substance, some bioassays and microscopic techniques do yield useful information. The reduction in animal growth rates, although in most instances caused by diminished nutritional intake, might be due to the suppression of pituitary GH secretion. Similarly, a decrease in testicular weight following the administration of certain chemicals can be due to interference with pituitary gonadotropins and not a simple direct toxic effect upon the primary target.[154,155]

Chemically induced changes that affect pituitary–target organ relationships seldom are manifested after a single administration of a toxic substance; rather, compounds that have the potential to exert deleterious effects on the endocrine system ordinarily require multiple administrations and longer durations of time before hormonally complex events can occur. Whereas chemically induced stress could provoke a rapid response in catecholamine secretion and production of GCs, other hormonal responses would not be as immediate. For those chemicals that initiate the induction of hepatic microsomal enzyme systems that affect hormone metabolism (i.e., catabolism), it may be a week or longer before any changes are detected in the endocrine system. Even those chemicals or drugs purposely designed to suppress a particular hormone target organ secretion (e.g., antithyroidal agents) may exhibit an onset of action of several days.

Many steps are involved in the regulation of target organs by the endocrine system (see Figure 36.1). No less than four possible sites can hormonal messages be disrupted by various toxic agents. Chemicals, including certain classes of therapeutic drugs, can interfere with the release of tropic hormones or can affect their synthesis. Still other toxic agents can exert disruptive actions on the CNS or at

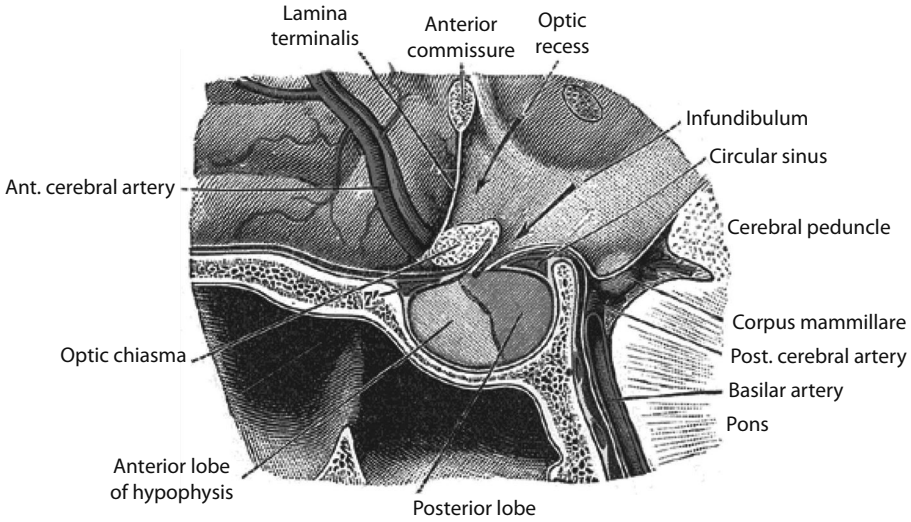

FIGURE 36.6 Pituitary gland. (From Gray's Anatomy.)

TABLE 36.6
Major Hormones Secreted by the Adenohypophysis and Their Respective Releasing Hormones

AdenohypophySeal Tropic Hormone	Hypothalamic-Releasing Factors	Hypothalamic Release–Inhibiting Factors	Target	Effect
ACTH	CRH	—	Adrenal gland	Secretion of GLs (Gls and androgens) in adrenocortical cells
Follicle-stimulating hormone (FSH), luteinizing hormone (LH)	Gonadotropin-releasing hormones (GnRH)	—	Ovary, testis	Females: maturation of ovarian follicles Males: spermatogenesis; enhances production of androgen-binding protein by the Sertoli cells of the testis
LH	GnRH	—	Gonads	Females: ovulation Males: stimulates Leytid cell production of testosterone
GH or HGH, Somatotropin	Growth-hormone-releasing hormone (GHRH); somatotropin	Somatotropin release–inhibiting factor (SRH)	Liver, adipose tissue	Promotes growth; lipid metabolism Releases insulin-like growth factor-1 from liver
Prolactin (PRL)	Prolactin-releasing hormone (PRH)	Prolactin-inhibitory hormone (PIH); prolactin-releasing hormone (PRH); dopamine	Ovaries and mammary glands	Secretion of estrogens and progesterone; milk production in mammary glands; sexual gratification after sexual acts
TSH	TRH	Somatostatin	Thyroid gland	Secretion of thyroid hormones (thyroxine (T) and triiodothyronine (T_3)
Melanocyte-stimulating hormone (MSH or α-MSH)	Melanocyte-stimulating release hormone (MRH)	Melanocyte-inhibiting hormone (MIH)	Melanocytes	Synthesis of melanin by melanocytes in skin and hair

Anterior Pituitary, 2014, http://en.wikipedia.org/wiki/Anterior_pituitary.

the hypothalamus or target organ itself in the biosynthesis of target organ hormone regulatory secretions. Thus, various chemicals have several sites of action on adenohypophyseal–target organ feedback systems.

The sites of a chemical's action may differ in their sensitivity. Target organs such as the gonads are frequently sensitive to toxic substances, particularly because rapidly dividing cells (e.g., spermatogonia) are often vulnerable to chemicals and drugs. Furthermore, stress can affect the secretory activity of certain of the hypothalamic-releasing hormones and hence alter pituitary–target organ relationships (e.g., ACTH and prolactin). Often, toxic agents bind to circulating blood proteins and alter the ratio of free to bound target organ hormones. Such changes in binding also can modify the pituitary–target organ relationship. Numerous target organs, then, can be affected by chemical perturbation.

Adenohypophysis

The adenohypophysis, also called the *anterior pituitary*, comprises the anterior lobe of the pituitary gland (see Figure 36.6). Hormone secretion from the anterior pituitary gland is regulated by hormones secreted by the hypothalamus. Neuroendocrine neurons in the hypothalamus project axons to the median eminence, at the base of the brain. At this site, these neurons can release substances into small blood vessels that travel directly to the anterior pituitary gland (the hypothalamo-hypophysial portal vessels). The anterior pituitary gland secretes hormones that regulate processes such as growth, stress, and reproduction. The major hormones of the adenohypophysis and their hypothalamic-releasing hormones and targets, as well as effects, are shown in Table 36.6. The glycoproteins include TSH, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG). Each hormone is a heterodimer of two noncovalently associated subunits α and β, which are encoded by separate genes situated on different chromosomes. It is the β subunit that generally confers the unique biological specificity of each hormone. This biological activity is dependent on the intact dimers; free subunits are biologically inactive.

Accurate measurement of these proteins to understand their biological functions and molecular mechanisms of the functions is crucial. Because tropic hormones are either

protein or glycoproteins with half-lives of 20 min to 6 h, traditional laboratory methods, such as RIA and ELISA, are not able to measure multiple proteins with a small sample volume. MILLIPLEX® MAP Human Pituitary Magnetic Bead Panel 1[156] as well as the rat, dog, and nonhuman primate panels can be used for the simultaneous measurement of the following analytes in any combination: ACTH, FSH, GH, LH, and TSH. This system allows simultaneous identification of pituitary hormones with antibodies chemically attached to fluorescently labeled microbeads. The beads are resuspended in assay buffer, and the reaction mixture can be quantified using a protein array reader. This multiplex assay can analyze these seven proteins simultaneously and uses a small sample volume 25 μL.

Although bioassays may be useful for certain of the adenohypophyseal hormones, such tests are often inaccurate or have been replaced by more sensitive methods. Bioassays, however, might be employed when there is only a secondary interest in determining if a particular toxicologic agent is affecting tropic hormone levels. Sometimes, a target organ that is known to be directly influenced by a particular tropic hormone can be measured and hence provide some general insight into the nature of the chemically induced alterations in the endocrine system. Target organs whose secretions (e.g., estrogen, testosterone, and T_4) act back upon the adenohypophysis are usually low-molecular-weight hormones.

MEASUREMENT OF ANTERIOR PITUITARY HORMONES

Adrenocorticotropin

ACTH stimulates the growth and the maintenance of the adrenal gland, in addition to stimulating the adrenal cortex to secrete cortical steroids. Many pathologic states can alter ACTH secretion. Stress, caused by a variety of environmental or chemical stimuli, including surgery, trauma, infection, hypoxia, and anxiety, can cause a rapid elevation in ACTH blood levels. ACTH and cortisol exhibit diurnal variations, with the highest levels occurring in the morning (about 8:00 a.m.) and the lowest levels in late afternoon. The hypothalamic–pituitary–adrenal axis has many modulators, many of which are mediated through the CNS and stimulate or inhibit the secretion of ACTH. Measurements of plasma ACTH are extremely useful in the diagnosis of both Cushing's syndrome and adrenal insufficiency.

Prior to the development of RIA, the bioassays employed for the determination of ACTH were highly complex, time-consuming, and costly in terms of the number of animals used. Gravimetric assay of adrenal glands represented one of the simplest methods for indirectly evaluating ACTH activity. This bioassay uses hypophysectomized animals; injections of ACTH-like material can enhance the weight of the adrenal glands. Their sensitivity was such that the normal early morning peak of ACTH could not be determined.

The introduction of immunoassay methodology enabled the measurement of low-normal ACTH concentrations. Immunological recognition of ACTH by the antibodies employed offered improvements with regard to specificity. The development of two-site immunometric assays further improved specificity and the ability to measure low-normal ACTH concentrations without the need to extract large volumes of plasma. The quantification of ACTH is now routinely performed in clinical laboratories, with nonradioisotopic methods becoming increasingly popular. The highly sensitive IRMA ACTH assay has been very useful in diagnosing adrenal deficiencies.[157] In addition to the MILLIPLEX® MAP Pituitary Magnetic Bead Panel, other methods such as ELISA (manual), two-site IRMA (manual), double-antibody RIA (manual), one-step immunochemiluminometric assay, and two-site sequential immunochemiluminometric assay. The current commercially available two-site immunometric assays have an analytical sensitivity between 0.6 and 9 pg/mL (0.12–19.8 pmol/L).[158] Plasma ACTH concentrations are usually between 10 and 60 pg/mL (2.2 and 13.3 pmol/L) at 8 a.m. with the values decreasing during the waking hours. The plasma ACTH values are usually less than 20 pg/mL (4.5 pmol/L) at 4 p.m. and usually less than 5 pg/mL (1.1 pmol/L) within 1 h after the usual time of falling sleep. This circadian rhythm in plasma ACTH concentrations is the cause of the parallel changes in cortisol secretion by the adrenal glands and the resulting rhythm in serum cortisol concentrations.

Because ACTH stimulates increases in plasma cortisol and corticosterone and elevates urinary 17-hydroxycorticosteroids and 17-ketosteroids, these steroid levels can also be used to assess ACTH. ACTH causes involution of the thymus gland and deposition of hepatic glycogen and leads to a decrease in circulating eosinophils in hypophysectomized rodents. ACTH can also cause depletion of adrenal ascorbic acid. In addition to those assays for ACTH that rely on adrenal gland responses (see section on adrenal glands), radioligand–receptor assays have been developed for ACTH. Often, cortisol levels are used to assess ACTH. Cortisol can be determined using commercially available antibody-coated tube RIA kits.

Thyroid-Stimulating Hormone

TSH is a glycoprotein that is synthesized and secreted by the thyrotrope cells of the anterior pituitary gland. This hormone regulates the growth and proliferation of cells of the thyroid gland. In this case, the hypothalamus produces TRH, which subsequently stimulates the anterior pituitary to produce and release TSH. TSH, in turn, stimulates the thyroid gland to secrete the hormone T_4, which has only a slight effect on metabolism. T_4 is converted to triiodothyronine (T_3), which is the active hormone that stimulates metabolism. About 80% of this conversion is in the liver and other organs, and 20% in the thyroid itself.[159] Somatostatin is also produced by the hypothalamus and has an opposite effect on the pituitary production of TSH, decreasing or inhibiting its release.

TSH is a glycoprotein and consists of two subunits, the α and β subunits. The α subunit (i.e., chorionic

gonadotropin alpha) is nearly identical to that of hCG, LH, and FSH. The α subunit is thought to be the effector region responsible for stimulation of adenylate cyclase (involved in the generation of cAMP). The α chain has a 92-amino acid sequence. The β subunit (TSHB) is unique to TSH and therefore determines its receptor specificity. The β chain has a 118-amino acid sequence. TSH is secreted throughout life but particularly reaches high levels during the periods of rapid growth and development.

These tyrosine-based hormones function to increase the basal metabolic rate and make changes to the rate of protein, carbohydrate, and fat synthesis. T_3 and T_4 (thyroid) as well as somatostatin (hypothalamus) negatively feedback to inhibit TSH production. The TSH receptor site is complex and involves an extracellular domain as well as a transmembrane component.[160] The TSH receptor is found mainly on thyroid follicular cells.[161] Stimulation of the receptor increases T_3 and T_4 production and secretion. Stimulating antibodies to this receptor mimic TSH and can cause Graves' disease. In addition, hCG shows some cross-reactivity to the TSH receptor and therefore can stimulate production of thyroid hormones. In pregnancy, prolonged high concentrations of hCG can produce a transient condition termed gestational hyperthyroidism.[162]

In addition to the MILLIPLEX MAP Pituitary Magnetic Bead Panel, other methods such as immunochemistry assays are also available for measuring TSH.[163,164] A liquid-phase, two-site IRMA has been described for human TSH (hTSH). The TSH IRMA is based on the simultaneous addition of affinity-purified sheep anti-hTSH IgG-^{125}I and rabbit anti-hTSH antiserum. This assay is specific for hTSH and exhibits no cross-reactivity with other pituitary glycoprotein[165]; thus, the IRMAs for TSH may be more specific than current RIAs for TSH. The one-step IRMA method involves the use of monospecific antibody against two immunogenic sites on the TSH molecule.[166] Other assays for thyrotropin involve a combination of bioluminescence and immunoassay techniques.[167] The therapeutic target range TSH level for patients on treatment ranges between 0.3 and 3.0 μIU/mL.[168]

Growth Hormone (Somatotropin)

GH is also referred to as *somatropin*, *somatotropin*, or *somatotrophin*. Somatotropic cells constitute 30%–40% of anterior pituitary cells. They release GH in response to GHRH, or somatocrinin, or are inhibited by growth-hormone-inhibiting hormone (GHIH) (somatostatin), both received from the hypothalamus via the hypophyseal portal system vein and the secondary plexus. Somatotrope cells are classified as acidophilic cells. These cells take years to grow and mature very slowly. If these cells grow large enough, they can impair vision, cause headaches, or damage other pituitary functions.

Human GH is a peptide composed of 191 amino acids with a molecular weight of 22,000 Da. The structure contains four helices that precisely interact with the GH receptor. GH is secreted by the somatotrope cells found in the anterior pituitary. It has been found that transcription factor Pit-1 stimulates the development of somatotrope cell and subsequently the production of GH. GHRH released from the hypothalamus promotes the secretion of GH, while somatostatin from the periventricular nucleus inhibits GH production, as does the concentration of GH and insulin-like growth factor 1 (IGF-1), a protein similar in structure to insulin that is produced by target cells and the liver and is involved in the regulation of metabolism. GH exerts its actions on a variety of cells to stimulate lipolysis, protein anabolism, and hyperglycemia. Its actions on bone and cartilage are mediated primarily through IGF-1. A deficiency in GH leads to a reduction in the incorporation of amino acids into protein. GH causes a marked stimulation of cartilaginous growth at the epiphyses of long bones.

A constant flow of stimulating and inhibiting peptides enhances or suppresses the rate of secretion of GH. In addition, many physiological events effect changes in GH secretion. Many of the agents and physiological factors that can affect the rate of GH secretion are listed in Table 36.7. Hypoglycemia or insulin can cause a sudden and dramatic increase in serum GH. Starvation can affect GH levels, while cold, stress, or surgical trauma can lead to an increase in serum GH. Drugs and chemicals that affect catecholamine neurotransmission and the autonomic nervous system can influence GH secretion.

It has been shown that most of the physiologically critical GH secretions generally occur as several large surges over the course of the day that may extend from 10 to 30 min, with the largest GH peak occurring during the first hour of sleep.

TABLE 36.7
Effects of Various Factors on GH Levels

Increased GH Levels	Decreased GH Levels
Apomorphine	Dietary carbohydrate and GCs
Argininea[a]	Genetic conditions
Clonidine[a]	Sleep
a-Deoxyglucose	Somatostatin
Dietary protein	Pituitary adenoma
L-DOPA[a]	Severe head injury
Endorphins	Autoimmune disease
Enkephalins	Interference with the blood supply to the pituitary gland
Epinephrine	Pituitary damage radiotherapy
Estradiol	
Exercise	
Insulin (hypoglycemia)[a]	
Norepinephrine	
Prostaglandins	
Serotonin	
Stress	
Substance P	
TRH	
Vasopressin	

[a] Used as a provocative test for the diagnosis of GH disorders.

The frequencies are most pronounced (8 peaks per 24 h), and the levels of GH are highest during early childhood and at puberty during adolescence, whereas the mature adult averages approximately 5 peaks per 24 h.

GH has been assessed using bioassays. Some GH assays simply use a 10-day body weight gain test in hypophysectomized female rats. The hormone has also been assayed by measuring the width of the tibial epiphyseal growth plate. Sensitive RIAs have been developed for experimental animals (e.g., rat) and for humans. Human GH concentrations can be measured with double-antibody RIAs. Immunocytologic assays for GH can also be performed on epon-embedded, semi-thin sections of tissue using the avidin–biotin–peroxidase complex technique.[169] Microdissection techniques[170] and other in vitro assays for the release of GH have been employed.[163]

Over the last few decades, measurement technology has evolved from less sensitive, mainly radioactive assays based on polyclonal antisera, to the latest generations of highly sensitive chemiluminescence methods employing mAbs. Sensitive RIAs have been developed for experimental animals (e.g., rat) and for humans. Human GH concentrations can be measured with double-antibody RIAs. In addition, an ultrasensitive immunofluometric assay[171] and a chemiluminescence-based GH assay[172] are now available.

Whether GH is assessed using bioassays or by the more accurate and sensitive RIA procedures, the experimental design of either acute or chronic toxicity tests must closely monitor the nutritional and behavioral status of the animals. Several toxic agents can affect dietary intake and hence reduce body weight. Experimental designs using paired-feeding protocols are often necessary for interpreting GH activity in any well-designed toxicology protocol.

Gonadotropins (FSH and LH)

Gonadotropins are hormones secreted by the gonadotrope cells located in the anterior pituitary gland. The two primary gonadotropins are the FSH and LH, both of which are glycoproteins that contain α and β peptide subunits. The α units in both hormones are essentially identical, but there is some functional and immunologic specificity with the β subunits of the gonadotropins, including hCG, which is produced by the placenta during pregnancy.

Gonadotropin receptors are found on the surface of the gonads, and these are connected to the G-protein system. G-proteins are guanine nucleotide–binding proteins, a group of specific proteins involved in second-messenger feedback systems. Second messengers are used in signal transduction to relay signals within a particular cell in response to an external signal received by a transmembrane receptor. These signals are relayed by cyclic AMP when the receptor is bound by the G-protein.

The critical gonadotropins, FSH and LH, are secreted from the adenohypophysis as directed by the gonadotropin-releasing hormone (GnRH) from the hypothalamus. Their principal stimulatory actions and primary targets are the testes or ovaries. FSH stimulates follicular development in the ovary and spermatogenesis in the testes. LH, also referred to as *interstitial-cell-stimulating hormone* (ICSH) in the male, causes luteinization of the ovary and stimulates androgen production in testicular Leydig cells. The gonads contain receptors for LH and FSH, which are involved in intracellular signaling.[26]

In the human female, blood levels of FSH and LH vary according to the phase of the menstrual cycle. In human males, although some diurnal fluctuation in FSH and LH may occur, blood levels are noncyclic.

In response to FSH, Sertoli cells in the seminiferous tubules secrete a number of proteinaceous substances, including androgen-binding protein (ABP), which binds testosterone within the testes presumably to maintain high levels of testosterone at the site of the developing germ cells. ABP has been used as an indicator of toxicologic insult following the administration of potentially damaging chemicals or drugs. FSH or LH levels can be assessed by direct measurement of the hormones or by indirect assays that reflect an influence of these hormones on their target tissues. RIAs are available to measure gonadotropins.

Earlier methods in classical endocrinology studies often employed bioassays. FSH has been bioassayed by assessing its ability to enhance ovarian weight in immature rats treated with a placental gonadotropin. A sensitive assay for LH once employed ovarian ascorbic acid depletion. The bioassay of gonadotropins has largely been abandoned because of low sensitivity and expense. The sensitivity of RIAs offers substantial advantages over bioassays, even though the biological and immunological activities do not always correlate.

Indirect measurement of gonadotropins in women often includes the measurement of ovarian steroids or the study of vaginal cytology (see later section on gonads). In men, indirect assays include the measurement of androgens or the histological assessment of spermatogenesis. Chromosome studies to rule out Klinefelter's syndrome or Turner's syndrome can also be of some value when assessing hypogonadism for pituitary gonadal activity. Localization of FSH and LH and their receptors can be detected using immunoperoxidase techniques.

In addition to the MILLIPLEX® MAP Pituitary Magnetic Bead Panel, other methods such as ELISA, two-site IRMA, double-antibody RIA, one-step immunochemiluminometric assay, and two-site sequential immunochemiluminometric assay. Normal FSH and LH levels will differ depending on a person's age and gender. The FSH levels for males are 0–5.0 mIU/mL (before puberty); 0.3–10.0 mIU/mL (during puberty); and 1.5–12.4 mIU/mL (adult) while for females the levels are 0–4.0 mIU/mL (before puberty); 0.3–10.0 mIU/mL (during puberty); 4.7–21.5 mIU/mL (during menstruation); and 25.8–134.8 mIU/mL (postmenopausal).[173] The LH levels for males are <0.5 mIU/mL (before puberty) and 1.7–8.6 mIU/mL (adult) while for females the levels are 0.5 mIU/mL (before puberty); during child-bearing potential (2.4–12.6 mIU/mL [follicular phase], 14.0–95.6 mIU/mL [ovulation phase], and 1.0–11.4 mIU/mL [luteal phase]; and 7.7–58.5 mIU/mL [postmenopause]).[174]

Inhibin (A and B)

Inhibin, a proteinaceous substance found in the mammalian gonad, is involved in the negative feedback regulation of FSH secretion.[175] Dimeric inhibin is produced by the testes in the male (B only) and ovary in the female (A and B), together with the fetoplacental unit in pregnancy (A only). These various inhibin forms act in direct negative feedback on the pituitary production of FSH in the control of folliculogenesis and spermatogenesis. Inhibin is a heterodimer, where the α and β subunits are linked by disulfide bonds. In men, inhibin can be detected in the testes, seminal plasma, rete testes fluid, and spermatozoa. The Sertoli cells are the only testicular cells that secrete an inhibin-like substance referred to as *Sertoli cell factor* (SCF). Inhibin, as well as SCF, can suppress the pituitary secretion of FSH. Inhibin (A or B) is synthesized in granulosa cells, and production is stimulated by FSH and estradiol. The biological activities of various inhibin preparations, including SCF, can be assessed in vitro using pituitary cell cultures.[176,177] This in vitro assay consists of evaluating the degree of suppression of basal FSH release following an incubation with the test material relative to that of a control culture. In addition to RIAs,[178] several ELISAs for inhibin A and B have been developed.[179,180]

Prolactin

Prolactin is a protein hormone whose amino acid composition is quite similar to GH. It is synthesized and secreted by lactotrope cells in the adenohypophysis. Prolactin is a single-chain polypeptide structure of 199 amino acids resulting in a molecular weight of about 24,000 Da. Interestingly, it is also produced in decidua and the breast tissue. Prolactin secretion is initiated in the hypothalamus by Pit-1 transcription factor, which binds to the prolactin genes at several sites. Estrogen also enhances the growth of lactotrope cells. Dopamine suppresses the production of prolactin and itself is controlled by estrogen, which inhibits the release of dopamine. Prolactin causes initiation and maintenance of lactation in women. It has no known physiological function in men. In rodents, prolactin maintains the corpus luteum. In many species, milk ejection cannot be produced by suckling unless prolactin first stimulates the myoepithelial cells of the mammary glands.

Prior to the development of sensitive RIAs for prolactin, it was bioassayed. Prolactin has the ability to stimulate the crop sac of the pigeon. The prolactin blood test is based on an immunometric solid phase direct sandwich ELISA method. The samples and diluted antiprolactin HRP conjugate are added to the wells coated with mAb to prolactin. Prolactin in the patient's serum binds to antiprolactin MAb on the well and the antiprolactin HRP then binds to prolactin. Unbound protein and HRP conjugate are washed off by wash buffer. Upon the addition of the substrate, the intensity of color is proportional to the concentration of prolactin in the samples. A standard curve is prepared relating color intensity to the concentration of the prolactin garnered with the prolactin blood test. Reference ranges vary from laboratory to laboratory but are generally within the following values: adult male and female (0–20 ng/mL) and pregnant female (20–400 ng/mL).

Prolactin can also be identified in tissues using in vitro immunoassays, but a number of test system conditions in vitro can affect the detectable levels of prolactin (Table 36.8).[181] It is important to determine the optimal conditions for assessing tissue prolactin. Many drugs, chemicals, or even some physiological conditions can affect blood levels of prolactin (Table 36.9). Several of the actions of these agents are mediated by dopaminergic mechanisms. Prolactin secretion can be increased by physical exercise, coitus, suckling, and surgical stress. Such factors must be taken into consideration when assessing prolactin levels in toxicologic protocols.

[a] Response may vary quantitatively depending on the dose and the particular species.

POSTERIOR PITUITARY

The posterior pituitary gland, or neurohypophysis, comprises the posterior lobe of the pituitary gland (see Figure 36.6). It consists primarily of neuronal axon nerve fiber projections from the hypothalamus. The hormones of the posterior pituitary are produced in the hypothalamus and are transported through the hypophyseal vein to the posterior pituitary, where they are stored until needed for use. The posterior pituitary is not a gland in the conventional sense, but rather an extension of the hypothalamus from the supraoptic nuclei (SON) and paraventricular nuclei (PVN) of the hypothalamus.

Neurohypophyseal Peptides

The posterior pituitary contains a group of peptides known as neurophysins, as well as oxytocin and vasopressin (ADH). The neurophysins appear to be synthesized in the same hypothalamic neurons as the nonapeptides oxytocin and vasopressin. Whereas the physiological function of oxytocin and vasopressin are well established, less is known about the biological function of the neurophysins. It appears that oxytocin and vasopressin are packaged with the protein neurophysin into discrete granules, which then move down the SON and PVN of the hypothalamus axon and are stored in the posterior pituitary. When the hypothalamus is stimulated, these hormones are then released into the bloodstream.

The principal physiological function of vasopressin is conservation of fluids, and it exerts its action on the renal tubule, leading to the reabsorption of water. The release of vasopressin is mediated by neural impulses from osmoreceptors located in the hypothalamus. The principal physiological function of oxytocin is to stimulate uterine smooth musculature and to aid in the process of lactation. Oxytocin is released in response to suckling, and it may also play a role in parturition.

Drugs, other hormones, and physiological state can affect the secretion of vasopressin or oxytocin (Table 36.10). Nonspecific stress also can stimulate the release of ADH and hence is an important variable to consider in any toxicologic protocol involved with monitoring water balance. Some chemicals and drugs affect the central release of posterior pituitary hormones at the source, whereas others may block their peripheral actions. Physiological factors also affect the secretory rate of oxytocin, and considerable differences exist among species. Suckling and mammary duct dilation and cervical distension lead to enhanced secretion of oxytocin. Estrogens and pregnancy enhance the sensitivity of the uterine smooth muscle to oxytocin.

Oxytocin

Oxytocin is a oligopeptide that contains 9 amino acids (termed a nonapeptide) and has a molecular weight of 1007 Da. Oxytocin is produced by the oxytocin-producing magnocellular neurosecretory cells located within the SON and PVN. The oxytocin neurons affect CRH. The oxytocin receptor is a G-protein-coupled receptor, a protein family of transmembrane receptors that transduce extracellular signals into intracellular signals and requires magnesium and cholesterol. Oxytocin is released after the stimulation of the nipples and distention of the vagina and cervix to prepare the female for birthing and breastfeeding. It is also released in males and females during orgasm and has been shown to be involved in bonding between individuals.

In females, the three critical actions involving oxytocin are as follows[182]:

- Uterine contraction, which is critical for cervical dilation in late labor and for blood-clotting mechanisms with parturition
- Letdown reflex, which occurs during lactation and permits the milk to accumulate in the collecting

TABLE 36.10
Effects of Various Factors on the Release or Action of Neurohypophyseal Hormones

Enhanced Release	Inhibited Release	Blocked Peripheral Action
Vasopressin		
Acetylcholine	Ethanol	Lithium

Distention of the cervix		

chambers for the infant to suckle (suckling activity at the nipple stimulates increased secretion of oxytocin)
- Maternal behavior, which appears to have an oxytocin chemical component in some female animals such as voles and sheep

In males, the actions of oxytocin include the following[183]:

- Facilitation of sperm transport with orgasm (which releases oxytocin into the bloodstream)
- Enhanced sexual arousal

General actions of oxytocin that affect both sexes include the following:

- Secretion into the bloodstream at orgasm in both males and females[184]
- Reduced anxiety, blood pressure, and cortisol levels, as well as mediation of fight-or-flight behavior
- Increased tolerance to pain
- Stimulation of sodium excretion from kidneys (natriuresis)
- Possible cardiac development involvement (specifically, by enhancing cardiomyocyte development)[185]

Recent studies have begun to investigate oxytocin's role in various behaviors, including orgasm, social recognition, pair bonding, anxiety, and maternal behaviors.[186] For this reason, it is sometimes referred to as the *love hormone*. The inability to secrete oxytocin and feel empathy is linked to sociopathy, psychopathy, narcissism, and general manipulativeness.[187] However, there is some evidence that oxytocin promotes *tribal* behavior, incorporating the trust and empathy of ingroups with their suspicion and rejection of outsiders.[188]

The biologically active form of oxytocin, commonly measured by RIA and/or high-performance liquid chromatography (HPLC) techniques, is also known as the octapeptide *oxytocin disulfide* (oxidized form), but oxytocin also exists as a reduced dithiol nonapeptide called oxytoceine.[189] A solid-phase RIA for the direct measure of plasma oxytocin has been developed that is rapid, relatively sensitive, and reproducible and does not require the prior extraction of plasma samples.[190]

Oxytocin may also be measured by bioassay. Because oxytocin can stimulate the contraction of smooth muscles, several bioassays have been developed using isolated muscle strips. Oxytocin can be assayed employing the mammotonic activity of the hormone on strips of lactating rat mammary gland. The increment of tension developed by the muscle strip is used as an index of oxytocic activity. A four-point assay can be carried out using United States Pharmacopeia (USP) posterior pituitary standard as a reference.

Arginine Vasopressin

AVP, also known as vasopressin, argipressin, or ADH, is a neurohypophysial hormone found in most mammals. Vasopressin is an oligopeptide that contains 9 amino acids (termed a nonapeptide) and has a molecular weight of about 1084 Da. Vasopressin is produced by the vasopressin-producing magnocellular neurosecretory cells located within the hypothalamic SON and PVN. Interestingly, vasopressin is also secreted from the parvocellular neuroendocrine neurons found in the paraventricular nucleus, which transports the hormone to the anterior pituitary, where it becomes a releasing factor for ACTH.

Vasopressin is secreted from the posterior pituitary gland in response to reductions in plasma volume, increases in the plasma osmolality, and cholecystokinin (CCK) secreted by the small intestine:

- Secretion *in response to reduced plasma volume* is activated by pressure receptors in the veins, atria, and carotids.
- Secretion *in response to increases in plasma osmotic pressure* is mediated by osmoreceptors in the hypothalamus.
- Secretion *in response to increases in plasma CCK* is mediated by an currently unknown pathway.

The neurons that make AVP, in the SON and PVN, are themselves osmoreceptors, but they also receive synaptic input from other osmoreceptors located in regions adjacent to the anterior wall of the third ventricle. These regions include the organum vasculosum of the lamina terminalis and the subfornical organ.

Vasopressin is also released into the brain by neurons of the suprachiasmatic nucleus of the hypothalamus, which generates a circadian rhythm of neuronal activity, ultimately regulating many different body functions over a 24 h period. In addition, vasopressin released into the brain has been shown to be involved with delayed reflexes, memory, aggression, blood pressure modulation, and temperature regulation.

Peripheral actions of vasopressin primarily include activities at three receptor sites:

- V1a, which is located in various tissues and is involved with vasoconstriction, gluconeogenesis in the liver, platelet aggregation, and release of factor VIII
- V1b, which is located in the anterior pituitary and is involved with corticotropin secretion
- V2, which is located primarily in the distal convoluted tubules and collecting ducts of the kidneys, where it is involved with the control of free water reabsorption in the cortical collecting ducts of the renal medulla

Vasopressin has two effects in the kidney by which it contributes to increased urine osmolarity (increased concentration) and decreased water excretion:

1. Increasing the water permeability of distal tubule and collecting duct cells in the kidney, thus allowing water reabsorption and excretion of more concentrated urine, that is, antidiuresis. This occurs through V2 receptor–mediated insertion of water channels (aquaporin-2) into the apical membrane of distal tubule

and collecting duct epithelial cells.[191] Aquaporins allow water to move down their osmotic gradient and out of the nephron, increasing the amount of water reabsorbed from the filtrate (forming urine) back into the bloodstream. Vasopressin also increases the concentration of calcium in the collecting duct cells, by episodic release from intracellular stores.

2. Increasing permeability of the inner medullary portion of the collecting duct to urea by regulating the cell surface expression of urea transporters,[192] which facilitates its reabsorption into the medullary interstitium as it travels down the concentration gradient created by removing water from the connecting tubule, cortical collecting duct, and outer medullary collecting duct.

Vasopressin also acts on the cardiovascular system by increasing peripheral vascular resistance (vasoconstriction) and thus increasing arterial blood pressure. While this effect appears small in healthy individuals, however, it becomes an important compensatory mechanism for restoring blood pressure in hypovolemic shock.

Vasopressin released within the brain has many actions:

- Vasopressin released from centrally projecting hypothalamic neurons is involved in aggression, blood pressure regulation, and temperature regulation.
- It is likely that vasopressin acts in conjunction with CRH to modulate the release of corticosteroids from the adrenal gland in response to stress, particularly during pregnancy and lactation in mammals.
- Recent evidence suggests that vasopressin may have analgesic effects. The analgesia effects of vasopressin were found to be dependent on both stress and gender.[193]
- It has been implicated in memory formation, including delayed reflexes, image, and short- and long-term memory, though the mechanism remains unknown; these findings are controversial.
- Selective AVPr1a blockade in the ventral pallidum has been shown to prevent partner preference, suggesting that these receptors in this ventral forebrain region are crucial for pair bonding.[194]

Evidence for this partner preference comes from studies in several species, which indicate that the precise distribution of vasopressin and vasopressin receptors in the brain is associated with species-typical patterns of social behavior. In particular, there are consistent differences in the distribution of AVP receptors between monogamous species and promiscuous species, and sometimes in the distribution of vasopressin-containing axons, even when closely related species are compared.[195] Studies involving either injecting AVP agonists into the brain or blocking the actions of AVP support the hypothesis that vasopressin is involved in aggression toward other males. There is also evidence that differences in the AVP receptor gene between individual members of a species might be predictive of differences in social behavior. One study has suggested that genetic variation in male humans affects pair-bonding behavior. The brain of males uses vasopressin as a reward for forming lasting bonds with a mate, and men with one or two of the genetic alleles are more likely to experience marital discord. The partners of the men with two of the alleles affecting vasopressin reception state disappointing levels of satisfaction, affection, and cohesion.[196] Vasopressin receptors in monogamous prairie voles are distributed along the reward circuit pathway, specifically in the ventral pallidum. These pathways are activated when AVP is released during social interactions such as mating. The activation of the reward circuitry leads to conditioned partner preference and thereby initiates the formation of a pair bond.[197]

ADH can be measured by RIA or bioassay. With bioassay, ADH or extracts of posterior pituitary tissue can be measured for their antidiuretic activity in the rat using ether anesthesia and a constant water load; the diminution in urine flow is an index of antidiuretic activity. Unanesthetized trained dogs also have been employed in the bioassay, but stress must be minimized because it can reduce urinary output and hence the ADH assay. Simple and rapid RIAs for vasopressin are available.[198] Because vasopressin is present in biological fluids in low concentrations (picograms), tests must be sensitive. It ordinarily has been difficult to measure basal levels or small fluctuations resulting from particular experimental designs.

In vitro assays include a quantitative RIA. Arg^8-Vasopressin immunoassay is a competitive enzyme immunoassay (EIA) designed to measure Arg^8-Vasopressin in cell culture supernates, saliva, urine, serum, and plasma. This assay is based on the competitive binding technique in which Arg^8-Vasopressin present in a sample competes with a fixed amount of alkaline phosphatase–labeled Arg^8-Vasopressin for sites on a rabbit polyclonal antibody. During the incubation, the polyclonal antibody becomes bound to the goat antirabbit antibody coated onto the microplate. Following a wash to remove excess conjugate and unbound sample, a substrate solution is added to the wells to determine the bound enzyme activity. Immediately following the color development, the absorbance is read at 405 nm. The intensity of the color is inversely proportional to the concentration of Arg8-Vasopressin in the sample.

THYROID GLAND

The thyroid gland controls how quickly the body uses energy, makes proteins, and controls how sensitive the body is to other hormones. It is unique among endocrine organs in three ways; it is able to store large amounts of hormones with slow turnover rates, providing prolonged protection against depletion should synthesis cease[199]; it has a web of feedback systems providing redundant and compensatory responses to maintain thyroid hormone signaling, and it is one of the largest endocrine glands, weighing about 3 g in neonates and 18–60 g in adults. Located in the neck anterior to the spinal cord between vertebrae C-5 and T-1 (see Figure 36.7) and below the thyroid cartilage (which forms the laryngeal prominence or "Adam's apple"), it is shaped like a butterfly,

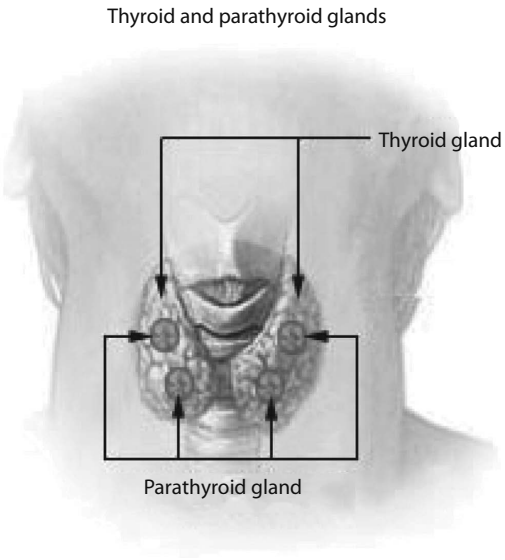

FIGURE 36.7 Parathyroid and thyroid glands. (Courtesy of U.S. National Cancer Institute Surveillance, Epidemiology, and End Results [SEER] Program.)

with the wings extending over each side of the trachea. The thyroid gets its name from the Greek word for "shield," due to the shape of the related thyroid cartilage.

The follicle is the unit of thyroid structure, consisting of closed sacs, containing homogeneous, slightly acidophilic colloid, that are lined by epithelium cells. The sacs are relatively uniform in size but appear in variable sizes in histological sections. Follicles are grouped into lobules, each supplied by a terminal branch of an extremely profuse blood supply. Estimates of blood flow to the parenchyma of the thyroid exceed the blood flow to the kidneys.[200] Iodine is selectively absorbed using the sodium/iodine transporter by these follicles whose purpose is to secrete the hormones T_3 and T_4. The follicles also contain a protein, thyroglobulin. Iodination of thyroglobulin to T_3 and T_4 is catalyzed by thyroid peroxidise. Parafollicular cells (C cells) are found throughout the gland; these cells secrete calcitonin (also known as thyrocalcitonin), which participates in the regulation of Vitamin D, bone mineralization, and reduction of calcium in the blood.

The secretory process of the thyroid gland is modulated by the HPT axis, which is highly conserved among vertebrate species and is mediated by a negative feedback relationship. TSH[201,202] is a glycoprotein hormone synthesized and secreted by thyrotrope cells in the anterior pituitary gland and regulates endocrine function of the thyroid gland. The nuclear thyroid receptor TRβ2, expressed in the pituitary gland and hypothalamic paraventricular nucleus, appears to be the predominant mediator of the negative feedback action of thyroid hormones on TSH release.[203] TSH stimulates the thyroid gland to increase the secretion and release of T_3 and T_4. The initial step in the synthesis of these thyroid hormones is the uptake of iodide (normally derived from dietary iodine) into the follicular cells of the thyroid in response to TSH (Figure 36.8). Internalized iodide is then oxidized and chemically combined

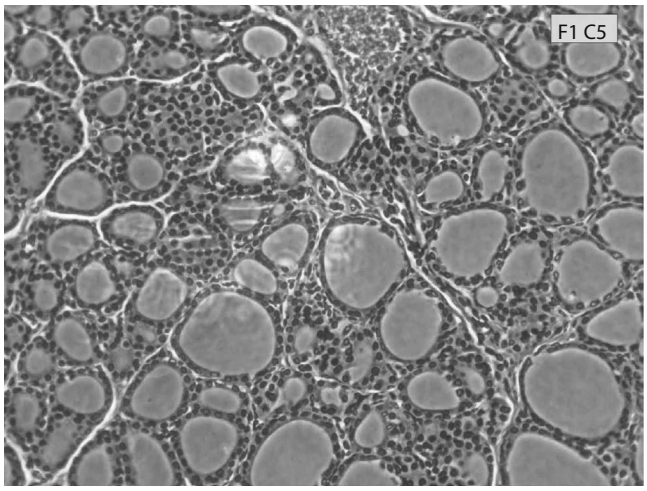

FIGURE 36.8 Histology of rat thyroid follicular cells. (From U.S. EPA Guideline Female Pubertal Assay.)

with the tyrosine components of the protein, thyroglobulin, to form either monoiodotyrosyl or diiodotyrosyl residues. Monoiodotyrosyl and diiodotyrosyl combine to form triiodothyronine, aided by the enzyme thyroid peroxidase (TPO). As much as 40% of the T_4 is converted to T_3 by the liver, spleen, and kidney; hence, T_3 is many more times active than T_4, although the ratio can be altered by certain physiological states.[204] T_3 and T_4 remain incorporated in the thyroglobulin, stored in the follicular colloid material of the gland (see Figure 36.8) until released in response to TSH. The release results from the proteolytic cleavage of thyroglobulin by lysosomes into the thyroid hormones and component amino acids. Monoiodotyrosine and diiodotyrosine are then enzymatically degraded, liberating iodide, which is eventually reincorporated into protein by the gland. Normally, thyroglobulin does not reach the circulation but remains inside the thyroid cell.

Once released into circulation, T_3 and T_4 may be free in the blood or bound in plasma to specific transporter proteins. Although there are species differences in the protein-binding patterns of the thyroid hormones, the primary binding protein in humans is thyroxine-binding globulin (TBG) as well with transthyretin and to a lesser extent albumin. TBG is an acidic glycoprotein (molecular weight 40,000) synthesized primarily in the liver that binds T_4 with a relatively high binding affinity and T_3 with a lower binding affinity. TBG has no inhibitory function unlike many other members of this class of proteins. Researchers have identified two forms of inherited TBG deficiency: the complete form (TBG-CD), that results in a total loss of TBG, and the partial form (TBG-PD), that reduces the amount of this protein or alters its structure.[205] These deficiencies are usually identified during routine blood tests that measure thyroid hormones. Although inherited TBG deficiency does not cause any health problems, it can be mistaken for more serious thyroid disorders (such as hypothyroidism). Therefore, it is important to diagnose inherited TBG deficiency to avoid unnecessary clinical intervention.

A second transport protein, thyroxine-binding prealbumin, although present in higher amounts than TBG, has a

TABLE 36.11
Diseases of the Thyroid Gland

Type of Effect	Disease	Specific Condition
Hypothyroidism (myxedema)	Hashimoto's thyroiditis or thyroiditis	Autoimmune disorder where antibodies destroy thyroid cells
	Ord's thyroiditis	Atrophic autoimmune disorder common in Europe
	Postpartum thyroiditis	Inflammation and dysfunction of thyroid after delivery, due to antibodies
	Silent thyroiditis	A variant of chronic autoimmune thyroiditis similar to postpartum thyroiditis
	Postoperative thyroidism	Development of hypothyroidism upon surgical removal of the thyroid
	Acute and subacute thyroiditis	Inflammation and dysfunction of the thyroid
	Iatrogenic hypothyroidism	Dysfunction of the thyroid after exposure to irradiation
Hyperthyroidism (thyrotoxicosis)	Graves' disease	Autoimmune disorder where antibodies stimulate the thyroid cells to overproduce
	Thyroid storm	An acute, life-threatening, thyroid-hormone-induced hypermetabolic state
	Toxic thyroid nodule	Autonomously functioning thyroid nodules that secrete excess thyroid hormone
	Toxic nodular struma (Plummer's disease)	Enlarged thyroid gland containing small, rounded masses called *nodules* that secrete excess thyroid hormone
	Hashitoxicosis	Autoimmune disorder where thyroid cells are sporadically stimulated to overproduce
	De Quervain thyroiditis (giant cell thyroiditis)	Viral infection that initially causes oversecretion and then undersecretion of thyroid hormone
	Iatrogenic hyperthyroidism	Overtreatment of hypothyroidism with thyroid hormone replacement
Additional thyroid pathology	Goiter	Swelling of the thyroid gland because of lack of iodine (endemic); toxic goiter (from inflammation, neoplasm); nontoxic goiter (caused by autoimmune or chemical reaction); diffuse/multinodular goiter (spread throughout the thyroid)
	Thyroid adenoma	Usually benign tumors of the follicular epithelium of the thyroid gland
	Thyroid cancer	Cancer in one of the following forms: papillary, follicular, medullary, or anaplastic
	Cretinism (congenital hypothyroidism)	A congenital defect that results in an underdevelopment of the thyroid; thought to be a result of iodine deficiency

Sources: Data from Greenspan, F.S., in *Basic and Clinical Endocrinology*, 7th edn., Greenspan, F.S. and Gardner, D.G., eds., McGraw-Hill, New York, 2004, pp. 215–294; Wikipedia, http://en.wikipedia.org/, 2006.

lower binding affinity for the thyroid hormones and is considered of secondary physiologic importance. In humans and most other mammals, the thyroid hormones can also bind to albumin following the occupation of the higher-affinity binding sites. As a consequence of this plasma protein binding, less than 0.1% of the total plasma thyroid hormones exist in a free or unbound form. Care must be exercised when monitoring thyroid function in a species such as the rat, which does not possess TBG (a high-affinity binding protein) and therefore has lower plasma levels of protein-bound thyroid hormone. Many factors can affect the measurement of rodent thyroid hormones (see Table 36.12). It is the free hormone that is available for degradation, and the plasma half-life for T_4 would be longer in a species with a TBG than in a species without the protein. The T_4 plasma half-life in the human, which has a TBG, is 5–9 days. In the rat, which does not have a TBG, the T_4 plasma half-life is 12–24 h.

The thyroid gland can be affected by various disease states (Table 36.11), drugs, and environmental agents. Antithyroidal drugs can alter the biosynthesis of thyroid hormones. Some agents interfere with the uptake of iodine or by inhibiting TPO, resulting in a reduction in T_3 and T_4 levels, while other chemicals affect thyroid hormone secretion (Table 36.12). Industrial or environmental agents that affect thyroid function in humans typically do so by interfering with the intrathyroidal synthesis or secretion of thyroid hormone (i.e., primary hypothyroidism).[16] The liver regulates T_3 and T_4 levels through up- and downregulation of catabolic reactions that removes these hormones from the blood. The route of elimination is through conjugation and excretion through the bile.

TABLE 36.12
Chemicals Producing Abnormal Thyroid Function

Blocks Iodide Trapping	Blocks Iodide Oxidation	Mechanism Not Established
Chlorate	Amphenone	Acetazolamide
Hypochlorite	Carbimazole	Auranofin
Iodate	Cobalt	Amiodarone
Nitrate	Methimazole	Chlorpromazine
Perchlorate	*p*-Aminosalicylate	Chlortrimeton
Periodate	Phenylbutazone	Frentizole
Pertechnetate	Phenylindanedione	Thiopental
Propylthiouracil	Propylthiouracil	Tolbutamide
Thiocyanate	Resorcinol	

Note: Iodide is an iodine ion (I^-).

The thyroid hormones, especially T_3, are important in thermoregulation and regulation of metabolism. Polychlorinated biphenyls (PCBs) affect thyroid hormone metabolism. Amiodarone, an antiarrhythmic drug, is an iodinated benzofuran derivative with a chemical structure similar to thyroxine that may cause hyperthyroidism. PCBs are goitrogenic in some animals. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) can reduce T_4 levels in experimental animals, and dichlorodiphenyltrichloroethane (DDT) can produce avian hypothyroidism. Hydroxyphenols (e.g., resorcinol) and hydroxypyridines have been shown to inhibit TPO; likewise, phthalates (also known as plasticizers) can be degraded by certain bacteria producing dihydroxybenzoic acid (DHBA), which also can inhibit TPO.[16] The development of the brain is susceptible to hypothyroidism, and endocrine fetal hypothyroidism, regardless of the cause, is considered teratogenic.[206] In addition to the various drugs, chemicals, and environmental pollutants that can affect the thyroid gland, other factors can influence the measurement of TSH, T_3, and T_4 levels (see Table 36.13).

Measurement of Thyroid Hormones

Assays for thyroid hormones are used to monitor and confirm the extent of hyper- or hypothyroidism. A large number of laboratory tests are available that can be used to assess the function of the thyroid gland (Table 36.14). Laboratory tests can be divided into various categories, including those that directly measure thyroid function (e.g., ^{131}I uptake), those that measure blood levels (free vs. bound), those that measure metabolic actions (e.g., cholesterol lowering), and those that provide insight into the modulations of thyroid function by the adenohypophysis (e.g., thyroid suppression test).

TSH (thyrotropin) is generally elevated in hypothyroidism and decreased in hyperthyroidism.. Free thyroxine (Free T_4) and free triiodothyronine (Free T_3) are generally elevated in hyperthyroidism and decreased in hypothyroidism (Table 36.15).

TABLE 36.15
Reference Values for TSH, Free T_3, and Free T_4

Thyroid-Stimulating Hormone

Patient Type	Lower Limit	Upper Limit	Unit
Adults—standard range	0.3	3.0	mIU/L
Infants	1.3	19	mIU/L
Free thyroxine (free T_4)			
Normal adult	0.7	1.4	ng/dL
Infant 0–3 days	2	5.0	ng/dL
Infant 3–30 days	0.9	2.2	ng/dL
Child/adolescent 31 days–18 years	0.8	2.0	ng/dL
Pregnant	0.5	1.0	ng/dL
Free triiodothyronine (free T_3)			
Normal adult	0.2	0.5	ng/dL
Children 2–16 years	0.1	0.6	ng/dL

RIAs can be used to determine serum T_3 and T_4 levels. The RIA is based on the binding of endogenous hormone to a specific antibody, thereby displacing a proportional amount of radiolabeled hormone from that antibody. Obviously, the hormone-binding proteins in the sample (e.g., TBG, thyroxine-binding prealbumin, and albumin) tend to compete with the antibody for the hormone. This interference can be prevented by extracting the serum prior to the assay or adding chemical agents to block the binding of hormone to binding proteins. Another difficulty in measuring T_3 or T_4 by RIA is that the hormones are small and similar in structure; hence, it has been difficult to produce a specific antibody for T_3 and T_4 without the need for prior chromatographic separation.

Both T_4 and T_3 can be measured using a competitive protein-binding assay that is based on the displacement of radiolabeled hormone from TBG. The amount of label displaced is proportional to the amount of hormone added to the assay in the sample serum. T_4 and T_3 can be effectively measured using the competitive protein-binding assay, but the hormone must first be extracted from the sample serum to eliminate any interference from endogenous binding proteins, which would tend to compete with the binding protein used in the assay. Nonisotopic immunotechniques can also be used to measure thyroid hormones (e.g., EMIT). The principles of these tests are comparable to RIAs except that the labeled analyte may be an enzyme, as in ELISA.[209] EMIT is an enzymatic method that does not require separation of the free and bound portions of the hormone.

PARATHYROID GLANDS

Parathyroid glands are small glands (size of a grain of rice), usually four or more, located in the neck and situated on the posterior surface of the thyroid gland. The parathyroid glands usually weigh between 25 and 40 mg in adult humans. They produce parathyroid hormone (PTH) (see Figure 36.7) and are regulated independently of the thyroid and the HPT axis. The parathyroid glands are quite easily recognizable histologically from the thyroid as they have densely packed cells, in contrast with the follicle structure of the thyroid. However, fat makes them harder to differentiate from the thyroid tissue at surgery.

The densely packed parathyroid gland contains two primary types of cells: oxyphil cells and chief cells. Oxyphil cells stain lighter, are larger in size, less numerous, usually appear in clusters, and contain large numbers of mitochondria. The specific function of oxyphil cells is unknown. The chief cells synthesize PTH in the rough endoplasmic reticulum; it is packaged by the Golgi apparatus and then stored in secretory granules. PTH is synthesized as a prohormone consisting of 115 amino acids, whereas PTH itself contains 84 amino acids. PTH is a small protein that takes part in the control of calcium and phosphate homeostasis, as well as bone physiology, and has effects antagonistic to those of calcitonin.

The balance of endogenous calcium is maintained by several intrinsic factors that modulate the remodeling of bone and the absorption and excretion of calcium and phosphorus homeostasis. PTH, vitamin D, and calcitonin are the principal factors involved in calcium homeokinesis.[210,211] About 98% of endogenous calcium resides in skeletal tissue, with the remainder sequestered in soft tissues and extracellular fluids. About 50% of serum calcium exists in an ionized form, which is the biologically active form of the cation. Hypocalcemia activates calcium-sensing receptors, which induces the release of PTH, which, in turn, stimulates osteoclasts to break down bone and release calcium into the blood. Although the direct involvement of PTH, calcitonin, and vitamin D is important in modulating calcium, other hormones such as thyroxine, GH, estrogens, and corticosteroids also contribute to the maintenance of calcium homeostasis.[211]

Many conditions are associated with the disorders of parathyroid function and can be divided into those causing hyperparathyroidism and those causing hypoparathyroidism. Hyperparathyroidism is overactivity of the parathyroid glands resulting in excess production of PTH. Excessive PTH secretion may be due to problems in the glands themselves (hyperplasia, adenoma, or rarely carcinoma), referred to as *primary* hyperparathyroidism, which leads to hypercalcemia (raised calcium levels). It may also occur in response to low calcium levels, as encountered in various situations such as vitamin D deficiency or chronic kidney disease; this is referred to as *secondary* hyperparathyroidism. In all cases, elevated PTH levels are harmful to bone, and treatment is often needed.[212]

Hypoparathyroidism is a decreased function of the parathyroid glands with underproduction of PTH. This leads to low levels of calcium in the blood, often causing cramping and twitching of muscles or tetany. The condition can be inherited, but it is also encountered after thyroid or parathyroid gland surgery, and it can be caused by immune system–related damage as well as a number of rarer causes. The diagnosis is made with blood tests as well as other investigations such as genetic testing. The treatment of hypoparathyroidism is limited because at this time there is no artificial form of the hormone that can be administered as replacement; calcium replacement or vitamin D can ameliorate the symptoms but can increase the risk of kidney stones and chronic kidney disease.[213]

The evolution of PTH assays can be divided into three types of methods: the competitive immunoassays (first generation), the immunometric assays (second generation), and the new assays recently described (third generation). In the first generation, a single polyclonal antibody competes for labeled PTH. In the second generation assays, two distinct antibodies (usually monoclonal), directed against different epitopes, bind the PTH forms present in the sample. One of the antibodies is bound to a solid phase, and the other is labeled. In the third generation of assays, the recognition of PTH employs a detection antibody that has specificity for the first four amino acids in the PTH molecule, giving a higher precision and accuracy.

A commonly used in vitro assay involves activation of renal adenylate cyclase in response to PTH. PTH can be measured by immunoassay. The majority of assays are directed

against the more stable *C*-terminal fraction.[22] Assays for this *N*-terminal fragment are available and are better suited to detect rapid fluctuations in PTH levels; however, the *C*-terminal assay is the method of choice for assessing abnormal PTH function, particularly with concomitant hypercalcemia.[214] An mAb assay for human vitamin-D-binding protein is also being used.[215] The antihuman vitamin-D-binding protein antibodies cross-react with monkey and pig vitamin-D-binding protein, but not with vitamin-D-binding protein from the rat, mouse, or chicken.

ADRENAL GLANDS

Also known as *suprarenal glands*, the adrenal glands are triangular-shaped glands located on the anteriosuperior aspect of both kidneys (avian and fish species have interrenal glands). In humans, they are found at the level of the T-12 vertebra; they have their own blood supply through the adrenal arteries and measure about 1/2 by 3 in. and weigh 7–10 g combined in an adult human (see Figure 36.9). They are surrounded by an adipose capsule and renal fascia.

The adrenal gland consists of an outer layer (i.e., adrenal cortex) and an inner layer (i.e., adrenal medulla). The inner and outer layers can be readily distinguished by histologic preparations (Figure 36.10). These glands are regulated by both the endocrine and neural systems. The adrenal medulla is a primary source of the catecholamine hormones (epinephrine and norepinephrine) and responds to

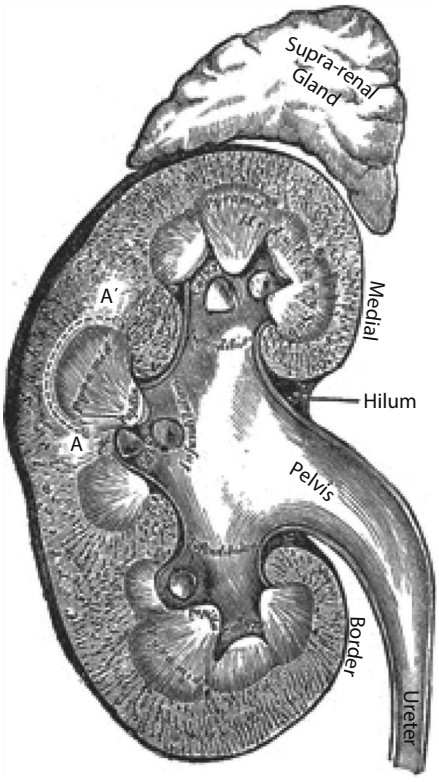

FIGURE 36.9 Relationship of adrenal glands to the kidneys. (Courtesy of U.S. National Cancer Institute Surveillance, Epidemiology, and End Results [SEER] Program.)

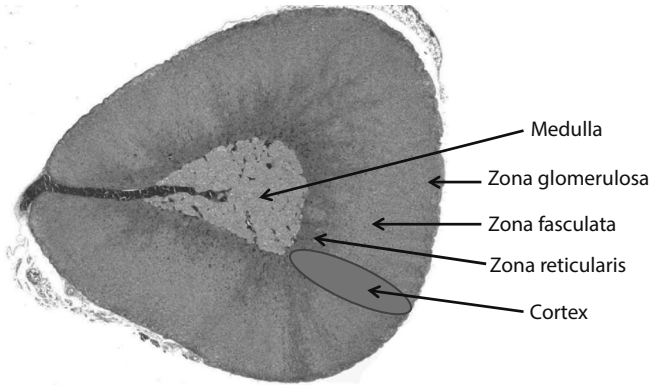

FIGURE 36.10 Histology of rat adrenal cortex (outer area) and medulla (inner area) (original magnification, 126×).

sympathetic nerve stimulation. The release of these hormones produces systemic effects resembling generalized sympathetic nerve stimulation. The adrenal cortex produces two major groups of hormones—namely, mineralocorticoids and GCs. The hypothalamic–pituitary–adrenal axis controls reactions to stress and functions in regulating various body processes such as digestion and the immune system.

Adrenal Medulla

The adrenal medulla can synthesize tyrosine into epinephrine and norepinephrine. The adrenal medulla is considered to be a ganglion of the sympathetic nervous system, as it is derived from neuronic neural crest and from modified neurons. In response to imminent danger, medullary cells release epinephrine and norepinephrine into the bloodstream at a ratio of about 70:30. The adrenal gland also produces androgens and affects kidney function through the secretion of aldosterone, a hormone involved in regulating the osmolarity of blood plasma.

The adrenal medulla is composed primarily of chromaffin cells, which secrete epinephrine (adrenaline), norepinephrine, and enkephalin, which are critical to the fight-or-flight response. Because the autonomic nervous system, specifically the sympathetic division, exerts direct control over the chromaffin cells, hormone release can occur rather quickly. Release of catecholamines is stimulated by nerve impulses, and receptors for catecholamines are widely distributed throughout the body. In response to stressors such as exercise or imminent danger, medullary cells release catecholamines into the blood. Notable effects of adrenaline and noradrenaline include increased heart rate and blood pressure, blood vessel constriction in the skin and gastrointestinal tract, smooth muscle (bronchiole and capillary) dilation, and increased metabolism, all of which are characteristic of the fight-or-flight response.

Adrenal Cortex

Situated along the perimeter of the adrenal gland, the adrenal cortex mediates the stress response through the production of mineralocorticoids and GCs, including

aldosterone and cortisol, respectively. It is also a secondary site of androgen synthesis.

The adrenal cortex is composed of three tissue layers. The external layer, the *zona glomerulosa*, secretes mineralocorticoids such as aldosterone as part of the renin–angiotensin system regulating blood pressure. The intermediate layer, the *zona fasciculata*, produces cortisol, which is involved in the response to stress, increased blood pressure, hyperglycemia, and suppression of the immune system. ACTH causes corticol-producing cells to release GCs as part of the hypothalamic–pituitary–adrenal axis. The inner layer of the adrenal cortex is the *zona reticularis*. The cells of *the zona reticularis* are arranged in a network that has the same functions as cells of the *zona fasciculata*. Evidence suggests that the zona reticularis is the primary source of GCs and adrenal androgens, such as AND (the precursor to testosterone).

The adrenal gland is essential for life, especially the salt-retaining and water-balancing properties of the mineralocorticoids. In the absence of mineralocorticoids, the extracellular fluid potassium concentration rises, and sodium and chloride concentrations fall. In humans, the main mineralocorticoid is aldosterone, although deoxycorticosterone (DOCA), a precursor molecule for the production of aldosterone, also exhibits mineralocorticoid activity. DOCA potency is reported to be only 1/30th that of aldosterone. A rise in serum potassium causes a rise in DOCA secretion.[216] Aldosterone is produced in the cortex of the adrenal gland, and its secretion is mediated principally by angiotensin II but also by ACTH and local potassium levels.[217] The total lack of aldosterone secretion can cause the urinary elimination of up to 20% of the total body sodium in 1 day. The salt elimination can cause a life-threatening reduction in the extracellular and blood volume, which, if untreated, leads to diminished cardiac output and death.

Cortisol, more formally known as hydrocortisone, is the major GC produced in humans and also exhibits a small amount of mineralocorticoid activity. The basic physiological effect of aldosterone is on extracellular fluid volume. It promotes the renal reabsorption of sodium in the ascending portion of the loop of Henle, the distal tubule, and the collecting tubule by acting on the mineralocorticoid receptor. Sodium reabsorption is accompanied by the reabsorption of the chloride anion. In addition to stimulating sodium reabsorption, aldosterone enhances the urinary excretion of potassium and hydrogen ions. The increased elimination of hydrogen ions can lead to alkalosis and an increased extracellular content of bicarbonate ions, which, when combined with an increased extracellular sodium and chloride content, promotes tubular reabsorption of water.[218]

The major GC secreted in humans is cortisol, or hydrocortisone, produced by the *zona fasciculata* of the adrenal gland, although both corticosterone and cortisone possess some GC activity. Their primary functions are to increase blood sugar through gluconeogenesis; suppress the immune system; and aid in fat, protein, and carbohydrate metabolism. With regard to carbohydrate metabolism, the GCs stimulate gluconeogenesis and decrease glucose utilization by the cells leading to hyperglycemia. Cortisol also breaks down protein and lipids, which increases blood glucose, with a resulting increase in glycogen in the liver.[219] The GCs also produce a marked reduction in cellular protein content. An exception to this protein catabolic action is the liver, where protein content increases as does the production of plasma protein by the liver in response to decreased blood glucose levels.

Cortisol suppresses the immune system by downregulating the interleukin-2 receptor (IL-2R) on *helper* T-cells.[220] This results in the inability of interleukin-2 to upregulate the Th2 (humoral) immune response and results in a Th1 (cellular) immune dominance. This leads to a decrease in B-cell antibody production. Cortisol prevents the release of substances in the body that cause inflammation. This is why cortisol is used to treat conditions resulting from overactivity of the B-cell-mediated antibody response, such as inflammatory and rheumatoid diseases, and allergies. Low-potency hydrocortisone, available over the counter in some countries, is used to treat skin problems such as rashes and eczema.

Cortisol is an essential chemical in the restoration of homeostasis after exposure to stress. Among other things, it promotes gluconeogenesis by inhibiting insulin. GCs interfere with the transport of amino acids into extrahepatic cells, and this action combined with continuing protein catabolism in these cells produces an increase in plasma amino acid content. Increased plasma amino acids and their subsequent transport into the liver promote gluconeogenesis (i.e., the conversion of amino acids to glucose). The GCs also promote mobilization of fatty acids from adipose tissue, which raises plasma fatty acid levels. This effect, along with increased oxidation of fatty acids in the cells, is involved in the metabolic conversion from glucose utilization to fatty acid utilization as a source of energy during the periods of stress.

Corticosteroids can bind to plasma protein fractions. A corticosteroid-binding globulin (CBG), also known as transcortin or serpin A6, has a high affinity but a low binding capacity. CBG is produced by the liver and is regulated by estrogens. Therefore, plasma transcortin levels increase during pregnancy (unbound plasma cortisol in term pregnancy is approximately 2.5 times that of nonpregnant women)[221] and are decreased in cirrhosis. Under physiological conditions, most of the hormones (cortisol, corticosterone, aldosterone, and progesterone) are bound to CBG.

It is now recognized that many drugs and chemicals can produce lesions of either the adrenal medulla or the adrenal cortex (Table 36.16). Still other agents can specifically inhibit particular enzymatic steps involved in adrenal steroidogenesis (Figure 36.11). Not only have metyrapone, aminoglutethimide, and *o,p′*-DDD been used as agents to aid in the diagnosis of adrenal cortical dysfunction, but some have also been used as adrenolytic drugs in treating inoperable adrenal adenocarcinomas.

MEASUREMENT OF CORTICOSTEROIDS

Several methods have been used to measure plasma and urinary aldosterone levels. Among them are double-isotope dilution techniques, gas–liquid chromatographic techniques,

TABLE 36.16
Agents Causing Lesions to the Adrenal Gland

Adrenal Cortex	Adrenal Medulla
Adriamycin	Acrylonitrile
Aminoglutethimide	ACTH
4-Aminopyrazolo-(3,4-*d*)pyrimidine	Alloxan
Cadmium	Blocadren
Carbon tetrachloride	Chlordecone
Chloramphenicol	*o*-Chlorobenzylidine
Chlordane	Malononitrile
Chloroform	Cysteamine
Chlorphentermine	Dichloromethane
Chlorpromazine	7,12-Dimethylbenzanthracene
Copper	Estrogens
Cyclosporin	GH
Cyproterone	Interleukin-2
o,p′-DDD	Lactitol
Danazol	Lactose
Dichlorvos	Malathion
7,12-Dimethylbenzanthracene	Mannitol
Etomidate	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyrine (MPTP)
5-Fluorouracil	Neuroleptics
Kepone	Nicotine
Ketoconazole	Pyrazole
Nicotine	Reserpine
Phenobarbital	Retinol acetate
Polychlorinated biphenyls	Sorbitol
Spironolactone	Thiouracil
Tamoxifen	Thyroid hormones
TCDD	TSH
Tetrahydrocannabinol	1,1,2-Trichloroethane
Toxaphene	Xylitol

and RIAs.[112] A competitive immunoassay for cortisol reportedly is based on a capillary electrophoresis and laser-induced fluorescence technique.[223] Several analytical procedures have been used for the quantitation of GCs. One of the earliest procedures involved a colorimetric reaction between the GC and a phenylhydrazine reagent. The Porter–Silber method and Zimmerman reactions are colorimetric assays used for measuring corticoids. Both cortisol, which is the primary GC in humans, and corticosterone, which is the primary GC in the rat, have also been measured using a competitive protein-binding assay that takes advantage of the binding affinity of the GC-binding globulin found in the plasma. Many drugs can interfere with the measurement of corticosteroids and ketosteroids; see Table 36.17. With the development of immunochemical techniques, it was found that plasma GCs could be effectively measured using the RIA. A complicating factor was the existence of competition between the endogenous GC-binding globulin and the added antibody for the radioligand.

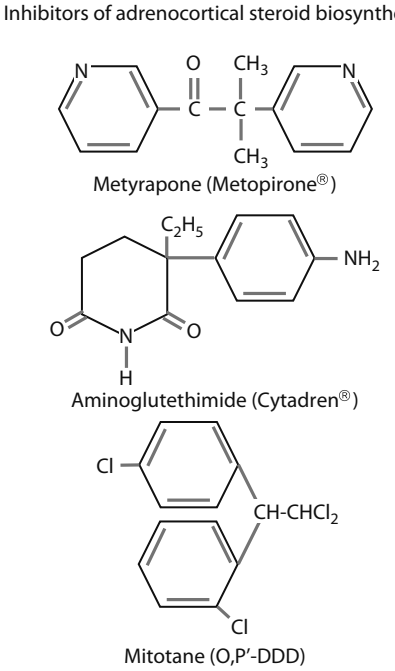

FIGURE 36.11 Agents that inhibit adrenocortical steroid biosynthesis.

TABLE 36.17
Drugs That Interfere with the Measurement of Corticosteroids and Ketosteroids

Antibiotics/antibacterial agents:
- Nalidixic acid
- Sulfamerazine
- Triacetyloleandomycin

Sedatives/tranquilizers:
- Chloral hydrate
- Chlordiazepoxide
- Chlorpromazine
- Ethinamate
- Meprobamate
- Phenaglycodol
- Reserpine

Monoamine oxidase inhibitors:
- Etryptamine

Oral hypoglycemic agents:
- Acetohexamide

Miscellaneous drugs:
- Colchicine
- Phenytoin (DPH)
- Quinidine
- Quinine
- Spironolactone

Note: Ketosteriods have a ketone functional group at the 17 position and include AND, androsterone, estrone, and dehydroepiandrosterone.

Stress can produce a rapid increase in ACTH production, which in turn promotes the secretion of adrenocortical hormones; thus, the conditions under which the animal is prepared for blood sampling can modify the corticoid levels. It has been demonstrated that under ether anesthesia, blood corticoid levels are higher than those levels found after pentobarbital administration, which are higher than those measured following decapitation. Likewise, the time elapsed following the administration of pentobarbital influences blood hormone levels. Thus, stress can be a major problem affecting the interpretation of results. An additional related problem is that fairly large volumes of blood must be drawn for adrenocortical hormone measurement, which also leads to stress.

Noninvasive measures of stress may be obtained by quantifying corticosteroid metabolites excreted in feces. This method has been shown to be useful to assess corticosteroid levels preceding stress in numerous species, including rats and mice.[224] Adrenocortical function can be effectively monitored by measuring corticosteroid levels in 24 h urine samples. Major advantages to this approach are that (1) the animals can be housed stress-free in metabolic cages during toxicity testing and (2) serial measurements can be conducted in the same animal by noninvasive techniques without sacrificing the animal. This approach cannot be used to measure urinary aldosterone in the rat because the primary site of degradation for aldosterone is the liver, and only about 1% of the secreted aldosterone is excreted unchanged in the urine. Nevertheless, relative changes in the urinary corticosteroid patterns could be of value as a screen for adrenotoxicity during chronic toxicity studies. RIA is the method of choice for the determination of urinary corticosteroids.

GONADS

Male Sex Hormones (Androgens)

During mammalian development, gonads are capable of becoming either ovaries or testes. In humans, starting at about week 4, the gonadal rudiments are present within the intermediate mesoderm adjacent to the developing kidneys. At about week 6, epithelial sex cords develop within the forming testes and incorporate the germ cells as they migrate into the gonads. In males, certain Y chromosome genes, particularly SRY, control the development of the male phenotype, including conversion of the early bipotential gonad into testes. In males, the sex cords fully invade the developing gonads. The mesoderm-derived epithelial cells of the sex cords in developing testes become the Sertoli cells, which will function to support sperm cell formation. A minor population of nonepithelial cells appear between the tubules by week 8 of human fetal development. These are Leydig cells, and soon after they differentiate, they begin to produce androgens.

Androgens control and maintain masculine characteristics. These actions are generally mediated by binding to intracellular steroid receptors that specifically bind testosterone and dihydrotestosterone (DHT). Testosterone is produced from cholesterol in the Leydig cells of the male testes and, to a much lesser degree, in the thecal cells of the ovaries. Small amounts of testosterone are produced in both males and females by the *zona reticulosa* of the adrenal glands.

Testosterone is the primary male sex steroid hormone and is found in mammals, reptiles, birds, and other vertebrates.[225,226] It is essential for health and well-being as well as for the prevention of osteoporosis. It acts as a virilizing agent and promotes secondary male sex characteristics such as increased muscle, bone mass, the growth of body hair, and anabolic effects, such as increased bone and muscle strength and size and inhibition of estrogenic effects. In addition, testosterone enhances libido, immune function, normal bone growth, and general well-being. Average plasma concentration in adult human males of testosterone is about 7–8 times as great as the concentration in adult human females' plasma,[227] but because the metabolic consumption of testosterone in males is greater, the daily production of testosterone is about 20 times greater in men.[228] Testosterone binds to sex-hormone-binding globulin (SHBG), which is a glycoprotein that specifically binds testosterone and estradiol. The exact role of SHBG is not clear; however, it is thought that SHBG in concert with other carrier proteins provides a dynamic equilibrium between free and bound androgens in response to fluctuations in the secretion of androgens.[229]

Testosterone not bound to SHBG can bind to ARs or can be reduced to 5α-DHT by 5α-reductase. DHT is a more potent agonist than testosterone. Once activated, the ARs are transported to the nucleus, where they bind to specific areas of chromosomes to form hormone response elements (HREs), which ultimately enhance the appropriate gene transcription activity and result in anabolic or virilizing protein production. Anabolic steroids (e.g., 19-norsteroids) bind the AR, resulting in increased protein synthesis, and simultaneously block the effects of cortisol, thus reducing the rate of catabolism, especially of the muscle mass.

Besides testosterone, other androgens include the following: (1) Dehydroepiandrosterone (DHEA), also called dehydroisoandrosterone or dehydroandrosterone, is a steroid hormone produced in the adrenalcortex from cholesterol. It is the primary precursor of natural estrogens. (2) AND is an androgenic steroid produced by the testes, adrenal cortex, and ovaries that can be converted metabolically to testosterone and other androgens and the parent structure of estrone. AND has been used as an athletic or bodybuilding supplement and is banned by most sporting organizations. (3) Androstenediol is the steroid metabolite thought to act as the main regulator of gonadotropin secretion and is found in approximately equal amounts in the plasma and urine of both males and females. (4) Androsterone is a chemical by-product created during the breakdown of androgens, or derived from progesterone, that also exerts minor masculinizing effects, but with less intensity than testosterone. (5) DHT is a metabolite of testosterone and a more potent androgen than testosterone in that it binds more strongly to ARs. It is produced in the adrenal cortex.

Male reproductive toxicology endpoints can be assessed in several ways (Table 36.18). The components of normal human male semen are listed in Table 36.19. Androgens can be chemically measured, or androgen-dependent organs can be used to determine the endocrine status of male sex hormones. Androgens and other steroids can be biotransformed in several anatomical sites (Table 36.20). In considering these processes, there are numerous potential targets for the action of chemicals ranging from the action of dopamine antagonists on the hypothalamous interrupting the normal secretion of GnRH to the action of estrogens on the pituitary and hypothalamus to interfere with gonadotropins (LH and FSH) production through direct effects on spermatogenesis—where the vast majority of toxicants have their site of action. There are a number of examples of nutritional deficits or over exposure to some vitamins and minerals (vitamin A and zinc) and testicular vasculature effects of cadmium that lead to direct effects on spermatogenesis. CCl_4 can disturb the normal metabolism of sex steroids, leading to changes in clearance, indirectly perturbing the HPG axis and its effect on spermatogenesis.[231] An overview of the hormonal regulation of spermatogenesis in the rat, monkey, and man has identified differences in male fertility between these species. The review reports that FSH and androgens act both separately and synergistically to support a range of events in spermatogenesis, from spermatogonial stem cell division to final sperm release.[232]

Proper functioning of the mammalian testis is dependent upon an array of hormonal messengers acting through endocrine, paracrine, and autocrine pathways. These hormonal messengers are critical not only for regulation of male germ cell development, but also for the proliferation and function of the somatic cell types required for proper development of the testis.[233] These cell types include the interstitial steroidogenic Leydig cells, whose primary function appears to be the production of testosterone; the myoid cells that surround the seminiferous tubules and provide physical support and contractile motion to these structures; and the Sertoli

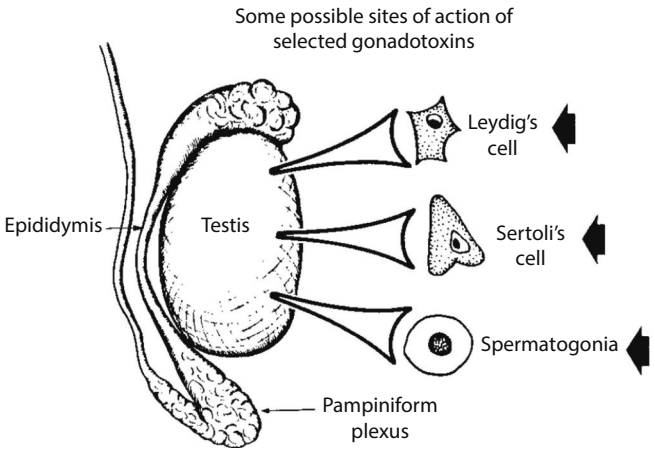

FIGURE 36.12 Testis site of action.

cells, whose direct contact with proliferating and differentiating germ cells within the seminiferous tubules makes them essential for providing both physical and nutritional support for spermatogenesis. Each of these cell types is a direct target for one or more of the hormones whose actions are essential for unimpaired male fertility. Some cell types of the testes are more sensitive to chemical insult than are others. The various subpopulations of cells within the testes include the germ cells, the Sertoli cells, and the Leydig cells (interstitial cells) (Figure 36.12). Cross-sections of the mammalian testes reveal the seminiferous tubules containing the germinal epithelium and the Sertoli cells. Leydig cells lie outside these tubules and are located in the interstitium (Figure 36.13).

Gonadotoxicants may act directly on the testes, indirectly via the CNS, or by a combination of the two. Relative to the germinal epithelium, the Leydig cells are not as sensitive to the toxic effects of chemicals. A pig Leydig cell culture system has been devised to evaluate testicular toxicity.[234] This in vitro system can test the ability of a compound to inhibit steroidogenesis. Some physiochemical characteristics of gonadotoxicants are shown in Table 36.21. The toxicity of a particular gonadotoxicant depends to some extent on its ability to penetrate the blood–testes barrier, which is the barrier formed by tight connections between the Sertoli cells. In younger animals, the testicular gap junctions are still relatively permeable, and the germinal epithelium may be more vulnerable than in the adult testes.

Androgens are steroids (Figure 36.14) that can be measured fluorometrically, by chromatography, and by RIA. They also can be bioassayed using various biological responses such as the stimulation of accessory sex organ weights in castrated animals (e.g., prostate gland or seminal vesicle weights). Still other androgen assessments can be made by measuring male sex accessory gland constituents (e.g., seminal vesicle fructose levels and zinc concentrations).

Androgens possess three primary biological actions: (1) virilizing or masculinizing actions, (2) protein anabolic or myotropic actions, and (3) antiestrogenic properties. All of these biological effects can be bioassayed in experimental animals, with rodents the most commonly used animal

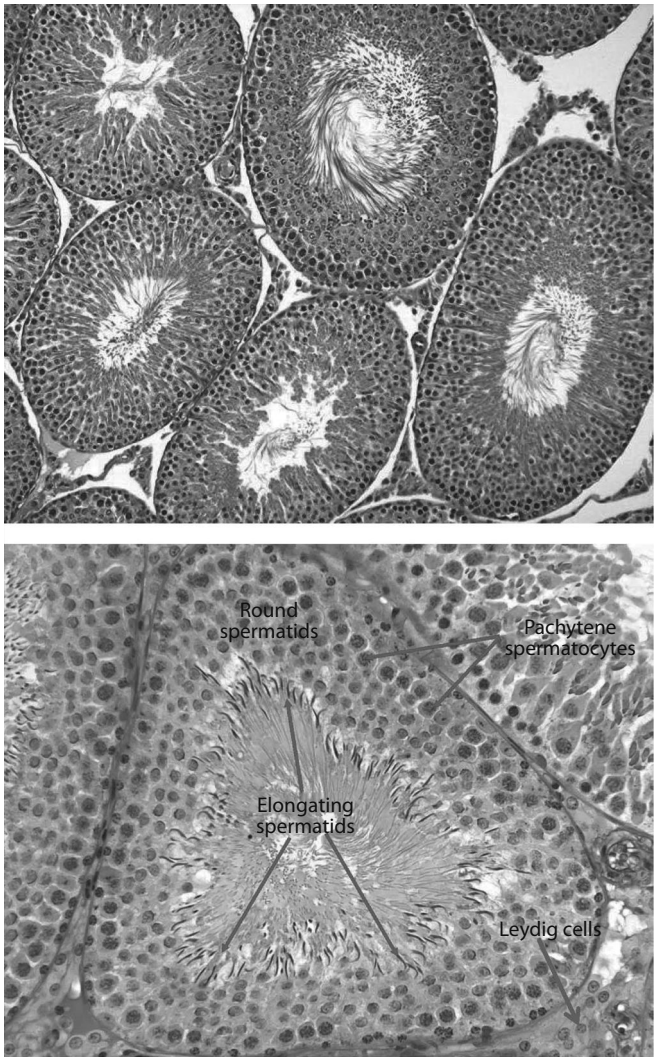

FIGURE 36.13 Normal rat testes.

model. The actions of male sex hormones (i.e., their masculinizing actions) are usually bioassayed on the basis of gravimetric responses in sex accessory organs (Figure 36.15). Generally, either the rat seminal vesicle or ventral lobes of the prostate gland are used to bioassay androgens. For the bioassay, rats are castrated, and the sex accessory glands are allowed to regress for about 7 days. Using testosterone as a standard, castrated rats are injected for several days, the

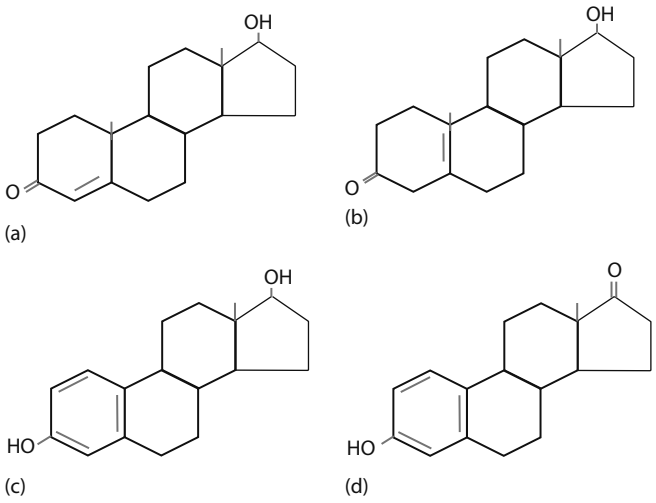

FIGURE 36.14 (a) Testosterone, (b) dihydrotesterone, (c) estradiol-17β, and (d) estrone.

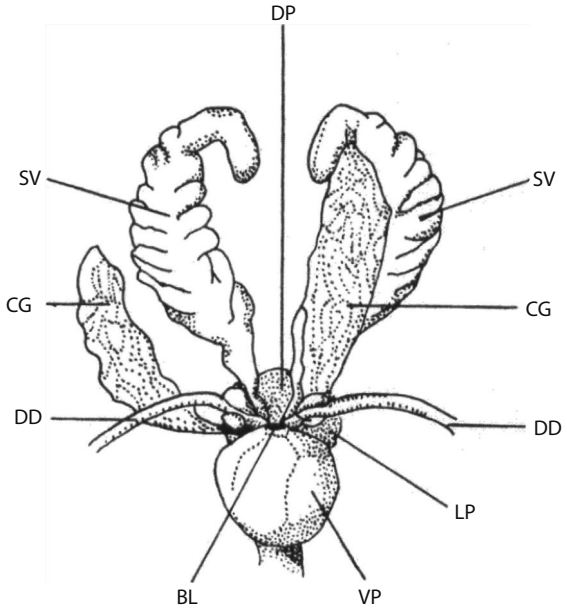

FIGURE 36.15 Anatomical components of rodent sex accessory glands. DD, ductus deferens; BL, bladder; VP, ventral prostate; LP, lateral prostate; CG, coagulating gland (also called anterior prostate); SV, seminal vesicle; DP, dorsal prostate.

animals are killed, and either the seminal vesicles (empty) or the ventral prostate glands are removed and weighed (Figure 36.16). The data reveal that organ weights of both the seminal vesicles and the ventral prostates increase directly proportional to the increase in concentration of injected testosterone. Sometimes, immature rats are used for the bioassay instead of castrated animals.

The rat levator ani muscle weight has been used to bioassay the protein anabolic actions of androgens. The levator ani bioassay was developed following the observations of the myotropic and nitrogen-retaining activities of certain androgenic steroids. This test lacks specificity as a measure of

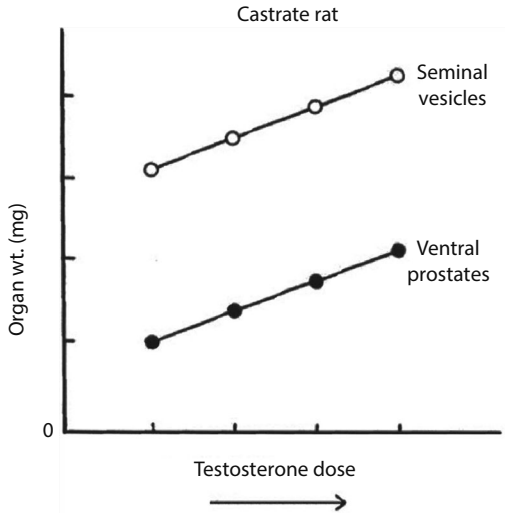

FIGURE 36.16 Bioassay of androgens using rat seminal vesicles or ventral prostate glands from castrated rats.

protein anabolic activity. The levator ani test ordinarily uses immature castrated rats that have been treated for 1 week with the steroid. In addition to androgen bioassay methods using rodent sex accessory organs and muscles, male sex hormones, which exert a renotropic action in mice, can be utilized. Androgens can stimulate the growth of the kidneys in castrated or immature mice.

Chemical indicator tests also have been used to assess androgen activity. Sex accessory organs contain several biochemical constituents that are androgen-dependent and quantifiable[236]; for example, sex accessory gland fructose decreases following castration and can be restored by androgen administration. Sex accessory gland fructose has been used as a sensitive chemical indicator for testosterone and other androgens. Fructose can be measured spectrophotometrically by several colorimetric reactions. Similarly, sex accessory organ citric acid can be used to assess androgenic activity. These chemical indicator tests for androgens are more sensitive than the gravimetric responses used in bioassay procedures. A number of different endpoints to assess male reproductive function have been proposed for food and color additives.[164]

Urinary creatine profiles have been used as a chemical indicator for testicular toxicity.[237] Several chemicals (e.g., methoxyacetic acid)[238] have been assessed for their testicular toxicity, as evidenced by increases in urinary creatine (Table 36.22). Creatine is associated primarily with cells of the seminiferous epithelium. Several chemicals can destroy the germ cells, as reflected by creatinuria. Chemicals that destroy primarily Leydig cells do not lead to creatinuria; for example, ethane dimethane sulfonate (EDS) exerts a direct cytotoxic action on the Leydig cells. Creatinuria is related to testicular degeneration, and a substantial portion of the testicular creatine is associated with the cells of the seminiferous epithelium.

Testosterone levels have been determined using double-isotope derivative methods, gas–liquid chromatography,

and fluorometric procedures. Although these testosterone methods are specific and sensitive, elaborate purification is essential for accuracy, and routine application is often time-consuming. Competitive protein-binding assays and RIAs are available. In the RIA, antiserum against testosterone can be produced in rabbits immunized with testosterone-3-oxime-beef serum albumin. Biological samples must undergo solvent extraction and be eluted on microcolumns. If the extraction and purification of the samples are appropriately carried out, the RIA of testosterone is highly sensitive and accurate; it is capable of detecting testosterone in nanogram to picogram amounts. A method has been described for assessing androgens under field or remote site conditions.[239] mAb techniques can be used for assessing ARs.

Male Infertility/Testicular Toxicity

The inability of a male to achieve a pregnancy in a fertile female is referred to as male infertility. It is estimated that 40%–50% of infertility in humans is due to the male partner.[240] The etiology of male infertility may be genetic (Y chromosome microdeletions to Klinefelter syndrome) or nongenetic (trauma, disease, and cancer). Infertility may or may not be due to direct toxic insults to the testicles. The primary functions of the testes are to produce sperm and to produce androgens, primarily testosterone. Both functions of the testicle are influenced by gonadotropic hormones produced by the anterior pituitary. LH results in testosterone release. The presence of both testosterone and FSH is needed to support spermatogenesis. It has also been shown in animal studies that if testes are exposed to either too high or too low levels of estrogens (such as estradiol; E2), spermatogenesis can be disrupted to such an extent that the animals become infertile.[241]

In mammals, the testes are found outside of the body cavity within the scrotum. Because spermatogenesis cannot occur at body temperature, scrotal temperature is a few degrees lower than internal body temperature. The physiological temperature of the adult human testis is 31°C–35°C.[242] Several mechanisms aid in maintaining testicular temperature within defined limits as environmental conditions change. For efficient dissipation of heat, the scrotum is rich in sweat glands and has only minimal amounts of subcutaneous fat. Importantly, the pampiniform plexus is an effective heat-exchange system that aids in decreasing scrotal temperatures. A two-muscle system lowers and lifts the testis. The tunica dartos is a muscular layer of the scrotum, and the cremaster muscle extends from the body wall through the inguinal canal, surrounding the spermatic cord (see Figure 36.17). When environmental temperature is elevated, the muscles relax in unison, and the testes are lowered from the body, permitting the escape of excess heat. Under cold conditions, the muscles contract, pulling the testes toward the warmth generated by the body.

Numerous factors, both neural and hormonal, may contribute to male infertility. The hormonal factor can be affected by gonadotoxicants, which cause spermatogenic arrest and degeneration of seminiferous tubules, leading to infertility (i.e., low sperm count). Some industrial chemicals can cause sterile tubules and result in infertility[243]; examples include DBCP[243] and alkylating agents (e.g., nitrogen mustards).[244] X-rays[245] and cryptorchidism (undescended testes)[246] can also lead to infertility.

Most testicular toxicity can occur with no change in hormone levels. More broadly, a recent survey of industry practices indicated that most investigative studies of blood hormone concentrations (most often testosterone) used five to eight animals per group.[247] Measuring circulating levels of male reproductive hormones can provide essential evidence to support a hormonally mediated mechanism of toxicity; however, the success of the study will depend on the hormonal study being adequately powered by enough animals. Based on the coefficients of variation of the different hormones, the following group sizes are recommended to obtain a reasonable (80%) chance of detecting a 50% change in hormone level: for testosterone in rats, n = 30/group; for FSH and LH in rats, n = 10–20/group; for testerosterone in dogs and monkeys, sample every 10–20 min over a 2–2.5 h period and pool the samples for an integrated value; otherwise, group sizes of n = 20 would be needed if only a single sample is taken.[248] When conducting hormonal measurements in any species, it is important to establish that the animals have attained sexual maturity and to control for factors such as diurnal variation and stress.

Many useful tests can aid in determining reproductive success, but such tests must be undertaken in both the male

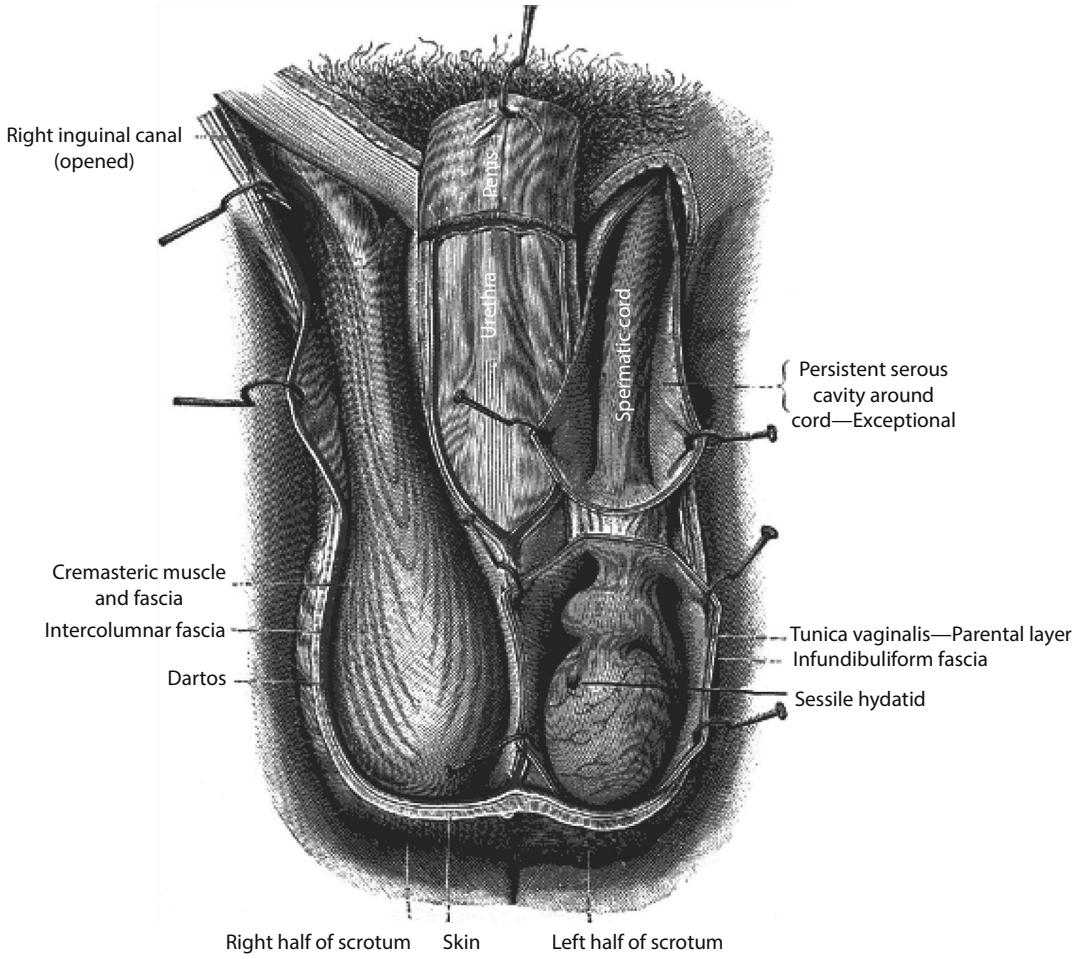

FIGURE 36.17 Male reproductive tract. (Courtesy of U.S. National Cancer Institute Surveillance, Epidemiology, and End Results [SEER] Program.)

(Table 36.23) and the female (Table 36.24). Although the measurement of fertility is imprecise, it does have the advantage of integrating all reproductive functions from both the male and the female.[249] Testicular histology is not quantitative but provides some information about gonadal physiology (or pathology).

Due to transgene technology, several animal models are now available for studying male sterility.[250] Knockout mouse models have been produced for the key components of the hypothalamo–pituitary–testicular axis, including the GnRH gene (hpg), FSH and LH receptors, FSH and LH subunits, ERs, and the aromatase enzyme. Germ cell transplantation models are based on the transplantation of spermatogonial stem cells from wild-type or factor-deficient animals into infertile hetero- or homozygous recipients.[251] Genetic aberrations are evident not only in the processes involved in spermatogenesis but also in anatomical defects observed in sex accessory organs. GnRH cell lines have been developed and can produce a transgenic mouse with hypothalamic hypogonadism[252]; hence, transgenic mouse models can be used to study the mechanisms of spermatogenic arrest as well as altered neuroendocrine systems that interfere with gonadotropin secretion.[253]

Female Sex Hormones (Estrogens)

Estrogens are a group of compounds important in the estrous and menstrual reproductive cycles of humans and other animals, being the primary female sex hormones. Animals that have estrous cycles resorb the endometrium if conception does not occur during that cycle, whereas animals that have menstrual cycles shed the endometrium through menstruation. Natural estrogens are steroid hormones, while some synthetic ones are nonsteroidal. The name comes from the Greek word for "gadfly" and the suffix "gen", meaning "producer of." Estrogens are synthesized in all vertebrates as well as some insects.[254,255] Estrogens are biosynthesized primarily by theca interna cells of the developing follicles in the ovaries, the corpus luteum, the placenta, and, in lesser amounts, the adrenal cortex. Secondary sources such as the breasts, liver, and adrenals are an important source of estrogens in postmenopausal women. Fat cells produce estrogen as well.[256]

The three major naturally occurring estrogens in women are estrone (E1), estradiol (E2), and estriol (E3). Estradiol is the predominant estrogen during reproductive years both in terms of absolute serum levels as well as in terms of

estrogenic activity. During menopause, estrone is the predominant circulating estrogen, and during pregnancy, estriol is the predominant circulating estrogen in terms of serum levels. Though estriol is the most plentiful of the three estrogens, it is also the weakest, whereas estradiol is the strongest with a potency of approximately 80× that of estriol.[257] Thus, estradiol is the most important estrogen in nonpregnant females who are between the menarche and menopause stages of life. However, during pregnancy, this role shifts to estriol, and in postmenopausal women, estrone becomes the primary form of estrogen in the body. Another type of estrogen called estetrol (E4) is produced only during pregnancy.

All of the different forms of estrogen are synthesized from androgens, specifically testosterone and AND, by the enzyme aromatase. Cholesterol is converted from AND to pregnenolone by the enzyme P450 side-chain cleavage; another enzyme, CYP17A, converts pregnenolone to 17α-hydroxypregnenolone and then to DHEA, which is converted to estrogens. Cholesterol, also synthesized to AND in the theca interna cells, is subsequently absorbed into the nearby granulosa cells of the ovary. In granulosa cells, AND is converted primarily to estradiol-17β. Evidence suggests that estrone is also secreted in the process and can be further metabolized to estradiol by hepatic enzymes (Figure 36.18). Of these three main naturally occurring estrogens, estradiol-17β is undoubtedly the most potent. All of these naturally occurring estrogens are steroids. Synthetic estrogens such as DES and dienestrol are not steroids. Although steroidal and nonsteroidal estrogens can be bioassayed using similar tests, their different molecular structures do not allow them to be measured by similar chemical methodologies. Testing guidelines for evaluating reproductive and developmental toxicity in the female are described on FDA, ICH, EPA, and OECD websites and are described in Hood and Parker.[258]

The two methods once commonly used to bioassay estrogenic hormones in rodents involve either histological

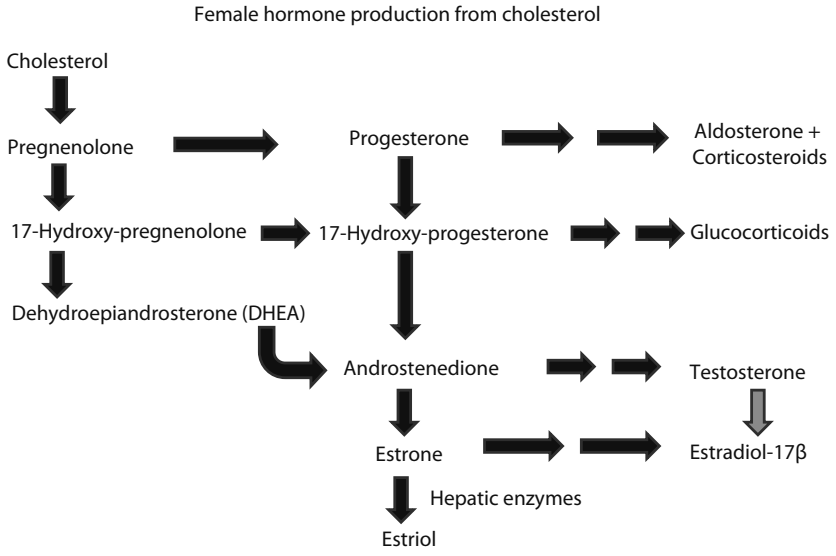

FIGURE 36.18 Biosynthesis of sex steroids.

changes in the vaginal epithelium or an increase in uterine weights. Both assays require the use of ovariectomized animals.

The mouse vaginal smear bioassay uses ovariectomized animals with different standard doses of estradiol as controls. To establish that the animals are responding, vaginal smears are characterized by nucleated epithelial cells or cornified cells. Vaginal responses characterized by epithelial cornification are considered positive responders to estradiol. Estrogen bioassays also include using an increase in

uterine weight in the ovariectomized rat or mouse. Uterine weight falls precipitously after ovariectomy. The reduced uterine weight can be restored by daily injections of estradiol. Ovariectomized mice are injected subcutaneously and killed, and the uteri are removed and weighed. Like the vaginal smear bioassay, at least two dilutions of the unknown substance are run concurrently with the estradiol dose–response curve.

These bioassays (i.e., vaginal cornification and uterine weights) are quite sensitive to estrogen but have largely been abandoned for newer and more expedient and accurate assays. Several useful tests can be utilized in determining reproductive toxicity in the female reproductive system (see Table 36.24). Estrogens can be measured colorimetrically, by RIA, monoclonal assays, and other immunotechniques. Estrogen and progesterone receptors can also be measured by mAb techniques that employ EIAs.[259] The evaluation of techniques for the detection of functional estrogenicity has received renewed attention.[260]

Female Infertility/Ovarian Toxicity

The ovaries are homologous to the testicles in the male. In humans, they are located internally on the posterior wall of the pelvis lateral to the position of the uterus called the ovarian fossa and are structurally supported by three ligaments: the suspensory ligament, the broad ligament, and the ovarian ligament. The ovaries are close to but not attached to the ovarian (fallopian) tubes, which transport the ovum as it is expelled from the ovary to the uterus (Figure 36.19). Usually, each ovary takes turns releasing eggs every month; however, in cases where one ovary is absent or dysfunctional, then the other ovary would continue providing eggs each month. Ovaries secrete both estrogen and progesterone. Estrogen is responsible for the appearance of secondary sex characteristics for females at puberty and for the maturation and maintenance of the reproductive organs in their mature functional state. Progesterone prepares the uterus for pregnancy and the mammary glands for lactation. Progesterone functions with estrogen by promoting menstrual cycle changes in the endometrium. Toxicants can affect reproductive outcomes at a number of points in the female reproductive process through their direct effects on the ovaries, ovulation, fertilization, implantation, and the developing fetus.

A paucity of research data exists regarding ovarian toxicants in humans leaving animal research, usually the rat, to provide much of the ovarian toxicity data. Direct effects on the ovary can produce a reduction in ovarian hormonal secretion, resulting in a change in the LH and FSH levels as a result of reduced negative feedback signals to the pituitary and hypothalamus. Direct ovarian toxicants could also hinder the production of follicles, which could result in early menopause or in a disruption of menses. Reproductive toxicants produce changes in ovarian functions at different levels. Some agents are known to be toxic to the ovaries, such as nitrogen mustards, chlorambucil, cyclophosphamide, busulfan, vinblastine, and polycyclic aromatic hydrocarbons[261]; hence, the ovary is clearly vulnerable to chemical injury.[262,263] A decrease in ovarian follicle count is usually considered a biomarker of an adverse reproductive event because no recovery is possible.[264] Both the granulosa cells and the thecal cells may be targets for chemical injury (Table 36.25). Chemicals that inhibit gonadotropin secretion, damage gonadotropin receptors, or uncouple the receptor from other molecules necessary for hormone action would be expected to adversely affect granulosa cells. Thecal

cells provide precursors for granulosa cell steroidogenesis. Xenobiotics can alter either granulosa cells or thecal cells. The oocytes themselves are also targets for chemical insult or injury. Alkylating agents, lead, and mercury can be destructive to the mammalian oocyte.[263]

PANCREAS

Pancreatic tissue is present in all vertebrate species, but its precise form and arrangement vary widely. There may be up to three separate pancreases, two of which arise from ventral buds and the other dorsally. In most species (including humans), these fuse in the adult; however, there are several exceptions. Even when a single pancreas is present, two or three pancreatic ducts may persist, each draining separately into the duodenum (or equivalent part of the foregut). Birds typically have three such ducts. In fish and a few other species (such as rabbits), there is no discrete pancreas at all, with pancreatic tissue being distributed diffusely across the mesentery and even within other nearby organs, such as the liver or spleen.[266]

In humans, the pancreas is a retroperitoneal lobulated organ located posterior to the stomach and in close association with the duodenum, approximately 1 in. in height and 5 in. in length and weighing up to about 100 g (Figure 36.20).[267] The pancreas has two primary functions: (1) The exocrine pancreas produces enzymes for digesting lipids and proteins that break down various categories of digestible foods from asini cells, and (2) the endocrine pancreas secretes hormones from clusters of glandular epithelial cells called *pancreatic islets* (islets of Langerhans) that produce the hormones glucagon, insulin, and somatostatin. Four main cell types exist in the islets. They are relatively difficult to distinguish using standard staining techniques, but they can be classified by their secretion: α cells secrete glucagon (increase glucose in blood), β cells secrete insulin (decrease glucose in blood), delta cells secrete somatostatin (regulates/stops α and β cells), and PP cells or gamma cells secrete pancreatic polypeptide (Figure 36.21).[268]

Under a microscope, stained sections of the pancreas reveal two different types of parenchymal tissue. Lightly staining clusters of cells are called islets of Langerhans, which produce hormones that underlie the endocrine functions of the pancreas. Darker-staining cells form acini connected to ducts. Acinar cells belong to the exocrine pancreas and secrete digestive enzymes into the gut via a system of ducts. The acini cell secretions collect in the acini ducts, which communicate directly with the intralobular ducts, eventually draining into the major pancreatic duct or the duct of Wirsung. This duct subsequently unites with the common bile duct, which enters the upper end of the duodenum in a duct common to both organs termed the *hepatopancreatic ampulla* or the *ampulla of Vater*. At this juncture, the exocrine pancreatic secretions enter the duodenum and exert their effects upon the intestinal chyme. The morphologic arrangement of the rat pancreas is depicted in Figure 36.20.

The endocrine pancreas secretes two hormones important in the regulation of carbohydrate metabolism: insulin and glucagon. Insulin is the primary regulator in carbohydrate homeostasis, as it controls blood glucose levels. Additionally, insulin regulates muscle tone, the uptake of amino acids

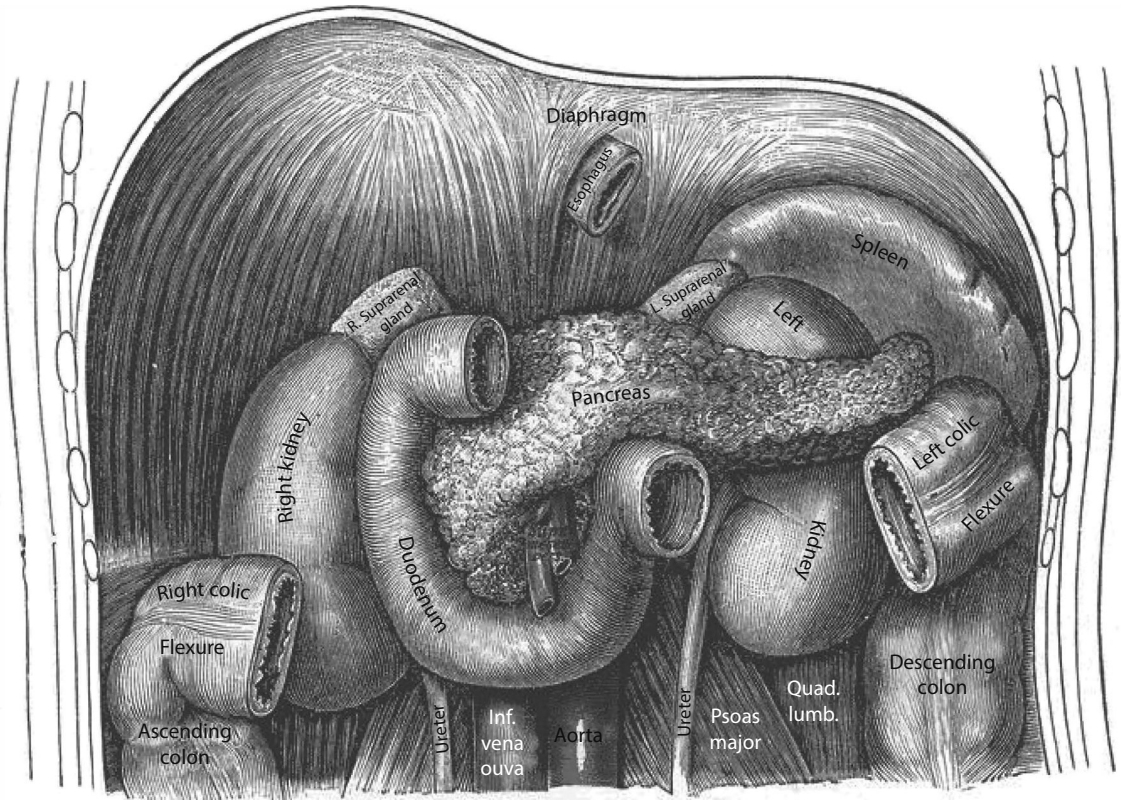

FIGURE 36.20 Anatomical relationship of pancreas to adjacent organs.

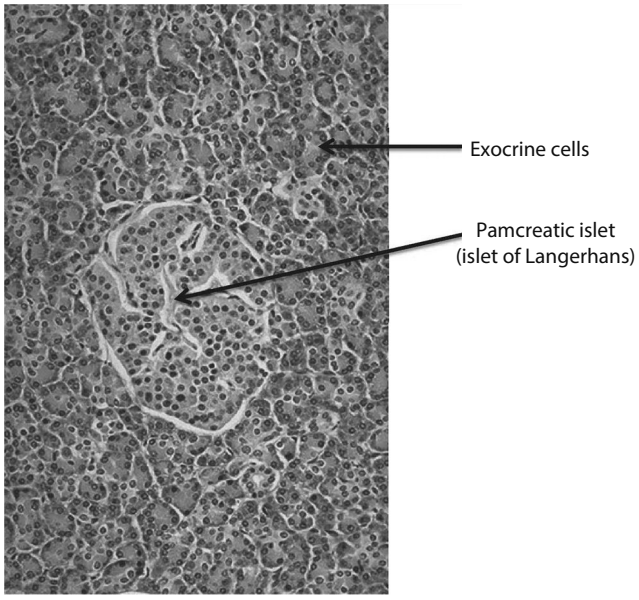

FIGURE 36.21 Histology of rat pancreas. Note the acini ducts (original magnification, 256×).

and electrolytes, and the release of triglycerides. By binding to specific hepatocyte receptors, glucagon also assists in the regulation of the level of glucose in the blood, resulting in (1) the release of stored glycogen as glucose into the bloodstream (termed *glycogenolysis*) and (2) the synthesis of additional glucose for release into the bloodstream (termed *gluconeogenesis*). Glucagon stimulates the release as well as the synthesis of glucose in response to hypoglycemia. These hormones are synthesized in the islets of Langerhans by α cells (glucagon) and β cells (insulin). Somatostatin is considered an inhibitory hormone that can retard the release of growth-hormone-releasing factor (GHRF), GH, TSH, insulin, and glycogen. It also suppresses the release of gastrointestinal hormones such as gastrin, CCK, secretin, motilin, gastric inhibitory polypeptide, and enteroglucagon and generally slows the rate of smooth muscle contractions and the flow of blood into the small intestine.

A concern when testing for toxicity is the potential for the agent to interfere with the normal functioning of the pancreatic β cells. The indicator that often alerts the toxicologist to a possible pancreatic side effect is hyperglycemia. Although this increased blood glucose level would usually be detected during routine clinical chemistry analyses, additional tests may be required to pinpoint specific pancreatic toxicity.

The interactions between insulin and carbohydrate, fat, and protein metabolism represent some of the complexities seen in diabetes mellitus. Hyperglycemia may result from impaired utilization of glucose by cells due principally to the insufficient production of insulin. The failure of glucose to penetrate adipose tissue mobilizes fat, producing a rise in the free fatty acid and triglyceride content of plasma and the triglyceride content of the liver. A diabetic fatty liver can occur from the absence of lipoprotein synthesis due to accelerated gluconeogenesis. If glucose oxidation is impaired, fatty acids form the major source of energy. This condition

generates an excess of intermediary metabolites, collectively described as ketone bodies (acetone, acetoacetic acid, and β-hydroxybutyric acid), which can lead to metabolic acidosis. Nitrosamine compounds, which are widely present in processed foods, and streptozotocin, a nitrosamine-related compound, have been shown to contribute to the pathogenesis of diabetic fatty liver.[269]

Hyperglycemia also can lead to the presence of glucose in the urine (glycosuria) when the blood glucose levels exceed the renal threshold of approximately 180 mg/dL. At lower levels, all the filtered glucose is normally reabsorbed by the renal tubules. Blood glucose levels increased to the point of glycosuria also can be caused by emotional stress and the concomitant release of glucose from liver glycogen in response to epinephrine. Several drugs can affect blood glucose levels and can either increase or antagonize glucose levels (Table 36.26). Glycosuria also can be the consequence of impaired renal tubular function caused by compounds such as the glycoside phlorizin.[270] Renal glycosuria can produce an osmotic diuretic effect that leads to dehydration and polydipsia. Glycogenolysis and gluconeogenesis are increased in diabetes mellitus, generating glucose, which in turn increases blood glucose levels.

Experimental diabetes mellitus can be produced by destroying β cell function with alloxan or streptozocin (Figure 36.22). In addition to chemically induced destruction of β cells by alloxan and streptozocin, these chemicals can be diabetogenic.[271,272] Alloxan, a cyclic urea analog, can produce permanent hyperglycemia in the rabbit. Streptozotocin, a methylnitroso–urea analog, has generally replaced alloxan to produce experimental insulin-dependent diabetes in laboratory animals. Both agents destroy pancreatic β cells, but

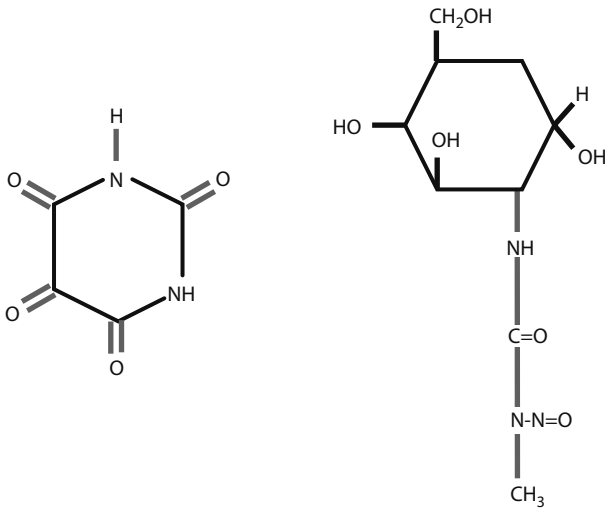

FIGURE 36.22 Agents that inhibit pancreatic insulin and glucagon secretion.

streptozotocin may involve the alkylation of critical cell components. Chlorozotocin, an analog of streptozocin, is lethal to β cells in culture. Vacor (pyriminil), cyproheptadine, and pentamidine are all capable of causing pancreatic dysfunction. Experimental animal models for diabetes mellitus may exploit genetic susceptibility (diabetes susceptible or diabetes resistant) (Table 36.27) or may involve the chemically induced destruction of β cells.[273]

Several inbred strains of mice are sensitive to *db* gene-induced diabetes, with sexual dimorphism in some inbred strains emphasizing the relationship between the obesity

TABLE 36.26
Interaction of Drugs with Oral Hypoglycemic Agents and Insulin

Enhanced Effect[a]	Antagonist Effect
Anabolic steroids	Acetazolamide (Acetamox and Acetazolam)
Chloramphenicol	Corticosteroids
Dihydroxycoumarin	Diuretics (e.g., chlorthalidone, ethracrynic acid, furosemide, thiazides, triamterene)
Ethanol	
Guanethidine	D-Thyroxine
K^+ salts	Epinephrine
MAO inhibitors	Marijuana
Oxytetracycline	Oral contraceptives (estrogen plus progestogen)
Phenylbutazone	Phenothiazines
Phenyramidol	Orinase
Probenecid	Diabinase
Propranolol	Barbiturates
Salicylates	Rifampin
Sulfinpyrazone	Laxatives (after protracted use)
Sulfonamides	Diazoxide

[a] Greater hypoglycemic action.

TABLE 36.27
Genetically Altered Rodents Used to Study Diabetes Mellitus

Diabetes-susceptible strains	
Mice	C57BLK/J
	DBA/2J
	SWR/J
	C3H.SW/SnJ
	C3HeB/FeCHp (males only)
	CBA/Lt (males only)
	NOD (IDDM)
Rats	BB(IDDM)
	BHE
	BHE/cdb
Diabetes-resistant strains	
Mice	C57BL/6J
	129/J
	Ma/MYJ

gene and sex. A major genetic regulator of inbred-strain diabetogenic sensitivity is gender related. In the rat, the Bureau of Home Economics (BHE) strain is an excellent animal model for the study of noninsulin-dependent diabetes mellitus (NIDDM). The Cdb:BHE stock is a subline of the parent BHE stock. The nonobese diabetic (NOD) mouse is an ideal animal model of insulin-dependent diabetes mellitus.[274] Spontaneous diabetes in the biobreeding (BB) rat, like human Type 1 diabetes mellitus, results from the destruction of the pancreatic islets by autoreactive T lymphocytes recognizing β-cell-specific antigens.

Chemical insult is not unique to the endocrine pancreas; indeed, many agents can cause acute pancreatitis (Table 36.28). Side effects resulting from a number of cytotoxic agents (e.g., colchicine), antibiotics (e.g., tetracyclines), antibacterial drugs (e.g., sulfonamides), and diuretics (e.g., thiazides) can produce irritation and inflammation of pancreatic cells, resulting in symptoms of severe epigastric pain radiating to the back, nausea, vomiting, diarrhea and loss of appetite, fever/chills, hemodynamic instability, which include shock, tachycardia, respiratory distress, and peritonitis.[276]

TABLE 36.28
Drugs Implicated in Acute Pancreatitis

Definite	Possible
Acetaminophen	Anticholinesterase
Azathiorine	Bumetanide
Cisplatin	Carbamazepine
Chlorthiazide	Chlorthalidone
Colaspase (L-asparaginase)	Chlorthalidone
Clozapine	Clonidine
Corticosteroids	Colchicine
Furosemide	Co-trimoxaz
Lisinopril	Cyclosporin
Sulfonamides	Cytarabine (cytosine arabinoside)
	Diazoxide
Tamoxifen	Enalapril
Tetracycline	ERCP contrast media
Thiazides	Ergotamine
Probable	Ethacrynic acid
Cimetidine	Isoniazid
Diazinon	Isotretinoin (13-*cis*-retinoic acid)
Estrogens	Mercaptopurine
Indomethacin	Methyldopa
Fonofos	Metronidazole
Mefenamic acid	Nitrofurantoin
Opiates	Oxphenbutazone
Pentamidine	Piroxicam
Phenformin	Procainamide
Valproic acid	Rifampicin
	Salicylates
	Sulindac

Measurement of Insulin

Although the RIA techniques that are available are similar with regard to the interaction between antigen and antibody, numerous variations exist in the methods for separating free insulin from antibody-bound insulin: gel filtration, salt precipitation, alcohol precipitation, precipitation with anti-gamma-globulin serum, and absorption on anion-exchange resin, cellulose, dextran-coated charcoal, antibody-coated tubes, or Sephadex-coupled antibodies. A radioreceptor assay has been developed for quantitation of plasma insulin levels.

Insulin in the specimen competes with a fixed amount of ^{125}I-labeled insulin for the binding sites of the specific insulin antibodies. Bound and free insulin are separated by adding a second antibody, centrifuging, and decanting. The radioactivity in the pellet is then measured. The radioactivity is inversely proportional to the quantity of insulin in the specimen.[277] This test is used to measure insulin levels in the bloodstream and is also useful in determining pancreatic β-cell activity.

Insulin plasma levels may also be determined by ELISA. The kit is a solid phase (ELISA) based on the sandwich principle. The microtiter wells are coated with an mAb directed towards a unique antigenic site on the insulin molecule. An aliquot of sample containing endogenous insulin is incubated in the coated well with enzyme conjugate, which is an anti-insulin antibody conjugated with biotin. The amount of bound complex is proportional to the concentration of insulin in the sample. Generally, ELISA has a number of drawbacks that preclude its routine use for the measurement of insulin, including a lower sensitivity than is seen with RIA. A hyperglycemic clamp can be used to assess insulin secretion and insulin sensitivity.[278] Insulin receptors can be isolated from a variety of sources, including placenta, rat liver plasma membranes, human lymphocytes, and guinea pig kidney.

Glucose Tolerance Tests

The oral glucose tolerance test (OGTT), useful for evaluating endocrine pancreatic function, is based on the compensatory regulation of blood glucose levels by insulin following the ingestion of a glucose load. A zero time (baseline) blood sample is collected. The glucose load is administered orally to a fasting patient; the intervals and number of blood samples vary according to the purpose of the test. If 50 g of glucose is taken orally by drink within a 5 min time frame, the blood glucose level rises rapidly for approximately 30–60 min and then falls rapidly to obtain fasting levels by 2–3 h. Fasting plasma glucose (measured before the OGTT begins) should be below 6.1 mmol/L (110 mg/dL). Fasting levels between 6.1 and 7.0 mmol/L (110 and 125 mg/dL) are borderline (impaired fasting glycemia), and fasting levels repeatedly at or above 7.0 mmol/L (126 mg/dL) are diagnostic of diabetes. The 2 h OGTT glucose level should be below 7.8 mmol/L (140 mg/dL). Levels between this and 11.1 mmol/L (200 mg/dL) indicate impaired glucose tolerance. Glucose levels above 11.1 mmol/L (200 mg/dL) at 2 h confirms a diagnosis of diabetes.[280]

In situations where the synthesis or release of insulin is insufficient, ingestion of the glucose load leads to an excessive rise in blood glucose levels, followed by a slow, gradual decline to preingestion levels. Abnormal glucose tolerance curves are evident in diabetes mellitus but may also be abnormal in other pathologic states. For example, elevated OGTT values can indicate any one of the following conditions or diseases: acromegaly, chronic renal failure, Cushing's syndrome, stress, hyperthyroidism, pancreatic cancer, pancreatitis, or the use of various drugs (e.g., tricyclic antidepressants, epinephrine, diuretics, and lithium). On the other hand, decreased OGTT response may indicate any one of the following conditions or diseases: adrenal insufficiency, liver disease, polycystic ovary syndrome, hypothyroidism, hypopituitarism, insulinomas, or the use of acetaminophen and anabolic steroids.[13] Glucose oxidase methods involving colorimetric reactions are routinely used to measure blood sugar. Capillary blood glucose can be used to monitor diabetes mellitus.[214]

Cytological Evaluation of Pancreatic Islet Cells

α and β cells can be differentiated using an aldehyde–fuchsin stain (Scott stain) following fixation of the tissue in Bouin's solution.[281] The α cells stain light, and the β cells stain dark (purple/black), permitting calculation of the ratio of α cell to β cells. Pseudoisocyanic staining permits direct demonstration of insulin in the β cells. The reaction involves the development of SO_2 groups formed by the oxidative splitting of the disulfide bridges of insulin with potassium permanganate. Organ culture techniques for studying pancreatic islets have been investigated.[282] The availability of suitably characterized dispersed islet cell preparations offers another in vitro test system to examine the effects of various drugs and chemicals on the pancreas.[283] mAb methods are also available to assay for islet cell antibodies.[284]

QUESTIONS

Essay

36.1 Briefly diagram and describe the HPG axis.

36.2 Outline the biosynthesis of thyroid hormones and the influence of TSH.

36.3 Describe factors that modulate secretions of the endocrine pancreas.

Multiple choice

36.4 Which serum protein(s) can specifically bind to hormones?
- a. SHBG
- b. CBG
- c. TBG
- d. All of the above

36.5 Which gonadal cell(s) produce testosterone?
- a. Germ cells
- b. Sertoli cells
- c. Leydig cells
- d. Endothelial cells

36.6 Suppression of ACTH occurs with
- a. Dexamethasone
- b. TSH
- c. Triiodothyronone
- d. None of the above

36.7 Destruction of pancreatic beta cells is most likely to occur following
- a. FSH administration
- b. Streptomycin
- c. PRL administration
- d. None of the above

36.8 Biosynthesis of adrenocortical steroids can be inhibited by
- a. Mitotane (*o*,*p*′-DDD)
- b. Aminogluthethimide
- c. Metyrapone
- d. All of the above

36.9 Castration can lead to the following endocrine modifications:
- a. Elevation of blood levels of FSH and LH
- b. Reduced levels of testosterone
- c. Atrophy of sex accessory organs
- d. All of the above

36.10 Infertility may be due to
- a. Failure to ovulate
- b. Reduced sperm count
- c. Absence of germinal epithelium
- d. All of the above

True/false

36.11 Monoclonal antibody techniques represent a very sensitive method for determining certain hormones.

36.12 Bioassays have largely been replaced by newer and more reliable hormone tests.

ACRONYMS AND ABBREVIATIONS

3β-HSD	3β-Hydroxysteroid Dehydrogenase
ASDN	1β-Androstenedione
ACTH	Adrenocorticotropic hormone (Corticotropin)
AhR	Aryl hydrocarbon receptor
AND	Androstenedione
AVP	Arginine vasopressin
CD molecules	Cluster of differentiation molecules
CG	Chorionic gonadotropin
CRH	Corticotropin-releasing hormone
CRH-BP	Corticotropin-releasing hormone binding protein
cRNA	Antisense RNA
DEST	Data entry spreadsheet template
DHEA	Dehhydroepiandrosterone
DHEAS	DHEA sulfate
DER	Data evaluation record
DES	Diethylstilbestrol
DIT	Diiodothyronine
E2	Estradiol

E3	Estriol
EAT	Estrogen, androgen, and thyroid
ED	Endocrine disruptor
EDC	Endocrine disrupting chemical
EDSP	Endocrine disruptor screening program
EDSTAC	ED Screening and Testing Advisory Committee
ELISPOT	Enzyme-linked immunosorbent spot assay
EMIT	Enzyme-multiplied immunoassay technique assay
EPA	U.S. Environmental Protection Agency
ER	Estrogen receptor
ERE	Estrogen-responsive element
FD&C	Federal Food, Drug, and Cosmetic Act
FISH	Fluorescence in situ hybridization
FSH	Follicle-stimulating hormone
FSHR	Follicle-stimulating hormone receptor
GC	Glucocorticoid
GHRH	Growth-hormone-releasing hormone
GH	Growth hormone
hCG	Human chorionic gonadotropin
HHPS	Hypothalamo-hypophysial portal system
HRP	Horseradish peroxidase
HPA	Hypothalamus–pituitary–adrenocortical
HPG	Hypothalamo–pituitary–gonadal
HPI	Hypothalamic–pituitary–interrenal
HPT	Hypothalamo–pituitary–thyroidal
IRMA	Immunoradiometric assay
LH	Luteinizing hormone
LHR	Leutinizing hormone receptor
mRNA	Messenger ribonucleic acid
MT TATA	Mouse metallothionein (MT) promoter TATA element
OCSPP	Office of Chemical Safety and Pollution Prevention
o,*p*-DDD	*o*,*p*′-Dichlorodiphenyldichloroethane
P4	Progesterone
PACAP	Pituitary adenylate cyclase–activating polypeptide
PCR	Polymerase chain reaction
PRL	Prolactin
PTH	Parathyroid hormone
PVDF	Polyvinylidenefluoride
qPCR	Quantitative polymerase chain reaction or real-time polymerase chain reaction
qRT-PCR	Quantitative real-time polymerase chain reaction
RIA	Radioimmunoassay
rRNA	Ribosomal RNA
RNA-seq	RNA-sequencing
RRT-PCR	Real-time reverse transcription polymerase chain reaction
RT-PCR	Reverse transcription polymerase chain reaction
SAGE Assay	Serial analysis of gene expression assay
SEP	Standard evaluation procedure
SHBP	Sex-hormone-binding protein
snRNA	Small nuclear RNA
SRIF	Somatotropin-release-inhibiting factor
STTA	Stably transfected transcription activation
T_3	Thyroid hormone (triiodothyronine)
T_4	Thyroid hormone (thyroxine)
TA	Transcription activation
TD	Thyroid disruptor
TG	Thyroglobulin
TGB	Thyroid-binding globulin
TR	Thyroid hormone receptor
TRH	Thyrotropin-releasing hormone
TRHR	Thyrotropin-releasing hormone receptor
tRNA	Transfer RNA
TSH	Human thyrotropin
V1aR	Vasopressin-1
WTSS	Whole transcriptome shotgun sequencing
ZF	*Zona fasciculata*
ZG	*Zona glomerulosa*
ZR	*Zona reticularis*

37 Immunotoxicology
The Immune System Response to Toxic Insult

Robert V. House, Michael I. Luster, Jack H. Dean, and Victor J. Johnson

CONTENTS

INTRODUCTION

The immune system is a complex multicellular organ system consisting of granulocytes, macrophages, lymphocytes, and dendritic cells with various functions and phenotypic characteristics, as well as various soluble mediators. These cells are of hemopoietic origin and, in adults, are found in the peripheral blood, lymphatic fluid, and organized lymphoid tissues, including bone marrow, spleen, thymus, lymph nodes, tonsils, and mucosa-associated lymphoid tissue (MALT). The immune system is in a constant state of self-renewal involving cell proliferation, differentiation, activation, and maturation. It exists to defend the body against invasion by infectious and opportunistic microorganisms and spontaneously arising neoplasia. This network of cells and soluble factors is highly regulated and interdependent, must discriminate self from nonself, and can react to nonself with many different (pleiotropic) defensive responses [1]. In addition, this immune system occasionally develops an unwanted response to a chemical or its metabolite that binds to or alters a host protein resulting in allergy or autoimmune disease. The immune system of experimental animals, while exhibiting some obvious differences from that of humans, is still sufficiently similar that data obtained from lower species are instructive of a potential human response [2].

IMMUNE MECHANISMS RESPONSIBLE FOR HOST DEFENSE

The host defense functions of the immune system are provided by two major arms: an innate arm that does not require prior sensitization with the inducing foreign agent to elicit a response and an adaptive arm directed against the eliciting agent to which the individual has been previously sensitized. Penetration of the skin or mucosal defense barriers by an invading material results in nonspecific reactions by phagocytic cells (granulocytes and macrophages [MØ]). If the microorganism is not controlled and persists, specific responses involving antibody production and the induction of effector lymphocytes follow. The effector lymphocytes respond through cytokine mediators to seek out and destroy the invading microorganism. Both antibody-producing lymphocyte responses (B-lymphocytes or B-cells) and thymus-dependent lymphocyte responses (T-lymphocytes or T-cells) are triggered by the presentation of foreign antigen to appropriate lymphocytes by dendritic cells, MØ, or other antigen-presenting cells (APCs). Following antigen-induced activation, B-cells proliferate and differentiate into plasma cells (PCs), with the support of T-helper 2 (Th2) cells, and produce large quantities of antigen-specific immunoglobulins (antibodies). Antibodies enter the plasma where they bind the foreign material and either neutralize, lyse, or facilitate phagocytosis of the agent. Antibody–antigen interactions are expanded by actions of the complement (C′) system and other inflammatory mediators (e.g., prostaglandins and leukotrienes). With the support of Th1 cells, another population of T-cells, referred to as cytotoxic T-cells, proliferate and recognize virally infected cells that they can destroy these cells before viral replication can occur.

Innate and Adaptive Mechanisms of Immunity

Two categories of phagocytic leukocyte, the polymorphonuclear phagocyte (PMN) or granulocyte and the mononuclear phagocyte or MØ, are involved with nonspecific mechanisms of host resistance. Both cell types originate from myeloid progenitor cells in the bone marrow and normally pass through several maturation stages before entering the bloodstream. PMN readily traverses blood vessels and provides the primary defense against infectious agents. The inflammation associated with a splinter is typical of a nonspecific PMN and MØ response. Both PMN and MØ exhibit phagocytic activity toward foreign material, especially MØ in the presence of specific opsonic antibodies and C′, and can destroy most microorganisms. MØ is recruited to the site in the event that PMN either cannot contain or is destroyed by the infectious agent, as is the case with certain bacteria (e.g., Listeria). MØ can be activated to a state of enhanced bactericidal or tumoricidal activity by soluble lymphocyte products (e.g., cytokines) produced by T-lymphocytes sensitized to the invading microbe.

The immune responses that characterize adaptive host defense represent a series of complex events that occur following the introduction of foreign antigenic material into the body. There are two major types of specific immune response: *cell-mediated immunity* (*CMI*), which is initiated by specifically sensitized T-cells and is generally associated with delayed-type hypersensitivity (DTH), rejection of

tumors or foreign grafts, and resistance to viral agents, and *humoral immunity* (*HI*), which involves the production of antibodies by PC following sensitization to a specific antigen and is important in resistance to extracellular pathogens.

Organization, Differentiation, and Function of Primary Lymphoid Tissue

The cellular elements of the immune system arise from *pluripotent stem cells*, a unique group of unspecialized cells that have self-renewal capacity. These cells are found in the blood islands of the embryonic yolk sac and in the liver of the fetus during fetal development and later in the bone marrow. The pluripotent stem cell differentiates along several pathways, giving rise to erythrocytes, myeloid series cells (i.e., MØ and PMN), megakaryocytes (platelets), or lymphocytes. Maturation generally occurs within the bone marrow, although lymphoid progenitor cells are disseminated through the blood and lymphatic vessels to the primary lymphoid organs where they undergo further differentiation under the influence of the humoral microenvironment of these organs (Figure 37.1).

The *primary lymphoid organs* include the *thymus* in all vertebrates and the bursa of Fabricius (in birds) or *bursa-equivalent tissue* in other vertebrates; the latter is believed to be bone marrow and gut-associated lymphoid tissue (GALT) in mammals (Table 37.1). Primary lymphoid organs are lymphoepithelial in origin and are derived from ectoendodermal junctional tissue in association with gut epithelium. During the beginning of the second half of embryogenesis (days 12–13 in the mouse), stem cells migrate into the epithelia of the thymus and bursa-equivalent areas, where they differentiate independently of antigenic stimulation into immunocompetent T- and B-cells, respectively (Figure 37.1). The thymus, which is derived embryologically from the third and fourth pharyngeal pouches, is an organization of lymphoid tissue located in the chest, above the heart. Thymus development occurs during the 6th week of embryological development in humans and day 9 of gestation in the mouse. The thymus reaches its maximum size at birth or shortly thereafter in most mammals and then begins a slow involution that is complete between the ages of 5 and 15 years in humans.

Histologically, the thymus consists of multiple lobules, each lobule containing a cortex (outer) and a medulla (inner) (Figure 37.2). Lymphocyte precursors from bone marrow proliferate in the cortex of the lobules and then migrate to the medulla. In the medulla, they further differentiate, under the influence of the thymic epithelium and hormonal factors, into mature T-lymphocytes before emigrating to secondary lymphoid tissues. The neonatal/postnatal thymus has a significant endocrine function supported by nonlymphoid thymic epithelium cells. These cells produce a family of thymic hormones essential for T-lymphocyte maturation and differentiation. In contrast, B-cell differentiation occurs in the bursa of Fabricius in birds, a lymphoepithelial organ that develops from a diverticulum of the posterior wall of the cloacae. The thymus is divided into a medullary region, containing lymphoid follicles and a cortical region (Figure 37.2). The mammalian bursa equivalent is believed to be the fetal liver, neonatal spleen, GALT, and adult bone marrow, depending on age. Mature B-lymphocytes migrate from the bursa-equivalent tissue to populate the B-dependent areas of the secondary lymphoid tissues.

Neonatal removal or chemical destruction of primary lymphoid organs prior to the maturation of lymphocytes into T- or B-cells, or prior to their population of secondary peripheral lymphoid tissue, dramatically depresses the immunological capacity of the host. However, removal of these same organs in adults has little influence on immunological capacity. In addition, neonatal thymectomy in mammals dramatically impairs the development of CMI but does not generally influence the generation of immunoglobulin-producing cells involved in antibody-mediated immunity (unless they strictly require T-lymphocytes help for the induction of antibody production). In contrast to the removal of primary lymphoid organs, removal of secondary lymphoid organs does not inhibit the development of immune competence, although it may suppress the magnitude or alter the tissue location of the responsive cells.

Organization and Function of Secondary Lymphoid Tissue

The organization and function of secondary lymphoid organs is extremely important for immune competence and host defense (Table 37.1). The organized areas of secondary lymphoid tissue are the spleen, lymph nodes, GALT, and bronchus-associated lymphoid tissue (BALT). The anatomical organization of these tissues provides a microenvironment for functional development of lymphoid cells and vital immune responses.

Lymph nodes are discrete, organized secondary lymphoid organs that serve as filtering devices for lymphatic fluid [3]. Lymph nodes are divided structurally into three areas—cortex, paracortex, and medulla (Figure 37.3)—and are served by several afferent lymphatic vessels that collect lymphatic fluid (lymph) from distal tissue sites. Since lymph may contain foreign antigens, the efferent lymphatic vessel, which drains lymph from the node, contains antibodies, cytokines, and lymphocytes produced in response to foreign antigenic stimulation occurring within the node. The cortex, located underneath the subcapsular sinus, receives the afferent lymph and serves as the major site of B-lymphocyte localization. The cortex consists of a narrow rim of small lymphocytes in the absence of antigenic stimulation. Also located in the cortex are aggregations of small lymphocytes, termed lymphoid follicles, which contain dendritic reticulum cells capable of retaining antigens on their plasma membranes. When lymphocytes within the lymphoid follicles are stimulated by antigens, they proliferate, giving rise to dense aggregations of lymphocytes, termed *germinal centers*. These germinal centers serve as sites for differentiation of B-lymphocytes into PC capable of antibody production. Following antigenic stimulation, germinal centers are easily detectable as spherical or ovoid structures containing many large- and medium-sized lymphocytes, predominantly B-lymphocytes. The paracortex, lying between the cortex and the medulla, is composed predominantly of T-cells and

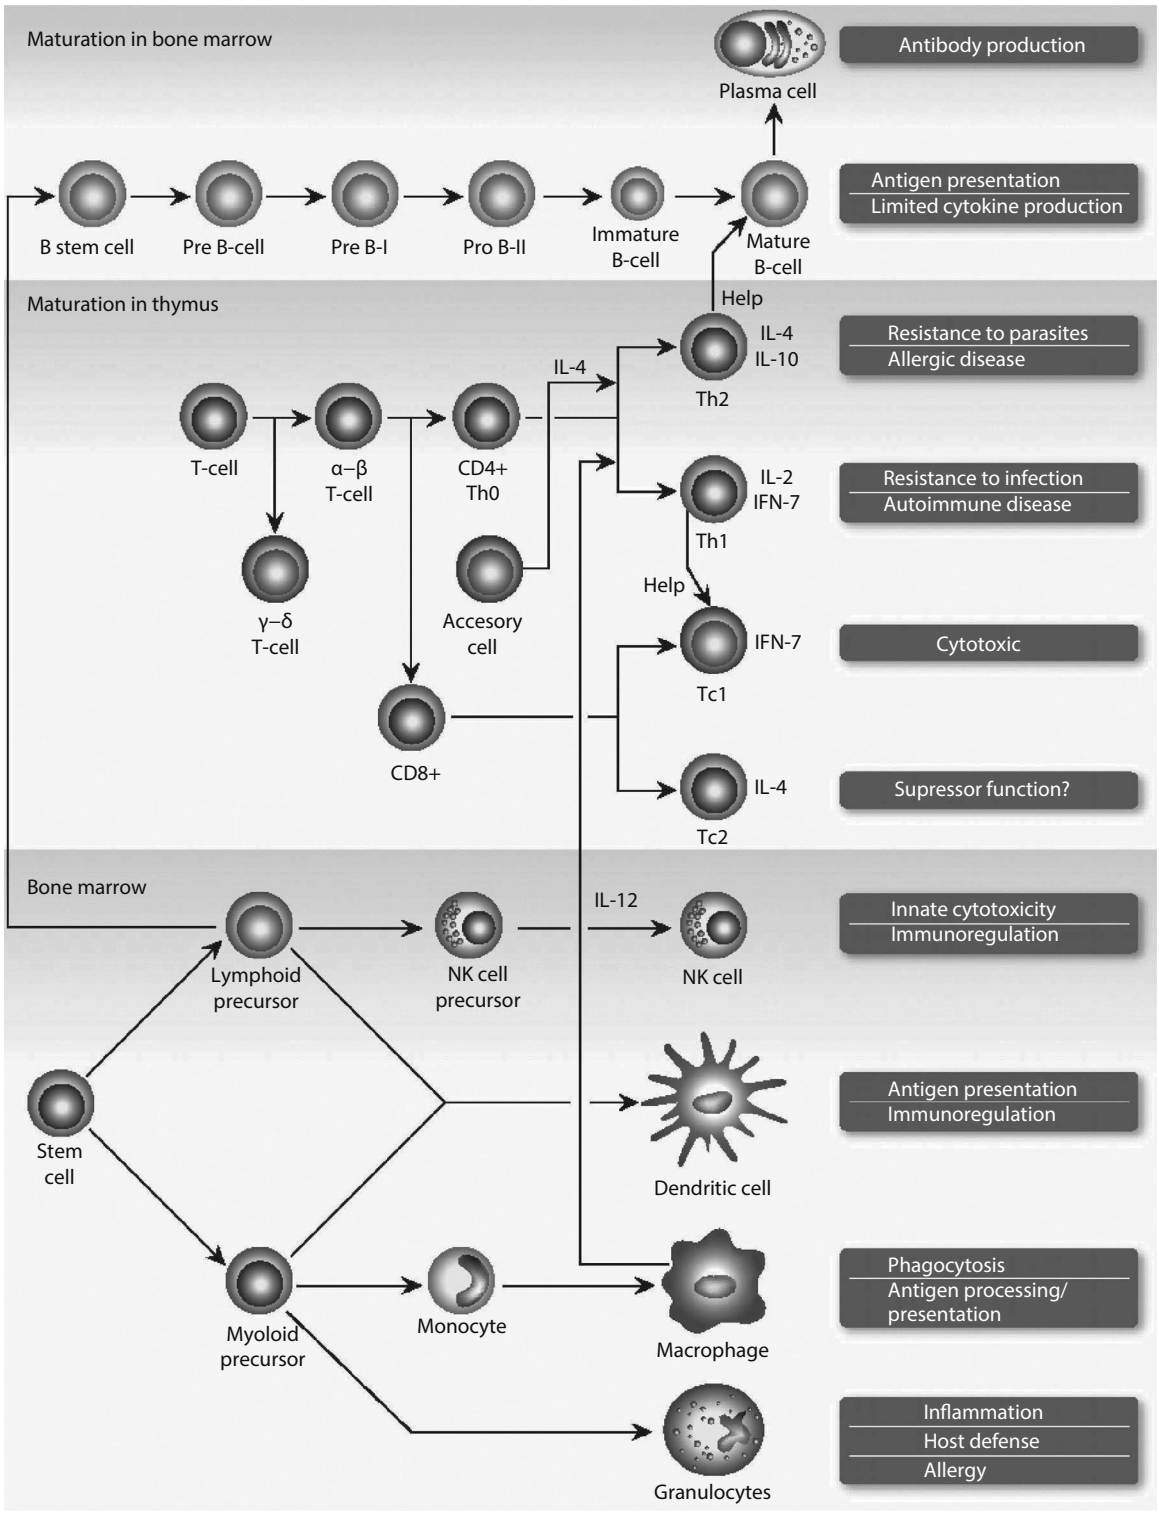

FIGURE 37.1 Origins and interactions of cells of the immune system.

is a major site of MØ and T-cell interaction. Neonatal thymectomy or lymphocyte depletion by cytolytic drugs reduces the production of paracortical lymphocytes, leading to depressed immune capacity. In addition, the paracortex contains a specialized blood vasculature, termed postcapillary venules, that serves as a point of entry for recirculating lymphocytes from the bloodstream. The medulla of the lymph node is composed primarily of networks of cords and sinuses; it serves as an effective filter for removing particulate material from lymphatic fluid. Following antigenic stimulation, the majority of antibody that is produced comes from the PC found within these medullary cords of the nodes.

TABLE 37.1
Organization and Characterization of Primary and Secondary Lymphoid Organs

Primary Lymphoid Organs	Secondary Lymphoid Organs
Thymus	Spleen
Bursa of Fabricius (avians)	Lymph nodes
Fetal liver (mammals)	GALT
Adult bone marrow	BALT
Origin: ectoendodermal junction	Origin: mesoderm
Thymus: days 9–10 in mouse; week 6 in man	
Bursa equivalent: days 10–13, mouse; week 10, man	
Independent of antigenic stimulation	Dependent on antigenic stimulation
Function: generation and maturation of cells	Function: expansion of cells after antigenic stimulation
Stem cells only	Differentiated lymphocytes
Effect of depletion: persistent effect if stem cells targeted	Effect of depletion: likely to regenerate

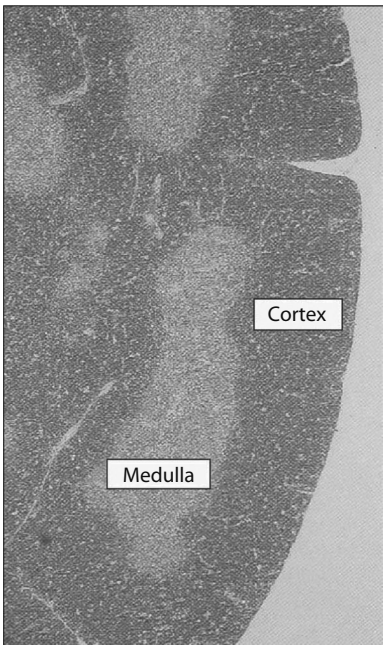

FIGURE 37.2 Histology of the thymus. Photomicrograph of a rat thymus with a densely populated cortex and a less densely populated medulla (H&E-stained section).

The spleen is the major filter of blood-borne antigens and the site of immunological response to these antigens [4]. In addition, the spleen is a site of extramedullary hematopoiesis (nonbone marrow–red blood cell production) and responsible for the removal of damaged blood cells. There are two major histological regions within the spleen: the red pulp and the white pulp containing IgM-staining B-cells and T-cells (Figure 37.4a and b). These areas have been named for their

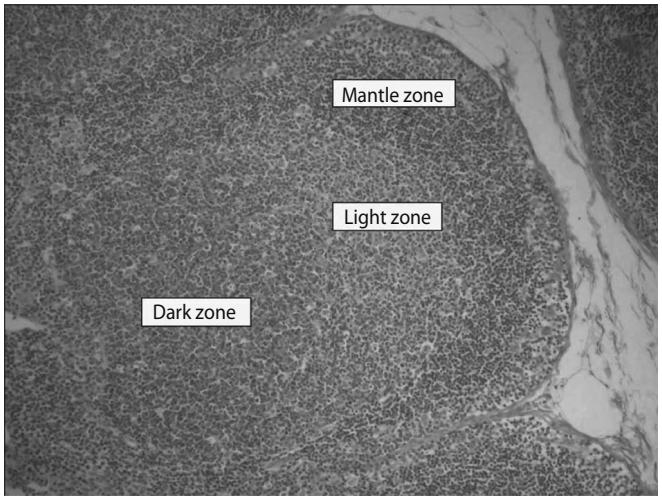

FIGURE 37.3 Histology of the lymph node. Photomicrograph of a rat lymph node showing a secondary lymphoid follicle including a mantle zone and a germinal center with a dark and light zones (H&E-stained section).

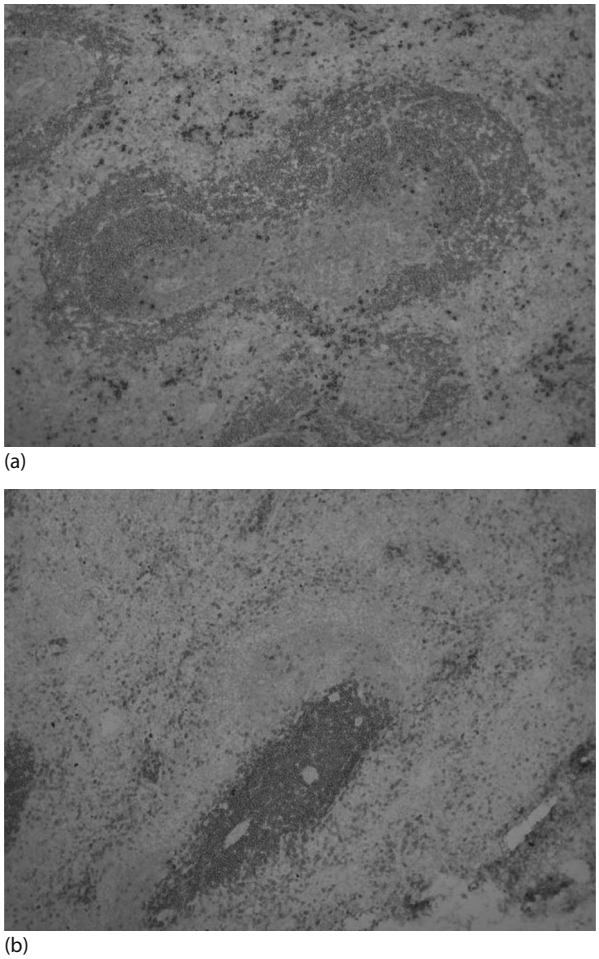

FIGURE 37.4 Histology of the spleen. (a) Photomicrograph of rat spleen showing IgM staining cells (original magnification, 50×). (b) Photomicrograph of rat spleen showing T-lymphocytes stained with immunoconjugated antibody (original magnification, 50×).

colors in a freshly cut spleen. The white pulp consists of numerous white blood cell aggregates and lymphoid follicles. The red pulp contains cords and venous sinuses analogous to the medullary region of lymph nodes. The spleen has no afferent lymphatic vessels; and thus, all antigenic material or cells enter the spleen through the blood vasculature. The marginal sinus in the spleen is structurally and functionally similar to the subcapsular sinus of the lymph node.

IMMUNE FUNCTION AND RESPONSES

Bone Marrow

The bone marrow functions as a primary lymphoid organ and serves as the principal source of uncommitted stem cells, including both myeloid and erythroid precursor cells. The bone marrow architecture is highly organized and complex, consisting of a matrix or cellular stroma derived from local mesenchymal cells, as well as cells of hemopoietic parenchyma that are descendants of circulating stem cells. The bone marrow matrix consists of reticular-dendritic cells, fibroblast-like cells, and immune cells within the bone marrow microenvironment.

Bone marrow stem and stromal cells have been shown to possess a significant capacity for metabolic activation because they contain cytochromes of the P450 and P448 families as well as peroxidases and can generate reactive oxygen species, which could also activate xenobiotics via oxidant-dependent mechanisms [5]. This metabolic activity is thought to contribute to the sensitivity of bone marrow elements to toxicants such as benzene, which is extensively metabolized within the bone marrow. In light of the cell proliferation and differentiation occurring within the marrow, this tissue is also one of the most sensitive tissues to drugs or chemicals affecting cell division. Dose-limiting bone marrow toxicities are a significant problem with antiproliferative drugs including cytotoxic agents, antifolates, AIDS therapeutics, and certain cytokines [6,7].

Mononuclear Phagocytic System

Whether an antigen induces CMI, antibody production, or both depends on the physical and chemical characteristics of the antigen, the mode of presentation of the antigen to lymphocytes, the pattern of antigen distribution within lymphoid tissue, and the molecular configuration of the antigen. In many instances, antigen is initially phagocytized and processed by APC. Antigenic peptides are transported to the cell surface, where they are presented to lymphocytes through cell surface interactions via specific surface proteins (e.g., class II molecule antigens).

Cells of the MØ/monocyte lineage are found in many tissues, including liver (Kupffer cells), lung (alveolar and interstitial MØs), skin (Langerhans cells), and brain (astrocytes and microglia). These cells, because of their proximity to portals of entry, are often the first cells to interact with drugs, chemicals, and physical agents entering the organism via air, food, or blood. The capacity of cells of the mononuclear phagocytic system (formerly known as the reticuloendothelial system) to carry out these functions is associated with their state of activation, which in turn is a function of both endogenous (e.g., interferon gamma [IFN-γ]) and exogenous (e.g., bacterial lipopolysaccharide [LPS]) stimuli. Responsive MØ obtained from the peritoneal cavity is relatively quiescent and requires extracellular signals or *priming*, followed by a second signal induced by triggers such as LPS to be fully activated.

Although the mononuclear phagocyte system is designed to protect the host, once a xenobiotic has gained entry, extensive and/or persistent tissue damage can result mediated, in part, by MØ products. Silicosis and asbestosis are two examples of diseases where MØ mediators are involved in the pathology [8]. In this condition, tissue damage from an environmental or infectious agent results in the influx of phagocytic cells mainly PMNs. In most instances, these cells effectively eliminate the agents by digesting them in internal vacuoles. However, if the foreign material persists (as, e.g., silica crystals or asbestos fibers), a chronic inflammatory process ensues in which PMNs are replaced by monocytes/MØ as the predominant effector cells. These cells release a variety of active molecules (cytokines, nitric oxide, amines, lipid mediators, etc.) that damage tissue, as well as recruiting other inflammatory cells into the local environment. This sometimes leads to the development of a granuloma, a collection of inflammatory cells surrounded by fibrotic tissue [9].

Humoral Immunity

The principal function of B-lymphocytes is production of specific antibody in response to antigenic stimulation. B-cells recognize antigen via a specific receptor, comprising membrane immunoglobulins associated with accessory proteins either directly or in the presence of an APC. Binding of the receptor with its cognate antigen triggers transmembrane signaling leading to activation of the B-cell. The antigen is subsequently internalized, where it is processed and associated with class II major histocompatibility complex (MHC) molecules. Antigen-derived peptides, along with MHC proteins, are then transferred to the cell surface where they are free to interact with helper T-cells.

Within 3–5 days following antigen exposure, this T-/B-cell interaction results in the B-lymphocytes differentiating into blast cells, then into immature PC, and finally into antibody-secreting PC. The establishment of HI is characterized by an early rise in IgM antibody titer in the serum, followed several days later by the appearance of IgG antibodies. During this differentiation process, some of the lymphocytes develop into long-lived or memory cells (sensitized but nonblast cells), so that subsequent antigen encounters result in an enhanced (secondary) response. This secondary response is characterized by a shorter latency for antibody appearance, as well as an increased affinity and synthesis of IgG antibodies. Antibody molecules react with specific antigenic determinants (epitopes) on their target, facilitating its removal (e.g., lysis or enhanced phagocytosis).

TABLE 37.2
Biological Properties of Mammalian Immunoglobulin Classes

Class	Serum Concentration (mg/dL)	Molecular Weight	Placental Transfer	Half-Life (Days)	Biological Function	Abnormalities
IgG	670 ± 33	150,000	+	23	Primarily synthesized during secondary immune response. Readily diffuses into extra vascular tissue. Fixes complement	Increased in liver disease chronic infection. Reduced in B-cell depression
IgM	61 ± 5	890,000	—	5	Produced early in immune response. Isoagglutinins. Fixes complement	Increased in infection. Reduced in B-cell depression
IgA	40 ± 4	170,000	—	6	Major Ig in seromucous secretions	Increased in liver disease. Increased or decreased in sinopulmonary infection
IgD	—	150,000	—	2.8	Lymphocyte receptor	Decreased following thymectomy
IgE	0.02	196,000	—	1.5	Mediator of allergic reactions and atopic diseases	Increased in parasitic and allergic diseases, homocytotropic

Based on chemical structure and biological function, the five classes of antibody molecules in mammals are IgM, IgG, IgA, IgD, and IgE; some of the physical and biological characteristics of each of these classes are listed in Table 37.2. Antibodies operate via several mechanisms to protect the host from infectious agents. Some of these mechanisms include virus neutralization, in which antibodies bind and prevent virus particles from infecting target cells; opsonization, the process by which antibody molecules react with infectious agents and thus enhance their phagocytosis; and antibody-dependent cellular cytotoxicity, the process whereby antibody-coated target cells are killed by Fc receptor–bearing lymphocytes.

Of increasing interest is the concept that naturally occurring IgM antibodies (i.e., antibodies that are secreted in the absence of antigen stimulation) may play an important role in immune surveillance against neoplasia [10,11]. This concept has not as yet been explored in the context of immunotoxicology but may be a contributory factor in decreased resistance to tumors following immunotoxic insult.

Cell-Mediated Immunity

CMI, often referred to as T-CMI, refers broadly to any host resistance mechanism in which cellular elements play a direct role and are part of the acquired arm of immunity. This is in comparison to HI in which there are certainly cellular interactions but in which the final host resistance products are soluble factors such as an antibody. There are a number of host defenses mediated directly by cells including MØ-mediated cytolysis, antibody-dependent cellular cytotoxicity, and natural killer (NK) cell cytotoxicity although cytotoxic T-lymphocytes (CTLs) usually predominate, particularly in the destruction of virus-infected cells.

Functions associated with CMI are commonly considered the province of T-lymphocytes, although immune cells (e.g., B-cells and MØ) as well as nonimmune cells (e.g., fibroblasts and dendritic cells) contribute to the development of CMI. As the primary effector cell in CMI, the T-cell represents one of the most complex and multifunctional immune cells. Antigens that generally elicit CMI include tissue-associated antigens, chemicals, and drugs that covalently bind to autologous proteins and antigenic determinants on persistent intracellular microorganisms. The route of exposure also plays a major role in the type of response generated. For example, sheep erythrocytes elicit antibody production (but not CMI) when injected intravenously in humans but elicit both when injected intracutaneously. The induction of CMI proceeds when small lymphocytes differentiate into large pyroninophilic cells and ultimately divide, giving rise to cells responsible for effector function as well as immunological memory. In contrast to HI, which is more effective against extracellular pathogens, CMI helps protect against intracellular bacteria, viruses, and neoplasia and is responsible for graft rejection.

T-cells can differentiate into populations responsible for either regulatory or effector function. For example, regulatory and inducer T-cell functions are provided by CD3/CD4 positive T-helper cells. T-helper function facilitates antibody responses by B-cells and assists in other T-cell responses. For most antigens, B-cells require assistance from T-cells for differentiation into PC. T-helper cells are integral in the B-cell response by participating in two distinct mechanisms: major histocompatibility locus–restricted B-/T-cell collaborations and cytokine-mediated differentiation. Helper function is a result of interactions between surface molecules on T-helper cells and B-cells, as well as the production and secretion of immunoregulatory cytokines.

Effector functions take the form of cytotoxic activity (CD3/CD8 phenotype), manifested by CTL. These cells are able to specifically lyse target cells via the release of various bioactive molecules. Another effector function is the ability of T-cells to mediate suppressor activity for both

T- and B-cell responses. Suppressor activity is also mediated by cells bearing the CD3/CD8 phenotype, although recent studies suggest that this activity may be the result, at least in part, of differential cytokine production by this population (Figure 37.1). This responsibility for both helper and suppressor activities indicates the crucial role of T-cells in normal immune function.

T-Helper 1/T-Helper 2 Cell Paradigm

An important conceptual breakthrough in immunology was the finding that two major populations of T-helper cells exist that have different, sometimes opposing, functions. Mosmann et al. [12] first established the concept by demonstrating that cloned murine T-cells exhibited differential patterns of cytokine production. One population, designated T-helper-1 (Th1)-type cells, was found to produce interleukin-2 (IL-2), IFN-γ, and lymphotoxin. The second major population (designated Th2 cells) produces IL-4, IL-5, IL-10, and IL-13. Both populations of T-cells produce IL-3, granulocyte–macrophage colony-stimulating factor (GM-CSF), and tumor necrosis factor (TNF). Later, a third population, Th0, was described and was found to exhibit an intermediate pattern of cytokine production. These cells are less well defined but may be an early precursor of Th1 and Th2, or alternatively, they may represent an intermediate stage in development of the other two populations.

Although there were initial doubts that human T-cells followed this paradigm, it is now known that a similar paradigm exists for human T-cells [13]. The major differences appear to be in the profile of cytokine production, cytokine response (e.g., human Th1 and Th2 proliferate in response to IL-4, while only Th2 cells proliferate in the presence of IL-4 in rodents), and cytolytic potential. Despite these differences, the human and rodent systems are similar enough to make experimental rodent models meaningful for understanding the human immune response.

Recent studies suggest that Th1 and Th2 cells may not necessarily represent distinct lineages descending from a common precursor but rather may be seen as points in a continuum. For example, development of each population is influenced by type, location, and concentration of eliciting antigen. More important may be the cytokine milieu (Figure 37.1). For example, the cytokines IL-12 and IFN-γ-inducing factor (from MØ) and IFN-γ (from NK cells) drive the development of Th1 cells, whereas IL-4 (from the ill-defined *T-accessory* cell, mast cells, or other sources) drives the development of Th2 cells [14]. Interestingly, IL-4-driven development of Th2 appears to take precedence over IL-12-induced Th1 production; this may have ramifications in the etiology of some disease states.

The Th1/Th2 paradigm is important for immunotoxicology in that certain immunopathology has been associated with the predominance of one helper cell type over another, particularly in human disease states. For example, Th1 polarization has been associated with organ-specific autoimmune diseases such as multiple sclerosis and Hashimoto's thyroiditis, whereas systemic autoimmune conditions such as rheumatoid arthritis and Sjogren's syndrome lack a clear T-cell polarization [15]. On the other hand, strong Th2-type responses appear to result in many hypersensitivity disorders, including asthma. The extent to which cytokine polarization contributes to these pathologies, as opposed to being a sequel of other mechanisms, remains to be elucidated. It is possible, however, that assignation of Th1/Th2 patterns may eventually become much more important when designing and performing mechanistic immunotoxicology studies [16].

Natural Killer Cells

NK cells are a population of non-B-, non-T-lymphocytes that exhibit cytotoxicity toward a variety of target cells, including tumor cells and virally infected cells. NK cells express a unique panel of cell surface markers (e.g., asialo GM1) and are morphologically distinct, being larger than other lymphocytes. In addition, they contain numerous granules, leading to their designation as large granular lymphocytes (LGLs) [17,18]. Unlike CMI, NK cell–mediated cellular cytotoxicity is MHC-unrestricted and does not require prior exposure to the target.

NK cells have been seen principally as mediators of so-called immune surveillance [19], resulting in the concept of a constant removal of spontaneously arising neoplastic cells [20,21]. In fact, the standard methodology for assessing NK cell function relies upon the in vitro lyses of tumor target cells. However, NK cells are more likely to play a role in resisting the progression and metastatic spread of tumors once they develop, rather than preventing initiation [22].

In contrast to previous models in which NK cells were considered independent of the acquired immune response, recent studies have revealed an important role for these cells in the induction and regulation of acquired immunity [23–25]. NK cells respond to, and produce, key immunoregulatory cytokines and thus play an important role in the normal immune response. In fact, studies of individuals with NK cell deficiency states, most of which are associated with single-gene mutations, have helped identify a role for NK cells in the defense against human infectious disease. A resounding theme of NK cell deficiencies is susceptibility to herpes viruses [26–28].

Related to NK cells are the NKT cells, a population of CD1d-positive lymphocytes that exhibit properties of both NK cells and T-cells [29,30]. These cells appear to have primarily immunoregulatory functions and serve in the coordination of functions between the innate and adaptive immune responses [31]. To date, this cell population has not been a target of immunotoxicology assessment, although it is conceivable that these cells would be as likely a target as NK cells. Moreover, NKT cells have been associated with immunotoxicologically important endpoints including resistance to infection and autoimmunity [32,33].

Other Immunoregulatory Circuits

Cytokines

Cytokines are glycoproteins that are generally produced in response to cellular activation. Most cytokines studied have multiple and overlapping actions, and they frequently function via cascading mechanisms referred to as the cytokine network, interacting with each other both synergistically and antagonistically. Two important features of cytokines are that they usually act at a local level and they are rapidly cleared from the circulation. This combination of features helps ensure that cytokines remain compartmentalized, undoubtedly an important consideration given the potent bioactivity of these molecules [34,35].

Cytokines serve as immune system mediators and regulators. They are produced predominantly by T-helper lymphocytes but are not exclusive to the immune system. In fact, some cytokines are phylogenetically ancient and highly conserved. Furthermore, both IL-1 and TNF are intrinsically involved in apoptosis and cellular proliferation, both fundamental biological processes. Thus, cytokines should be recognized for their role as conveyers of bioinformation, rather than as simple effector molecules involved in a single physiological process such as immunity and host resistance. For convenience, cytokines may be grouped into several classes (Table 37.3). These classifications are necessarily arbitrary due to the overlapping activity of these molecules.

Chemokines

Another related group of molecules is the chemokines. Chemokines are small peptide molecules that, like cytokines, were originally associated with the immune system but which now are recognized as being produced by almost all cells of the body and involved in a multitude of biological functions (Table 37.3). Chemokines play many roles, including modulation of the Th1/Th2 balance associated with autoimmunity and hypersensitivity [36], as mediators of allergic inflammation [37], and modulating the function of leukocytes in disease states such as rheumatoid arthritis and asthma [38].

Immune/Nervous/Endocrine System Axis

It has been recognized for some time that the nervous, immune, and endocrine systems, rather than being separate in function and structure, share many features and appear to cross regulate each other's function [39–43]. The ramification for immunotoxicology of the existence of this nervous–immune–endocrine axis is that xenobiotics can affect the immune response indirectly by affecting other organ systems; conversely, modulation of the immune system may have secondary effects on other organ systems. To date, these interactions have not been extensively studied as they relate to immunotoxicology.

TABLE 37.3
Major Classes of Cytokines and Chemokines

Class	Members	Functions
Interleukins (ILs)	IL-1 (α and β), IL-1 receptor antagonist, IL-2, IL-4, IL-5, IL-6, IL-7, and IL-9 through IL-30	Primarily immunoregulatory, act on immune system cells (generally lymphocytes) in either stimulatory or inhibitory fashion.
Colony-stimulating factors (CSFs)	Granulocyte (G-CSF) Macrophage (M-CSF) Granulocyte/macrophage (GM-CSF), IL-3, MEG-CSF	Involved in the proliferation of leukocyte progenitors. GM-CSF and IL-3 share certain immunoregulatory functions.
Interferon (IFN)		
• Type I	IFN-α, IFN-β, IFN-δ, IFN-ω	Primarily antiviral activity, some immunoregulatory functions.
• Type II	IFN-γ	Primarily immunoregulatory.
TNF ligand superfamily	TNF-α, TNF-β, TNF-related apoptosis-inducing ligand (TRAIL). CD27 ligand, CD30 ligand, CD40 ligand, CD95 ligand, FAS ligand	Immunoregulatory activities; antitumor effector functions; apoptosis growth regulation.
Hematopoietins	Stem cell factor, stem cell growth factor, erythropoietin, thrombopoietin	Involved in the regulation of bone marrow function and the production of hematopoietic cells.
Miscellaneous	Oncostatin M, leukemia inhibitory factor, transforming growth factor(s)	Various pleiotropic functions.
Chemokines		
C	Lymphotactin	Chemotactic for lymphocytes.
CC	C10, eotaxin, I-309, leukotactin-1, MARC, MCP, MIP-1, MIP-3, MPIF-1, PARC, RANTES, TARC, TECK	Primarily active on monocytes/macrophages.
CXC	IL-8, 6Ckine (Exodus), BLC, CINC-1, CINC-2, CRG, ENA-78, gro, KC, MIG, MIP-2, NAP-2	Primarily active on neutrophils and T-cells.
CX3C	Fractalkine	Modulates calcium flux; involved in cell adhesion.

An updated listing of all known cytokines may be found at http://www.copewithcytokines.de/cope.cgi.

CONCEPTS AND APPROACHES FOR DETECTING IMMUNOTOXICITY IN EXPERIMENTAL ANIMALS

Immunosuppression

Basic Considerations in Study Design

For the most part, adverse effects observed in the immune system are due to the general properties of the chemical (e.g., interaction with specific macromolecules) but are amplified by the complex nature of the immune system. Dean et al. [44] suggested a *tier* approach with the idea that each subsequent tier provides identification of a more defined effect on the immune system. Tiered screening panels have been the basis for several risk assessment guidelines [45], and most regulatory agencies in the United States, European Union (EU), and Japan have established or are developing requirements or guidelines [46–48]. Although the configurations of these testing panels vary by laboratory and species, they generally include measures for (a) altered lymphoid organ weights and histomorphology; (b) quantitative changes in cellularity of lymphoid tissue, peripheral blood leukocytes (PBLs), and bone marrow; (c) impairment of cell function at the effector or regulatory level; and (d) increased susceptibility to experimental challenge with infectious agents or transplantable tumors cells. While it is generally agreed that functional tests provide the greatest level of sensitivity, some guidelines do not suggest functional tests until Tier II. Instead, these guidelines suggest reliance on careful histological and hematological evaluation, particularly inclusion of extended histopathology endpoints [49,50].

There are a number of advantages and limitations to using such test panels in animals or humans. For example, although the sensitivity of these methods to detect immune system changes in animal models is probably high, it is difficult to extrapolate the clinical significance of subtle immune changes on the development of neoplasia or infectious diseases in humans. Furthermore, some of the tests require invasive procedures such as immunization and either require additional animals in standard 28 day toxicology studies or are not feasible or ethical for inclusion in human studies.

A variety of factors must be considered when evaluating the potential of an environmental agent or drug to adversely influence the immune system. Assessment requires validation of the endpoints to be measured (quality control and biological relevance) as well as knowledgeable selection of animal models, exposure parameters, and consideration of general toxicological parameters, including metabolism, distribution, and toxicokinetics. The treatment protocol should take into account the potential route and level of exposure expected in humans, the biophysical properties of the agent (e.g., protein binding, bioavailability, and toxicokinetics of the agent), as well as information on the agent's mechanism of action. Dose selected should attempt to establish a clear dose–response curve as well as a no-observable-effect level (NOEL), up to or near the maximum tolerated dose (MTD). While in some instances it might be beneficial to include a dose level that induces overt toxicity, any immune change observed at such a dose should be interpreted cautiously, as either severe stress or malnutrition can impair immune responsiveness. It is often recommended that the highest dose used be considerably lower than a dose producing severe weight loss. Although laboratories routinely employ three dose levels, dose range–finding studies are recommended prior to a full-scale immunotoxicology evaluation. The selected exposure route should parallel the most probable route of human exposure, which is most frequently oral, respiratory, or dermal. Since these major routes of exposure are also associated with local immunity, attention may need to be directed to assessment of local immune responses.

Selection of the most appropriate animal model for immunotoxicology studies has been a matter of some discussion. Ideally, toxicity testing should be performed in a species that will elicit chemical-related pharmacology and toxicities similar to those anticipated in humans. For most immunosuppressive therapeutics, results from rodent studies have been predictive of clinical observations [51,52] although differences exist (e.g., glucocorticoids are lympholytic in rodents, but not in primates). While for the most part mice and rat results have also compared well, exceptions have been shown to occasionally occur in their immune response to an agent [53].

The quantitative and qualitative response of an experimental animal to an immunotoxic agent can be influenced by their genetic composition (genotype), indicating a need to consider not only species but in some cases also strain. Rao et al. [54] described two approaches to the selection of genotypes for rodent toxicity studies. The first approach is to select a strain where the genotype is representative of the animal species, in the hope that the choice will also exhibit sensitivities similar to humans. This can best be accomplished by using randomly bred rodents. However, due to the variability in immune responses associated with outbred animals, it may be necessary to use a greater number of animals to identify a sensitive population. A second approach attempts to identify genotypes that are uniquely suitable for evaluation of a specific class of chemicals. This requires considerable knowledge of the mechanisms of toxicity for the particular compound. One compromise would be to use F1 hybrids that contain the stability, phenotypic uniformity, and background information of an inbred animal and yet have heterozygosis.

At present, it is impossible to determine how applicable these conclusions will be for immunotoxic compounds with different immune profiles. However, as more comparative analyses become available, the ability to accurately estimate the potential clinical effects from immunological tests in animals should increase.

Introduction and Fundamental Concepts

Based on the preceding discussion of the important role that the immune system plays in protection of the host from infectious organisms and incipient neoplasia, it is logical to expect that disruption of this system following exposure to xenobiotics would have serious consequences. A large body

TABLE 37.4
Examples of Drugs and Chemicals Associated with Immunosuppression

Pharmaceuticals	Cytoreductive agents	Transplantation drugs
	Opiates	Therapeutic immunosuppressants

of information has developed demonstrating that xenobiotic exposure can produce immune suppression and altered host resistance in experimental animals (Table 37.4) following acute or chronic exposure. Since the number of reports documenting immune dysfunction following human exposure to xenobiotics is limited, animal studies form the basis for human risk assessment [55].

Given the complexity of the immune system (both natural and acquired) and the many potential target cells and molecules, it is impractical to enumerate all of the potential targets of immunosuppressive agents. For this reason, a number of immune function assays have been developed and validated for evaluating immunotoxicity. These techniques and approaches are discussed in the following sections.

Techniques for Assessing Immunosuppression

The basic approach to immunotoxicity testing, as it is currently practiced, is based on the work of Luster et al. [56–58]. This early work validated the concept of the *tier* approach in which test materials are evaluated for effects on the immune system using a biphasic system of descriptive and functional assays. A fairly comprehensive evaluation of immune structure and function is shown in Table 37.5 and is based upon the work of Luster et al. [56–58]. Tier I includes tests that are incorporated into a standard 28-day safety study and include routine hematology, selected organ weights (spleen, thymus), and histology of lymphoid organs. The inclusion of the T-dependent antibody response (TDAR) using either sheep red blood cell (SRBC) or keyhole limpet hemocyanin (KLH) requires the use of additional animals and specialized technical training. Also, sometimes included in an assessment are measures of NK cell activity and/or immunophenotype profile, neither of which requires additional sets of animals.

The following tests are commonly performed using the B6C3F1 mouse or the Fischer 344 or Sprague Dawley rats, although they are readily applicable to other rodent strains. Many of these are now well developed for use in nonhuman primates [59], while fewer of the tests are validated for use with canines [60].

Routine Tests and Extended Immunopathology

A hemogram (complete blood count [CBC] and differential) and examination of lymphoid organ weights, including the spleen, thymus, and lymph node, are useful for assessing the immunotoxic activity of a material [61–63]. Because of the structural division of the spleen and lymph nodes into thymus-dependent and thymus-independent compartments, immunocytochemical staining may indicate preferential effects for T- or B-cells, although this is seldom conducted. Likewise, microscopic examination of the thymus may reveal a compound that affects thymocyte viability, although careful measurement of thymus weight is easier and provides equal, if not more, sensitivity. As indicated previously, extended histopathology provides considerably more information than routine histopathology and does not involve any specialized stains. This involves a semiquantitative assessment to estimate histological changes within different anatomical compartments of the spleen, thymus, and lymph node and considers changes in cell density and anatomical compartment size [49,50]. Five endpoints are examined in the spleen: cellularity of periarteriolar lymphoid sheaths (PALSs), lymphoid follicles, marginal zone, red pulp, and the number of germinal centers. Three endpoints are examined in the thymus: cortex cellularity, medullary cellularity, and the corticomedullary ratio. Four endpoints are evaluated in the lymph node: grade of cellularity in the follicles, paracortical areas, medullary cords, and sinuses.

T-Cell-Dependent Antibody Response

Within a few days following in vivo injection of a foreign antigen, antibody molecules of the IgM class are produced. The antibody-forming cell (AFC) assay (alternatively referred to as the plaque-forming cell [PFC] assay) quantitates the production of a specific antibody through the enumeration of antibody-producing cells in the spleen following a primary antigenic stimulus such as SRBCs [64]. The plaque assay has been, for the most part, replaced by ELISA techniques in which antibody levels are determined directly from serum [65]. In addition, KLH is often used in lieu of SRBCs as the immunizing antigen as it is more amenable to laboratory quality control [66,67]. Although the TDAR is, strictly speaking, a measure of B-cell function rather than T-cell function, it is an excellent functional parameter to examine, as this response requires cognate cell interaction and regulation by MØ, T-cells, and soluble regulatory molecules such as cytokines. The steps involved in this assay are illustrated in Figure 37.5.

IgM Plaque Assay

Materials and Reagents Required:

- Earle's balanced salt solution (EBSS) supplemented with 25 mM HEPES buffer
- SRBC in Alsever's solution
- Guinea pig complement (GPC′)
- Dulbecco's phosphate-buffered saline (DPBS)
- DEAE-dextran, 30 mg/mL in saline, pH 6.9
- Bacto-agar
- Petri dishes and cover slips

Procedure:

1. Four days prior to assay, immunize animals with an intravenous injection of washed SRBC in sterile saline. Recommended inocula are approximately 1×10^8 SRBC for mice and approximately 2×10^8 SRBC for rats.

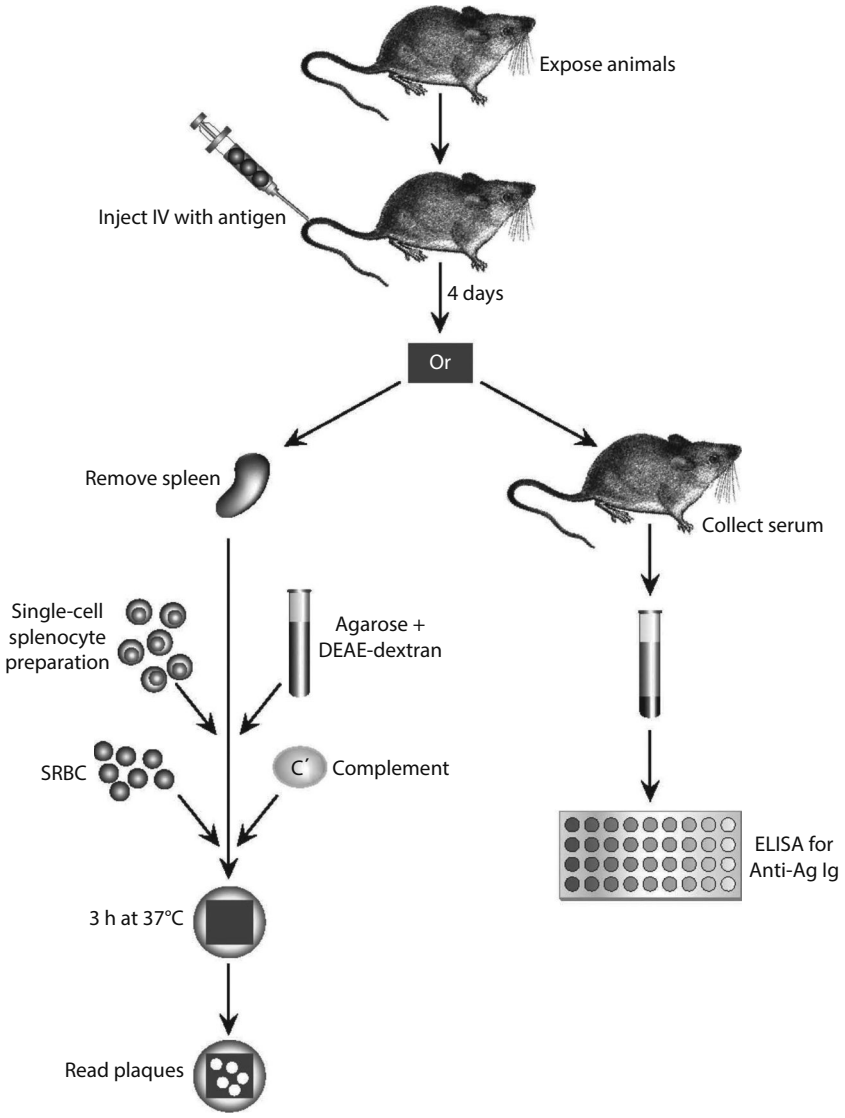

FIGURE 37.5 TDAR assay.

2. Euthanize the animals, remove the spleens, and prepare a single-cell splenocyte suspension in EBSS. Prepare two dilutions of the cell suspension in EBSS.
3. Wash SRBC three times by centrifugation. After the final wash, retain approximately 100 µL of SRBC, and then adjust the remaining cells to a final density of 10% in EBSS. Add GPC' to the reserved SRBC, mix well, and hold on ice until needed.
4. Prepare a solution containing 0.5% agar in DPBS, add DEAE-dextran (1.6 mL stock solution per 100 mL agar), and mix. Dispense the agar in 0.35 mL aliquots into polypropylene culture tubes, and maintain these tubes at 45°C.
5. For the assay, each tube contains 0.35 mL agar solution, 100 µL cell dilution(s), and 25 µL GPC'. Add SRBC first and then the cell suspension, and immediately remove the tube from the water bath. Add the GPC' and mix the contents of the tube. Dispense the contents into a Petri dish, and then drop the cover slip so that an even layer of fluid forms underneath.
6. Incubate the plates at 37°C for approximately 3 h, and enumerate the plaques. While the plates are incubating, determine the cell number and viability of the original splenocyte suspensions.
7. Calculate the results as follows:
   a. Plaques counted under each cover slip × 10 × dilution factor = PFC/mL of the original cell suspension (since 0.1 mL of the cell dilution is counted)
   b. PFC/mL × volume of original cell suspension = PFC/spleen
   c. PFC/mL/number of viable cells/mL = PFC/10^6 viable splenocytes

Anti-SRBC IgM ELISA
Materials and Reagents Required:

- SRBC in Alsever's solution
- Horseradish peroxidase (HRP)–conjugated, affinity-purified goat antimouse/antirat IgM antibody
- Peroxidase substrate (2-azino-bis-3-ethylbenzthiazoline-6-sulfonic acid [ABTS])
- ABTS buffer (phosphate–urea–hydrogen peroxide)
- Phosphate-buffered saline (PBS)
- 96-Well microplates
- General reagents and supplies for ELISA

Procedure:

1. Immunize mice or rats with SRBC as for the plaque assay. Five days (mice) or 6 days (rats) later, obtain serum from both immunized and naive animals. Pool each as appropriate to use as standards or controls and freeze at –20°C.
2. Treat mice or rats with test material and vehicle (and a positive control, if necessary). On day 5 or 6 posttreatment (respectively), obtain serum from animals. *Note*: If serum is collected via the retro orbital sinus, additional samples may be collected later for time-course studies.
3. Prepare SRBC membrane antigens by lyses and solubilization [64]. This antigen serves as the capture reagent in the ELISA.
4. Obtain anti-SRBC IgM monoclonal antibodies to use as standards. *Note*: Anti-SRBC must be of the appropriate species depending on the test animal (i.e., mouse or rat).
5. Dilute membrane antigen to 1.0 µg/mL in PBS and coat the wells of the microplates at approximately 4°C using 125 µL/well of the antigen preparation.
6. On the day of assay, wash the plates three times with 0.01% Tween-20 in water. Block any unbound sites on the plates by incubating the plates with 200 µL/well of PBS/0.05% Tween-20, 3% bovine serum albumin, or 3% powdered milk.
7. Prepare serial twofold dilutions of test sera and antibody standards. Add to the plates and incubate for at least 1 h at room temperature.
8. Wash the plates three times, then add HRP-conjugated secondary antibody. Incubate for at least 1 h at room temperature, and then wash the plates three times.
9. Add peroxidase substrate (ABTS) and incubate the plates at room temperature for 45 min. Stop the reaction by adding 3% oxalic acid to all wells.
10. Read the plates at 405 nm and calculate the results based on curves prepared using the antibody standards.

Positive Control:
Cyclophosphamide is routinely used as a positive immunosuppression control for the AFC assay (either plaque or ELISA format). For mice, cyclophosphamide is administered intraperitoneally at 80 mg/kg once approximately 24 h prior to euthanasia. For rats, it is given intraperitoneally at 20–25 mg/kg daily for 4–5 days prior to euthanasia.

Notes:

1. The AFC response varies depending on the day of analysis following immunization. Each species and strain should also be evaluated for the optimum response, although for intravenous injection, the optimum assay period is usually 4 days following immunization.
2. The dose and route of antigen exposure alters the peak AFC response. Intravenous injections shift the optimum response to an earlier time, whereas an intraperitoneal injection delays the peak response.
3. Each new test lot of complement should be tested and titrated prior to use.
4. The day of antibody induction relative to the last dose of chemical exposure should be considered when designing a study.
5. SRBC membrane antigens are generally prepared individually by a laboratory. Monoclonal and

polyclonal antibodies specific for SRBC are commercially available from a variety of sources.
6. The direct comparability of results between the plaque assay and the ELISA is the source of some discussion. The AFC assay measures antibody production in one organ (spleen) only, whereas the ELISA is a measure of systemic antibody production that may have a different time course.
7. The current trend in TDAR assessment favors the use of an ELISA against KLH, a widely used T-dependent antigen. Methodology for standardizing this technique and applying it to immunotoxicology assessment has been published [66–69].

Anti-KLH IgM ELISA (for Rats)
Reagents:

- KLH purified protein
- Positive controls: Mouse and rat anti-KLH and anti-KLH IgG (commercially available)
- HRP-conjugated, affinity-purified goat antimouse/antirat IgM antibody
- Peroxidase substrate (ABTS)
- ABTS buffer (phosphate–urea–hydrogen peroxide)
- PBS
- 96-Well microplates
- General reagents and supplies for ELISA

Materials and Reagents Required:

- SRBC in Alsever's solution
- HRP-conjugated, affinity-purified goat antimouse/antirat IgM antibody
- Peroxidase substrate (ABTS)
- ABTS buffer (phosphate–urea–hydrogen peroxide)
- PBS
- 96-Well microplates
- General reagents and supplies for ELISA

Procedure:

1. Immunize rats with 1000 mg/animal KLH in 0.4 mL PBS by the IP route following test agent treatment.
2. On day 5 following KLH administration (IgM) and day 17 (IgG), obtain blood samples and collect serum.
3. Store in aliquots and freeze at –70°C until testing.
4. Prepare QC and test samples by diluting 1:200 (IgM) or 1:50 (IgG) in blocking buffer.
5. The day before the test, coat microtiter plates with 2.5 mg/mL of KLH, 100 mL/well.
6. Seal the plates and incubate overnight at 4°C.
7. On the day of assay, wash the plates three times with 0.01% Tween-20 in water. Block any unbound sites on the plates by incubating the plates with 200 µL/well of PBS/0.05% Tween-20, 3% bovine serum albumin, or 3% powdered milk.
8. Prepare serial twofold dilutions of test sera and antibody standards. Add to the plates and incubate for at least 1 h at room temperature.
9. Wash the plates three times, and then add HRP-conjugated secondary antibody. Incubate for at least 1 h at room temperature, and then wash the plates three times.
10. Add peroxidase substrate (ABTS) and incubate the plates at room temperature for 45 min. Stop the reaction by adding 3% oxalic acid to all wells.
11. Read the plates at 490 nm and calculate the results based on curves prepared using the antibody standards.

Notes:

1. The AFC response varies depending on the day of analysis following immunization. Each species and strain should also be evaluated for the optimum response, although for intravenous injection, the optimum assay period is usually 4 days following immunization.
2. The dose and route of antigen exposure alters the peak AFC response. Intravenous injections shift the optimum response to an earlier time, whereas an intraperitoneal injection delays the peak response.
3. Each new test lot of complement should be tested and titrated prior to use.
4. The day of antibody induction relative to the last dose of chemical exposure should be considered when designing a study.
5. SRBC membrane antigens are generally prepared individually by a laboratory. Monoclonal and polyclonal antibodies specific for SRBC are commercially available from a variety of sources.
6. The direct comparability of results between the plaque assay and the ELISA is the source of some discussion. The AFC assay measures antibody production in one organ (spleen) only, whereas the ELISA is a measure of systemic antibody production that may have a different time course.
7. The current trend in TDAR assessment favors the use of an ELISA against KLH, a widely used T-dependent antigen. Methodology for standardizing this technique and applying it to immunotoxicology assessment has been published [65,67].

Natural Killer Cell Assay

NK cell activity is measured in vitro by culturing single-cell suspensions of lymphoid cells with a tumor cell line known to be sensitive to NK-mediated cytotoxicity. The target cells are radiolabeled prior to the assay; thus, any cells that have been lysed will release their radioactivity into the culture medium, where it can subsequently be quantitated. The procedure described in the following is modified from the microculture method described by Reynolds and Herberman [70] and is

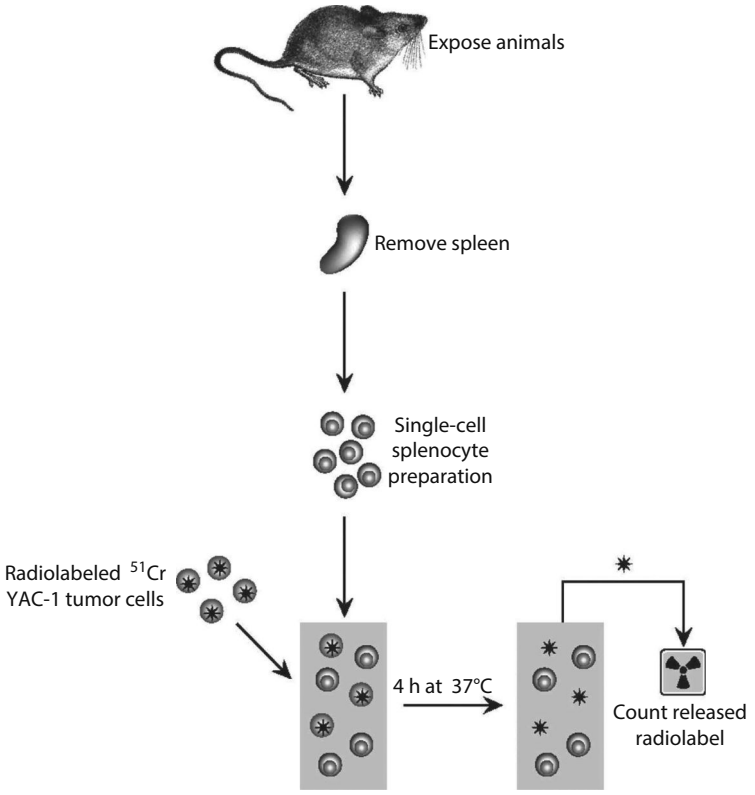

FIGURE 37.6 The NK cell assay.

the standard approach for immunotoxicity assessment. The procedure for this assay is illustrated in Figure 37.6.

Materials and Reagents Required:

- RPMI-1640 culture medium supplemented with 25 mM HEPES buffer, 10% FBS, 2 mM L-glutamine, and 50 μg/mL gentamicin
- Fetal bovine serum (FBS)
- DPBS
- Wash solution (DPBS/1% FBS)
- YAC-1 cell line (for rodent NK evaluation, ATCC #TIB 160) or K562 cell line (for primate NK evaluation, ATCC #243) maintained in log-phase growth in the culture medium described previously
- 96-Well round-bottom microculture plates
- 0.1% solution of Triton X-100 in distilled H_2O
- ^{51}Cr as sodium chromate in sterile saline; specific activity of 200–500 mCi/mg
- Supernatant collection system

Procedure:

1. Prepare a single-cell suspension of the effector spleen cells, and adjust to a density of 5×10^6 viable cells/mL in culture medium.
2. Prepare two serial 1:3 dilutions of the cell suspension in culture medium. Dispense 100 μL of each dilution in quadruplicate wells of 96-well, round-bottom microculture plates.
3. Centrifuge a log-phase culture of target cells and suspend the cell pellet in 0.5 mL FBS. Add 200 μL ^{51}Cr to the cells, mix well, and incubate at 37°C for 1 h. Wash the cells three times.
4. Suspend the target cells in culture medium, determine cell number and viability, and adjust the cells to a final density of 5×10^4 viable cells/mL in culture medium. Add the target cells to all wells in a volume of 100 μL/well. Include a row containing 100 μL target cell suspension and 100 μL culture medium/well (spontaneous release) and one row consisting of 100 μL target cell suspension and 100 μL 0.1% Triton X-100/well (total release).
5. Incubate the plates at 37°C, 5% CO_2 for 4 h. Harvest all wells with a supernatant collection system, and determine radiolabel release in a gamma counter.
6. Harvest supernatant fractions either manually or by using a semiautomatic harvesting system. Quantitate radiolabel released into the supernatant fractions in a gamma counter, and determine percent cytolysis using the following formula:

$$\text{Percent cytolysis} = \frac{\text{Experimental release} - \text{Spontaneous release}}{\text{Total release} - \text{Spontaneous release}} \times 100$$

Positive Controls:
Immunosuppression control: Unless the laboratory has extensive experience, a positive suppression control of the

NK response should be included. Approximately 24–78 h prior to euthanasia, a separate group of animals is injected intravenously with an optimum concentration of anti-asialo GM1 antibody. The exact amount to be given will vary from lot to lot and between suppliers. Treatment with an optimum dose of anti-asialo GM1 will result in an essentially complete abrogation of the NK response in rodents [71].

Immunostimulation control: In some cases, it may be useful to include a positive control for NK cell augmentation. Although cytokines (IL-2 and IFN-γ) can enhance this response both in vivo and in vitro, an equally efficient, and more economical/reproducible, option is the use of interferon inducers such as polyinosinic/polycytidylic acid (poly I/C) [23]. Poly I/C is administered intraperitoneally at a concentration of 100 μg/mouse or 500–1000 μg/rat approximately 24 h prior to assay.

Notes:

1. NK activity is highest in young mice, declining after 12 weeks of age. Basal NK activity may be highly variable or undetectable in mice over 20 weeks old.
2. The target cells must be in log-phase growth to achieve adequate labeling with ^{51}Cr. In addition, the target cell lines should be assessed for *Mycoplasma* contamination at periodic intervals.
3. The assessment of NK cell activity has been utilized most extensively in rodents and primates. In instances in which evaluation of canine NK cell function would be useful, modified techniques have been published [72].
4. For laboratories unable or unwilling to use radioisotopes, flow cytometry serves as a useful alternative [73]. A full comparison has not been made between these alternative methodologies and the standard chromium release assay, although a study by Motzer et al. [74] found little advantage in flow cytometry in comparison to the standard radiolabel assays.

Phenotypic Analysis of Cell Surface Markers by Flow Cytometry

There are both pros and cons for including immunophenotypic analysis as part of an immunotoxicology screen [74]. It offers a rapid, sensitive, and quantitative measure of a heterogeneous cell population in blood or cell suspensions prepared from lymphoid organs. The major concern is that the test is not well validated in rodents, particularly with respect to sensitivity or how minor changes relate to disease. For mechanistic studies, however, they are of unquestionable relevance especially when considering the vast array of well-defined surface markers now available for rodent and human immune cells as well as nonhuman primates (75). The technique involves treating cells with monoclonal antibodies covalently bound to different fluorochromes. These antibodies recognize surface antigens, referred to as *cluster of differentiation* (CD), unique to different cell types. The availability of fluorochromes, which emit light at different wavelengths following excitation, combined with flow cytometers that are capable of performing multiple color analysis, provides a rapid and effective method of analyzing cell types. The most commonly examined CDs in the mouse are those that recognize pan T-cells (CD90 and T-cell receptor [TCR] complex), T-helper cells (CD4), T-suppressor cells (CD8), and pan B-cells (CD45R/B220 or CD19).

Materials and Reagents Required:

1. Prepare single-cell suspensions from the spleen (Ficoll-separated and whole blood have both been used occasionally). For washing and staining, use DPBS (0.01 M).
2. Centrifuge conjugated reagents at $15 \times 10^3 \times g$ to remove aggregates.
3. Pipette desired concentration of antibody or control sera in 50 μL volumes to a small test tube or 96-well microtiter plates. For two-color analysis, both conjugated antibodies can be added together.
4. Add 10^6 viable cells in a volume of 50 μL to the test tube or well containing the antibody.
5. Incubate 30 min on ice in the presence of 0.1% sodium azide.
6. Wash with 2.0 mL if in tubes or two 100 μL washes if in wells.
7. Suspend to a volume of $1–2 \times 10^6$ cells/mL in cold PBS containing 0.1% sodium azide and perform analysis.
8. Cell fluorescence and integrity can be preserved for up to 5 days by rapidly suspending the cell pellet in 50 μL cold PBS containing 1% paraformaldehyde.

Mechanistic Immunotoxicology Assays

From its beginnings, the discipline of immunotoxicology has constantly evolved and incorporated new techniques and paradigms to understand the nature of immunomodulation. The assays described previously in this section allow one to make a first-pass evaluation of drugs and chemical agents for generalized immunotoxicity. That is, the assays will indicate that the immune system had been perturbed, although the cellular and molecular mechanisms involved will not necessarily be obvious. These assays are valuable for quick and relatively accurate identification of toxic agents. On the other hand, the tools and concepts of immunotoxicology are increasingly being utilized as research tools to understand the function of the immune system. For example, it may be useful to know not only whether or not an agent modulates the immune response but why. This is especially important in the discovery and development of pharmaceutical agents, where therapeutic manipulation of the immune system may be a desirable goal. In response to these novel applications of immunotoxicology, assays are needed that will allow us to determine the precise mechanism of immunomodulation.

The methodology for Tier II-type assays such as T-cell-mediated immune function (CTL/DTH), MØ function, IgG antibody cell forming response, and host resistance models has been reviewed in detail elsewhere and will not be

reiterated here [76–79]. These assays are still valuable tools for understanding the mechanistic basis of immunotoxicity. In addition to these assays, several other methodologies are now being included in the immunotoxicology armamentarium.

Assessment of apoptosis: Apoptosis (programmed cell death) is increasingly recognized as a fundamental process in both health and disease states, including the response to toxic insult [80]. Apoptosis plays a vital role in the immune response, regulating the number and action of immune cells such as lymphocytes [81,82]. Given the important role apoptosis plays in normal regulation of the immune system, as well as its implication in immune-related disease, it is a logical and potentially valuable endpoint for mechanistic immunotoxicology evaluation [83]. Apoptosis has been found to play an important role in the immunotoxicity of a number of compounds including organotins [84], polychlorinated biphenyls [85], methylmercury [86], and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [87].

Numerous techniques are available for assessing apoptosis, including analysis of DNA degradation, flow cytometry, morphological analysis, 3′-OH end labeling, and endonuclease analysis [88]. More recently, a number of ELISAs have become available for assessing apoptosis; these ELISAs are based on the detection of Bcl-2 or histone-associated DNA fragments. The ELISA format offers a number of benefits over the other techniques including rapidity, simplicity, and cost-effectiveness.

Cytokine analysis: As described previously, cytokines represent an important mechanism not only for regulating the function of the immune system but also for linking the immune system with other organ systems. Early studies employing cytokine analysis in immunotoxicology studies were more descriptive [89,90]. However, as the intricacies of the cytokine/chemokine network become better understood, these assays are allowing us to assess the mechanisms responsible for a variety of immunomodulatory effects. As an example, a variety of nonbiological agents have been described that either specifically or nonspecifically alter cytokine production. These agents act via myriad mechanisms including direct toxicity to cytokine-producing cells (cyclophosphamide), inhibition of cytokine production (cyclosporin, FK506, pentoxifylline), inhibition of cytokine release (pentamidine), induction of immunosuppressive factors (leflunomide), alterations in cellular homeostasis (tenidap), alterations in cellular activational or transcriptional mechanisms (thalidomide), alteration of cell cycle progression (Rapamune), and miscellaneous or undefined mechanisms (glucocorticoids, phosphodiesterase isozyme inhibitors, metalloproteinase inhibitors, and p38 kinase inhibitors) [91].

There are currently four major types of cytokine assays used: bioassays, immunoassays, mRNA gene expression, and flow cytometry. Sometimes used is what may be termed the *hybrid assay*, employing elements of two or more of the main assay categories, and molecular biology assays to examine cytokines and cytokine receptors [92]. Each of these assay types exhibits advantages and disadvantages, and no one type of assay is best suited for all applications. The type of assay chosen is subjective and will depend on the capabilities of the laboratory, as well as the type of information to be gained.

One recently developed and not yet validated, a cytokine profiling test based upon procedures initially developed by RBM Myriad (Austin, TX) and Meso Scale Discovery (Gaithersburg, MD) may be useful as an immunotoxicology screening test. In this assay, spleen cells from treated animals are collected and stimulated in vitro with a cocktail that stimulates the release of Th1, Th2, and monocyte cytokines. The levels of released cytokines are then measured in relation to baseline (no stimulation). Since the stimulation is performed ex vivo, there is no need for an additional group of animals. Specific changes in profiles likely coincide with various aberrant immune responses. Cytokines play key roles in the initiation, amplification, and specificity of immune responses as well as inflammation. Aberrant production of cytokines can lead to modulation of the immune response such that the host may be more susceptible to infectious agents or development of allergic or autoimmune response to agents.

Allergy and Autoimmune Reactions to Xenobiotics

Introduction and Fundamental Concepts

Immune reactions to xenobiotics (e.g., industrial and naturally occurring chemicals, metals, and drugs) can give rise to allergy and autoimmunity, and these reactions are frequent and can encompass a broad spectrum of diseases and organs. To decrease the health risks associated with exposure to these agents, it is important to understand the pathogenic mechanisms involved and to identify human subjects at risk of developing these reactions prior to serious clinical manifestations.

Allergic or hypersensitivity reactions, which include allergic asthma, food and environmental allergies, and allergic contact dermatitis, are one of the most common and costly health problems in the United States afflicting a large part of the population. Individuals with potential occupational exposure (e.g., agricultural or manufacturing workers) are at a higher risk than the general public for the development of respiratory and cutaneous contact hypersensitivity to chemicals. The indirect costs, such as wages lost because of illness, are estimated to be in excess of $1 billion annually for asthma alone, with more than 35 million workdays lost to sickness each year [93]. Food allergy affects 5%–7.5% of all children and 1%–2% of adults. Industrial processes utilize many materials capable of inducing occupational immunological lung disease or contact hypersensitivity in workers and thus must be rigorously controlled to ensure worker safety. Studies in the metal-refining industry, for example, suggested that many workers regularly exposed to the complex salts of platinum develop disorders of the respiratory tract. A study of workers exposed to toluene diisocyanate (TDI), a substance used in the manufacture of polyurethane, revealed that 5% of those surveyed developed occupational asthma to TDI.

Drug allergy is also a significant problem and among the most common causes for new pharmaceuticals being

withdrawn from the market after they are released. This adverse immune reactivity is not well predicted from the current battery of preclinical safety assessment methods [52]. A distinction should be made between immunologically mediated adverse drug reactions that represent true drug allergy reactions and those that are autoimmune in nature. In drug allergy, the adverse reaction occurs as a consequence of an immune response directed against the drug. Examples of drug allergy include immediate anaphylactic reactions mediated by IgE antibody or cell-mediated reactions. Drugs are unique in that they can provoke allergic and autoimmune reactions against blood cells including erythrocytes and platelets, as well as a variety of other antigens including the haptenated drug. Usually the reaction occurs to the drug or drug metabolites, in which case it is necessary for both the drug and the antibody to be present to produce the allergic or autoimmune reaction. In addition to producing allergic manifestations or pathology under certain conditions, drug-specific antibodies can also alter the pharmacokinetics and clearance of the drug in plasma. Thus, drug-induced allergy reactions can come in many forms producing either allergic or autoimmune phenomena.

Allergy (acute hypersensitivity) is a pathological state resulting from prior sensitization to a specific molecule or structurally related compound. Because of the clinical and pathological similarities between xenobiotic-induced allergy, autoimmunity, and GVH reactions, there is considerable evidence that these reactions are initiated and maintained by sensitized T-cells [94]. The major difficulty in trying to study these immune reactions is the fact that the ultimate neoantigen formed by the chemical or drug is often unknown. Based on our understanding, it is assumed that allergic reactions to most xenobiotics involve the formation of protein adducts (i.e., hapten–carrier conjugates). Metal ions react by oxidizing proteins or forming stable protein–metal chelates through multiple binding points with several amino acid side chains in the protein. A second mechanism for xenobiotics not reactive enough to bind covalently to proteins is through the direct antigen recognition by γ–δ and α–β T-cells. This hypothesis is supported by evidence of human gamma–delta T-cells specific for the drug lidocaine [95] and human CD8+ alpha–beta T-cells that recognize pollen-derived carbohydrate antigen [96].

Thus, there appear to be multiple mechanisms by which xenobiotics can become sensitizers. Highly reactive organic compounds most often act as electrophiles and react with protein nucleophilic groups such as thiol, amino, and hydroxyl groups to form hapten–protein conjugates (reviewed by Griem et al. [97]). Examples of reactive, haptenic chemicals that frequently lead to sensitization after dermal or inhalation exposure are TDI, trimellitic anhydride, phthalic anhydride, benzoquinone, formaldehyde, hexyl cinnamic aldehyde, ethylene oxide, dinitrochlorobenzene (DNCB), picryl chloride, penicillins, and D-penicillamine. In contrast, most xenobiotics are unable to bind to proteins until they are converted to reactive metabolites and are thus considered prohaptens.

The liver is the main organ for metabolic conversion of chemicals and drugs, and in spite of this, immune reactions to liver or its constituents are relatively rare. However, such reactions, although rare, have been observed as seen with autoimmune hepatitis that results from chronic treatment with the diuretic tienilic acid and are believed to result from the production of autoantibodies against the cytochrome P450 isozyme 2C9, the enzyme that converts this prohapten [98]. Two other examples of drug-induced autoimmune hepatitis involving a similar mechanism where autoantibodies are raised against the enzyme converting the prohapten to a reactive metabolite are produced by the anesthetic halothane (anti-CYPE1 [99]) and dihydralazine (anti-CYP1A2 [100]).

Extrahepatic metabolism appears to play a more critical role in hypersensitivity reactions in prohapten conversion, and the skin is a good example of an organ with metabolic conversion potential via dendritic Langerhans cells (isoenzyme CYP1A) or inflammatory leukocytes (myeloperoxidase [MPO], prostaglandin H synthase, and CYPs). Examples of prohaptens converted in the skin include the polyaromatic hydrocarbon dimetylbenz-[*a*]-anthracene that is converted to a potent haptenic sensitizer [101] and urushiol, a mixture of allergenic 2-alkyl and 3-alkenyl catechols from poison ivy and poison oak that are oxidized to reactive quinones that elicit specific T-cell responses [102].

Exposure to any of a number of industrial chemicals and drugs has been associated with the development of allergic or hypersensitivity reactions (Table 37.6). In addition, in some cases, the reactive metabolite of the xenobiotics acts as a hapten, and producing the adverse immune response has been identified in rodents, man, or both (Table 37.7).

What is not well understood is why only a few of the hapten–protein conjugates formed in the body induce clinical

TABLE 37.6
Materials Associated with Contact, Food, or Respiratory Allergy

Pharmaceuticals	Phenylglycine acid chloride	Ampicillin
	Piperazine	Spiramycin
	Amprolium hydrochloride	Antibiotic dust
	Antihistamines	Quinidine
	Anesthetics	Plasma substitutes
Foodstuffs	Castor bean	Pancreatic extracts
	Green coffee bean	Grain and flour
	Papain	Molds
	Tree nuts	Shellfish
	Peanuts	
Industrial chemicals	Ethylenediamine	Phthalic anhydride
	Diisocyanates (TMI, HDI, MDI)	Trimellitic anhydride
	Metallic salts	
Miscellaneous	Wood dusts	Animal products
	Latex proteins	Fragrance components
	Flour	Detergent enzymes (subtilisin)

TABLE 37.7
Examples of Allergic Reactions to Xenobiotics That Involve Reactive Metabolites

Parent Compound	Allergic Reaction Observed	Candidate Metabolite
Dihydralazine	Drug-induced lupus, autoimmune hepatitis	Hydralazine radical
Gold thiomalate	Dermatitis, glomerulonephritis	Gold (III)
Halothane	Autoimmune hepatitis	Trifluoroacetyl chloride
Practolol epoxide	Oculomucocutaneous syndrome	Practolol
Procainamide	Drug-induced lupus	*N*-Hydroxyprocainamide
Propylthiouracil	Vasculitis, drug-induced lupus	Propyluracilsulfonic acid
p-Phenylenediamine	Contact dermatitis	Bandrowski's base
Tienilic acid	Autoimmune hepatitis	Thiophene sulfoxide
Urushiol	Contact dermatitis	3-Pentadecyl-*o*-quinone

allergy or autoimmunity. Administrative route, dose, and genetic background clearly all play an important role in this process. Cutaneous sensitization of mice to the hapten dinitrofluorobenzene (DNFB) does not occur if the animals are orally pretreated with DNFB [103]. This is believed due to the induction of both hapten-specific CD8+ T-cells and CD4+ suppressor T-cells. In the case of dose, subsensitizing doses of oxazolone induce tolerance, while higher doses sensitize. Genetic background further complicates our ability to predict since gold thiomalate induces a Th2-like response in brown Norway rats, but not in Lewis rats. This induction of autoimmunity in brown Norway rats is explained by a polymorphism in a putative enhancer element in the second intron of the IL-4 gene [104].

Autoimmunity is a multifactorial pathological process comprised of at least two processes. Initially, an immune response is initiated to normal components of the host, and second, a pathological condition may ensue in which the response causes structural or functional damage (e.g., pathology). An autoimmune response does not necessarily reflect disease, although it is a prerequisite for disease to occur. The autoimmune response induced can be cellular in nature, mediated by CD4 and/or CD8 T-cells, or more often, it arises from antibody, mediated by specific B-cells. The most common autoimmune diseases are rheumatoid arthritis and those associated with the thyroid, such as Graves' disease. In total, they represent a significant and chronic morbidity problem with recent estimates indicating that 1 in 31 individuals in the United States are affected, with women at 2.7 times greater risk than men [105].

What is the underlying problem in autoimmunity and autoimmune disease? It is well understood that the immune system is able to recognize and produce a response against foreign material but is tolerant toward the body's own constituents. Unfortunately, immunological tolerance to self is not absolute and autoantibodies can be produced experimentally and are seen in a variety of human autoimmunity diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus (SLE), and myasthenia gravis). The mechanism(s) responsible for conversion from an autoimmune response to autoimmune disease is not clear. It is believed that the failure of any one of several immune processes can lead to the development of autoimmune disease. However, the key process involves the loss of self-tolerance, such as the missed deletion or activation of autoreactive lymphocyte precursors. This process may be exacerbated by altered immunoregulation, such as overexpression of the immunoregulatory cytokine IL-4 or underexpression of IFN-γ. Autoimmunity may also occur in the absence of an aberration in the immune system, such as when microbial agents express cryptic determinants [106]. Although autoimmunity is a disease of the immune system, nonimmunological genetic and epigenetic factors play a major role in disease development. For example, autoimmunity is influenced strongly by infectious agents, stress and diet (epigenetic), as well as polymorphisms in the TCR and drug metabolizing phenotypes (genetic). The association of autoimmune diseases with certain MHC haplotypes, such as HLA-DR3 in systemic lupus, is striking. A detailed description of the potential mechanisms and the influential factors leading to autoimmune disease is beyond the scope of this section, and the reader is referred to several excellent reviews [107–110].

In drug-induced autoimmunity, the adverse reaction results from an immune response directed against the body's own tissue, subcellular or cellular components. A variety of drugs, with a molecular weight of less than 1000 Da, from a variety of different chemical classes, have been shown to induce autoimmunity. These include aromatic amines (procainamide, practolol), hydrazines (hydralazine), hydantoins (phenytoin, mephenytoin, ethotoin, nitrofurantoin), thioureylenes (methimazole, propylthiouracil), oxazolidinediones (trimethadione, paramethadione), succinimides (ethosuximide, methsuximide, phensuximide), dibenzazepines (carbamazepine), phenothiazines (chlorpromazine), sulfonamides (sulfasalazine, sulfadiazine), pyrazolones (phenylbutazone), amino acids (D-penicillamine, captopril, methyldopa), allylamines (zimeldine, halothane), and certain metal salts (mercuric chloride, gold salts). It is important to note that drug-induced autoimmune disease is different than the classical spontaneous counterpart. For example, in drug-induced autoimmune disease, the disease is usually milder, there is minimal organ involvement, autoantibodies to native DNA are seldom observed in the circulation, and disease remission occurs following cessation of drug treatment. The latter phenomenon may be unique to compounds that induce autoimmunity via the haptenization of native proteins. Nonetheless, the health significance of this adverse effect can be significant.

The most common examples of drugs that have produced autoimmune disease are those that cause hematological disorders such as neutropenia, thrombocytopenia, and immune hemolysis and include a variety of antibiotics as well as anticonvulsants such as phenytoin (Table 37.8). Approximately 10%–20% of patients receiving procainamide and 5%–20%

TABLE 37.8
Examples of Drugs and Chemicals Implicated in Autoimmune Disease

Pathology	Agent	
SLE	Hydralazine	Heavy metals
Immune complex glomerulonephritis	Penicillamine	Isoniazid
	Chlorpromazine	Organic solvents
	Anticonvulsants	Procainamide
	Alfalfa sprouts (L Canavanine)	
Hemolytic anemia	Methyldopa	Diphenylhydantoin
	Penicillin	Interferon α
	Mefenamic acid	Sulfa
Thrombocytopenia	Acetazolamide	*p*-Aminosalicylic acid
	Chlorothiazide	Rifampin
	Gold salts	Quinidine
Scleroderma-like disease	Vinyl chloride	L-Tryptophan
	Silica	
Pemphigus	Penicillamine	
Thyroiditis	PCBs	Lithium
	Iodine	IL-2

receiving hydralazine develop drug-induced SLE. More recently, unexpected hematologic toxicity was related to treatment with a biotherapeutic treatment [111].

Autoimmunity can also be induced by substances found in food or the environment. Regarding food consumption, strong associations have been found to exist between the consumption of iodine and autoimmune thyroiditis, L-5-hydroxytryptophan and scleroderma, and alfalfa seeds and SLE. Exposure to occupational agents has also been linked to autoimmune diseases. Epidemiological studies suggest that exposure to silica-containing mineral dusts is associated with elevated risk for a number of systemic autoimmune diseases, including rheumatoid arthritis (known as Caplan's syndrome), systemic sclerosis, SLE, and antineutrophil cytoplasmic antibody (ANCA)-related vasculitis/nephritis. Although some authors have considered these adjuvant effects, silica may influence circulating immunocompetent cells, particularly Treg and Tresp cells. Epidemiological studies also have suggested a higher than expected risk of systemic autoimmune disease among asbestos-exposed populations [112]. Scleroderma-like skin diseases can result from exposure to vinyl chloride or aniline derivatives; the latter were presumably the active agent resulting in the *toxic oil syndrome* [113]. Agents such as heavy metals, nitrofurantoin, and organic solvents such as trichloroethylene are associated with SLE or glomerulonephritis, the latter being supported by a number of epidemiological studies. Like their idiopathic counterparts, xenobiotic-induced autoimmune diseases are also associated with certain genetic backgrounds. Individuals with the low acetylator phenotypes are associated with drug-induced SLE. The relative risk for developing autoimmunity from gold salts increases 32-fold in individuals who possess the HLA-DR3 allele. Likewise, experimental studies of mercury-induced autoimmunity in the brown Norway rat and B.10 mice suggested that the same genetic influences apply in animals as in humans [114].

Techniques for Assessing Contact and Respiratory Allergy

Given the potential economic and medical importance of hypersensitivity, the importance of sensitive and reliable assays for the detection of sensitizing potential for drugs and chemicals is obvious. For over 100 years, the guinea pig has served as the principal model for allergic reactions in humans since they demonstrate many similarities in their response to pulmonary hypersensitivity (response to histamine, demonstration of immediate and delayed allergic reactions, etc.), as well as dermal hypersensitivity. In addition, the lightly pigmented skin of albino guinea pigs and their relatively small size and docile nature make them manageable model animals. Thus, they have traditionally been used for assessing the human safety of drugs, as well as other chemicals, for contact and respiratory sensitization. Based on the specific experimental needs at hand, a variety of modifications have been described. In this section, we will discuss only two, that is, the Buehler assay and the guinea pig maximization test, which are probably the two most widely used guinea pig tests for risk evaluation of contact sensitization [115].

The mouse has been developed as an alternative model to the guinea pig. The impetus for this development has been the mouse's small size and reduced cost, more thoroughly understood immune system, and the perceived need of a more quantitative endpoint than the subjective degree of erythema that is the hallmark of most guinea pig assays. Of the various mouse models developed including the mouse ear swelling test (MEST) [116], the murine local lymph node assay (LLNA) first described by Kimber and Weisenberger [117] has undergone extensive validation studies [118] and is rapidly replacing guinea pigs tests as the method of choice for identifying contact sensitizers and, thus, will be described in detail in this section.

Considerable efforts have been devoted to establishing relatively simple tests to identify respiratory and food allergens. Guinea pig models have been used historically for the assessment of potential respiratory sensitizers [119,120]. One is directed to a number of excellent reviews on the use of these assays in risk assessment and drug development [121–123]. In addition, murine models for assessment of respiratory sensitizing potential, such as cytokine fingerprinting and the mouse IgE test, have been examined for their utility [124–126]. Likewise, a number of models are being developed to identify food allergens including the development of IgE antibody in brown Norway rats or BALB/c mice and a transgenic mouse strain engineered to produce class II HLA molecules (reviewed by Tryphonas et al. [127]).

Buehler Assay

The Buehler assay [128] was originally developed to evaluate strong and moderate contact sensitizers, leaving only negative or weakly positive compounds for testing in humans.

The hallmark of the Buehler assay was the use of an occlusive patch to enhance or exaggerate exposure to test materials. This method also has the advantage of using an exposure method similar to that encountered in human exposure.

The specific technique for performing this assay is involved and is only summarized in the following. A detailed description of the assay has been provided by Buehler [128,129].

Materials and Reagents Required:

- Young adult albino guinea pigs (Dunkin–Hartley strain)
- Guinea pig restrainers
- Patch delivery system (e.g., Hilltop chambers, Webril patch, PMP patch)
- Dental dam

Procedure:

1. On the day before induction exposure, clip the guinea pig's fur. Expose the skin to the selected test dose using a patch delivery system and then restrain the animal using a combination of guinea pig restrainer and dental dam. Duration of exposure, number of inductions, and induction regimens may vary but are generally three 6 h induction exposures with an interval of 5–9 days.
2. Approximately 2 weeks after the last induction exposure, the animals are exposed to the test material again but at a different skin site that has not been previously exposed. Again, the timing and duration of exposure may vary.
3. If necessary, an animal may be rechallenged with test material between 6 and 14 days following the primary challenge.
4. The day after the challenge or rechallenge, depilate the animals using a commercial depilatory. Two hours later, the animals are ready to be scored.
5. Results are scored as 0 (no reaction), ± (slight patchy erythema), 1 (slight but confluent erythema), 2 (moderate erythema), and 3 (severe erythema, with or without edema). Scoring should be performed at 24 and 48 h after the challenge or rechallenge.
6. Scores of 1 or greater in the test group usually indicate that the test material is a sensitizer, if the scores in control animals are less than 1. Results of the challenge and rechallenge should be expressed as both incidence and severity.

Positive Control:
DNCB has been the traditional positive control for this assay. Suggested test concentrations are 0.3% DNCB in ethanol for induction and two concentrations of DNCB in acetone (0.05% and 0.01%) for challenge. Inclusion of two different challenge doses provides for a range of response [129].

Notes:

1. An irritation screen is performed prior to the actual test. This assay requires an induction concentration that will not produce severe irritation or toxicity. The concentration used for challenge should produce only a slight degree of irritation.
2. Proper technique is essential to the success of this assay. In particular, animal restraint, test material occlusion, and consistency in scoring are all critical aspects. Whenever possible, it would be advisable to learn these techniques from a laboratory that has already demonstrated success with the assay.
3. Due to the relatively small number of animals and the nature of the readout, statistical analysis has not generally been practical for this assay. Rather, hazard assessment has been defined in terms of threshold levels.
4. It is important to maintain occlusion for the entire duration of the exposure in this assay. Proper use of the restraining devices is considered to be critical to obtaining consistent, meaningful results. Proper clipping and depilation of the animals are also important variables.

Guinea Pig Maximization Assay

The maximization assay was described by Magnusson and Kligman in 1964 [130] and was developed to *maximize* the sensitivity of guinea pig tests. This was accomplished by intradermal injections of test material, inclusion of Freund's complete adjuvant (FCA), and the use of a pretreatment to irritate the skin at the site of exposure. These treatments enhanced the chance of a test material to penetrate the skin and subsequently produce allergic contact dermatitis [131]. Perhaps even more so than the Buehler assay, the maximization assay is technically detailed, and only the basics of its performance are summarized in the following.

Materials and Reagents Required:

- Young adult albino guinea pigs (Dunkin–Hartley strain)
- FCA
- Hilltop chambers or PMP patches
- Hypoallergenic tape and elastic wrap
- Dental dam

Procedure:

1. Similar to the Buehler assay, a preliminary irritation/toxicity screen must be performed to determine the highest concentration of test material that can be tested. Both intradermal injection and occlusive patch tests are performed.
2. For the induction step, the animal's fur is clipped over the back on either side of the spine, and test material is injected intradermally in a volume of

0.1 mL. Each animal receives a total of six injections: two each of diluted adjuvant, two each of adjuvant containing test material, and two each of test material in vehicle. Control animals are treated similarly but do not receive test material. Let the animals rest for 6 days.

3. If the test material being used is not an irritant, the injection sites should be treated with 10% sodium lauryl sulfate in petrolatum under an occluded patch for 24 h. This step may be skipped if the test material is a known irritant.
4. Place 0.8 mL of test material on a PMP patch (booster patch) and place this patch over the injection sites. Cover with dental dam and wrap the animal with elastic tape. Control animals should be treated with vehicle only. Remove the booster patch after 48 h.
5. Challenge the animals 10 days later by exposing to test material (or vehicle) under an occlusive patch (PMP patch or Hilltop chamber). Wrap the animals with dental dam and elastic tape. *Note*: Animals must be clipped prior to challenge, since the fur will have grown back.
6. Remove the patches 24 h later. Approximately 21 h later, remove any remaining fur with depilatory. Grade the reactions approximately 24 and 48 h, after the challenge patches are removed.
7. Animals may be rechallenged with the same test material at the same or a different site within 2 weeks of the primary challenge. Naive test sites should be used on the animals.
8. The grading of this assay is similar to that of the Buehler assay.

Positive Control

The positive control material generally used in the maximization test is 1-chloro-2,4-dinitrobenzene, at a concentration of 0.1% in a vehicle of propylene glycol for the intradermal injections. The booster patch incorporates 0.1% (w/v) of test material in an 80:20 ethanol/water (vol/vol) vehicle.

Murine Local Lymph Node Assay

Guinea pig contact sensitization models have been used for assessing the potential of compounds to induce hypersensitivity reactions for some time, but they have certain drawbacks. The endpoints are subjective and require skilled technicians to evaluate the intensity of the reaction; in addition, this subjectivity precludes the use of statistical analysis. Moreover, the assays are relatively expensive and time-consuming, and there are animal welfare issues regarding the use of an adjuvant. Although none of these issues alone are major detriments, together they led to the search for an alternative method.

In 1989, Kimber and Weisenberger [117] reported the development of an alternative approach to assess potential contact hypersensitivity using the mouse as a model system referred to as the LLNA. In contrast to the guinea pig tests described previously, sensitizing activity is assessed as a function of events occurring in the induction, rather than the elicitation phase of sensitization and, thus, does not utilize a secondary (challenge) exposure to the test material. The test involves quantifying cell proliferation in the draining lymph node following topical application of the test material. The LLNA exhibits a number of advantages over guinea pig assays including more quantitative and objective endpoints, insensitivity to colored compounds, reduced turnaround time and cost, being independent of specialized reagents or materials (adjuvant, wrapping material), and benefits to animal welfare. Currently, the LLNA has become the preferred method for assessing skin sensitization hazard by most regulatory authorities.

The biological basis of the LLNA is simple. Test materials are applied epicutaneously to the dorsal surface of the pinnae (Figure 37.7). The test agent is transported from the skin by Langerhans cells to the draining (i.e., local) lymph node, where it is presented to T-lymphocytes. Contact sensitizers induce proliferation of these T-cells. By radiolabeling

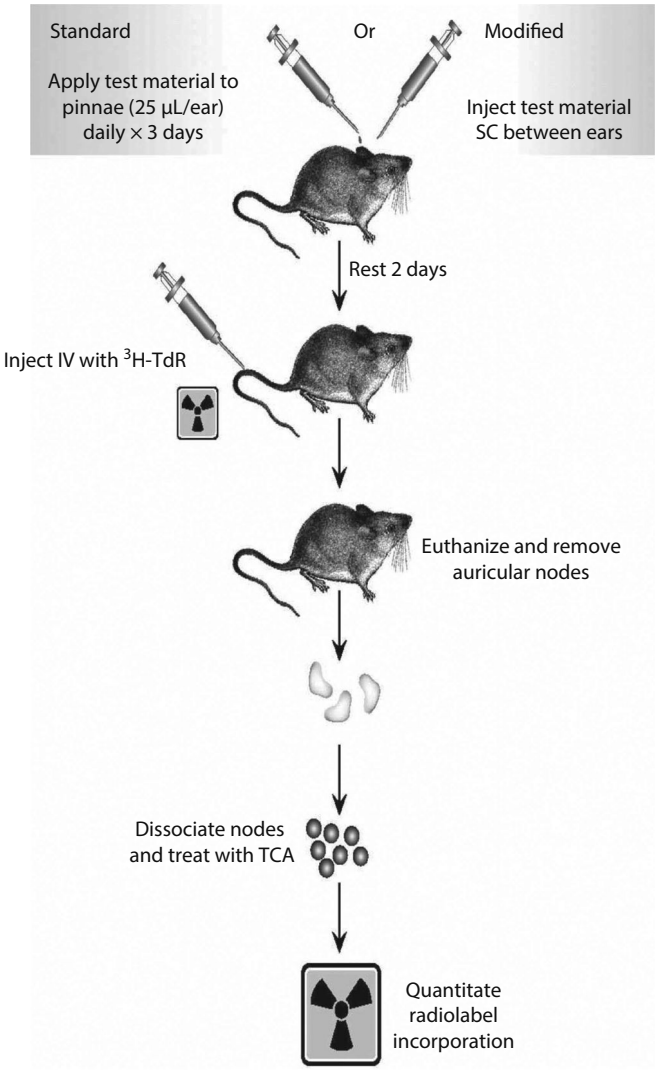

FIGURE 37.7 The murine LLNA.

these proliferating cells in situ using a radioactive tracer or a direct cell count, it is possible to determine the degree of proliferation induced. It is important to note that the LLNA does not utilize a secondary exposure (challenge) to the test material, as do the guinea pig assays. Thus, the LLNA differs fundamentally in that it evaluates only the induction phase of the hypersensitivity response. A chemical is classified as a skin sensitizer if at one or more test concentrations it induces a threefold or greater increase in draining lymph node cell proliferation compared with concurrent vehicle-treated controls (stimulation index [SI] ≥ 3). In the original LLNA, four mice per treatment group were used. Recently, the use of a reduced (r) LLNA has been approved by the International Coordinating Committee on the Validation of Alternative Methods (ICCVAM) under certain circumstances. Since the rLLNA does not provide dose–response information, its utility for risk assessment purposes is limited.

The LLNA has been the subject of numerous international validation studies, including a round of international validation studies employing a standardized protocol [132–134]. The LLNA validation data were evaluated by ICCVAM, and the assay was found to provide an equivalent prediction of the risk for human contact dermatitis when compared to guinea pig assays [135,136]; in addition, the method was robust, sensitive, and reproducible. More recently, efforts have been made to define how the LLNA can be used to measure the relative potency of contact allergens including a two-category system for the classification and labeling of sensitizers under the Globally Harmonized System of Classification and Labeling of Chemicals (high or low potency), which correlates well with findings in humans [137,138].

The following protocol is the standard procedure recommended by the ICCVAM Working Group (IWG) [139]:

Materials and Reagents Required

- Female CBA/J mice, 6–9 weeks old at initiation of assay
- Tritiated thymidine ([^{3}H]TdR), specific activity 5–10 Ci/mM
- PBS
- Nylon mesh (100 μm opening size)
- 15 mL conical capped polypropylene centrifuge tubes
- 5% (w/v) trichloroacetic acid (TCA)
- Scintillation vials and scintillation cocktail

Method:

1. Apply vehicle, test compound, or positive control compound to the dorsum of each pinna (25 μL/ear), ensuring that the vehicle is evenly distributed on the pinna. Dose the animals daily for 3 consecutive days.
2. Rest the mice for 2 days, and then inject each mouse intravenously with 20 μCi of [^{3}H]TdR in saline.
3. Five hours following [^{3}H]TdR injection, euthanize the mice by CO_2 and remove the lymph nodes draining the ear. Place the nodes from individual mice in culture tubes containing 4 mL of PBS.
4. Transfer the nodes from the culture tubes to Petri dishes containing a 1 in.^{2} of nylon mesh. Gently rub the lymph node cells through the mesh, then transfer the cell suspension back to the tube, and allow it to settle for approximately 5 min.
5. Transfer the cell suspension to a 15 mL centrifuge tube containing 6 mL of PBS, taking care not to transfer the sedimented debris. Centrifuge the tubes for 10 min at approximately 200 × *g*. Wash the cells a second time in PBS.
6. After the second wash, suspend the cell pellet in 3 mL of 5% TCA and incubate at approximately 4°C for approximately 18 h.
7. Centrifuge the cell suspensions at approximately 200 × *g* for 10 min, discard the supernatant, and suspend the pellet in 1 mL of 5% TCA. Transfer this suspension to a scintillation vial. Rinse the culture tubes with an additional 1 mL of TCA, and add this to the scintillation vial. Mix the contents of the vial thoroughly.
8. Count the samples in a scintillation counter for 5–10 min, and record the counts as disintegrations per minute (DPMs).
9. Using the results obtained with the vehicle controls as baseline, calculate the SI (i.e., mean experimental results divided by mean control results). Test compounds that induce an SI of 3 or greater at any concentration evaluated in this assay, and for which test DPM are statistically different from control DPM, are considered to be contact sensitizers.

Positive Control:

Hexylcinnamaldehyde (a contact sensitizer of moderate activity) in a solution of 20% serves as a useful positive control for this assay.

Notes:

1. The LLNA is technically straightforward and has been demonstrated to be forgiving of technical modifications. Perhaps the only difficulty a new investigator might have is in locating the lymph nodes draining the pinna. A relatively simple way to determine this is to inject the ears with a dye (e.g., Evans Blue) and subsequently identify the nodes incorporating the dye. In 2010, the Organization for European Cooperation and Development (OECD) adopted two modified skin sensitization LLNA (OECD 442A [*Skin Sensitization: Local Lymph Node Assay: DA*] and OECD 442B [*Skin Sensitization: Local Lymph Node Assay: BrdU-ELISA*]) without the use of radioactive material.
2. The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) has developed standard performance for the LLNA [140].

Techniques for Assessing Autoimmunity

A number of experimental animal and in vitro models are available to study the mechanisms of autoimmune disease (Table 37.9). However, immunotoxicology screening studies to identify autoimmune-inducing agents have historically used autoimmune-prone rodents and monitored for the accelerated development of autoimmune disease as indicated by elevated levels of serum autoantibodies and/or Ig levels as well as histopathological changes in the target organ(s) or changes in serum chemistries. While a number of syndromes similar to those observed clinically in humans can be mimicked in animal models, the diversity of immune mechanisms and pathogenesis of autoimmune diseases limits the utility of any single model as a screening tool and validated tests do not exist. The primary reason for the lack of validated assays probably stems from the complexity of the disease. Autoimmune disease is not one disease but a group of over 25 diseases affecting distinct organs, often through different mechanisms. Unless a common early process is identified, a single test would be unlikely to provide an adequate degree of concordance to be useful for predictive risk assessment. Secondly, in humans, intrinsic factors (e.g., specific gene polymorphisms, sex-related hormones, and age) and extrinsic factors (e.g., lifestyle, infectious agents) are sometimes strongly associated with the induction, development, and exacerbation of autoimmunity. Lastly, when using animal models, there is some uncertainty regarding what actually constitutes autoimmunity. This is also reflected by a lack of well-defined diagnostic tests for identifying autoimmune disease in humans. Despite these challenges, attempts to develop predictive screening assays for detecting xenobiotic-induced autoimmunity have been undertaken in several laboratories. While screening approaches have most often used spontaneous autoimmune-prone rodents [135], other approaches have included the following: identifying immunoglobulin complexes or immunoglobulin deposits using immunohistological procedures, monitoring for increased levels of serum autoantibodies, and the use of the popliteal lymph node assay (PLNA) with reporter antigens [112,141].

The successful use of exacerbating disease by chemical exposure in autoimmune-prone rodent species has been illustrated by administering streptozotocin in diabetic mice [137] or $HgCl_2$ in glomerulonephritis-prone rodents [142]. Less studied has been the monitoring of Ig deposits or autoantibody production. In the PLNA model, the *autoimmunogenicity* of a chemical, believed to mimic the GVH reaction, is determined by its ability to stimulate specific IgG responses to TNP–Ficoll and TNP–ovalbumin in the popliteal lymph node (PLN). It is independent of the nature of the neoantigens and eliminates many of the potential genetic confounders. In this assay, the test compound is coinjected with 10 μg TNP–Ficoll or 10 μg TNP–ovalbumin subcutaneously into the right hind paw of BALB/c mice. The amount of test substance injected can be equimolar to a related compound or, if known, a concentration demonstrated to be stimulatory in the PLNA. Seven days following treatments, the thickness of the paw is measured using a micrometer and the draining PLN is isolated. Specific AFCs from the PLN are quantitated by any one of several methods such as ELISPOT. For memory responses, mice are similarly treated and then challenged in the right paw with 10 μg antigen, 4–5 weeks following the primary immunization, and antibody-producing cells from the PLN determined 6 days later. Serum samples can also be collected weekly following the primary immunization and serum antibodies determined using commercial procedures.

TABLE 37.9
Examples of Potential Experimental and Screening Models for Autoimmunity

Experimental models to study autoimmunity

Organ-specific autoimmunity
- Induced by immunization (EAE, AA)
- Spontaneous mice (NOD, transgenics)
- Toxicant induced (streptozotocin, Cd)

Systemic autoimmunity
- Allogeneic reactions
- Neonatal thymectomy
- Spontaneous mice (NZM)

Models to evaluate the potential of xenobiotics to induce autoimmunity
- PLNA with reporter antigens
- Increased titers of antibodies to self-constituents
- Examination of Ig complexes/deposits (immunohistochemical staining for immune complexes)
- Spontaneous animal models

Notes: PLNA, popliteal lymph node assay; Ig, immunoglobulin; EAE, experimental autoimmune encephalitis; AA, autoimmune arthritis; NOD, nonobese diabetic (develop immune diabetes); Cd, cadmium; NZM, New Zealand mixed (prone to develop lupus).

EVALUATION OF IMMUNOLOGICAL CHANGES IN HUMANS

Fundamental Concepts

Although infectious disease is the most obvious adverse consequence of immunotoxicity (immunosuppression), the etiology, progression, and/or severity of a much broader range of disorders including certain cancers, allergy, and autoimmune disease can result. Establishing the quantitative relationship between altered immune responses and frequency or severity of diseases in human populations is challenging, as many factors may contribute [143]. This can be summarized schematically in Figure 37.8, where the appearance, progression, and outcome of infectious disease are viewed as an interrelationship between the virulence of the organism, infectious dose (number of organisms required to produce illness), the integrity of the host's anatomical and functional barriers, and the overall immunocompetence of an individual. The latter, in turn, is affected by genetics as well as age, gender, use of certain medications, drug/alcohol use, smoking history,

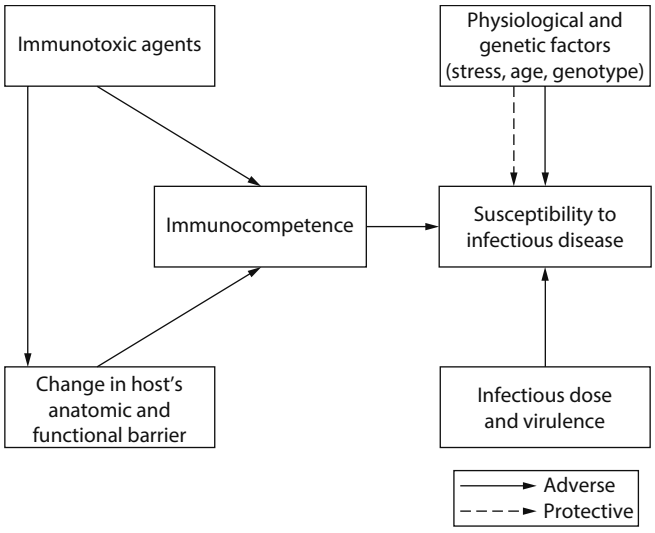

FIGURE 37.8 Relationship between altered immune responses and frequency or severity of human disease.

stress, and nutritional status. These factors probably account for most of the variability reported in mean immune values, which in some instances demonstrate two standard deviations.

Infectious agents associated with immunodeficiency disorders include community-acquired (common), opportunistic, and latent pathogens. Community-acquired pathogens, such as influenza virus, occur in the general population at frequencies associated with their infectious nature. The respiratory system is the most vulnerable target for common pathogens. Upper respiratory infections occur in all age groups but, due to their lack of immunocompetence, can be more severe in the very young and very old. Although influenza is responsible for more morbidity and mortality than any other infectious agent in recorded history [144], the low individual rates of infections in the general population (only one or two episodes in an individual per year), combined with underreporting, make changes in infection rates difficult to detect in prospective epidemiological studies. While infections with common pathogens occur in the healthy population, opportunistic infections, such as *Candida albicans*, *Mycobacterium avium* complex (MAC), and *Pneumocystis carinii*, are most often seen in patients with profound forms of immunosuppression such as HIV/AIDS or primary immunodeficiency diseases. A third group of infections that are observed in immunosuppressed individuals is reactivation of latent infections. The most common agents are from the herpes virus family, which include cytomegalovirus (CMV), herpes simplex virus (HSV), and Epstein–Barr virus (EBV). These viruses remain in the tissue in a latent form following primary infection for the duration of the host's life. In healthy individuals, the immune system usually maintains viral latency. When the cellular immune response is compromised, viral replication can ensue and clinical consequences ensue such as the appearance of cold sores although in some instances, severe complications can ensue. Preceding viral activation, a vigorous immune response to viral-specific antigens occurs in response to replication. Infections with these viruses can occur in individuals with secondary immunodeficiency disorders where mild-to-moderate immunosuppression exists (reviewed in [145]).

Immunodeficiency is also associated with an increased incidence of certain virally induced tumors, such as non-Hodgkin's lymphomas (NHLs) and tumors of the skin [146]. In contrast to cancers of internal organs, in particular those in the lung and liver that are often induced by chemical carcinogens, virus-induced cancers are more immunogenic and, thus, more likely influenced by immunological factors. Suppression of CMI has been associated with higher incidences of skin cancers, leukemias, and lymphoproliferative disorders in transplant patients, whereas Kaposi's sarcoma and EBV-associated B-cell lymphomas are associated with severe immunosuppression as seen in patients with AIDS.

General Testing Considerations and Approach

The design of human studies can range from controlled clinical trials to large, population-based observational studies. Clinical studies offer advantages in that exposure parameters of interest can often be controlled (e.g., clinical drug trials, chamber studies of inhaled toxicants, challenge studies of adenovirus infection) and outcomes can be prospectively monitored. However, there are also disadvantages as ethical considerations provide little opportunity for exposure with suspected toxic chemicals. Furthermore, studies with extensive biological monitoring and functional immune tests can be expensive, and exposures as well as outcomes of interest may be difficult to study in the available time frame as study participants are not typically available for long-term exposures or extended follow-up. For the purpose of obtaining data for immunotoxicological risk assessment, clinical studies are particularly useful as they provide an opportunity to collect data on the frequency of infections or the level of immune response to vaccines. Variations on this type of study design might include follow-up of patient populations administered immunosuppressive therapy (i.e., transplant patients) that, as described in the following, may also have many of the characteristics of observational studies. Other types of human studies that have been employed in immunotoxicology are typically classified as observational or epidemiological. Observational studies can be of varying size and be cross-sectional (one point in time), retrospective, or prospective in nature, each design having advantages and disadvantages. The initial means of control in observational studies is introduced through the study design, and the quality and validity of results can be greatly affected by the methods used to select the study sample and the rigor with which exposures and outcomes are measured. In addition to high costs, observational studies are challenging for many reasons, including potential confounding by host (age, gender, and lifestyle) and environmental (frequency of exposure to chemicals and infectious agents) factors. A secondary measure of control in observational

studies is through the use of multivariable analysis techniques (e.g., regression modeling), provided there is sufficient sample size and information on potential confounders. Overall, well-designed epidemiological studies (e.g., absence of selection bias, exposure or outcome misclassification, and control of confounding) can contribute valuable information to the assessment of risk due to immunotoxic exposures. Because of concern about individual variation, a confirmatory evaluation and a cross-sectional or longitudinal study design can be employed using randomized normal, nonexposed individuals. It is also imperative to obtain a careful medical history, that covers the clinical features of immune dysfunction and accurate exposure assessments.

Testing for primary immunodeficiency diseases is normally undertaken by a stepwise (tiered) approach [147] and is usually initiated because the patient has a history of excessive infectious disease episodes. Initial screening tests include measurements of general parameters, such as CBCs, serum immunoglobulin levels, chest radiograph of the thymus (for adolescents), and delayed hypersensitivity tests. In immunotoxicology, this screening paradigm may be appropriate for clinical studies or in individuals where significant immunosuppression is suspected. However, this approach is unlikely to detect subtle immune changes, and there are no currently validated tests for determining immunotoxic effects in human epidemiological studies. A systematic approach based on simple screening procedures followed by more specialized tests of immune function should provide the best overall assessment. This approach should include the functional evaluation of cellular immunity (T-cell), an antibody response (B-cell), and nonspecific resistance (e.g., PMN function). Recently, it has been suggested that immunization through vaccination, in order to elicit a primary immune response, may be the best criterion to establish immunotoxicity [148]. Most investigations have included one or more of the following: CBCs and differential, immunophenotypic analyses, quantification of serum immunoglobulin levels, and subject's recall of infectious disease frequency.

Tests Commonly Conducted in Humans

Complete Blood Count and Differential

Complete white blood cell counts (WBCs) and a cell differential on all individuals whose immune status is being evaluated are routinely incorporated into a Tier I panel (Table 37.10). The data should be expressed as absolute lymphocyte count for each cell type that is the total WBC multiplied by the differential percentage for that cell type. Higher absolute lymphocytes counts should be expected in children than adults and in certain ethnic groups. Lymphocyte counts consistently below 1500/mm^3 are indicative of lymphocytopenia and may signal a defect in the T-cell system. Lymphocytopenia can be associated with primary immune deficiency disease but also can occur secondary to viral infections, malnutrition, severe stress, autoimmune diseases, and hematopoietic malignancy. When lymphocytopenia is repeatedly observed, a bone marrow biopsy is recommended as an important adjunct for exclusion of other diseases and for identification of normal PCs, pre-B-cells, or diagnosis of bone marrow depression or dysplasia. Individuals with lymphocytopenia should be reevaluated and further assessed for changes in CMI. Lymphocytosis can be caused by chronic infections or allergic reactions. Monocytosis is often associated with stress, infections, and hematologic disorders. Eosinophilia can be caused by allergic reactions, parasitism, skin diseases, neoplasia, and adrenocortical dysfunction.

Immunoglobulin Concentrations

Serum concentration of the major immunoglobulin classes IgG, IgM, and IgA can be readily measured in epidemiological studies. There are several standardized laboratory methods and reagents available for measuring these major classes of immunoglobulin. These methods include single-radial diffusion, double diffusion in agar gel, immunoelectrodiffusion, radioimmunoassay, enzyme-linked immunoassay, and automated laser nephelometry. Serum Ig concentrations vary with age, ethnicity, geographical location, gender, and

TABLE 37.10
Classification of Immune Assessment Tests for Humans

I. Basic Tests	General Indicators	Procedures
Should be included with general health panels along with immune status questionnaire	• Assay methods are standardized among laboratories. • Results are clinically interpretable. • Reference ranges established.	1. CBC and differential 2. Acute phase proteins (CRP) 3. HI: serum IgG, IgA, and IgM levels 4. CMI: delayed-type skin test
II. Confirmatory Tests	**More Specific Immune Tests**	**Procedures**
Should be included when indicated by clinical findings or prior test results	• Assay methods are less standardized. • Results are difficult to interpret. • Reference ranges less well established.	1. Surface marker analysis: assessment of phenotypes for major lymphocyte subsets (CD3, CD4, CD8, CD2) 2. HI: primary antibody response to immunogen; total serum IgE; secondary Ab response to proteins and polysaccharide antigens 3. Nonspecific: autoantibodies (ANA, DNA, mitochondria, RA); granulocyte/leukocyte function (oxidative burst) 4. Bank serum sample for additional analysis

environment. Thus, appropriate norms must be used with any type of population assessment. Patients with primary immunodeficiency disease can manifest a profound decrease in all Ig classes or only in a single class or subclass and are associated with increases in infectious disease frequency. The adverse health effects associated with small changes in immunoglobulin levels are unclear.

Delayed-Type Skin Testing

Skin testing is a commonly used procedure (Basic Panel, Table 37.10) to assess cellular immune competence since delayed cutaneous hypersensitivity, a localized immunological skin response, depends on functional T-cells and the production of inflammatory cytokines. Antigens commonly employed to elicit a positive skin response include purified protein derivative (PPD), mumps, trichophyton, candida, tetanus, or diphtheria. These antigens usually are employed in a panel and are administered by intradermal injection at the appropriate dilution. Skin responses are read at 48 and 72 h for maximal diameter of erythema and induration. The test is not considered very sensitive unless very severe immunosuppression is suspected, which is unlikely to occur.

Specific Antibody Assessment

Recently, efforts have been made to quantify the response to vaccines, either by measurement of antibody titers (HI) or lymphocyte proliferation tests (CMI) to specific vaccine epitopes following vaccination as an indicator of immune function. To use this test in children, the study will need to be conducted in specified age groups and serum samples collected at specific times following vaccination to help limit variability. A number of investigations have examined associations between chronic psychological stress and immune function in adults using hepatitis B, influenza virus, influenza, or pneumococcal vaccine responses [149,150]. More recently, Sleijffers et al. [151] demonstrated a decreased response to hepatitis vaccination in a subgroup of students exposed to ultraviolet radiation in association with polymorphisms in genes that control inflammatory cytokines. An excellent review on the use of vaccination in immunotoxicity testing has recently been published [152].

Although quantifying vaccination responses for clinical diagnoses has not been validated, the ability to detect changes in populations with moderate degrees of immunosuppression, likely associated with the previous examples, suggests a level of sensitivity that would unlikely be achieved with more commonly employed clinical tests such as immunophenotyping or determination of immunoglobulin levels. Historical values for normal vaccine responses in children can be found. For example, Swartz et al. [153] monitored changes in antibody titers in a large group of children following diphtheria–tetanus–pertussis (DTP) vaccination from birth to 8 years of age. Antibody titers to diphtheria, while significantly elevated shortly after the primary and secondary (booster) immunizations, were almost undetectable at 3 years of age. These data are applicable to epidemiological studies as they provide an indication of the antibody decay rates and the variability in titers that may be expected to occur within a normal population.

Phenotypic Analysis by Flow Cytometry

Enumerating cell surface markers (CD) on lymphoid cells by flow cytometry has provided considerable information on the ontogeny and activation state of the human immune system in children and adults, as well as assisting in the clinical diagnosis for immunological and hematopoietic disorders [154]. Specific CD markers have been identified for almost all lymphoid cell populations and subpopulations, as well as for specific stages of cell differentiation and activation. In contrast to adults, children in the first few years of life have a much larger number of total lymphocytes, and both the percentage and numbers of leukocyte populations can vary significantly during critical periods of development. Age-related differences in immunophenotypic profiles in children were recently addressed by the Pediatric AIDS Clinical Trials Group, sponsored by the National Institute of Allergy and Infectious Diseases and National Institute of Child Health and Human Development [155]. In this study, lymphocyte subsets were phenotyped in 807 normal children ranging from birth to 18 years of age. Despite efforts to control for inter- and intralaboratory methodological differences, the variance within each age group was significant, often exceeding twofold, even when discarding the highest and lowest 10th percentile. Certainly, not all the variability in human immunophenotyping studies is related to technical variability, as both genetic and environmental influences play even more significant roles [156]. Nonetheless, this database may prove useful for epidemiological studies in developmental immunotoxicology as it not only provides extensive reference values but can assist in developing appropriate study designs.

Immunophenotyping is conducted using flow cytometers that have multiple photomultiplier tubes (four or more) and are capable of measuring three-color fluorescence, 90° light scatter, and forward light scatter. When highly specific fluorochrome labeled monoclonal antibodies are used in these instruments, very quantitative measurements can be made of B- and T-cell subsets. The most commonly used procedure for processing peripheral blood samples for immunofluorescence is first to stain an aliquot of whole blood with fluorescent-conjugated monoclonal antibodies and then to lyse the erythrocytes. The proportion of circulating T-cells is then determined by immunofluorescence with Fluor-labeled CD2 or CD3 monoclonal antibodies in a flow cytometer. Normally, T-cells constitute 55%–80% of peripheral blood lymphocytes. Normal values reported for absolute numbers of circulating T-cells are 590–3090/mm^3 for individuals greater than 18 months of age [157]. If an immune defect is suspected, the ratio of CD4 to CD8 T-cells can also be beneficial. Although this method is quite quantitative, the ability of this test method to detect subtle immune changes in populations of individuals has recently been challenged [154].

Nonspecific Measurements

Neutrophil Function

The measurement of nitroblue tetrazolium dye reduction by actively phagocytosing PMN is a method that has been historically utilized when a PMN defect is suspected. Flow cytometric methods are also available [158].

Autoantibodies

It is often stated that the immune system is established on a principle of self-/nonself-recognition. In some cases, tolerance to self-antigens breaks down and autoantibodies are produced, which can be manifested as autoimmune disease. Antibodies to cellular components and nuclear antigens (ANA, DNA, mitochondria) and to rheumatoid factor (RA) and their frequency in a population may reflect an immune alteration. Standardized diagnostic kits are available to detect the presence of these autoantibodies in sera. Finally, it is a good practice to establish a freezer bank of an aliquot of each test subject's sera for later evaluation when new research questions or test methods are developed.

RISK ASSESSMENT AND DATA INTERPRETATION

Immunotoxicology data used in risk assessment are derived primarily from animal toxicology studies. When adequate data are available, epidemiological or controlled clinical exposure studies take precedence. The results obtained from in vitro studies, quantitative structure–activity relationships (QSARs), or mechanistic investigations are used normally as supportive information. Mechanistic studies, however, are important, as they help determine plausibility and human relevance [159]. Interpretation of immuntoxicology data is dependent upon the immunopathology studied, that is, suppression/stimulation, hypersensitivity, or autoimmunity.

Immunosuppression

Animal studies for testing immunosuppression or stimulation are used primarily for semiquantitative hazard identification. Since tests for immunosuppression use multiple and, to some extent, overlapping endpoints, the data can also be evaluated in terms of establishing an immune profile. This may help allow to identify the *mode of action*, such as direct cytotoxicity, hematopoietic toxicity, altered immune regulation, or altered regulatory circuits. At the least, the test panel can determine which arm of the immune system is the primary target. Hazard identification for immunosuppression can also be described as a weight of evidence approach as recommended by recent guidance documents prepared by the IPCS/WHO [159]. This approach suggests addressing seven specific questions in which weights are given for various endpoints including in vitro studies, QSAR, human studies, and other animal studies. The strength of association will also take into account dose–response relationships, consistency of association, temporal association, biological plausibility, specificity, coherence, and analogy.

Hypersensitivity/Allergy

In cases where ethical considerations prevent the use of human patch testing to establish the potential of agents to induce allergic contact dermatitis, animal models, particularly the Buehler-occluded and Magnuson–Kligman maximization tests in guinea pigs, have been used as predictive tests. Several graded doses of antigen may be examined simultaneously and comparing skin reactions in individual animals can generate an entire dose–response curve. However, it is expensive to purchase and maintain guinea pigs, there are few inbred strains, and immunological reagents are not widely available. Furthermore, there is some suggestion, although never fully substantiated that these models are overly sensitive when compared to the experience in humans and produce a low frequency of false positives.

While the strengths and weaknesses of the LLNA have been discussed earlier (see "Murine Local Lymph Node Assay" section), it is important to note that the assay has undergone a series of examinations to provide *technical refinement* and assess *inter- and intralaboratory reproducibility*, as well as relative sensitivity and specificity, referred to as *concordance* [135,140,160]. Concordance for a new assay should be established to previously used test models as well as to available human data. Such data for the LLNA [130,131] indicated that the LLNA was highly comparable to guinea pig tests (concordance almost 90%), but only about 70% accurate when compared directly to human studies. As this is similar to results obtained when guinea pig tests are compared to human studies, in terms of risk assessment, the LLNA can be used in lieu of guinea pig tests, but an alternative assay that could provide higher concordance with humans would be desirable.

In contrast to predictive tests for allergic contact hypersensitivity, the identification of proteins and chemicals capable of inducing respiratory hypersensitivity is in its infancy. As these tests are difficult to undertake, often involving respiratory exposure and lung function tests, efforts to develop and validate new methods are limited. Although the guinea pig has significant immunological differences compared to humans (e.g., IgG1 vs. IgE reaginic antibodies), it appears to be a predictive model for humans given the limited comparative data available and has been used to test for high- and low-molecular-weight sensitizers. This test requires a systemic or inhalation sensitization phase and an aerosol challenge, and both immediate and delayed-onset responses are measured, although this does not distinguish between nonspecific pulmonary hyperreactivity and specific immune responses [161]. The latter can be established by examining sera for the presence of reaginic antibodies.

Like immunosuppression, LLNA data are used primarily for hazard identification. Since multiple doses are evaluated, the results can be interpreted in a semiquantitative manner, or at least in terms of relative potency, based upon the lowest concentration that elicits a response above an EC3. Two-category systems have been introduced for the classification and labeling of sensitizers under the Globally Harmonized

System of Classification and Labeling of Chemicals (high or low potency), which correlates well with humans. LLNA results should also be evaluated broadly in terms of a weight of evidence approach as recommended by IPCS/WHO [159], using all available data including QSAR, additional animal studies, and human data.

Autoimmunity

General agreement exists among the regulatory and pharmaceutical communities that predictive tests for autoimmunity or systemic allergy are in most need of development in order to improve risk assessment in immunotoxicology [112]. While many models exist to study autoimmune processes, they do not readily lend themselves to use in risk assessment, as they do not consider the multifactoral nature of the disease. To improve the risk assessment process, screening models need to be developed and validated that not only incorporate mechanistic information into the assessment process but also allow for the consideration of the genetic, physiological, and environmental influences that lead to the loss of self-tolerance, autoimmune disease, or systemic allergy. Despite the challenges in developing such screening tests, the considerable amount of data generated by immunologists and pharmacologists pertaining to basic mechanisms of chemical-induced autoimmune diseases has provided a conceptual framework, which allows the establishment of potential QSARs. These QSARs are by no means definitive, and as the database increases, no doubt some will not be supported while others will be added. In all cases, a basic understanding of immunological and pharmacological processes supports these relationships. For example, estrogens are known to be a major factor in classical autoimmune diseases presumably due to their ability to stimulate certain components of the immune system [162], and as such, agents with estrogenic activity may be of concern.

Laboratory studies have also shown that thymolytic chemicals, such as cyclophosphamide and cyclosporin A, can induce autoimmunity when given neonatally by altering normal patterns of autoreactive T-cell deletion [163]. In this respect, the thymus has been shown to be a target for many toxic chemicals. As in the case of halothane, chemicals that form protein adducts or damage tissue in such a way to allow expression of cryptic determinants would provide novel host antigens that could now be recognized by T-cells. Agents that have adjuvant activity, or biologicals that stimulate certain cytokines, may shift the balance of Th1 and Th2 cells and allow exacerbation of preexisting autoimmune disease [164]. Common features associated with many drugs that induce autoimmune diseases are that they serve as myeloperoxidase substrates and/or cause changes in methylation [165]. The explanation for the latter association is less clear but may require identification of the specific antigenic epitopes responsible for the autoimmune response. In the case of the association with myeloperoxidase substrates, it has been suggested that many of the chemicals require metabolism in proximity to immune cells in order to be antigenic and immune cells such as monocytes contain high levels of myeloperoxidase.

In the interpretation of autoimmunity studies, any effect and/or dose–response relationship should be evaluated relative to generalized overt toxicity as well as for consistency, specificity, and coherence. The data should also be interpreted in context of all the tests that were examined for autoimmune potential whether supportive or not, as recommended in IPCS/WHO [159]. Again, this implies a weight of evidence using all available data including QSAR, in vitro, human, and laboratory animal data that are relevant to either induction or exacerbation of autoimmunity whether supportive or not.

REGULATORY GUIDANCE FOR ASSESSMENT OF IMMUNOTOXICITY

Overview

Some of the earliest codified immunotoxicology test guidelines were developed to augment toxicological assessment of pesticides. In 1996, the Office of Prevention, Pesticides, and Toxic Substances (OPPTS) of the U.S. Environmental Protection Agency (EPA) published guidelines entitled *Biochemicals Test Guidelines: OPPTS 880.3550 Immunotoxicity* [166], which described the preferred study design for evaluating potential immunotoxicity in biochemical pesticides. The panel of tests included in this guideline includes standard toxicology tests as well as immune function tests. A second document published concurrently (*Biochemicals Test Guidelines: OPPTS 880.3800 Immune Response*) [167] provided rationale for testing, detailed explanations for testing strategies, and additional mechanistic tests including host resistance and bone marrow function.

Whereas immunotoxicity evaluation encompassed by the 880 series of guidelines would arguably detect any type of immunotoxicity, its breadth would probably render it tremendously expensive and time-consuming. In 1998, EPA followed up with the *Health Effects Test Guidelines: OPPTS 870.7800 Immunotoxicity* [168], which described immunotoxicology testing for nonbiochemical agents that would be regulated by EPA. This document provides descriptions of both why and how, with a much more abbreviated panel of testing to be performed. Whereas the 880 series of immunotoxicology guidelines are excessive, the testing approach mandated by 870.7800 has stood up well in intervening years and reflects the more limited, case-by-case approach currently favored. Most notably, the functional assessment is pared down to T-dependent antibody formation, NK cell function and quantitation of T- and B-cells.

In Europe, the OECD regulates testing of chemicals for toxicity. OECD Guideline 407 entitled *Repeated Dose 28-day Oral Toxicity Study I Rodents*, while not specific for immunotoxicology, includes a variety of toxicological endpoints that can provide early evidence of immune system alterations. Missing, however, are any functional assays to directly measure any immune deficit.

Pharmaceuticals

In the United States, safety testing of small-molecule pharmaceuticals is the purview of the U.S. Food and Drug Administration's Center for Drug Evaluation and Research (FDA CDER). In October of 2002, CDER released a long-awaited document entitled *Guidance for Industry: Immunotoxicology Evaluation of Investigational New Drugs* [169]. This document is arguably the most comprehensive of any published guidance, describing a diversity of adverse events including immunosuppression, immunogenicity, hypersensitivity, autoimmunity, and adverse immunostimulation. The document describes each of these types of immunotoxicity (more accurately, immunomodulation) in detail and not only provides approaches but also suggests methodology for evaluating each type. Like the CPMP document (described in the following), the FDA/CDER guidance advocates the use of information derived from standard repeat-dose toxicity studies to provide early evidence of immunotoxicity, with subsequent evaluations to be rationally designed to use a minimum of animals and resources while deriving the maximum amount of information. Subsequent to the publication of the FDA/CDER document, the primary author of the guidance published a manuscript describing the implications of the guidance [170].

In Europe, safety testing of pharmaceuticals is regulated by the Committee for Proprietary Medicinal Products (CPMP). In October of 2000, CPMP published *Note for Guidance on Repeated Dose Toxicity (CPMP/SWP/1042/99)* [171]; although the primary purpose of this particular document was to describe an overall approach to safety testing of pharmaceuticals, it was important as the first guidance document mandating specific immunotoxicology screening for pharmaceuticals. An appendix in this document describes a staged evaluation, emphasizing that information gained in standard toxicology evaluation can be useful as a primary indicator for immunotoxicity. Functional tests may be incorporated to gain additional information, first as an initial screen and then progressing to extended studies as indicated. The choice of assays to be used includes combinations of functional tests known to be predictive of immunotoxicity, as described in the early National Toxicology Program publications.

As the first published document requiring immunotoxicology evaluation, *CPMP/SWP/1042/99* predictably was met with a combination of resistance and confusion. Much of this was allayed in a Drug Information Association-sponsored workshop held in Noordwijk, the Netherlands in November of 2001. A summary of findings from this workshop has been published [172]. Differences in how the U.S. and EU guidance to immunotoxicology assessment is interpreted have led to intense discussion regarding the best approach for performing this assessment on a routine basis. Having reached step 4 of the International Conference on Harmonization (ICH) process at the ICH Steering Committee meeting on September 15, 2005, S8 ICH Guideline was recommended for adoption to the three regulatory bodies [173]. This document was finalized in 2006 by FDA and in entitled *Guidance for Industry: S8 Immunotoxicity Studies for Human Pharmaceuticals.*

Biologicals

Biologicals (therapeutics derived by biotechnology) present a unique challenge for immunotoxicity assessment. Some of these agents, such as cytokines and other immunomodulatory molecules, are intended to therapeutically modulate the immune response; therefore, it can be difficult to differentiate between the agent's efficacy and a truly adverse reaction. Second, because many of these agents are proteins or peptides, their introduction into a host often triggers an immune response directed against the molecule itself; this can lead to alterations in pharmacodynamics or to other adverse reactions. Thus, development of appropriate guidance on testing these agents is problematic. One approach is promulgated by the International Conference on Harmonisation, with the document *Preclinical Safety Evaluation of Biotechnology-Derived Pharmaceuticals S6* [174]. This document includes sections on immunogenicity (as described previously) as well as a brief mention of immunotoxicity studies. In short, the S6 document recognizes the inappropriateness of a structured *tier* approach, opting instead for careful design of screening studies, followed by mechanistic studies to clarify any potential evidence of immunotoxicity. Specific techniques and approaches are not described in ICH S6.

Safety evaluation of biological drugs is regulated in the United States by the FDA's Center for Biologics Evaluation and Research (CBER). To date, CBER has not promulgated any written guidance on immunotoxicology; the reason for this lack of written guidance is the extreme diversity of biological therapeutics, which makes it difficult to design a standardized testing approach. Rather, CBER's approach to addressing potential immunotoxicology has been case by case and followed suggestions provided in ICH S6.

Vaccines

Along with certain biologicals, vaccines present a challenge for immunotoxicological evaluation since they are specifically designed to induce an immune response, a situation deemed undesirable (or potentially so) for most of the other agents described in this review. Since methodology is well established to evaluate the desirable immunomodulation produced by vaccine, the concern of regulatory agencies is the potential of these agents to produce an undesired or deleterious effect on the immune system.

European regulation of vaccines is described in *Note for Guidance on Preclinical Pharmacological and Toxicological Testing of Vaccines* published by the CPMP [175]. In this document, immunotoxicology is to be considered during toxicology testing. In particular, vaccines should be considered for their immunological effect on toxicity, such as antibody complex formation, release of cytokines, induction of hypersensitivity reactions (either directly or indirectly), and association with autoimmunity. No specific methods or approaches were described; each vaccine is to be evaluated on a case-by-case basis.

FDA/CBER is tasked with regulating vaccines in the United States. One of the primary documents describing vaccine studies is *Guidance for Industry for the Evaluation of Combination Vaccines for Preventable Diseases: Production, Testing and Clinical Studies* [176]. Animal immunogenicity is covered in detail in the document, although immunotoxicity is not specified as an area of concern. On the other hand, CBER's *Considerations for Reproductive Toxicity Studies for Preventive Vaccines for Infectious Disease Indications* [177], although intended primarily to assess effects of vaccination on reproductive function (including generalized toxicity such as fetal malformations), acknowledges the potential immunological reactions resulting from the vaccination process to exert unintended consequences. No specific guidance is provided on methods or approaches to be used in this evaluation.

Devices and Radiological Agents

It has been recognized by the FDA that immunotoxicity may result not only from chemical or biological agents that dynamically interact with humans' physiology such as small-molecule drugs or biological agents but also from medical devices that contact the body externally (via skin or mucosa), internally (implantable devices), or by external communication to the blood or tissue. Thus, the FDA Center for Devices and Radiological Health published the guidance entitled *Guidance for Industry and FDA Reviewers: Immunotoxicology Testing Guidance* in May 1999 [178] that addresses testing for medical devices. This guidance is based on the General Program Memorandum G95-1, an FDA-modified version of International Standard ISO-10993, *Biological Evaluation of Medical Devices Part 1: Evaluation and Testing*. The Immunotoxicology Testing Guidance provides detailed guidance for determining when immunotoxicity testing should be performed (including a flowchart and numerous tables) but does not provide details on which methods should be employed or for overall study design. Anderson and Langone [179] provided explanatory details on the use of this guidance.

Hypersensitivity

Although much attention is paid to immunosuppression (low immune response) in the majority of guidance documents, it is hypersensitivity (hyperactive immune response) that is the most common type of immunomodulation resulting from exposure to xenobiotics. Due to the acknowledged frequency of this occurrence, as well as the multiplicity of testing methods that have been developed, a complete coverage of this condition will not be included here. However, one method for assessing hypersensitivity has taken priority in assessing contact hypersensitivity, namely, the murine LLNA. Detailed explanations of this assay and its use are covered in the OECD 429, 442A, and 442B guidelines [180].

FRONTIER TECHNOLOGIES IN EXPERIMENTAL IMMUNOTOXICOLOGY

Biotherapeutics

The biopharmaceutical industry is already aware that biotherapeutics can be immunogenic, and the resulting production of antidrug antibodies (ADAs) can significantly alter their clearance safety and efficacy. Testing recommendations for predicting ADA have been suggested and are being validated [181]. Of particular concern, however, is the safety of biotherapeutic monoclonal antibodies, particularly those that are immunomodulatory. While generally proven to be safe, on occasion, they present exaggerated pharmacology that was not predicted based on an understanding of the intended function or results from nonclinical studies [182]. This first became evident following the well-publicized adverse events observed with an immunomodulatory anti-CD28 super agonist mAb (TGN-1412) during a clinical trial in the United Kingdom [183].

Nanotechnology

Another potential safety concern is the emergence of successful implementation of nanotechnology, the manufacture of materials and devices at the molecular scale. It is unknown at present whether these new materials will exhibit unanticipated toxicology, although several groups have already begun raising potential concerns [184]. One of the most immediate concerns is the effects on respiratory function following inhalation of nanoscale particles [185], although immunotoxicity has been often reported [186]. The fact that these materials can intercalate into DNA as well as cell organelles opens up the question of whether current immunotoxicity testing methods are adequate.

Interface between Innate and Adaptive Immunity

Although the innate immune system is often described as *primitive*, it is increasingly being recognized that the innate and adaptive systems represent a continuum of highly interactive and often complementary protective mechanisms. There are a number of effectors that form the bridge between these systems, including the Toll-like receptors [187], γ–δ T-cells [188], NK cells, dendritic cells [189,190], T-regulatory cells (TREG) [191], and Fas signals [192] to name but a few. As a better understanding of these complex regulatory circuits develops, it is becoming apparent that this system is responsible for immunomodulation of both normal [193,194] and pathologic processes such as autoimmune disease [195].

Alternative Methods

Alternative methods to replace the use of animals are a requisite for immunotoxicant screenings in the twenty-first century and the use of laboratory animals for such tests are generally prohibited in Europe. At present, alternative methods to screen and rank the sensitizing potential of chemicals

are being developed and under validation at the European Union Reference Laboratory for Alternatives to Animal Testing (EURL ECVAM) [196].

Developmental Immunotoxicology

There is an increasing link between early-life exposure to chemicals, developmental immunotoxicity, and the development of postnatal immune function. This concept introduces the need to identify chemical hazards to the developing immune system [197].

CONCLUSIONS

The discipline of immunotoxicology has grown in importance in toxicology since its inception in the mid-1970s. It has progressed from the early identification of chemicals that may cause immunosuppression/modulation and allergic contact dermatitis, through the validation of sensitive and quantitative assays that serve as biomarkers of immune system alterations in animals and man. More recently, academic, industrial, and government scientists have taken a more mechanistic approach to define how therapeutic and environmental agents alter immune function at a cellular and molecular levels as well as efforts to establish predictive tests to assess agents that may induce autoimmune disease and chronic inflammation. Immunotoxicity data derived from experimental and human immunosuppression and hypersensitivity studies play an increasing role in establishing health standards and defining permissible levels of toxic chemical exposure in humans.

What is still needed is better correlation between animal data with known immunotoxicants and epidemiological or clinical studies in order to ascertain the predictive value of the immune evaluation methods for human populations that may be occupationally or environmentally exposed. Well-controlled studies are still needed in human subjects exposed to environmental chemicals to establish concretely the relationship between documented exposure and immune-mediated effects. With pharmaceuticals where exposure is well documented, the correlations of the prediction value of animal studies for immunoalterations (e.g., immunosuppression or allergy) in man are more clearly defined.

QUESTIONS

37.1 The immune system exists to protect the body against the following:
- a. Specific invading pathogens and microorganisms
- b. Neoplastic cells
- c. Nonself-antigens
- d. Transplanted foreign antigen
- e. All of the above
- f. a, b, and d

Answer: e

37.2 Which of the following statements is false?
- a. Macrophages and leukocytes are types of phagocytic cells derived from the bone marrow
- b. Cell-mediated immunity represents a type of nonspecific immune response
- c. The two major mechanisms of immunity are nonspecific and specific
- d. Humoral immunity is associated with the production of antibody
- e. Pluripotent stem cells are found in the bone marrow and give rise to megakaryocytes and lymphocytes

Answer: b

37.3 Which of the following statements are true?
- a. The primary lymphoid organs are represented by the thymus and bursa-equivalent tissues
- b. Lymphoid tissue is derived from ectoendodermal junctional tissue

Answer: a

37.4 Autoimmunity is best defined as follows:
- a. It is an immune response to normal components of the host
- b. It is mediated by IgE
- c. It can best be measured in guinea pigs
- d. It reflects a single organ

Answer: a

37.5 Immunotoxicity assessment is most often conducted using the following:
- a. Epidemiology studies
- b. In vitro studies
- c. Animal studies
- d. Combinations of SAR and clinical trials

Answer: c

37.6 Chemical- or drug-induced autoimmunities differ from their idiopathic counterparts in that they
- a. Usually remit when the drug is withdrawn
- b. Only target the kidney
- c. Only target blood elements
- d. Are more common in females

Answer: a

37.7 Validation of animal models for immunotoxicology studies requires
- a. Laboratory validation
- b. Establishment of specificity
- c. Establishment of sensitivity
- d. Reproducibility
- e. All of the above

Answer: e

37.8 The most appropriate animal model for evaluating immunotoxicity appears to be
- a. Rodents
- b. Minipigs

c. Guinea pigs
d. Nonhuman primates

Answer: a

37.9 Allergic reactions to drugs may result from
a. Direct antigenicity of the drug moiety
b. Activation of complement proteins
c. Haptenation of self-proteins by the drug or a metabolite
d. Bone marrow ablation

Answer: a and c

37.10 Macrophages are an important potential target of immunotoxicants because of the following reasons:
a. They are capable of metabolizing xenobiotics
b. They are potent immunoregulatory cells
c. They secrete large quantities of inflammatory antibodies
d. a and b
e. b and c

Answer: e

38 Assessment of Behavioral Toxicity

Deborah A. Cory-Slechta and Bernard Weiss

CONTENTS

INTRODUCTION

To survive, organisms must be sensitive to events occurring in their environments and respond appropriately. At the most elementary level, organisms must avoid hazards such as predators and other threats, must secure food, and, for species survival, must pursue reproduction. The nervous system is the site at which such transactions with the environment are processed. The nervous system also governs endogenous transactions such as controlling neuroendocrine secretions and carries on commerce with the immune system, but such functions are processed in the background, so to speak. The integrity of the nervous system, paramount to both individual and species survival, is reflected predominantly by the integrity of behavior.

This chapter describes methods and issues related to the assessment of behavioral toxicity. Its complexities are significant because of the multiple dimensions and behavioral domains that comprise the human behavioral repertoire. Primary among these are motoric, sensory, and cognitive (e.g., learning, memory, attention) domains, each of which can range from simple to highly complex levels of function. Further, human behavior requires integration across these various domains. It is for this reason that in vitro methods are unlikely to ever provide sufficient alternative approaches for behavioral toxicology,[1] particularly when it is clear that even subtle functional differences can significantly influence neurochemical and neurophysiological outcomes.

Often, the first clues of toxicity to humans may be subjective disturbances such as nervousness (chlordecone) or personality changes (manganese), succeeded by more overt signs such as tremor (chlordecone) or akinesia (manganese). Regulatory standards aim for exposure levels, providing enough of a margin to preclude even these preliminary, nonspecific symptoms.[2] In contrast, early animal laboratory investigations tended to adopt exposure levels likely to evoke a clearly visible toxic response, a strategy requisite to develop and validate methods responsive to neurotoxic agents and to acquire corresponding information about mechanisms of toxicity applicable to lower exposure levels. Since then, animal studies have expanded to focus on lower-level and cumulative exposures and associated behavioral mechanisms, and both human and experimental studies now address issues such as fetal basis of adult disease and long-term effects of toxicants as well as reversibility of adverse effects.

In addition to providing a measure of functional competence, behavioral outcomes often give guidance to the underlying neurochemical, neurobiological, and histopathological substrates, an understanding continually increased by parallel advances in the fields of psychology and neuroscience. For example, elevated motor activity may indicate actions on specific neurotransmitter systems; an inability to distinguish geometric form would point to the visual cortex as a possible site of damage.

Given that behavioral functions can range from simple to highly complex, the assessment of behavioral toxicity often proceeds in stages. The first stage often examines dose–response relationships based on systematic observations of responses such as those included in functional observation batteries that generally evaluate a range of simple and innate behaviors. While alerting to potential behavioral toxicity, such evaluations typically provide little information about the specificity of a functional deficit,[3] which requires more complex assays that provide greater precision, thus yielding more specific and quantitative information to permit better prediction of possible adverse effects in humans.

The chapter proceeds from descriptions of the simpler behavioral techniques generally applied in the earliest steps of hazard identification to more complex approaches designed to clarify specific deficits and to understand both behavioral and neurobiological mechanisms. It addresses both human and animal behavioral testing. The techniques and paradigms described include those utilized in an experimental context, many of which are appropriate across species, including humans, with appropriate parametric modifications, a strategy that should facilitate risk assessment. In fact, some approaches were originally implemented in human subjects and subsequently modified for experimental animal use. The chapter aims to provide enough familiarity with these techniques to allow a more than elementary understanding of behavioral toxicology. Two early reports[4,5] aimed at the impact of neurobehavioral toxicants on public health demonstrate how behavior serves as the sentinel for less accessible endpoints.

Origins of Behavior

The behavioral repertoire varies along two dimensions: origin and modifiability. At one end of such a continuum are behaviors designated as innate or hardwired that include unconditioned reflexes, some fixed-action patterns, and instinctive behaviors that do not require learning. The components of such innate behaviors may be unique to a particular species and may be insensitive to modification by the environment. For some such behaviors, once evoked, the responses continue to completion even in the absence of the appropriate environmental substrates. On the other extreme are learned or acquired behaviors that are subject to modification by the environment. Such behaviors are based on voluntary emitted responses, which are increased or decreased in strength and altered or refined in a dynamic manner across time by environmental consequences through operant or respondent conditioning. Falling between these two extremes are instinctive behaviors such as some fixed-action patterns that are modifiable by environmental circumstances. The extent to which the behavioral repertoire of an organism is comprised of learned versus unlearned behaviors is dependent on the species, with a tendency for learned behaviors predominating at the higher end of the phylogenetic continuum.

Respondent Conditioning

In respondent conditioning, as shown in Figure 38.1 (left column), an *unconditioned reflex* elicited (evoked) by an unconditioned stimulus is the basis for a new conditioned respondent. The term *unconditioned* signifies the innate characteristics of the stimulus and response comprising the reflex. When the unconditioned stimulus is repeatedly paired with a neutral stimulus (*procedure*), the neutral stimulus comes to acquire eliciting properties similar to those of the unconditioned stimulus, that is, the neutral stimulus becomes a conditioned stimulus that can evoke a *conditioned reflex* that typically, though not uniformly, resembles the unconditioned response. Figure 38.1 uses the classic example from the Russian physiologist I.P. Pavlov, who used meat powder, an unconditioned stimulus, to evoke salivation, an unconditioned response, in dogs. Tones repeatedly paired with the meat powder eventually came to function as conditioned stimuli that elicited conditioned salivation. In respondent conditioning, pairing of the conditioned and unconditioned stimuli must occur at least intermittently for the conditioned stimulus to retain its ability to elicit a conditioned reflex.

Operant Conditioning

Operant conditioning (Figure 38.1, right column) is based on emitted or *voluntary responses* (not evoked responses such as in reflexes) that occur at some baseline level in the absence of any environmental influences. For example, newborn babies engage in voluntary skeletal muscle motions even at birth that can be modified by the environmental consequences that follow them (*procedure*) and thus serve as the basis of later, more coordinated movements and precise motor functions (operant behaviors). Operant conditioning is the process by

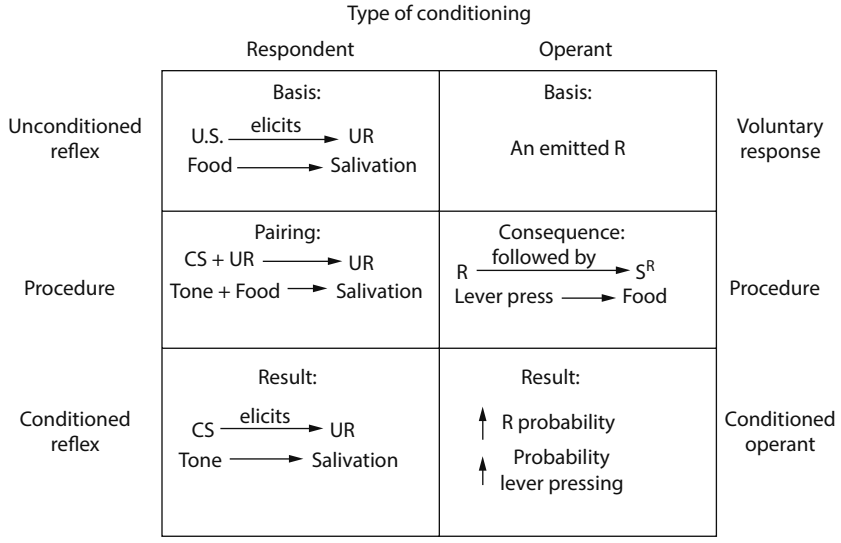

FIGURE 38.1 The two types of behavioral conditioning are illustrated. Respondent conditioning (left column) is based on unconditioned (innate) reflexes. In respondent conditioning, an unconditioned stimulus elicits an unconditioned response. When an initially neutral stimulus is paired with this unconditioned stimulus (procedure), it acquires eliciting properties; that is, it becomes a conditioned stimulus capable of eliciting a conditioned reflex. In the example, elicitation of salivation by food is an unconditioned reflex. When a tone is appropriately paired with the food (procedure), its subsequent presentation alone will come to elicit salivation. Operant conditioning (right column) is based on voluntary responses emitted by the organism. If these responses are followed by a reinforcing stimulus (procedure), the frequency of the response will subsequently increase (result). In the example, pressing of a lever by an organism results in food reward (procedure), thereby increasing the frequency of lever pressing. If reinforcement is withheld (extinction) or a punishing stimulus is presented, response frequency will decline.

which the frequency or strength of an operant (voluntary) response is modified by the consequences of that behavior. Figure 38.1 presents the example of a lever press response by a slightly hungry rat resulting in food as a reward that increases the future probability of the lever press.

Reinforcement

Reinforcement is the presentation of a stimulus contingent upon a voluntary response that results in an *increase* in the future frequency of that response (Figure 38.1). Reinforcers may be either positive or negative, a distinction that is purely procedural (Table 38.1). Specifically, a reinforcer strengthens a response; a *positive* reinforcer increases probability of the response by its *presentation*, such as the delivery of food to a hungry organism or the presentation of money for work performed. With *negative* reinforcement, a response is strengthened by the *removal* or diminution of a stimulus event or the prevention of its onset. Here, common examples used experimentally include cessation of electric shock or loud noise contingent upon a response; a human example might be the prevention of a parent's scolding by cleaning one's room. Shock avoidance and escape procedures fit into this category.

Reinforcers cannot be classified intuitively or categorically but only on the basis of the change in behavior subsequent to their presentation. Food may not serve as a positive reinforcer for someone with the stomach flu; attention and affection often fail to function as positive reinforcers for autistic children. Given the appropriate behavioral training conditions, electric shock presentation can actually maintain rather than suppress responding.[6] As these examples indicate, a stimulus that serves as a reinforcer for one person may not so function for another. The sum total of an individual's interaction with the environment and reinforcement contingencies is deemed its *behavioral history*. Because all individuals could never simultaneously be in the same place, make the same responses, earn the same reinforcers, and so forth, each person's behavioral history is unique. This becomes particularly important because differences in behavioral history can modify the response to drugs and, thus, perhaps to toxicants as well, an important possibility that as yet has received little experimental attention.

Reinforcers also are defined as primary (unlearned, S^R) or secondary (conditioned, learned, S^r). Primary reinforcers function as effective reinforcers without any prior experience or conditioning. Examples include food, water, and the opportunity to engage in sexual behavior. Conditioned reinforcers are stimuli that *acquire* their reinforcing efficacy through pairing with other established reinforcers. Money serves as an extremely effective generalized conditioned reinforcer because of its pairing with many other reinforcers, both primary and conditioned. Conditioned reinforcers frequently are generated in an experimental setting by repeatedly pairing an initially neutral stimulus, such as a light flash or tone, with a primary reinforcer, such as food delivery. After repeated pairings, the light stimulus acquires conditioned reinforcing properties of its own and can thereby maintain substantial operant responding itself. To retain its reinforcing efficacy, however, the conditioned reinforcer must be paired at least occasionally with the primary reinforcer.

TABLE 38.1
Consequences of Responding

Stimulus	Change in Response Strength	
Conditions	**Increased**	**Decreased**
Presentation	Positive reinforcement	Punishment
Withdrawal	Negative reinforcement	Extinction

Punishment and Extinction

Two operant procedures that *decrease* the frequency of learned responses are punishment and extinction. Table 38.1 summarizes these terms, with respect both to the procedures involved and to the subsequent behavioral outcome. In *punishment*, a stimulus presented after a response decreases the frequency of that response. Scolding a child who has drawn on the wall may constitute an example. Again, the stimulus must be classified only on the basis of the subsequent change in response frequency; if a promptly delivered scolding fails to decrease the frequency of writing on the wall, then by definition, it was not an effective punishing stimulus. In a clinical context, the presentation of ammonia to the nose contingent on self-abusive behavior often decreases the frequency of this self-injurious response sometimes observed in autistic children. In *extinction*, the reinforcer for a response is withheld and the frequency of the response eventually (usually after an initial increase) declines. Withdrawing social attention from a child who has thrown a temper tantrum will in many cases decrease the future incidence of tantrums, albeit after an initial increase in frequency.

Discriminative Stimuli

A stimulus in the presence of which an operant response is repeatedly reinforced comes to acquire *stimulus control* over the response; in the presence of this and related stimuli, the probability of the response is increased. This stimulus that defines the occasion on which an operant response is followed by reinforcement is called a *discriminative stimulus* (S^D). For example, the sight or smell of freshly baked cookies may be an S^D that sets the occasion for the response of reaching into the cookie jar to be reinforced with a cookie, whereas an empty cookie jar would be unlikely to occasion such a response. Similarly, a red light and a stop sign are both discriminative stimuli that control the responses involved in stopping a vehicle. Braking at other times (e.g., at a green light) may have disastrous consequences. It is important to remember that discriminative stimuli do not elicit or evoke responses as do unconditioned and conditioned stimuli in respondent conditioning procedures; they merely, but importantly, indicate the likelihood or probability of reinforcement for a given operant response and thereby influence response probability.

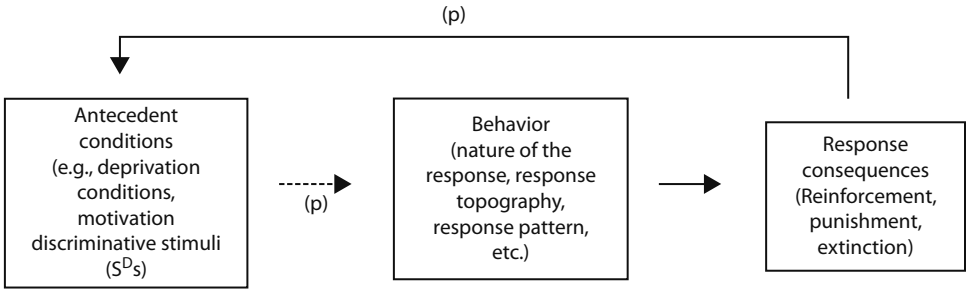

FIGURE 38.2 The three-term, contingency-describing operant behavior. In the presence of antecedent conditions, operant responses are followed by consequences. The nature of the consequence determines the future probability (frequency) of the response and will also alter the strength of the antecedent stimuli (discriminative stimuli) controlling the response. A toxicant may act by altering the antecedent conditions (e.g., functional deprivation level or motivation of the subject) or the efficacy of relevant discriminative stimuli. A toxicant may act by altering the characteristics of the response itself (e.g., its topography or duration). A toxicant may act to alter the response consequences (e.g., change the perceived magnitude of reward or punishment). Understanding how a toxicant interacts with these factors defines the behavioral mechanism of effect.

The response of an organism may be explicitly reinforced in the presence of one stimulus (S^+), such as a red light, while reinforcement is explicitly withheld in the presence of another stimulus, the S^- (or $S\Delta$), such as a green light. Using such a *discrimination procedure*, the organism soon comes to respond in a certain way only when the red light is on (i.e., in the presence of the S^+), such that the behavior is said to be under *stimulus control*, as noted earlier. When responding generalizes to other stimuli of the same or related stimulus classes, such as when a young child refers to all grown males as *daddy*, responding has *generalized* across the stimulus class *adult male*, that is, *stimulus generalization* has occurred. These processes of stimulus control and stimulus generalization are important aspects of such behavioral functions as concept formation and learning to learn.

In summary, a three-term contingency describes operant conditioning, as illustrated in Figure 38.2.[7] In the presence of antecedent conditions that include discriminative stimuli, operant behaviors occur and are followed by consequent events (response consequence) that alter the future probability or frequency of that response and the control by the antecedent S^D over the response. It should be noted that discriminative and reinforcing stimuli need not be external or visible/audible environmental events; internal stimuli, whether internal physiological changes such as headaches or our own nonvocal verbal behavior (thinking), can acquire important behavioral functions, including serving as both discriminative stimuli and conditioned reinforcers.

Precise and operational definitions are critical in behavior because a toxic agent, like a brain lesion, may affect any stage in this three-term contingency. A goal of behavioral toxicology is to understand how toxic agents alter function or, more precisely, the behavioral mechanisms of action of the compound. As discussed by Thompson and Schuster[8] and Thompson and Boren[9] in the context of behavioral pharmacology, attaining such a goal depends on a thorough knowledge of the variables that control behavior, just as the biologist must understand a biological system. Behavior is influenced by multiple factors: by antecedent factors, such as deprivation or motivational state, by the nature of the response and response parameters (i.e., its topography or physical characteristics), and by the consequences that serve to maintain the behavior. A toxicant may change behavior through its interaction with any or all such variables; that is, it may alter antecedent conditions such as functional deprivation levels (e.g., induce nausea), or it may interfere with the ability of the organism to discriminate among stimuli. Alternatively, it could modify the topography of the response, such as by evoking incoordination, or it could interfere with the ability to associate the S^D with the contingency, and so forth. Understanding the exact components of behavioral processes affected by toxic agents assists in understanding the underlying behavioral mechanisms of action and offers guidance as to the associated neurobiological substrates of effect.

SCREENING BATTERIES FOR ANIMAL STUDIES

Screening batteries are used for evaluating the potential neurotoxicity of new or existing chemicals. In animal studies, these have typically included two behavioral components: a functional observational battery (FOB) and motor activity. The behavioral tests utilized for such purposes are often referred to as *apical tests* because they require the integrated function of several organ systems, including the nervous system. Often, a distinction is made between what are deemed naturalistic behaviors, such as those scored on FOBs, and complex learned behaviors. But, all behaviors are naturalistic; none exceeds the bounds of biological possibility. For many naturalistic behaviors, there is simply a lack of understanding of the controlling variables rather than an absence of their sensitivity to environmental control. Even as apparently natural and spontaneous a behavior as self-grooming by monkeys can be brought under experimental control by reinforcing (rewarding) it with food.[10]

From the standpoint of screening and hazard identification, two points related to the interpretation of FOB

and motor activity studies deserve mention. First, effects observed in response to toxicant exposure in such batteries can either be the result of a direct effect of the toxicant on the nervous system or be secondary to changes in other systems, as such apical tests rely on the functional integrity of multiple systems. Under some circumstances, the fact that the toxic effect is ultimately expressed in behavior may minimize the importance of the source of the effect. A second point is that the concurrent presence of body weight loss or decline in food or water intake does not necessarily indicate that behavioral changes observed in an FOB or in locomotor activity are the result of malaise or sickness, as these measures may change independently of each other. Certain agents, such as volatile organic solvents, tend to enhance motor activity at low concentrations, so the problem of confounding with malaise is negligible with such results.[11]

Functional Observational Batteries

Figure 38.3 depicts the component tests of the FOB developed by Moser[3] which include an array of measures of both unconditioned operant and respondent behaviors. Such batteries have been shown to exhibit utility for screening potential neurotoxicity (i.e., hazard identification and elaboration). As an example of validation, it has been shown that components of the FOB directed toward cholinergic functions exhibited sensitivity to the effects of the anticholinesterase carbaryl, whereas few such signs of cholinergic disturbances were evident in the presence of the nonanticholinesterase pesticide chlordimeform. Further discussion of FOB measures by domain is provided by Moser et al.,[3] Baird et al.,[12] and Boucard et al.[13]

FIGURE 38.3 Typical measures used in many FOBs include aspects of home cage and handling, behavior in an open field, and various reflex and physiological responses. Measurement of locomotor activity is also often included in an FOB. (Modified from Moser, V.C., *Toxicol. Pathol.*, 39, 36, 2011.)

Motor Activity

Motor activity is one component of motor function.[14] Generally described as an unconditioned behavior, motor activity exists at some baseline (operant) level and is a complex behavioral class that includes numerous components such as ambulation, rearing, grooming, and sniffing, all of which can be environmentally influenced. Toxicants may alter motor activity by affecting any or all of its component behaviors. Numerous devices have been designed to measure motor activity. These vary in complexity and in the specific component of motor activity that they measure. One frequently employed device is the figure-8 maze, which consists of a series of interconnected alleys converging on a central open area. Motor activity is detected by photobeams, and an activity count is registered each time a photobeam is interrupted by the animal. In a device such as the open field (Figure 38.4), motor activity is quantified by counting the number of squares entered by the animal within some prescribed period of time. Over the years, such devices have become increasingly automated and generally locate photobeam devices in a manner that permits the detection, in a time course fashion, of different types of motor activity, such as ambulation versus rearing and utilize videotaping and computer-assisted scoring. This is particularly useful as it allows assessment of the time course of activity changes within a session, as reliance on total counts may obscure toxicant-induced differences in the time course of the activity. For example, in an open-field device, one could arrive at the same total number of squares entered in a designated period of time via substantially different patterns of behavior across time. The organism might show an initial period of rapid movement in the open field followed by immobility, or, alternatively, it could exhibit a continuous moderate rate of ambulation. Both patterns could result in the same total

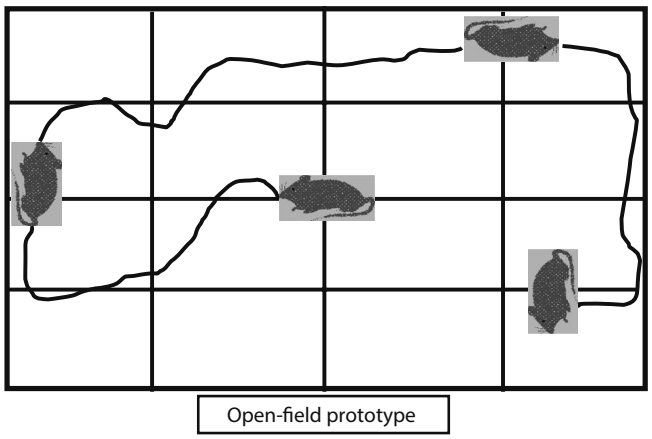

FIGURE 38.4 Open field for the measurement of locomotor activity. In nonautomated procedures, the number of movements per unit time is recorded by an observer. Automated devices typically rely on computerized measurement of photobeam breaks by the movement of the subject to access locomotor activity. Photobeams are typically positioned so as to measure aspects of both horizontal ambulation and rearing in rodents.

number of squares entered, even though the underlying patterns of behavior are quite distinct.

Behavioral Teratology

Although presented as if it were distinct from behavioral toxicity because of its focus on behavioral modifications resulting from toxic exposures during early development, many of the outcome measures of behavioral teratology are the same as those used in behavioral toxicology coupled with the development of physical landmarks and reflexes. Initially, its focus included behavioral changes related to toxicant exposures over the postnatal and possibly into the juvenile and early adult stages of the life cycle. Increasingly, this has extended to later stages of the life cycle based on questions related to the fetal basis of adult disease. Behavioral teratology studies frequently attempt to evaluate multiple behavioral functions, such as motor function and activity and sensory capabilities and learning, in the same experiment. In addition, testing for species-specific behaviors, such as aggression, play, and vocalization, may be included. Table 38.2 lists the criteria specified by the U.S. Environmental Protection Agency (EPA) for its developmental neurotoxicity test guidelines.

What distinguishes behavioral teratology is that testing during the infant, postnatal, and juvenile periods of development sometimes requires modifications of procedures utilized with adults or even the development of new paradigms. In other cases, behavioral paradigms identical to those used in more mature subjects may be employed, albeit with parametric modifications. An example of the former that has been widely used to assess olfactory and motor capabilities early in life is referred to as *homing behavior*, a behavior used by rodent pups to locate the nest should the pup be displaced. In such a test, a rat or mouse pup is placed in the center of a rectangular apparatus in which one side contains clean bedding material and the other side contains bedding from the pup's home cage. The time taken for the pup to orient to or to reach the home cage bedding constitutes the dependent variable of interest. Because this performance depends on memory, olfactory capabilities, and the development of appropriate motor skills, it represents a type of apical evaluation.[15] Other issues related to behavioral teratology, including appropriate fostering procedures to control for toxicant effects on the dam, statistical issues, and summaries of developmental effects of various toxicants, have been reported by others.[16–22]

TABLE 38.2
EPA Developmental Neurotoxicity Criteria

Physical measures	Body weights, sexually dimorphic indices
Brain weights	Regional brain weights on days 4 and 21
Neuropathology	PN days 4, 21; study termination; GFAP
Locomotor activity	N days 13, 17, 21, 45, 60
Reactivity	Auditory startle on PN days 22, 60
Learning and memory	Olfactory discrimination on PN day 21
	Active avoidance (or substitute) on PN day 60

OPERANT BEHAVIOR ASSESSMENT

Scope

The behavioral environment is a dynamic one in which multiple reinforcement processes are operating concurrently to produce, modify, refine, and eliminate aspects of learned operant behavior. The net result is a complex behavioral repertoire that includes a multitude of different behavioral domains and processes, any or all of which may be the target of a toxic agent. Enumerating all such possibilities is beyond the scope of such a chapter and, indeed, constitutes a subject matter having spawned numerous volumes of its own. Consequently, this chapter focuses on seven particular operant behavioral domains that have evolved as primary interest areas in neurotoxicology: motor function, sensory behavior, learning, memory, attention, schedule-controlled behavior, and stimulus and reinforcing properties of toxicants. The techniques and corresponding apparatuses designed to evaluate the entirety of these behavioral domains are numerous and cannot be fully enumerated here. This chapter therefore emphasizes those procedures that are widely used, as well as those that exemplify the range and scope of behavioral technologies.

Apparatus

The basic requirements for an assessment of complex operant behavior must include a defined or specified unit of behavior to serve as the designated response. An environmental consequence or reinforcing event appropriate to the species and experimental parameters is arranged to follow the designated response. For some types of experiments, environmental stimuli of different modalities (e.g., visual, auditory) that can be varied along certain dimensions may be used as discriminative stimuli and conditioned reinforcers. The choice of the operant response, reinforcing consequence, and external or environmental stimuli should be congruent with the physical and behavioral capabilities of the experimental species. Teaching the chimpanzee to vocalize speech sounds proved impossible because of the physical limitations of its vocal apparatus. When the operant response was changed instead to hand signing, experimental studies of the acquisition of verbal behavior proceeded successfully[23] and since have involved computer touch screen responses. Similarly, under certain conditions, visual stimuli may prove inappropriate for rodents, because of the poor visual capabilities of these species, which, instead, depend heavily upon olfactory information in their normal environment.[24]

A broad spectrum of reinforcers has been used in behavioral experiments. The choice depends on the species and the aim of the particular experiment. Reinforcers can include the delivery of food or liquid reinforcers such as water, fruit juice, or saccharin solutions; the delivery of money or tokens (exchangeable for other reinforcers) in the case of humans, the opportunity to engage in wheel running, sexual behavior, or aggressive behavior; the production of heat in a cold environment; the opportunity to self-administer a drug such as cocaine or electrical brain stimulation; and escaping from

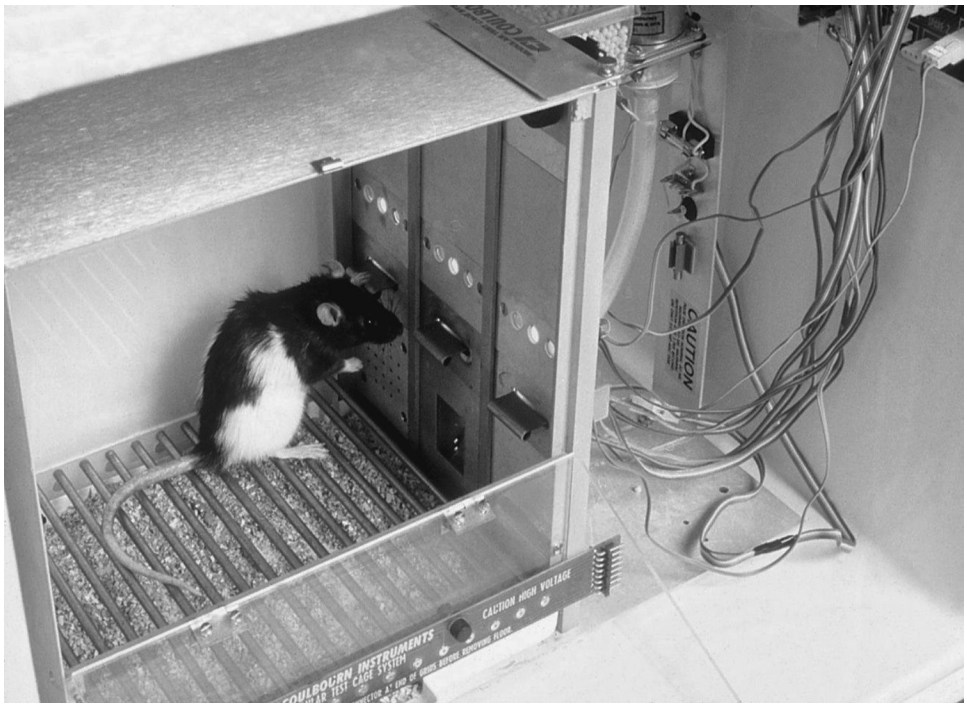

FIGURE 38.5 A prototypical operant chamber (Skinner box) for use with the rat here equipped with three-response levers (left, center, right) and a bank of lights above each lever. Also included are a sonalert for delivering tones, a speaker for the delivery of auditory stimuli (top right), and a houselight for use as a visual stimulus. Food deliveries used as rewards are delivered from a feeder outside of the operant chamber through a plastic tube into a pellet trough, here located below the middle lever. The rat can be seen pressing the left lever.

or avoiding the onset of electric shock. Such a breadth of choice in a standard experimental arrangement allows the experimenter enormous flexibility, such as to compare heat and food reinforcement in metabolically impaired animals.[25]

Many experiments on complex behavior are carried out in operant chambers typified by that illustrated in Figure 38.5. In conventional chambers, response devices typically include levers (rat, mouse, monkey, human), disks (pigeons, monkeys, humans), computer touch screens (monkeys, humans), running wheels (mouse, rat), and cones for snout insertion (mouse, rat, guinea pig). Typically, the execution of the response is operationally defined by the closure of a switch or electrical circuit that can be recorded and acted on by a computer. The operant chamber may contain multiple response devices, usually but not necessarily of the same type. In addition, stimuli of different modalities can be delivered to the chamber by lights, loudspeakers, and such, and the operant chamber may be adapted to utilize different reinforcers. Equally important are the ease and flexibility available to experimentally program behavioral contingencies (rules) in the operant chamber and the precision and resolution with which data can be collected. Computer technology allows responses and other events to be measured and stored sequentially with millisecond resolution. For these reasons, an operant chamber equipped to deliver stimuli of various modalities, containing multiple response devices, and offering a choice of reinforcement delivery systems provides the maximal flexibility and versatility for behavioral studies. It similarly permits a continuum in the pursuit of scientific questions directed by research findings as opposed to research questions that are dictated by the nature of the equipment, particularly in cases where the equipment has been designed to measure only a single specific behavioral function.

Over the years, however, different types of devices, some automated and others not, have been used to measure specific aspects of behavior, some commercially available, others designed to meet the requirements of a particular experiment. This has been the case particularly for the assessment of learning and memory functions, where mazes have been used, including the more traditional mazes such as the T maze and L maze; the radial arm maze, which consists of a central area from which eight or more arms radiate like spokes; and water mazes. The Wisconsin general test apparatus (WGTA) was used to study learning in primates, and modifications have been made to accommodate other experimental species. Nonautomated devices can require a far greater expenditure of personnel time and, ultimately, greater costs to carry out experiments and can also introduce the possibility of experimental bias. Although such devices can certainly provide in some cases a reasonable alternative to an operant chamber, as noted earlier, their generally limited utility for addressing a wide variety of other behavioral questions must also be considered when apparatus decisions are made and where resources are limited.

Shaping an Operant Response

Before implementing a behavioral experiment, an effective reinforcer must be identified, one that can be presented

immediately after the designated response occurs, because delayed reinforcement is less effective. A procedure known as *magazine training* is generally used to ensure the adequacy of the reinforcement contingency in an operant chamber, particularly in experimental studies. Magazine training consists of the presentation, at intermittent intervals, of the reinforcing stimulus, such as a food pellet, independently of behavior. After repeated presentations of food pellets in this manner, a slightly food-deprived organism will reliably approach the feeder and ingest the food whenever the noise generated by the operation of the feeder occurs. A stimulus such as a light is frequently paired with the food delivery and, along with the noise generated by the feeder, comes to serve as a conditioned reinforcer. Such conditioned reinforcers are especially important because they provide the immediate reinforcement for responding given the delay necessarily imposed by the time required for the organism to approach and ingest the food. For some reinforcers, no such training is required. For example, electric shock is used in escape and avoidance procedures in the absence of any prior training of subjects, as is money in human experiments.

Once a reliable reinforcer has been established, shaping of the designated response can proceed. At this point, the reinforcing stimulus is presented only when the organism emits responses that more and more closely resemble the final designated response, a process of reinforcing successive approximations to the desired response. For example, in the case of a lever press response by a rat, reinforcer delivery might first be contingent on touching the lever, then putting two paws on the lever, and eventually applying sufficient force to displace the lever downward and close the associated electric circuit. Reynolds[26] discusses these techniques in greater detail. In some cases, magazine training and shaping procedures can be automated,[27] a major advantage when a large number of experimental subjects must be used, allowing a more high-throughput approach.

Shaping procedures also may be used in other types of apparatus to train the initial response; for example, in the WGTA, the monkey is first shaped to reach out and retrieve food cups on the shelf in front of the enclosures. For other devices, such as mazes and running wheels, little overt shaping may be necessary, as exploring alleys and running usually occur spontaneously at a high enough frequency (high operant level) in rodents to ensure contact with the reinforcement contingency.

Once the organism is emitting the designated response at an adequate rate, it may still be necessary to progress through a series of training conditions before imposing a complex behavioral paradigm of experimental interest, just as a dancer must learn to connect the different steps of a choreographed performance. Likewise, a beginning reader could hardly be expected to tackle the plays of Shakespeare. In a similar way, requiring an organism to emit 100 responses for each food delivery will likely require intervening sessions with smaller response requirements to build response strength and to prevent the behavior from undergoing extinction. It is the shaping process that creates new behaviors and pieces together responses to produce increasingly complex chains of behavior.

An accumulating literature attests to the fact that many of the specific behavioral procedures described here are successfully used with both mice and rats, although differences between the two and between strains of each in operant level behavior may sometimes necessitate alterations in approach. In operant chambers, for example, higher overall activity levels may mean that high levels of lever pressing occur in the absence of any shaping; in this case, additional procedures must be implemented to bring the high rates of behavior under appropriate control of the operant contingencies, such as time-out procedures contingent on excess responding, specific implementation of differential reinforcement for low rates of responding, or the use of response devices such as nose cones rather than levers. Further, many of the behavioral paradigms emphasized in this chapter have been more broadly used across human and nonhuman species with appropriate parametric and response device modifications, an approach that should also facilitate extrapolation in a public health/risk assessment context.

MOTOR FUNCTION

Visible indications of toxic processes in the nervous system often occur as abnormal movements, impaired coordination, slowing of responses, and complaints of weakness. Because any reduction in the capacity for coordinated movement reduces an organism's ability to cope with the demands of its environment, even subtle defects will influence how effectively it functions. Learned motor skills play an especially salient role in human activities. Even apart from the advanced skills of the surgeon or violinist, which are the culmination of years of practice, consider how much we rely on proficiencies in writing and driving as part of our daily activities.

Despite many clear examples, the full scope of contributions to movement disorders by neurotoxic chemicals remains vague. Part of the vagueness arises because the etiology may lie buried many years in the past. For example, understanding whether and how pesticide exposures serve as risk factors for Parkinson's disease,[97] as suggested by experimental models and epidemiological evidence, is hampered by the inability to identify specific past exposures. The emergence of clinical signs may also reflect the diminished ability of compensatory mechanisms during advanced age to overcome the effects of earlier damage—that is, silent damage.[28]

Clear connections between exposure and motoric dysfunction have been established for several metals. Wrist drop afflicted many painters who were occupationally exposed to lead pigments. The cardinal sign of mercury vapor neurotoxicity is excessive tremor. One of the primary signs of methylmercury poisoning is ataxia. Manganese miners display a condition best described as dystonia but with some features of Parkinson's disease. Insecticides are designed as neurotoxicants, and the organophosphorous compounds produce axonopathies that impair both motor and sensory functions. The industrial chemical acrylamide also induces both motor and sensory neuropathies. Certain organic solvents produce central nervous system damage expressed as

motor dysfunction. Many of the chemical classes described in this volume, in fact, even those not classified primarily as neurotoxicants, can induce motor disorders.

The control of posture and movement is anatomically organized in the central nervous system as a collection of diverse motor centers arranged hierarchically from the least integrative, at the level of the spinal cord, through the basal ganglia and cerebellum, to the ultimate level of the cerebral cortex. Weaving through this basic hierarchical structure is a web of enormously complex pathways connecting the various motor centers and involving both afferent and efferent transmission. The total system depends on the functional integrity of many different components, all of which seem to present unique opportunities for the actions of toxic agents. Because they represent a leading clinical problem, the neural basis of movement disorders is the subject of a vast literature.

The basic properties of movement, however, subsume only a few fundamental dimensions described by mass, time, and displacement, expressed in measures such as force, duration, velocity, acceleration, momentum, amplitude, accuracy, and patterning in time. Screening batteries often rely on single global indices, such as spontaneous locomotor activity, which are influenced by many variables independent of motor capacity and do not encompass the full spectrum of motor functions. Some incorporate more specific assays of motor function such as the ability to maintain balance on a rotating rod. Because organisms effect change by producing patterns of muscular contraction, those measures of function likely to prove most sensitive to toxic impairment will typically be based on careful analyses of such patterns and will reflect the integration of multiple systems that yield complex movements.

Learned skills probably offer the most useful baselines for such an assessment because of the flexibility they offer to the experimenter for precise specification of the form of the response. Because of the inherent capacity to compensate for incipient difficulties, however, they are especially challenging to evaluate. For either learned or unlearned motor functions, it seems likely that detection of early subclinical toxic effects will require a detailed quantitative analysis of movement topography.

Response Duration

The time occupied by a particular component of a movement can be studied either as an intrinsic variable, arising indirectly from contingencies applied to another response component such as force, or as an explicit variable specified directly by the experimenter. Especially in the latter instance, the stimuli governing the response are almost wholly proprioceptive, arising from sources such as muscle spindle receptors. Assume a situation in which the required operant response is a lever press and the reinforcement contingency specifies that response durations must exceed *t* seconds to produce reinforcement. If no external stimuli that change systematically with time are presented, the primary stimuli available to the organism with respect to response duration are those arising from muscle and joint receptors. Because such proprioceptors are key elements in the control of movement, measures of response duration could prove useful in evaluating whether these proprioceptors have been damaged by agents such as acrylamide.[29]

Shaping long-duration responses is a fairly straightforward process, as described earlier. Once the designated response, such as lever pressing, has been learned, the additional requirement of maintaining it for a specified duration can be imposed. Early in training, the duration should be short enough that a substantial proportion of responses meet the criterion for reward. The duration, as in all shaping procedures, can then be raised gradually until the final value is attained. Both minimal and maximal durations can be imposed, so a band of durations comes to serve as the criterion. Stevenson and Clayton[30] trained rats to hold down a lever for at least 40 consecutive seconds, after which a white noise signal was sounded. Releasing the bar in the presence of the noise turned it off and triggered a feeder in the operant chamber to deliver a pellet of food.

Relatively few experiments with neurotoxic agents have sought to exploit such possibilities. Cory-Slechta et al.[31] trained rats to respond on a schedule that reinforced only durations above a specified minimum value. After preliminary training, during which the rats were first trained to press a lever for food reinforcement, the experimenters imposed a schedule based on differential reinforcement of response duration. Each lever press that exceeded a specified duration was followed by food pellet delivery. These durations ranged from 0.5 s at the beginning to 6.0 s during later training. Lead treatment reduced durations and also expanded within-group variability.

Several experiments with dogs have relied on response duration as the primary measure of performance. In one, dogs were trained to press a button with their snouts for a food reward.[32] The schedule did not specify response duration directly; instead, it specified that reinforcement would be delivered when 60 s of responding had been accumulated. The dogs adjusted to this contingency by pressing the button between 10 and 20 times for each reinforcement; short responses predominated. Response durations were longer under control conditions than after amphetamine, pentobarbital, or ethanol. In later experiments,[33,34] response duration was made the criterion for a titration schedule, that is, the duration required for reinforcement changed in accordance with the dog's performance. Each session began with a specified minimum duration of 0.25 s. Each time the dog (this time pressing its snout against a panel) ended a response that exceeded the current minimum, the required duration was raised to a higher level. In one variant of the program, the criterion also fell after a series of unsuccessful responses. The dogs learned the progression and, over the course of each session, emitted longer and longer responses. Amphetamine reduced this rate of rise, and alpha-methyl-para-tyrosine (α-MPT), a tyrosine hydroxylase inhibitor, lengthened it, even at doses as small as 3.12 mg/kg (Figure 38.6).

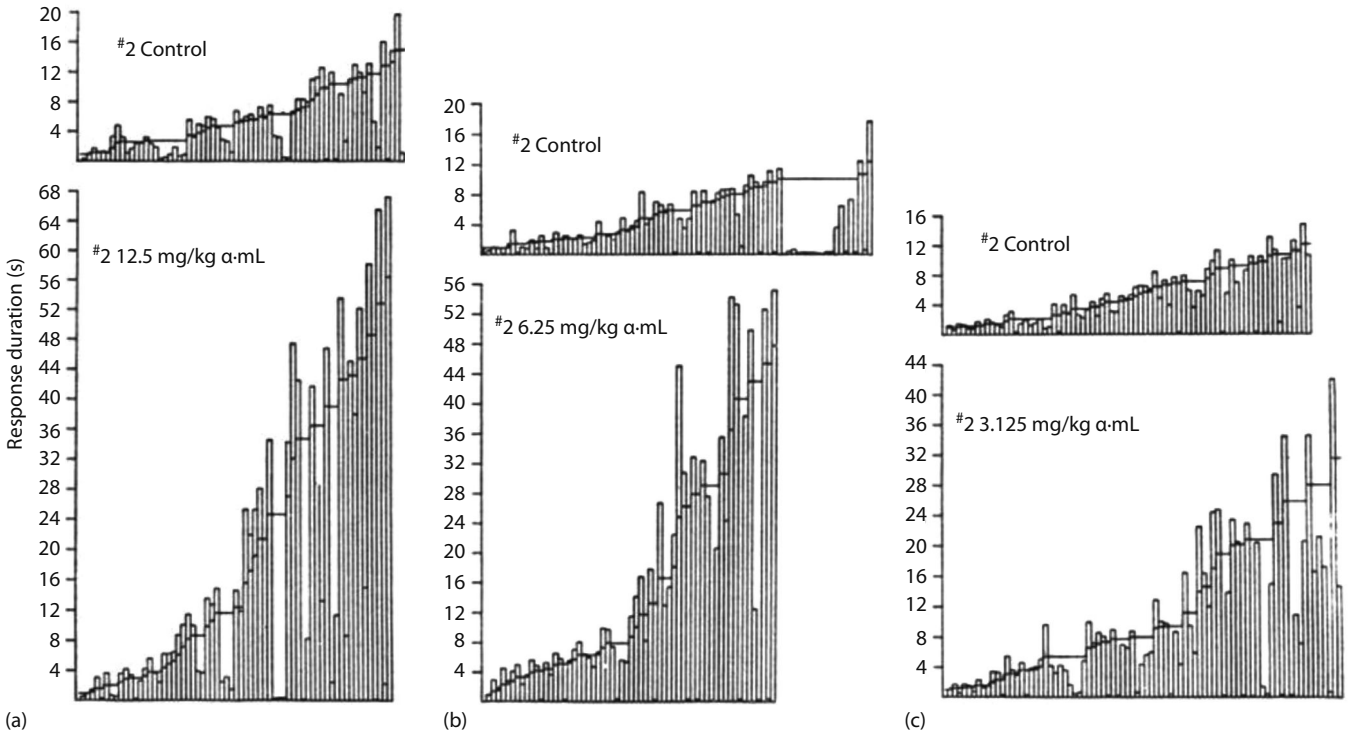

FIGURE 38.6 Complex duration discrimination in Basenji dogs. The dogs were trained to press a panel with their snouts. An experimental session began with a predetermined duration criterion of 0.25 s. Any response duration above the criterion produced delivery of reinforcement (dry dog food) and elevated the criterion by 25% of the difference between the old criterion and the new duration that had exceeded it. This proportion was chosen empirically. If the criterion were raised too quickly, the behavior would be lost, as it often is in shaping procedures that advance so rapidly that they lose contact with the behavior. Each panel shows response durations (seconds) on the *y*-axis in relation to session time on the *x*-axis. Under control conditions, the dogs learned to produce longer and longer durations through the session. The compound α-methyltyrosine, which inhibits the rate-limiting step in the synthesis of catecholamines, enhanced the rate at which successive response durations rose, even at doses many times lower than those used in neuropharmacology experiments. (Adapted from Weiss, B., Amphetamine and the temporal structure of behavior, in Costa, E. and Garratini, S., eds., *International Symposium on Amphetamine and Related Compounds*, Raven Press, New York, 1970, pp. 797–812; Weiss, B., Microproperties of operant behavior as aspects of toxicity, in Bradshaw, C.M., ed., *Recent Developments in the Quantification of Steady-State Operant Behavior*, Elsevier, Amsterdam, the Netherlands, 1981, pp. 249–265.)

Precision

In the absence of clear visual cues, movement precision is also guided largely by proprioceptive information. As an example, Falk and associates[35] trained rats to exert forces within a specified range (15–20 g) for a duration of 1.5 s. The rats responded on a lever that transmitted an electrical signal proportional to the applied force and were reinforced by food pellets for responses meeting the joint force–duration criterion. Training was carried out by approaching the joint criteria of force and duration in small increments and required only 5- to 11-h-long training sessions. With this system, Falk demonstrated that several common central nervous system drugs exerted unique effects on this form of discriminative motor control; for example, the relative amount of time spent within the specified force band varied with the dose of amphetamine and pentobarbital, declining as dose was raised.

A similar device, adapted for monkeys, enabled Preston et al.[36] to study deficits in fine motor control produced by various drugs. One side of a standard metal cage was modified with the addition of a Plexiglas® tube through which the monkey could extend its arm and make contact with a conically shaped response device connected to a force transducer. The monkeys were trained to emit forces between 25 and 40 g for a continuous 3 s to obtain small quantities of water. Various indices of performance demonstrated that the acute effects of methamphetamine, similar to the effects described earlier for rats, impaired performance after repeated high-dose treatment, the pattern of intake adopted by amphetamine abusers.

In another adaptation of this system,[37] monkeys were trained to insert a paw through a slot and to touch a Lucite® plate connected to a strain gauge. The strain gauge output was transmitted to an amplifier, the output of which was coupled to the analog-to-digital converter inputs of a digital computer. The analog-to-digital converter transforms the continuously varying electrical signal from the amplifier into a form that can be processed by the computer. The computer was used to specify upper and lower bounds of the force that defined the response. With this system, the gradual

degradation of fine motor control produced by methylmercury could be traced. The typical pattern before treatment consisted of a precise emission of force within the 25–40 g range specified as the response criterion, maintenance in that range for the required 2 s, and then release. After treatment, the first sign of coordination difficulty was overshoot at the beginning of the response—that is, a transient force above the specified ceiling. This early indication of impaired motor control was followed, after further dosing, by an increasing inability to maintain the force within the prescribed limits. Elsner[38] devised a somewhat similar system to study motor performance in rats, aiming to construct a model reflecting some of the characteristics of attention deficit disorder.

Because rodents remain the most widely used species for routine toxicological testing, additional techniques for the measurement of movement precision in rats and mice, in addition to those mentioned earlier, are especially appealing. All require some investment of time or instrumentation but can yield critical information about the dimensions of motor control. Lesion experiments designed to clarify the functional domain of certain brain areas are a useful source of approaches, and Newland[39] has compiled a table showing which basic tests have shown motor effects of lesions in cerebral cortex, basal ganglia, cerebellum, peripheral nerves, and the neuromuscular junction. In a combination of operant and observational methods, Whishaw et al.[40] examined the impact of motor cortex lesions in rats on their method of grasping food pellets. Before surgery, the rats were reduced to 90% of their initial body weight and trained to eat in a special filming box designed to capture their movements from various perspectives. Video records then were analyzed by a dance notation system adapted to describe animal motor behavior.[41] Such an approach, applied frame by frame, required considerable patience but revealed a spectrum of impairments that were not grossly obvious. A later study[42] used the technique to evaluate motor skills required to reach for food located on a shelf and to manipulate and eat pieces of pasta. Both the pyramidal tract and the red nucleus are also involved in skilled movements, but lesions in these sites suggested a greater role for the pyramidal tract in guiding limb movements.

Another technique designed to evaluate forelimb motor impairment was described by Schrimsher and Reier[43] in an evaluation of cervical spinal cord injury. Rats were trained in a special apparatus to reach into a recessed tray to retrieve a food pellet. Training occurred 2 weeks after body weight had stabilized on a food deprivation schedule. Videotape recordings provided the raw data for analysis. Hypometria turned out to be the primary disability, and it remained permanent in most of the rats. Note that automation of procedures such as the two just discussed, with the potential to yield more accessible and quantitative data, requires little additional training of the animals.[41]

Another situation devised for testing skilled movement in rats is the staircase test,[44] in which rats reach down from a central platform to retrieve food pellets located on each step of two adjacent staircases. The pellets are placed on the staircase and presented bilaterally at seven graded stages of reaching difficulty to provide measures of side bias, maximum forelimb extension, and grasping skill for each paw. Performance is measured by the number of food pellets obtained.

Tremor

Excessive limb tremor accompanies many neurological disorders, is a product of many drug treatments, and can result from exposure to many different classes of toxicants.[45] Tremor is associated with exposure to metals such as mercury and manganese; to insecticides such as chlordecone, dieldrin, and the organophosphates; and to solvents such as carbon disulfide. In a survey, Anger[46] noted tremor as a response to 177 chemicals or chemical classes. Newland[47] describes some of the characteristics of abnormal tremor associated with lesions or chemical exposures. Because of its pervasiveness as a marker of nervous system dysfunction, many techniques have been developed to measure tremor. The availability of inexpensive digital computers and appropriate programs makes the task of recording and analyzing tremor much simpler now than in the past. Because abnormal tremor is a marker for many different neurological syndromes and can be induced by damage at many sites in the nervous system, experimenters have to be wary of ascribing too much specificity to it.

Tremor is one of the cardinal signs of excessive mercury vapor exposure. Wood et al.[48] studied several women exposed to vapor in a factory workroom devoted to pipette calibration. When first seen clinically, the women exhibited visible tremor. After a prolonged absence from the factory, the pathological tremor faded. To follow the course of recovery, and especially to relate it to diminished blood mercury levels, a system was devised to quantify tremor using a strain gauge to which was attached a Lucite slot in which the patient placed her finger. She was instructed to maintain a force within a range designated by lights to mark the upper (40 g) and lower (10 g) bounds. The output of the strain gauge was transmitted to the analog-to-digital converter of a digital computer for processing to express the continuously varying electrical signal corresponding to the output of the strain gauge in the form of tremor frequency. Because physiological tremor is composed of many different frequencies, the analysis is designed to yield their relative contributions to the total signal. The algorithm by which this analysis is performed is called a *fast Fourier transform*.

Fast Fourier transforms demonstrated two features of the tremor induced by mercury vapor exposure (Figure 38.7). First, as expected, the total amount of tremor was greater than any seen with normal subjects. Second, and unexpected, the distribution of the relative amounts attributable to different frequencies showed multiple modes, indicating a very complex signal whose component could not be seen clinically. Eventually, the amplitude of the tremor returned to normal levels, and at the same time, the multiple modes collapsed into one dominant peak. Later, Langolf et al.[49] used a similar technique to monitor workers in a chloralkali

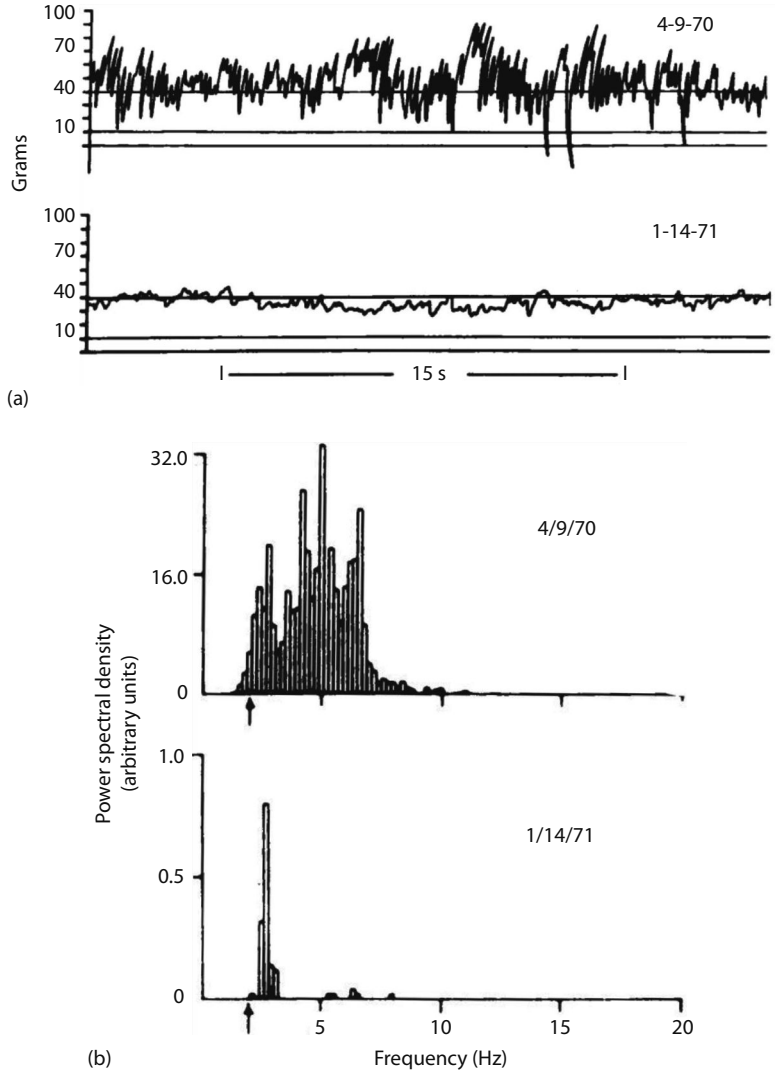

FIGURE 38.7 (a) Tremor tracings from a female worker chronically exposed to mercury vapor in a factory area devoted to pipette calibration. The worker rested a forefinger in a Lucite® slot attached to a strain gauge and was requested to maintain a force between 10 and 40 g, as signaled by lights. Strain-gauge output was amplified and transmitted to a digital computer for analysis. The upper tracing was recorded shortly after the worker entered the hospital for treatment. The lower tracing was recorded 9 months later, with no intervening workplace exposure and a marked decrease of mercury blood levels. (b) Power spectral density plots of tremor corresponding to racings shown in (a). These plots show the amount of total power (variance) contributed by each component frequency in the tremor spectrum and were calculated by fast Fourier analysis. They emphasize the feature of tremor, such as multiple modes, that cannot be evaluated by ordinary clinical examination. (From Wood, R.W. et al., *Arch. Environ. Health*, 26, 249, 1973. With permission.)

processing plant who were exposed to mercury from the massive electrodes used in such plants. They found that as urine mercury rose, the distribution of tremor frequencies began to show multiple modes. With removal from exposure and a parallel decline in urinary concentrations of mercury, the secondary modes declined.

Several later studies have confirmed the usefulness of this method, called *power spectral analysis*, for monitoring workers exposed to mercury. Chapman et al.[50] compared battery workers exposed to mercury with controls by instructing them to maintain a steady force on a displacement transducer. All of the battery workers were judged asymptomatic after interviews and clinical examinations; however, differences in power spectra were able to separate exposed from control workers. One distinguishing feature consisted of peak frequencies in the spectrum. The exposed workers generally showed a displacement toward the higher frequencies. Chapman et al.[50] noted similar findings in workers exposed to carbon disulfide in the grain industry and concluded that frequency differences more effectively indicate neurotoxicity than amplitude differences. The investigators noted that such subtle changes in tremor characteristics are not apparent in clinical examinations and are seen at relatively low exposure levels.

As the preceding examples illustrate, tremor measures may be sensitive to disturbances of motor function that are not clinically apparent; however, as Beuter and de Geoffroy[51] emphasize, the data yielded by tremor measurement techniques depend on the apparatus, the procedure, and the data analysis.

Studies of manganese-exposed workers by Roels et al.[52] tried to assess tremor by using a device that required the subject to hold a stylus in a hole without touching the sides. Small-diameter holes offer a greater challenge than large-diameter holes. Each contact is recorded as the completion of an electrical circuit. Workers with higher urinary values of manganese produced a greater incidence of contacts. A much more extensive test battery was applied to another population of workers exposed to manganese[53]; these data also indicate subclinical deficits in such populations. Both of these studies suggest that the methods used by Newland et al.[54] to study manganese neurotoxicity in monkeys might be directed to human assessment.

Strength

Complaints of weakness appear after exposure to acetylcholinesterase inhibitors, manganese, and other agents. In fact, weakness is one of the most frequent subjective indices of neurotoxicity. Although simple procedures for assessing strength in rodents, such as forcing them to pull against a spring (grip strength), have been devised, complex learned performance offers more direct answers to the kinds of questions likely to reflect human complaints or observations, such as the relationship between blood pressure and effort and greater sensitivity to subclinical effects.[55] With an apparatus similar to a rowing machine, requiring simultaneous applications of force by the legs as well as the arms (Figure 38.8), Newland and Weiss[56] found that low doses of *d*-amphetamine and L-dopa reduced rates when the behavior was maintained by multiple fixed-ratio (FR)/fixed-interval (FI) schedules. Domperidone, a peripheral dopamine-blocking agent, counteracted the effects of L-dopa, suggesting that at least some of these effects arose peripherally. These techniques are readily adaptable to questions about complaints about weakness and fatigue arising from other agents and, because they are based on apparatus developed for human physical conditioning, could play a role in human toxic assessments as well.

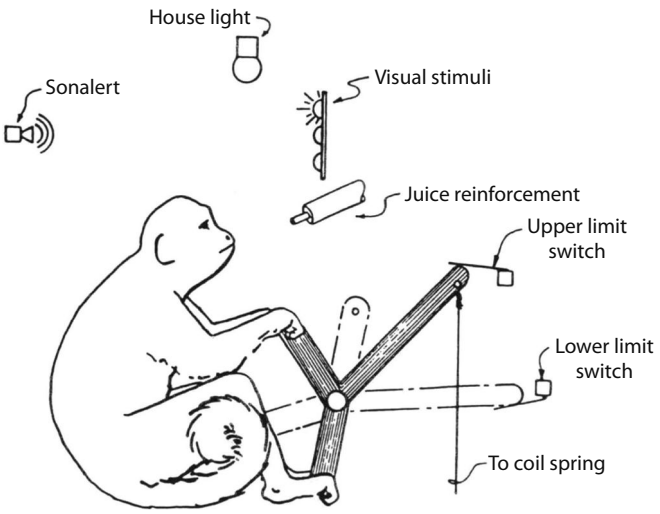

FIGURE 38.8 Apparatus for testing strength and endurance. As in rowing, the monkey pulled the lever with its arms while simultaneously thrusting with its legs. A complete response was defined in three steps: (1) beginning from the home position by closing the lower limit switch, (2) closing the upper limit switch, and (3) opening the lower limit switch. To meet these criteria, the monkey had to move the response device through an arc length of 10 cm against a 40 N (4 kg) circular spring. A brief tone followed each complete response. The visual stimulus panel indicated the schedule component in effect. (From Newland, M.C. and Weiss, B., *Pharmacol. Biochem. Behav.*, 36, 381, 1990. With permission.)

Lead at high doses, such as observed in painters exposed to lead pigments, produces neuropathies such as the syndrome of wrist drop due to radial nerve damage. Newland et al.[57] showed that prenatal lead exposure, at levels (21–760 μg/dL) insufficient to induce overt motor dysfunction, can cause deficiencies in strength. Squirrel monkey subjects, at 3–7 years of age, were trained to pull a T-shaped bar against a 1 kg spring through a distance of 1 cm. On FR schedules, which tend to evoke high rates of responding, the lead-exposed monkeys showed a higher incidence of incomplete responses than control monkeys. The authors concluded that in utero lead exposure at these levels produces subtle impairments in motor function detectable years after birth.

Studies such as those just described indicate how corresponding questions in toxicology may be approached. In its advanced stages, manganese intoxication results in signs sometimes interpreted as Parkinsonism but, as argued by Barbeau,[58] more closely corresponds to dystonia. In its earlier stages, feelings of weakness and excessive fatigue predominate. As with many questions of neurotoxicity, tracking its progression provides the key to identification of underlying neural substrates and appropriate measures on which to base quantitative risk estimates. The exercise device described earlier[56] offers such a means to track progression.[59] After training, monkeys were followed during a sequence of manganese or vehicle treatments. Performance measures included number of missed or incomplete responses, response durations, and interresponse times (IRTs). Figure 38.9, depicting a history of more than 400 days, shows the effect on one index: number of misses or failures to pull through the complete required arc. After the first manganese treatment (10 mg/kg i.v.), the frequency of misses on the FR component jumped sharply. Although this index occasionally drifted downward, it never returned to a pretreatment baseline. Additional manganese treatments produced further variability. Overt signs, such as tremor and dystonias, appeared late in the course of the treatment. Even with the cumulative dosing regimen adopted for this experiment, total exposure amounted to a small fraction of the doses reported by Suzuki et al.[60] to induce overt signs of manganese toxicity.

Gait, Balance, and Coordination

Some measures used to evaluate gait and balance have been described, such as the quantification of Parkinson's disease outcomes in clinical studies and their analogs in the animal laboratory—that is, studies of changes in the walking patterns of rats treated with organophosphate compounds[61] or the kind of kinematic analysis undertaken by Cohen and

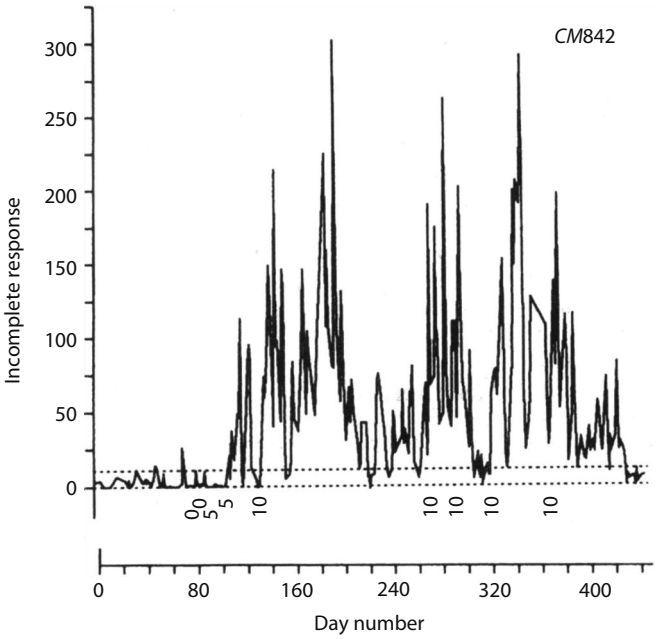

FIGURE 38.9 Performance of a Cebus monkey on a device shown in Figure 38.8 during a course of manganese treatments. Incomplete responses designate those defaulting on the criteria, typically because of failure to operate the upper limit switch. The performance charted was maintained by the FR 20 component of the FR FI multiple schedule of reinforcement. Manganese chloride was administered intravenously in doses of 5 or 10 mg/kg at times indicated on the baseline; saline infusions are represented by zeros. Dotted lines show the 5th and 95th percentiles calculated from baseline sessions. (From Newland, M.C. and Weiss, B., *Toxicol. Appl. Pharmacol.*, 113, 87, 1992. With permission.)

Gans[62] to describe the patterns of rat locomotion in running wheels. Kulig and Lammers[63] reviewed a wide range of techniques currently in use to investigate motor dysfunction. These techniques and approaches have now become increasingly refined and automated through videotaping and computer-assisted scoring and considerations for use described.[64]

A procedure frequently used for assessment of coordination, endurance, and balance is the rotarod. A mouse or rat is placed upon a rotating cylinder, the speed and rate of acceleration of which can be manipulated; the time the animal stays upon the device is measured. Albeit simple and shown to be affected by various neurotoxicants, this procedure can also be associated with significant behavioral problems, including animals who simply learn to engage in behaviors incompatible with staying on the device and which can confound the interpretation of any shortened time staying on the device.[65]

Wolthuis and Vanwersch[61] designed an ingenious procedure for recording and analyzing coordination deficits in rats. A traditional running wheel was modified with the addition of flanges spaced at 30° intervals around the interior surface. The wheel was driven at specified rates by a motor. The ability of rats to step from flange to flange as the wheel rotated was recorded on a videotape, and the analysis was performed by automated measures of the placement of the hind feet, which had been coded by color so appropriate software could be used to measure positions in the video image. With this system, the experimenters could demonstrate that organophosphate treatment produced coordination deficits not readily detectable by common early screening techniques such as the rotarod and hind limb foot splay.

Running wheels also served Cohen and Gans[62] in studies aimed at providing a detailed analysis of rat locomotion, given that the motor activity of rats is frequently monitored to determine the effects of physiological and behavioral variables. Adult male rats were trained to run in an activity wheel. Photoflood lights provided the S^D for running, and mild electrical stimuli delivered through an electrode provided a source of aversive reinforcement to encourage running. Electrodes implanted in forelimb muscles allowed the investigators to monitor muscle activity at the same time movement was being filmed. In an analysis of this functional morphology, running could be shown to represent a *complex and highly adaptable grouping of motor sequences*. The rat's forelimb was shown to act as a steering, propulsive, and supportive device with complicated temporal relationships defining their joint actions. Studies such as these underscore the fact that simple locomotor activity, which has been adopted widely as a component of screening batteries for neurotoxicology, or assays such as hind limb foot splay offer a misleading, perhaps even deceptive, simplicity and sometimes a lack of sensitivity with respect to motor function deficits. Moreover, these earlier studies have led to increasingly automated and commercially available means for acquiring such data.

One of the most easily recognized adverse effects of ethanol is incoordination. Newland and Weiss[66] arranged a situation to try to quantify some of the less overt consequences of ethanol consumption (Figure 38.10). They trained squirrel monkeys to grip a rod attached to the hub of a rotary transformer whose output voltage was proportional to angular displacement. The monkeys received juice reinforcement for maintaining the rod within 15° of horizontal for 8 s. The output voltage was sampled for 5.12 s, and tremor was measured using power spectral analysis.[47] Ethanol greatly reduced the amplitude of tremor, even at doses of 0.25 g/kg. It also tended to flatten the spectral distributions.

Simple tests of motor function almost always are included in screening batteries for humans. One of the most common is finger-tapping rate. Subjects or patients are asked to tap a key or button as rapidly as possible during a test period of several seconds. Both the preferred and alternate hands are usually tested. Chaffin and Miller[67] included both finger and toe tapping in a test battery applied to chloralkali workers exposed to metallic mercury and were able to show that performance correlated with exposure. In a more complex version of the tapping task, the subjects tapped between two copper plates with a stylus connected to a timer so that the intervals between taps could be recorded.[68] In addition, variations in difficulty were introduced by changing the size of or distance between the plates. With a similar technique, Sanes et al.[69] found slower rates in patients with Parkinson's disease than in controls.

Tests developed originally for assessing manual dexterity in workers also have been adopted for human behavioral

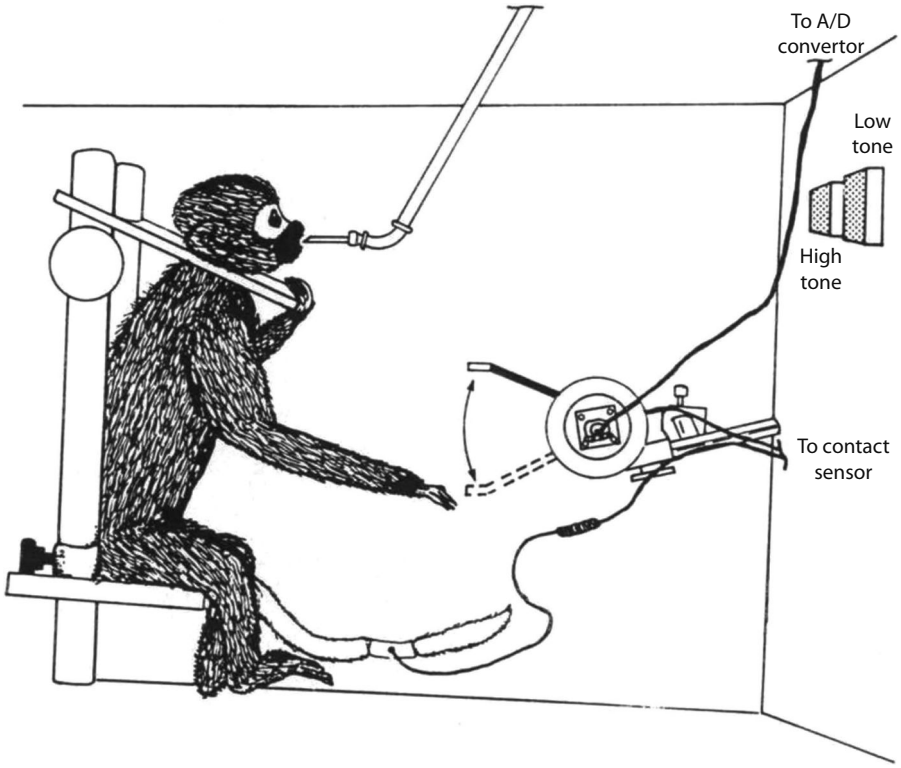

FIGURE 38.10 Depiction of a squirrel monkey (*Saimiri sciurea*) responding on a tremor assessment apparatus. The bar was insulated everywhere except the handle to limit response topography. A contact sensor circuit between the bar and the monkey's tail closed when the bar was gripped. The position of the bar provided a continuous electrical signal that was transformed into a digital code by the analog–digital converter input of the computer that controlled the experimental contingencies. When the bar was held in range, a tone sounded. If held for a sufficient duration, a high-frequency tone burst sounded; on a random ration 2 schedule of reinforcement, a pulse of fruit juice was delivered to the monkey. (From Newland, M.C. and Weiss, B., *J. Stud. Alcohol*, 52, 492, 1991. With permission.)

toxicology studies. The Santa Ana test requires the subject to remove pegs from holes in a board, turn them 180°, and reinsert them. The number rotated correctly within a specified time is taken as the score. It is similar to a test known as the *grooved pegboard*. Hanninen[70] first used the test in a study of workers exposed to carbon disulfide and then included it in the screening battery developed at the Finnish National Institute of Occupational Health. The Purdue pegboard, also developed to assess manual dexterity in factory workers, requires subjects to place pins in a series of holes, but they can then be asked to place collars or washers on the pins. Baker et al.[71] included it in a test battery and noted that it is one of the tests deemed acceptable for occupational studies by a World Health Organization (WHO)–National Institute for Occupational Safety and Health (NIOSH) expert committee.

SENSORY FUNCTION

Almost all behavioral processes depend ultimately on an organism receiving information from its environment. Many behavioral deficits can be traced to disturbances in the way this information is received or processed. Moreover, sensory systems seem to be special targets of certain agents. Acrylamide and methylmercury toxicity are characterized during their earliest stages by loss of sensitivity to touch. Both agents also damage the visual system, although by different mechanisms. A large number of agents, in fact, impair visual function, sometimes so subtly that human victims may be unaware of the deficit. Individuals with defective color vision or areas of scotoma often are detected only on clinical examination. Hearing is degraded by toluene, lead, methylmercury, salicylates, certain antibiotics and diuretics, and noise. Cadmium exposure and chronic solvent exposure have been reported to impair the sense of smell. Behavioral assessments of sensory function can be especially useful because they provide an integrated evaluation of the entire system, starting at the receptors and progressing through the intermediate to the final processing stages of the central nervous system. Furthermore, it may prove misleading to rely mainly on histopathology as the primary index of sensory system toxicity. The intactness of the visual system, for example, cannot be judged simply by examining the retina with a fundoscope or by the gross histological appearance of the visual pathways. The ability to discriminate colors requires a verbal response in humans and some form of motor response in trained animals.

Psychophysics

Psychophysics is a branch of psychology that studies the relationships between sensory stimuli and behavior.[72] One of its

central themes is the concept of a sensory threshold, or the limits of sensitivity for a particular sensory modality, defined as the minimum energy necessary to produce a sensation. Even with the trained observers who typically served as subjects in such experiments in early years, variation from trial to trial in sensitivity was apparent, leading to the development of procedures to cope with these fluctuations and to obtain precise estimates of thresholds. These methods have been refined and expanded since their introduction and have broad applicability across species.

A crucial ingredient of sensory testing is precise specification of the stimulus and its properties. Such descriptions are often lacking in much of behavioral toxicology, as in the reaction time literature discussed later in this chapter. Light and sound stimuli are used without any apparent reports of their parameters, such as brightness and loudness, despite evidence, extending to the beginning of the century, that reaction time latencies are related directly to stimulus amplitude. Many of the devices marketed for sensory testing are also deficient; rather than providing direct measures of stimulus qualities such as vibratory stimulus amplitude, they simply use a dial setting on a potentiometer, say, for specification.

The behavioral measurement of sensory function in laboratory animals also embraces a long history and was one of the earliest topics addressed by experimental psychologists and physiologists, including Pavlov. The development of operant behavior technology contributed major advances to the precision with which sensory function could be determined and to a marked elevation in the status of animal psychophysics. As Stebbins[73] noted, "Training and testing procedures based on the principles of operant conditioning have shown that animals can report on their sensory capabilities in as precise and reliable a fashion as humans." The basic technique in animal psychophysics is to reinforce responses to specified physical characteristics of the stimulus or stimuli. These stimuli serve no eliciting role. They exert control over behavior because they are associated with a particular history of reinforcement. This feature is of special relevance for extrapolation to humans, as many measurement techniques are applied to animals and humans with equal facility. All psychophysical experiments whether conducted with animals or humans are based on a discriminative response by the subject, lever presses and verbal responses happen to be functionally equivalent, a threshold is a statistical concept, it does not imply an absolute physical limit, and its value depends on the methods used to estimate it.

Psychophysical Methods

In most instances, the aim of psychophysical testing is to derive a threshold. During the extensive history of psychophysics, many procedures were developed for the collection of data (Tables 38.3 and 38.4). Most of these have been effectively translated into procedures that can be used with animals. As noted earlier, thresholds are not absolute values but statistical functions of the techniques used to derive them. For example, if the subject is called on to designate the presence or absence of a stimulus, the threshold is typically defined as the stimulus value at which it is detected on 50% of the trials. If the subject is required to discriminate a variable stimulus from a standard, the threshold is typically defined as the magnitude of the variable stimulus that can be differentiated from the standard on 75% of the presentations.

TABLE 38.3
Basic Psychophysical Methods

Method of limits	Series of stimulus intensities ascend and descend from above and below thresholds, respectively.
Method of constant stimuli	Equally spaced stimulus values are presented in random sequence.
Method of adjustment	Stimulus intensity is varied by the observer to exceed and dip below detection limits.
Adaptive methods	Stimulus intensity rises with failure of detection and falls with correct detection.

TABLE 38.4
Response Requirements for Psychophysical Assays

Forced-choice procedures	Subject must choose among alternatives.
Yes–no procedures	Subject responds if stimulus is detected and refrains if it is not.
Rating procedures	Subject reports likelihood of presence or absence using rating scale.

The traditional *method of constant stimuli* presents the observer with between five and nine different stimulus values, each tested repeatedly in a random sequence. The proportion of *yes* responses (indicating that the observer detected a stimulus event) to each stimulus intensity is calculated, a function drawn, and the threshold usually taken as the intensity yielding a 50% incidence of such responses. The correspondence with dose–response functions and their analysis is obvious. For animals and nonverbal humans, such as the mentally retarded, the *yes* response is converted into an action such as a lever press. Even for capable adults, actions such as key presses or computer touch screen responses are now preferred because they are compatible with computer-automated stimulus presentation and response recording. A modification of these traditional procedures known as a *forced-choice paradigm* requires the subject to choose between two stimuli presented either consecutively or simultaneously and so has the advantage of less ambiguity about whether or not a stimulus has been presented, thus controlling for attempts at guessing. As noted earlier, the threshold in this situation is calculated as the stimulus magnitude corresponding to 75% correct detections, because 50% incidence corresponds to chance. In the *method of limits*, the observer is presented with a series of stimulus intensities that begin either well above or well below the presumed threshold. The limits of detection are approached in steps of either diminishing or increasing stimulus values. With alternating descending and

ascending series of stimulus values, the transition intensities between *yes* and *no* responses in both directions become the value from which a threshold value is computed. An ascending series, for example, begins with a stimulus intensity well below the limits of detection. After each trial on which the observer fails to report detection, the intensity of the next stimulus is raised by a prescribed amount. Once the observer reports detection, the series is ended and the intensity recorded. A descending series is conducted in the same way, except that it begins with a stimulus intensity well above the detection limit. Thresholds are typically calculated as the average value or midpoint at which a transition between detection success and failure occurs.

In one variation of the method of limits, called variously the *up-and-down*, *staircase*, or *titration* method, stimulus intensity is modulated in accordance with the responses of the subject, so the threshold can be tracked continuously. A correct detection lowers the next stimulus amplitude, and an incorrect response raises it. This is the most efficient system for calculating thresholds and was a clever variation introduced into audiometry by von Békesy.[74] Because titration procedures are designed so the amplitude of the stimulus is governed by the behavior of the subject, they proved especially suitable for studies of analgesia,[75] providing a means for tracing the impact over time of drugs such as morphine and aspirin on thresholds of sensitivity to shock delivery. Alternative techniques would have required suprathreshold aversive stimuli to be applied to the animals, with inevitable behavioral disruption and unnecessary pain.

The theory of signal detection,[76] first proposed in the 1950s, conceives of the situation as one in which the task of the observer is to distinguish or detect the presence of a signal or stimulus against a background of random activity or noise. Techniques derived from the theory permit the experimenter to take into account variables such as guessing habits or biases on the part of the observer that lead to false detections. Unlike classical psychophysics, these techniques can make explicit the consequences of correct detections and false reports, such as in the form of monetary gains and losses.

In all psychophysical experiments, precise specification of stimulus attributes is essential,[77,78] a facet that may require complex equipment and procedures and thus partly explains why psychophysics remains a relatively neglected component of toxicology. Animal psychophysics introduces further complications, deriving mostly from the extended training sometimes required to extract precise and reliable data. Such investments in time and apparatus are worthwhile when the results are coupled closely to problems of human toxic exposure. Circumstances in which animal and human data require reconciliation are likely to generate questions that mandate the application of complex procedures for sensory assessment. For this reason, as in the other sections, the more advanced techniques are featured. Numerous descriptions of simpler approaches, such as reflex measures,[79] have already appeared in the toxicology literature, whereas the more complex procedures and the contexts in which they confer special advantages are less abundant.

Vision

Vision is the sensory system that has received the most attention from toxicology, where it is represented by at least two books[80,81] and chapters in textbooks.[82] Toxic reactions can take place at many different sites in the visual system. Grant[80] has compiled a list of over 2800 agents that can induce visual system toxicity. Corrosive chemicals can damage the cornea, certain drugs can induce cataract formation in the iris, many different chemicals can damage the retina, and even that part of the cerebral cortex subserving vision can be a toxic target. Vision is unique in the way that information is transmitted along the system. The representation of the visual field on the retina, which contains the light receptors and constitutes what has been labeled a retinotopic map, preserves an analogous spatial distribution in the neuronal pathways ascending from the periphery to the final cortical map. Although ancillary influences may act on these pathways and the distribution of information in the cortex involves secondary projections, parallel and topographic segregation in the primary projection areas is preserved with remarkable fidelity. This feature of the visual system makes testing simple and complicated at the same time.

Color sensitivity, for example, is localized to the center of the visual field (the fovea), in receptor elements called *cones*, which are coded chemically to respond to light of different wavelengths. Deficits in color discrimination arise when the function of these receptors is impaired. Humans, however, are often unaware of such deficits because they learn to compensate by relying on brightness or other contextual cues, which is why specialized tests are used to detect color blindness. An illustration of how easily color discrimination deficits may be masked was provided by the experience with the monoamine oxidase inhibitor pheniprazine, which had been prescribed to treat depression. The treated patients developed red–green color blindness, a toxic effect of which neither the patients nor their physicians were aware. Only later, when normal visual function could be recovered in a relatively small fraction of the patients, did clinical investigators learn of this problem. Once they did, it was possible to demonstrate a corresponding effect in pigeons, whose color discriminative capacity is close to that of humans.

Hanson et al.[83] trained pigeons to peck a translucent disk on which different colors could be projected. The birds were reinforced with food for pecking the disk when it was illuminated by green and orange stimuli but not by blue, yellow, and red stimuli. Discriminative responding quickly appeared; few responses were made in the presence of the negative stimuli. After about a month of daily administration of pheniprazine, however, discriminative capacity was lost, with pigeons responding equally to all stimuli. (The experimenters took care to match brightness so it could not be used as a cue.) When treatment with pheniprazine ceased, discriminative ability gradually recovered. This fairly simple discrimination procedure could have been used to preclude a serious, irreversible effect in humans had it been implemented.

Color vision deficits are recognized as one outcome of occupational exposure to organic solvents. Earlier, Raitta

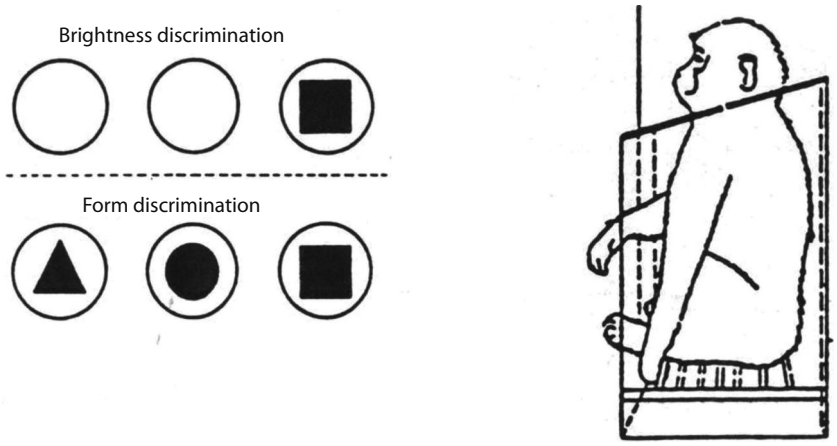

FIGURE 38.11 Testing geometric form discrimination in monkeys exposed to methylmercury. The monkey faced a panel of three disks. When examined for the ability to distinguish shape, the monkey was required to press the disk on which the square was projected. The position of the square varied randomly from trial to trial. When examined for its ability to perform simple brightness discrimination, the monkey was required simply to indicate which disk contained the square. (On the figure, the light and dark areas are reversed for ease of presentation.) Correct responses were reinforced by pulses of fruit juice. (Adapted from Evans, H.L., Early methylmercury signs revealed in visual tests, in Hutchinson, T.C., ed., *Proceedings of the International Conference on Heavy Metals in the Environment*, Vol. 3, University of Toronto Institute of Environmental Studies, Toronto, Ontario, Canada, 1978, pp. 241–256; Evans, H.L. et al., *Fed. Proc.*, 34, 1858, 1975.)

et al.[84] had noted such deficits among workers in the viscose rayon industry, where they are exposed to carbon disulfide, by using the Farnsworth–Munsell 100 hue panel, which requires subjects to arrange a series of 85 reference caps representing incremental changes in hue. Color vision function is based on the ability of the subject to place the color caps in order of hue. Modifications of the 100 hue test include the Farnsworth–Munsell dichotomous D-15 color test, requiring the subject to arrange 15 numbered disks with different hues, and the Lanthony D-15d desaturated hue panel claimed to be more sensitive. Geller and Hudnell[85] have noted the high incidence of errors sometimes made by control subjects and suggested revised test protocols to improve its diagnostic value.

Numerous studies, based on such techniques, have now been published in support of the claim that workplace organic solvent exposure impairs color vision. They implicate styrene, toluene, tetrachlorethylene, xylene, methyl ethyl ketone, and others.[85–87] A common finding in these studies is blue–yellow confusion, but red–green confusion seems to be a more specific marker for solvents.

Color vision deficits due to solvents are likely due to retinal damage or dysfunction. Toxicants that damage visual pathways at upstream sites in the central nervous system create other kinds of deficits that depend on the site of damage. Methylmercury is a potent central nervous system poison that in primates, including humans, tends to be most lethal to nerve cells buried deep in the folds of the cortex. The peripheral projections of the visual fields lie within the medial portions of the occipital cortex along the calcarine fissure, which is a principal site of damage induced by methylmercury. Humans who have undergone serious exposure show constriction of the visual fields, sometimes progressing to severe tunnel vision and, occasionally, blindness. Korogi et al.[88] found, by magnetic resonance imaging, considerable atrophy in several brain regions, including the calcarine fissure, of Japanese victims of methylmercury poisoning. Evans et al.[89,90] traced this progression in monkeys and related it to exposure and tissue levels of methylmercury (Figure 38.11). Monkeys were first accustomed to perching in a primate test chair. During testing, they faced a panel containing three Lucite disks illuminated from behind by three geometric forms—a square, a circle, and a triangle. Pressing any one of the disks closed a circuit and allowed the experimenter to record the source of the response and to arrange certain consequences as a result. In this experiment, the monkeys were reinforced with a small amount of fruit juice for pressing the key with the square.

The reasons for the choice of a geometric form discrimination to trace the progression of methylmercury toxicity illustrate how animal psychophysics is applied to toxicological questions. If methylmercury preferentially damages cortical cells receiving projections from the peripheral areas of the visual fields, then visual discriminations at low luminances should be differentially impaired. The periphery is represented in the retina by visual elements called *rods*, which are sensitive to low light levels. The cones in the center of the field, which are responsible for color vision and for fine acuity, function at high light levels. To detect a differential effect in the central and peripheral visual fields, the forms were illuminated on different occasions with a range of luminance values, the lowest of which made the forms visible only after the monkey had remained in the dark for at least 10 min so the rods had become adapted. Monkeys treated chronically with methylmercury began to show deficits in visual function revealed earliest by diminished accuracy on the form discrimination at the lowest luminances. Only much later did damage progress far enough in the cortex to produce deficits in discrimination at the higher luminances (Figure 38.12).

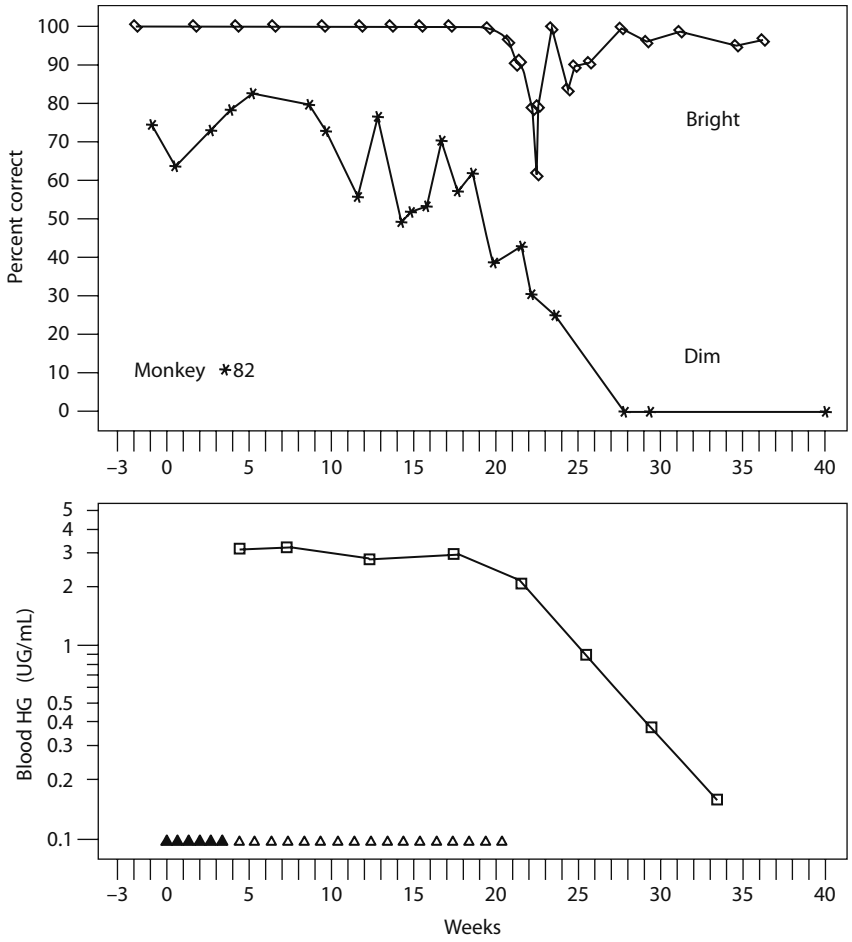

FIGURE 38.12 Form accuracy (top plot) of a monkey (*Macaca speciosa*) treated with methylmercury (see Figure 38.11). The methylmercury was administered in doses of 0.5 mg/kg on occasions marked by small triangles on the tower graph. Resulting blood levels are traced by the connected squares (bottom plot). Performance under dim (scotopic) target luminances deteriorated before performance under bright (photopic) luminances and eventually reached zero, where it remained even after treatment ceased. Note the sharp fall in photopic accuracy beginning at about week 20. At that time, methylmercury administration was discontinued and was followed by recovery, but performances at scotopic luminances continued to deteriorate, suggesting that sensitive assays might help identify toxicity at a stage during at which damage is still reversible. (Adapted from Evans, H.L., Early methylmercury signs revealed in visual tests, in Hutchinson, T.C., ed., *Proceedings of the International Conference on Heavy Metals in the Environment*, Vol. 3, University of Toronto Institute of Environmental Studies, Toronto, Ontario, Canada, 1978, pp. 241–256; Evans, H.L. et al., *Fed. Proc.*, 34, 1858, 1975.)

The primary health concerns aroused by methylmercury arise from its effects on brain development. Because visual deficits are such a conspicuous feature of adult poisoning, Rice and Gilbert[91] characterized visual function in two groups of monkeys (*Macaca fascicularis*) exposed developmentally to methylmercury. One group was dosed from birth onward with 50 μg/kg/day. A second group was exposed in utero by dosing the mother with 10, 25, or 50 μg/kg/day and was then exposed postnatally until 4.0–4.5 years of age with the same dose the mother had received. The authors based their assessment on what is now conceived by vision scientists to be the principles on which the visual system functions. They view the visual system as basically a frequency analyzer, responding to variations in both time and space. Variations in time are exemplified by flickering light sources. Spatial variations are illustrated by almost all natural scenes containing different textures. Low spatial frequencies are represented by objects with relatively broad features, such as faces. High spatial frequencies correspond to fine details, such as the print on the page. Figure 38.13 shows the kinds of variations in a visual display defined by spatial frequency. Spatial and temporal visual function was tested in both groups.

For spatial testing, subjects viewed a display composed of gratings or alternating light and dark bars. These bars were not sharply defined stripes but varied sinusoidally so the highest (lightest) luminance in the modulated signal represented the peak and the lowest (darkest) luminance the trough. In correspondence with temporal stimuli, the variables comprise spatial frequency (bar width), mean luminance, and contrast between peak and trough. High spatial frequencies are represented by narrow bars, which require intact visual acuity, and low frequencies by wide bars.

To access temporal acuity, the subject is asked to indicate whether a target, such as an oscilloscope screen, is flickering

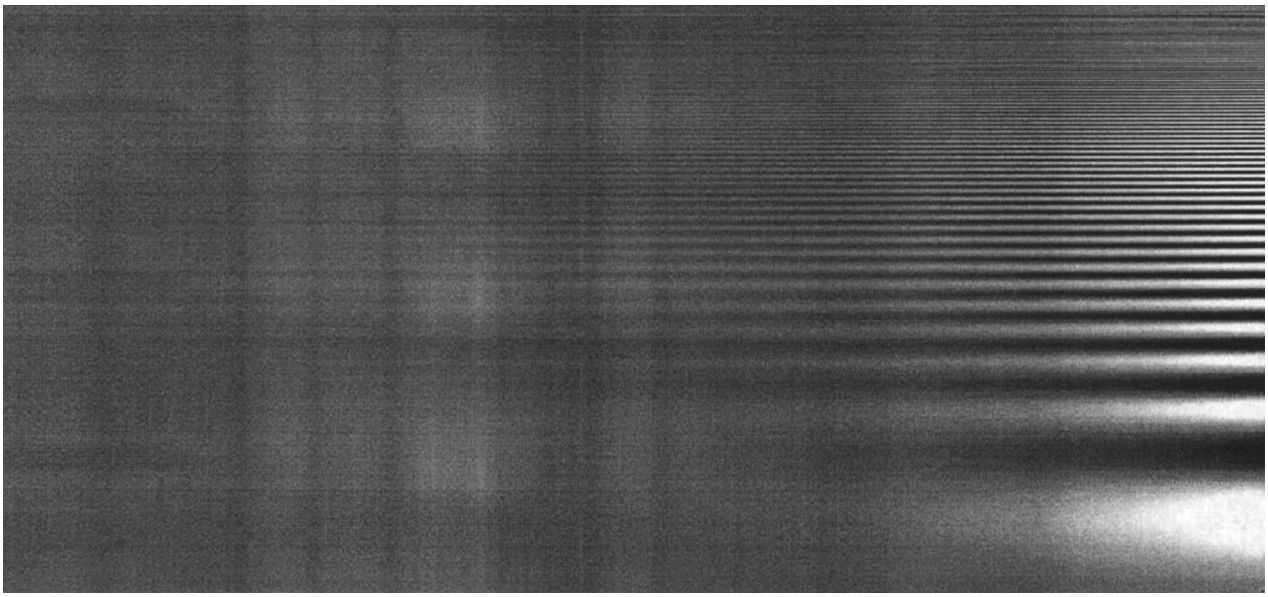

FIGURE 38.13 Spatial contrast model. Spatial frequency decreases from top to bottom, and contrast decreases from right to left. A conventional contrast sensitivity plot would be based on the display of a grating with a specified visual angle and would indicate the contrast level at which the grating appears uniform.

or steady. The ability to do so is measured by raising the frequency of flicker to a rate at which it no longer appears to vary. The current approach varies in both depth of modulation, or the difference in luminance between the brightest and dimmest extremes of the light source, and the mean luminance around which these values fluctuate sinusoidally.[92] Some neuropsychological test batteries[93] continue to rely on the old method, designed to provide a measure called *critical flicker frequency* (CFF), which typically flashes a bright light source on and off at different rates. The CFF is defined as that frequency at which the subject reports a shift from a flickering to a steady stimulus.

Earlier, Rice and Gilbert[94] had reported spatial contrast sensitivity deficits in the group dosed only postnatally. Monkeys exposed both in utero and postnatally exhibited deficits in both high- and low-luminance spatial sensitivities. They also exhibited deficits in low-frequency, high-luminance temporal discriminations (flickering light), while low-luminance temporal vision was superior to that of control monkeys. Those monkeys exposed from birth displayed superior low-luminance temporal vision and no impairment of high-luminance temporal vision. Constriction of the visual fields was not detected. The authors suggest that the pattern of visual deficits produced by methylmercury exposure during development differs from that seen in the adult and speculate that the developing visual system may be able to remodel in response to early damage by a neurotoxic agent.

Similar approaches indicate that the visual system is subject to damage from the axonopathic agent acrylamide. Until the report by Merigan et al.,[95] it had been assumed that acrylamide neurotoxicity, expressed predominantly as a central–peripheral distal axonopathy, was largely reversible. Moreover, none of the previous publications, including those reporting cases of human poisonings, had mentioned visual deficits. Merigan et al.,[95–97] in a series of experiments with acrylamide, trained monkeys to choose between two targets presented on two oscilloscopes. The monkeys sat in a special test stand positioned before a response panel that supported two push buttons and a spout for juice delivery. Before a test trial began, both screens were illuminated evenly. At the onset of a trial, a tone sounded and the test stimulus appeared on one of the oscilloscopes. For acuity testing, the test stimulus was a vertical grating. For tests of temporal resolution, it was a flickering screen. If the monkey pressed the push button corresponding to the position of the test screen (left or right), it received a juice reward. Each response terminated the trial. An adjusting or titration procedure governed the stimulus parameters. Correct responses made the gratings finer on the next trial during acuity testing and raised flicker rate during flicker fusion testing. Incorrect responses drove the stimulus values in the other direction. The positions of the variable and steady targets shifted randomly from trial to trial and stimulus position, and characteristics were controlled by a digital computer.

Treatment with acrylamide continued until the appearance of overt toxic signs, then it was stopped and recovery monitored. All measures of function recovered except for visual acuity, defined as the ability to resolve gratings at the highest contrast (Figure 38.14), which evidenced only partial recovery. A subsequent series of histological studies[98–100] demonstrated that the source of this deficit was the destruction of a class of cells in the retina that project to a particular site in the lateral geniculate nucleus of the midbrain, which in turn projects to the visual areas of the cerebral cortex. The degree of persisting functional impairment noted in some of these studies, however, might go unnoticed by many, if not most, people, just like color blindness.

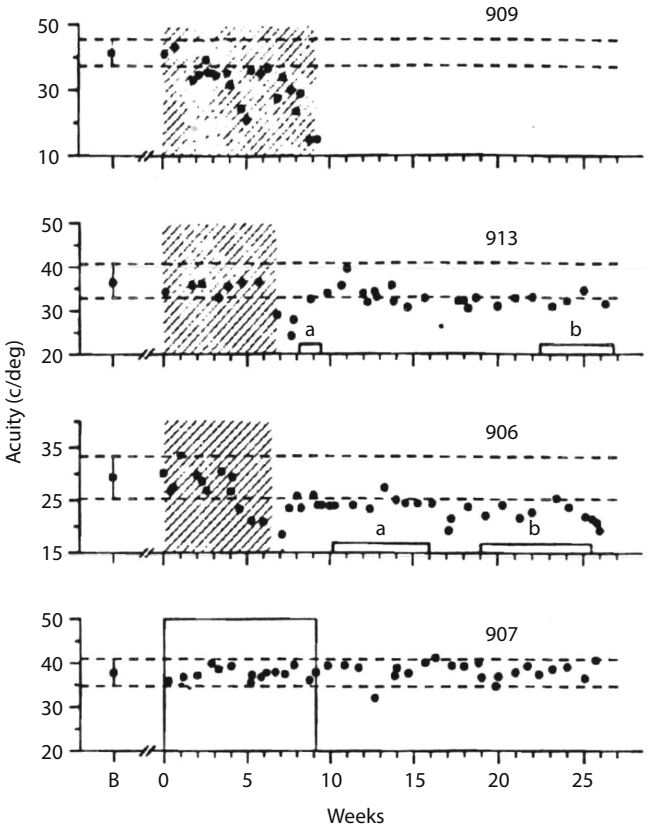

FIGURE 38.14 Visual acuity plots of four monkeys (*M. nemestrina*) dosed with acrylamide. The monkeys faced two high-resolution oscilloscopes during testing. One displayed a grating and the other a uniform field, according to a randomly chosen sequence. For expressing acuity, grating contrast, which describes the differences between the brightest and dimmest areas of the vertical grating pattern, remained constant at 0.55. Spatial frequency, based on the width of light and dark bars of the grating and expressed as cycles per degree of visual angle, was varied in steps according to an up–down procedure to obtain a threshold for the monkey's ability to distinguish a grating from a uniform display. Hatched areas show the period of acrylamide treatment. Acrylamide (10 mg/kg) was administered five times weekly until ataxia appeared. Monkey 907 received only sham treatment. The bottom panel shows the mean of eight baseline sessions (±2 SD), which was extended across the duration of the experiment (dashed tines). The intervals marked *a* and *b* for monkeys 913 and 906 designate collection of contrast sensitivity measures. Monkey 909 was sacrificed at the end of dosing for neuropathology. Monkeys 913 and 906, despite some recovery, failed to reach predosing acuity. (From Merigan, W.H. et al., *Invest. Ophthalmol. Vis. Sci.*, 26, 309, 1985. With permission.)

Merigan et al.[101] and Eskin et al.[102] adopted a similar approach to study the visual toxicity of carbon disulfide. Monkeys were exposed in inhalation chambers to 256 ppm for 6 h daily, 5 times each week, for 7 weeks. The visual acuity thresholds of the two exposed monkeys indicated severe functional losses after about 5 weeks. Further testing revealed a seven- to tenfold loss of acuity from which only one of the exposed monkeys partially recovered. Flicker fusion thresholds, however, showed much smaller, reversible effects. Retinal examinations by fundus photography and fluorescein angiography showed no evidence of the kind of damage to the vasculature, such as microaneurysms, reported in exposed workers,[103] nor was there any other clinical indication of damage. These results, like those of the acrylamide studies, argue that advanced psychophysical testing methods are the most dependable sources of information about the neurotoxic subclinical potential of agents acting on sensory systems. Color vision deficits, as noted earlier, have been observed among workers exposed to carbon disulfide[84] and among those exposed to solvents such as toluene.[104] These deficits were not accompanied by cogent evidence of ocular pathology. Further, Merigan[105] later showed impaired color discriminations in monkeys exposed to acrylamide and confirmed that the class of retinal ganglion cells damaged by acrylamide carried color information. For these experiments, contrast sensitivity measures were based on red–green and yellow–blue contrasts as the grating components.

Hearing

The most frequent cause of hearing loss after aging is exposure to excessive noise. Several classes of drugs also impair hearing. Some (e.g., salicylates) produce transient effects such as tinnitus. Others, such as the aminoglycoside antibiotics (streptomycin and kanamycin), damage the hair cells in the cochlea, where the mechanical movements of sound are transformed into nerve impulses. Loop diuretics and quinine, especially with prolonged administration, can cause similar damage. It is now standard practice for such classes of drugs to be tested for auditory system pathology, but behavioral testing may detect impairment at a stage when the cessation of treatment leads to recovery.

Stebbins and his coworkers[106] have produced an extensive body of data on ototoxicity from which two important conclusions have emerged. First, they demonstrated that hearing can be assessed by many different behavioral methods and in many different species. Second, they established correlations between histopathology and the results of behavioral testing that yield valuable information about how the auditory system works. In this work, a trial begins by pressing a key or contact-sensitive plate, a response that activates a light. At a variable time after light onset, the acoustic stimulus, usually a pure tone, is presented. If the subject responds during the tone, the reinforcer is delivered immediately. Premature releases are followed by termination of the trial and a delay of 6–10 s before the next trial. Trials on which no tone is presented (*catch* trials) are interspersed among the tone trials to estimate the subject's tendency to guess. Training is continued until guessing is reduced to a low, stable rate. Both the method of constant stimuli and the up–down or titration method have been used in these studies.

Measurements of relative loudness, which involve stimulus intensities well above threshold, are made with a modification of these methods. The animals are trained by differential reinforcement, to respond quickly, say within 500 ms.

This is basically a reaction time situation, and, as noted earlier, because greater stimulus intensities produce shorter response latencies, loudness, which is a subjective variable, can be measured in animals. For example, response latency in monkeys falls from about 900 ms at a sound pressure level of 10 dB to about 200 ms at a level of 90 dB. With these techniques, in species as diverse as macaque monkeys, cats, guinea pigs, and chinchillas, these investigators have been able to demonstrate the effects of aminoglycoside antibiotics on the progression of hearing loss and both the temporary and permanent consequences of exposure to noise. The earliest effects are seen at the high frequencies, a typical finding. Mattson et al.[107] notes that such specificity makes it unlikely that ototoxicity would be detected with the usual elementary screening techniques because their stimulus dimensions tend not to be precisely described.

With continued treatment, losses extend to lower and lower frequencies. Such a progression has its morphological counterpart in the hair cells attached to the basilar membrane, which stretches along the winding spiral structure of the cochlea. If the cochlea is examined at an intermediate stage of hearing loss, when high- but not low-frequency discrimination is impaired, it shows damage to hair cells in the lower half of the cochlea, where high frequencies are represented, but no damage to the upper half of the cochlea, where the basilar membrane responds maximally to low frequencies. Given such correlations as a guide, it has become possible to largely confirm the assertion that frequency is coded according to location along the basilar membrane from the base to the apex of the cochlea.

Lead and methylmercury have both been documented as ototoxicants. Schwartz and Otto[108,109] reported that thresholds to a 2 kHz tone rose almost linearly with blood lead levels in subjects 14–19 years of age. This function is based on conventional audiograms from more than 4000 individuals surveyed in the second National Health and Nutrition Examination Survey (NHANES II). In another analysis, based on a subset of Hispanic subjects between 6 and 19 years of age, an increase in blood lead level from 6 to 18 μg/dL was associated with a 2 dB loss of hearing at all frequencies tested. Although a difference of such magnitude is seemingly of little consequence to an individual, it is significant to a population because of the great magnification it undergoes at the extremes of the distribution.[37]

Complaints of hearing difficulties were voiced by individuals from Minamata, Japan, who were heavily exposed to methylmercury, but intensive testing beyond conventional audiometry has not been carried out. Rice and Gilbert[110] surveyed auditory function in *M. fascicularis* monkeys exposed to methylmercury from birth to 7 years of age. The testing was conducted at 14 years of age, after the monkeys were trained on an up–down detection procedure, as described earlier. Exposed monkeys generally exhibited deficits at frequencies above 10 kHz. The age at which these deficits began to appear is not known because auditory testing did not begin until long after exposure had ended. Another group of monkeys was exposed from gestation to 4 years of age.[111] As in the postnatal group, both mothers and offspring received daily doses of 0, 10, 25, or 50 μg/kg. Pure tone detection thresholds were determined at 11 and 19 years of age by the up–down psychophysical procedure. The degree of deterioration of hearing thresholds between 11 and 19 years of age in the treated monkeys greatly exceeded that observed in the controls and supports speculations that accelerated impairment of function during aging is one possible consequence of developmental exposure to neurotoxicants.

Other instrumental techniques have also been applied to questions of sensory function. A series of studies by Pryor and associates, for example, using conditioned avoidance responding, established that hearing loss could be induced in rats by chronic exposure to common organic solvents such as toluene.[112] Rats were trained to jump and grasp a pole upon presentation of a tone to avoid an aversive electric shock delivered through a grid floor in the chamber.

Most of the testing methods described earlier command extensive resources and time for their execution and limit the number of subjects that can be evaluated, and as such, they are not suitable for inclusion in a preliminary screening battery designed to identify potential hazards. Their advantage lies in their ability to respond to questions arising at later stages of evaluation. Even so, there is constant speculation about how these methods might be replaced by less expensive and lengthy approaches. One attractive alternative is the reflex modulation paradigm. It is based on the ability of a low-intensity stimulus, delivered before a stimulus intense enough to elicit a startle response, to modify the amplitude of that response.[113] The startle stimulus is typically a loud sound, and the response is measured in rats by confining them to a platform connected to a force or acceleration transducer. If a prepulse, such as a soft sound, appears at an appropriate interval, such as 80 ms before the startle stimulus, the amplitude of the startle stimulus will be reduced. If the prepulse stimuli consist of pure tones of various frequencies and energies, it is possible to chart what in essence is a conventional audiogram because the amount of reduction is directly related to prepulse amplitude.

Applications of the auditory startle response technique have established the potency of solvents as ototoxicants; for example, rats exposed to trichloroethylene at 4000 ppm for 6 h a day for 5 days showed elevated thresholds at 8 and 16 kHz, perhaps due to a loss of spinal ganglion cells.[114] Startle also can be inhibited by cutaneous and visual stimuli and by brief gaps in a continuous auditory stimulus. The reflex modification technique, nevertheless, is limited to relatively simple questions. It would be unsuitable for plotting contrast sensitivity functions, such as those reported by Merigan and his coworkers in studies of acrylamide and carbon disulfide, or for evaluating disorders of color sensitivity. The latter demand an extremely subtle form of stimulus discrimination that could be achieved only by highly trained and motivated subjects. What seems most reasonable is to include reflex modulation in preliminary screening batteries and to reserve the complex psychophysical methods for advanced questions.

Somesthesis

The skin contains a heterogeneous population of receptors whose central representation is equally diverse. Mechanoreceptors are specialized to respond to deformations of the skin. Some respond on the basis of depth of displacement, some on the basis of velocity, and others on the basis of acceleration. Still others are activated by the movement of hairs. Additional receptors are responsive to temperature. Free nerve endings are thought to subserve pain. Pathways transmitting information from the skin travel to the central nervous system through the peripheral nerves and then, except for the head region, penetrate the spinal cord through the dorsal roots. The head region is supplied by the 12 cranial nerves. At the level of the cerebral cortex, the skin surface is represented in accordance with the density of receptors in various areas, so the cortical areas devoted to the face and hands greatly exceed those devoted to the back, buttocks, and other low-density areas. A corresponding nonspecific system, which is less defined and which includes the reticular formation of the midbrain, makes a wider range of connections as it ascends and is thought to serve an arousal function.

Most disturbances of somesthesis are attributed to impaired function of the peripheral nerves (i.e., peripheral neuropathy), although one prototypical agent, acrylamide, apparently exerts its earliest peripheral effects on the acceleration receptors known as Pacinian corpuscles. Damage anywhere along the pathways from receptor to cortex may produce such disturbances, but methylmercury is the only poison clearly documented to be involved at the cortical level. A wide array of chemical classes, as listed in Table 38.5, seems to produce their somatosensory effects primarily through peripheral nerve damage, although some act as well at subcortical and cortical levels. This list includes metals, solvents, organophosphates, and other chemicals. A more complete list would include drugs from many different therapeutic classes.

In assessing the scope of such a dysfunction, histology will be of limited utility when the basic question is the risk to the health of a specific population such as workers. Moreover, the typical clinical neurological examination is generally inadequate because its aim is to uncover frank disease. The clinician may prick the skin with a pin, draw a wisp of cotton across the skin, or ask the patient to judge whether a tuning fork is vibrating. Even the most controlled of these stimuli, the tuning fork, is a crude device held in a hand that itself has an oscillation of much greater amplitude than is discriminable at the skin. The threshold for vibration detection at a frequency of, for example, 150 Hz lies close to 1 μm and requires precise instrumentation, calibrated to 0.1 μm, to determine. The simple vibration devices marketed by several producers and often used in clinical studies are too gross to yield useful data; moreover, they tend to be used with improper psychophysical procedures.[77,78] A major flaw is their lack of direct specification of stimulus characteristics, particularly amplitude. Some of the commercial units express stimulus output as volts, which refers to the setting on a dial; others use unspecified units that are equally arbitrary.

Despite the requirements for precision, however, vibration sensitivity testing has particular utility as a method for assessing sensory neuropathy. One is its underlying structural and functional diversity. It is thought to be mediated by at least two sets of large-diameter myelinated fibers originating from two kinds of receptors: the Pacinian corpuscles, presumed to be maximally responsive to stimulus frequencies from about 100 to 400 Hz, and Meissner corpuscles, maximally responsive to frequencies of about 50 Hz and below. As in the visual and auditory systems, then, vibration sensitivity can be evaluated by determining detection thresholds across a broad range of frequencies.

Monkeys and humans possess about the same degree of sensitivity to vibration and can be tested in essentially the same way. Maurissen and Weiss[115] tested monkeys perched in a primate chair, with one hand restrained by a Plasticine mold fitted individually for each monkey. An electromagnetic vibrator drove a rod in contact with the middle finger and was positioned to indent the skin at a constant depth in the absence of vibration. It is essential to use a vibrator powerful enough to maintain its calibrated amplitude when opposing the mechanical resistance of the skin. (One flaw of some commercial instruments advertised for vibration testing is their sensitivity to pressure, which renders them unsuitable for precise measurement of displacement.) The monkey's other hand was free to respond on a key. The frequency and amplitude of stimuli were determined by function generators whose outputs, in turn, were governed by parameters entered into a computer program that controlled the sequence of experimental events and that stored the results.

One experiment with this system sought to trace the onset and development of sensory neuropathy induced by the axonopathic agent acrylamide[116] in *Macaca nemestrina* monkeys. During training, they learned to press and release the key to obtain juice, succeeded by a phase in which they learned to wait for the onset of vibration delivered to the other hand before releasing the key. In the final protocol, a tone signaled the beginning of a trial. The monkey then held down the key. After a foreperiod of variable length, a vibratory stimulus was presented. If the key were released during this period, juice delivery followed. On catch trials, inserted to discourage and compensate for random guessing and on which no vibration occurred, the monkey earned juice

TABLE 38.5

Methyl-*n*-butyl ketone	

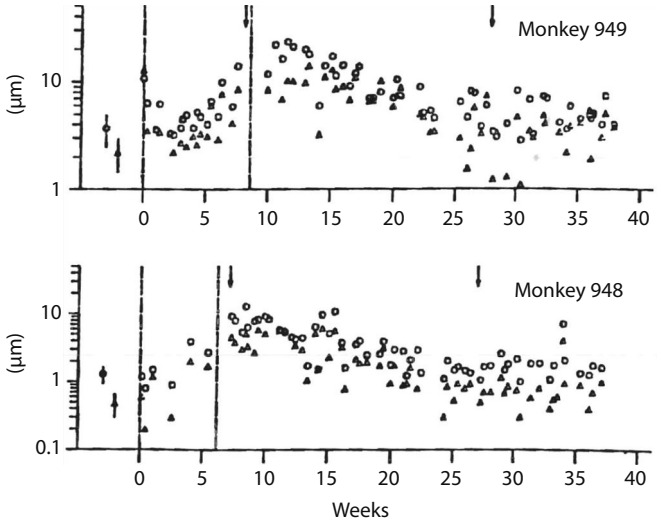

FIGURE 38.15 Vibration sensitivity of two monkeys (*M. nemestrina*) assessed by determining thresholds to stimulation by a vibrating rod applied to a finger. The rod was driven by an electromagnetic vibrator controlled by a voltage determined by the computer program that managed the experiment. The monkey's paw was maintained in a stable position by a Plasticine cast. The subjects were trained to press a telegraph key with the unrestrained hand when a vibratory stimulus was detected and to respond only at the end of the trial period when a stimulus was not detected. Correct responses were reinforced by the delivery of fruit juice. Baseline thresholds (±2 SD) are plotted in the area preceding acrylamide dosing at week 0 for vibration frequencies of 40 Hz (circles) and 150 Hz (triangles). Dashed vertical lines indicate the beginning and end of acrylamide treatment (10 mg/kg, five times weekly). Thresholds, given as vibration amplitude in grams on the ordinate, rose slowly for several weeks during treatment, then slowly declined. (From Maurissen, J.P. et al., *Toxicol. Appl. Pharmacol.*, 71, 266, 1983. With permission.)

delivery by holding down the key during the tone and releasing it only after the tone ceased. Correct responses lowered the amplitude of the stimulus on the next trial and incorrect responses raised it, as in the vision experiments described previously.

Figure 38.15 shows the results of this experiment. After stable baselines were established, monkeys were given 10 mg/kg acrylamide monomer in apple juice on weekdays during the treatment period. In addition to testing two vibration frequencies, 40 and 150 Hz, the monkeys were also tested, in a separate but identical apparatus, for electrical sensitivity. In this apparatus, the rod in contact with the monkey's finger was an electrode through which a 60 Hz electrical stimulus was delivered. As during vibration testing, correct detections lowered the amplitude of the stimulus on the next trial, and incorrect responses raised it. Gross motor deficits were assessed with an apparatus that allowed an observer to record the length of time required to retrieve marshmallow from a mesh grid. Body weights and the occurrence of standard clinical signs also were recorded.

As the figure shows, vibration thresholds rose soon after dosing began. Once dosing ended, they fell slowly after several weeks. Electrical sensitivity remained stable, presumably because it is subserved by small, unmyelinated fibers that are not as sensitive to acrylamide as the large, myelinated nerve fibers that carry information from the Pacinian corpuscles and other receptors that respond to vibration. A second course of acrylamide treatment, following the return to baseline sensitivity, duplicated the results obtained during the first course.[116] What is especially notable about both sets of data is the absolute sensitivity to vibration. Note the baseline thresholds, that lie in the range of a few micrometers. As noted earlier, measuring such thresholds, which is required if early intervention is sought, requires instrumentation that can be calibrated to within tenths of micrometers.

Rice and Gilbert[117] used this method to determine the effects of methylmercury and lead on vibration sensitivity. Methylmercury-exposed monkeys consisted of the same group described previously in discussions of visual and auditory functions. Lead-exposed monkeys had been treated throughout life. Paresthesias comprise the earliest indication of methylmercury neurotoxicity in adults, and peripheral neuropathies are a recognized consequence of lead exposure. Of five monkeys dosed with methylmercury from birth to 7 years of age, four exhibited reduced sensitivity to vibration when tested at 18 years of age. Two monkeys dosed prenatally through 4 years of age exhibited reduced sensitivity at 15 years of age, while two monkeys treated with higher doses showed little impairment. Lifetime lead exposure produced ambiguous but suggestive indications of impairment.

Quantitative sensory assessments are becoming more routine in clinical neurology because of the recognition that the traditional clinical methods are insensitive,[118] and vibration sensitivity is one of the more common indices. Quantitative measures are especially useful for monitoring patients treated with drugs, such as cancer chemotherapeutic agents, that induce peripheral neuropathies, so treatment can be interrupted before permanent damage is inflicted. Despite the availability of instrumentation capable of the precise control of amplitude and frequency, however, considerable misunderstanding remains about the appropriate procedures, including confusion as to the difference between psychophysical methods for the presentation of stimuli and the type of responses with which they are used. Maurissen[78] describes some of the typical errors made by investigators.

Smell

Olfaction is a primitive sense in the context of evolution. Its representation in the brain takes a different course than the senses already described because the olfactory pathways bypass the thalamus and travel directly to the piriform cortex. Recognition of odorants by the olfactory receptors comprises the first stage in odor discrimination, a process that is beginning to yield to a molecular understanding of odorant recognition. Only then do they link to subcortical structures in the limbic system, which includes the amygdala and hypothalamus. Because the limbic system is associated with behaviors such as those involved in reproduction, olfaction

carries a crucial responsibility in species as well as in individual adaptation to the environment. Even in humans, the sense of smell, although not critical in meeting most environmental challenges, is nevertheless the source of both pleasant and unpleasant stimuli that contribute to the quality of life. Moreover, some chemicals announce the approach of dangerous ambient levels by stimulating olfactory receptors, so diminished smell sensitivity might pose a danger.

Disorders of olfaction recently entered the argument about whether or not chronic, low-level exposure to volatile organic solvents inflicts neurotoxic consequences. Schwartz et al.[119] examined workers in the paint industry who had been exposed to a variety of solvents, all in settings well enough regulated that exposure concentrations did not exceed the threshold limit values (TLVs®). The workers were tested by asking them to identify standardized odor patches produced by the Monell Center at the University of Pennsylvania. Workers exhibited a lowered discriminative capacity. Such a test does not afford precise control over parameters such as concentration; it is a fairly blunt instrument designed for screening large groups. Precise control is achievable in both animal and human studies, although it requires specialized instrumentation, as shown by recent attempts to provide adequate precision for clinical use.[120] In animal studies, operant behavior, based on the use of odor as a S^D has proven successful.[121] In the presence of one odor, responses are reinforced with food delivery; in the presence of another odor or a neutral stimulus, responses are not reinforced. A simple discrimination procedure described by Enwere et al.[122] allows generation of actual concentration-effect curves for odor and determination of a threshold, based on techniques that are similar to those used in a later section (stimulus properties of chemicals). Differences in responding serve to index the ability of the subject to distinguish the specific odors at varying concentrations. A special reason for not neglecting olfaction is its exquisite elaboration in rodents, the most common laboratory species. Odor discrimination learning occurs rapidly in rats[123] and also seems sensitive to toxic intervention.

LEARNING

Learning refers to the process of behavioral adaptation to changes in environmental contingencies—that is, behavior in transition. As Laties[124] pointed out, "There can be as many ways of studying learning as there are ways of confronting organisms with changed reinforcement contingencies and then watching them adapt to the new contingencies." The procedures and apparatus devoted to the study of learning are so diverse and numerous that an adequate description of their domain is beyond the scope of this chapter. As previously noted, this chapter focuses on approaches that have been most frequently utilized, as well as those most promising for illuminating behavioral and neurobiological mechanisms of toxicity. It also highlights some of the important methodological issues involved in interpretation of changes in learning. Research reviews have described in greater detail the effects of specific toxicants on learning, as well as other procedural issue.[125–128]

Simple Mazes

The evaluation of learning processes has frequently been based on procedures involving a response choice from which measures including accuracy and latency can be derived. Before the advent of more sophisticated technologies, the assessment of learning often relied on the use of simple mazes. For example, in a T maze, so named because of its shape, the subject is reinforced for choosing (entering) the arm of the maze designated as the correct side, whereas entering the wrong arm results in no reinforcer delivery (extinction). Such procedures can be modified to some extent by the inclusion of external discriminative stimuli to signal which arm was the appropriate choice; for example, the black arm is the S^+ and the white arm the S^-. Typically, learning under such conditions is determined by the number of errors (entries into the wrong arm), the number of trials to some specified accuracy criterion, and the latency (time) from leaving the base of the T to enter the appropriate arm of the maze on each trial.

Such procedures not only have proven useful as indices of learning impairments, but they also entail potential disadvantages and caveats with respect to interpretation of outcome. Because such devices are not easily automated, they are personnel intensive; for example, after each trial, the animal must be replaced in the start box by the experimenter for initiation of the next trial. The necessity of handling animals and experimenter intrusion into the recording of data introduce the possibility of experimenter bias, unless procedures are carried out by personnel blind to all experimental conditions. Additionally, demands on personnel time by nonautomated versions of mazes markedly increase the operational costs of such procedures and may limit the number of experiments that can be undertaken. Objections to purchasing fully automated equipment such as operant chambers, based on the expense of instrumentation, often neglect to account for personnel costs incurred by procedures relying on human intervention. While such approaches have been facilitated by videotaping, computer scoring can still be time-consuming.

Moreover, simple mazes represent relatively simple learning tasks, thus decreasing sensitivity to drug or toxicant effects. The relative rapidity with which learning occurs also renders such baselines ineffectual for assessing learning deficits following exposures to toxicants that have a delayed onset of action or for detecting chronic effects or for tracking reversibility of any observed learning impairments. Finally, and perhaps most importantly, these dependent variables may be influenced by changes in other behavioral processes, limiting the ability to define a learning impairment. For example, the time to traverse the maze can be affected by changes in motor function. Increases in time to reach the correct arm via, for example, motor dysfunction can also delay time to reward itself a variable known to retard learning. Olfactory cues left by experimental animals can be shown under some conditions to influence the performance of animals tested

later. Such difficulties in controlling variables known to influence behavior may result in replication failures both within and across laboratories. Interpretation of a change in behavior as a true learning impairment, therefore, imposes the need to eliminate these potential confounds.

Radial Arm Maze

The radial arm maze is a more complex learning task (Figure 38.16) that can be partially automated. It consists of a central area from which, typically, eight arms radiate like spokes, and a single food pellet is available in each arm. The subject then has access to eight reinforcer deliveries, one in each of the eight arms radiating from the central compartment. The accuracy, efficiency, and speed with which the organism learns to retrieve all eight food deliveries constitute the data of interest, with maximal efficiency requiring only eight arm entries to collect all eight food pellets. The radial arm maze has been shown to be sensitive to the effects of a variety of toxic agents and prenatal insults. For example, Walsh et al.[129] reported an impairment of reacquisition of radial arm maze performance in rats that had been treated with trimethyltin (TMT), a toxicant that damages the hippocampus, a brain structure known to play a prominent role in learning and memory functions. Because it presents a more complex problem to the animal, the radial arm maze has advantages relative to the simpler mazes described earlier, with respect to sensitivity to detecting toxicant effects. Modification of the standard procedures used with the radial arm maze can make it amenable to evaluation of repeated learning (RL) and thus of long-term effects, delayed onset effects, and reversibility. Peele and Baron,[130] for example, accomplished this by baiting only four of the eight arms; the particular four arms that were baited changed during each successive experimental test session. Nevertheless, in parallel with the simpler maze procedures is the possibility that changes in the baseline may reflect not changes in learning processes per se but rather the effects of the toxicant on motor function, sensory capabilities, etc., that must be accounted for in the interpretation of behavioral changes.

Water Mazes

The water maze is a learning paradigm based on negative reinforcement procedures. A rodent is placed in a large pool of water that has been made opaque; escape from the water, that is, the reinforcer, is possible only by finding a platform submerged just under the surface so as to be invisible. Dependent variables include the number of trials to learn where the platform is hidden and the latency to find the hidden platform on each trial. The water maze has been employed widely in behavioral toxicology, in neuroscience,

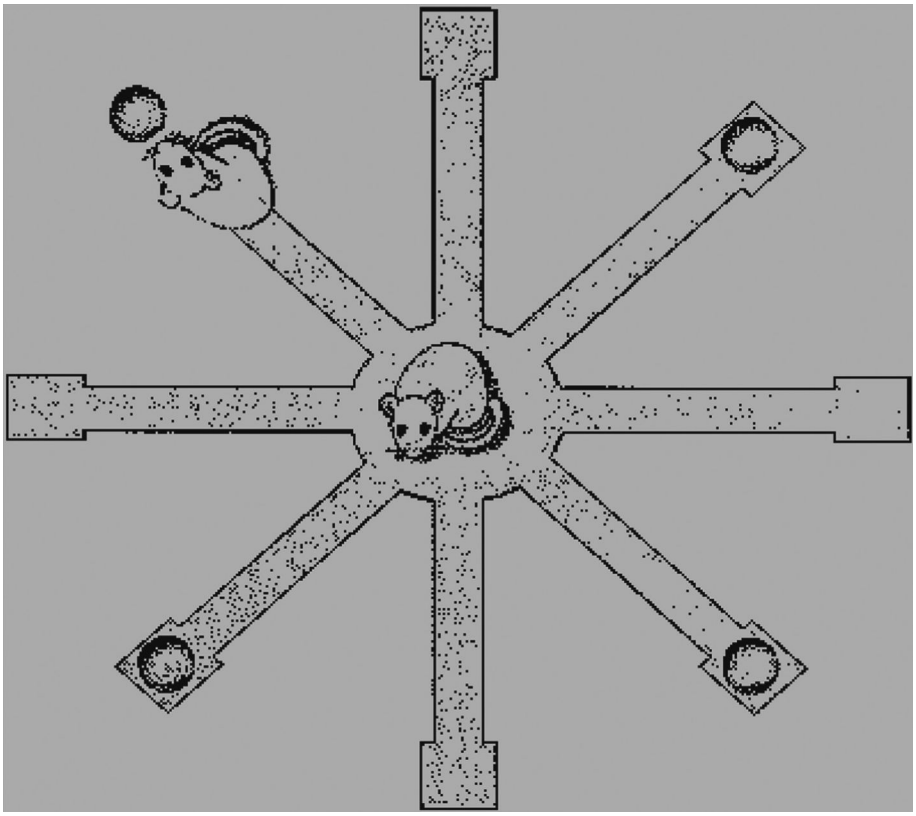

FIGURE 38.16 A prototypical radial arm maze for use with a rodent. The subject is typically placed in the center arena from which some number of arms radiate. Food reward is available under different configurations in various arms. Indices of performance include latencies to obtain rewards, number of arms visited to obtain rewards, and errors (e.g., returning to unbaited arms or arms in which the reward had already been obtained).

and in aging studies because of its ostensible simplicity and the lack of a training requirement or any food deprivation procedures. Performance on the maze has been reported to be influenced by a variety of manipulations, including lesions, toxicants, drugs, and aging. The procedure cannot be fully automated, rendering it a personnel-intensive approach to learning. Moreover, in the configuration described, it represents a relatively simple learning assay and thus may be of limited sensitivity and utility for studies of delayed onset of effect, reversibility, chronic exposure, etc. This simplicity can be addressed to some extent by movement of the platform to new locations requiring learning of a new spatial route for escape.

Like the maze procedures described earlier, it is important to note that the ability to define a selective effect on learning may be confounded by concurrent changes in other behavioral functions. These include impaired motor function, where, for example, a weaker animal will have to exert more effort to swim, a highly effortful response. Body temperature is also a determinant of performance, as has been demonstrated in aging animals. Changes of as little as 1°C in the water temperature may significantly alter performance, making the response more stressful and effortful.[131] Sensory alterations could impair the ability to utilize environmental stimuli to guide the response, and studies have shown that olfactory cues[132] in the water from prior subjects can influence the performance of animals tested subsequently. Such possibilities require the use of additional probes or experiments (e.g., cued platform, swim speed, endurance) for evaluation of a true learning alteration. Furthermore, in some studies, floaters have been identified who must be eliminated from the experiment, thus enhancing the possibility of experimental bias. Although frequently employed, the use of motor activity to rule out motoric deficits as contributing to latency differences in a water maze is unlikely to be adequate, given that swimming represents a far more effortful response than simple ambulation. Additionally, the task has been shown in particular to produce a significant neuroendocrine stress response, including increases in corticosterone levels and altered neurotransmitter levels, effects that may interact with the independent variable.[133,134]

Discrimination Paradigms

Discrimination procedures in operant chambers represent another approach to the evaluation of learning. Technically, the discrimination paradigm reinforces the designated response in the presence of one stimulus (S^+) but not in the presence of another (S^-). As an example, a child's asking for a cookie after eating dinner (S^+) is likely to pay off, whereas asking before dinner (S^-) is not. Given such training, responding becomes confined to those periods during which the S^+ is present and has a low probability of occurrence during S^- presentations. In an experimental situation, a lever press response may be reinforced only when a red light is on but never when the stimulus light is green. The dependent variable of primary interest is the proportion of the total responses occurring on the correct (S^+) lever (accuracy) and the number of sessions or session time until some specified accuracy criterion has been achieved. Discrimination paradigms are of two types: simultaneous or successive. In a simultaneous discrimination, both stimuli are presented at the same time; if only a single response device is available, responding on this device is reinforced during S^+ presentations but not during S^- presentations in a successive discrimination.

Discrimination paradigms carried out in operant chambers as shown in Figure 38.5 offer the distinct advantage of being conducted as free operant rather than discrete trial procedures such as must be used in the maze techniques described earlier. In trial procedures, the time between each trial or opportunity to respond (i.e., the intertrial interval) is determined by the experimenter, and a trial ends with a designated response. The necessity for an intertrial interval using mazes is imposed by the requirement of removing the animal from the reinforcement delivery site back to the start box. In free operant procedures, a response by the organism initiates a trial and no intertrial interval is necessarily imposed between responses. The advantage of this approach is that the subject's rate of responding can be used as a potential index of motivational and motor effects of a treatment, which may contribute to any presumed effect on discrimination learning (see also later discussion). Another advantage of the free operant procedure is that initiation of the trial by the subject rather than by the experimenter ensures the subject's attention to the relevant environmental stimuli and improves accuracy.[135]

A relatively simple operant discrimination procedure is exemplified by the study of Hastings et al.[136] examining the impact of neonatal lead exposure of rats in which a simultaneous visual discrimination task using lights as stimuli proved sensitive to lead exposure. In this discrete trial procedure, a trial was initiated by the insertion of two levers into the operant chamber. The light above one of these levers was illuminated, signaling it as the correct lever (S^+), whereas the other light was not illuminated (S^-). The lever associated with S^+ varied randomly from trial to trial. Criterion performance, defined as 90% correct responses during a daily test session, was reached significantly more slowly by lead-exposed rats.

An example of the kinds of complex problems that may be designed to confront the organism is a conditional discrimination procedure shown by Rice[137] to be impaired in monkeys following lead exposure. One of three disks (the sample) was illuminated with one of three colors on this delayed matching-to-sample paradigm. A press on this sample disk darkened it. After a delay period, which was constant under some conditions and variable under others, all three disks were illuminated, each with one of three colors. If the monkey pressed the disk with the color that had been presented on the sample disk (i.e., if it matched the previously presented sample), a fruit juice reward was delivered. The discrimination is described as conditional because the correct response for any trial is conditional on the sample stimulus for that trial. In this experiment, differences between control and lead-treated monkeys were not observed in the initial acquisition of the

behavior, but appeared when delays were imposed between the conditional stimulus and matching stimuli, with shorter delay values in treated monkeys impairing performance to a greater extent than in controls. In this matching-to-sample paradigm, the response to the sample (conditional) stimulus itself is called an *observing response*; requiring a response to this sample stimulus ensures that the organism is attending to the relevant stimuli when a trial or experimental sequence begins and improves the accuracy of performance.[135] A variant of the matching-to-sample procedure, the oddity paradigm, requires the organism to choose the stimulus that does not match the previously presented sample.

Typically, a specified criterion defines learning in discrimination procedures, such as 8 correct responses in a block of 10 trials. In a discrete trial experiment with both a control group and a treated group, the group mean total number of trials to reach the specific criterion can be compared. Using the free operant procedure, the proportion of the total responses occurring during the S^+ presentation (i.e., the correct responses) may be contrasted between the two groups. Alternatively, an organism can be used as its own control, in which case the accuracy of performance or the rate of learning can be compared before and after treatment. This approach has been made possible by the development of procedures that allow the repeated measurement of learning (discussed in the following).

Repeated Learning

As previously pointed out, one major limitation of many of the simpler procedures described is that, once the correct response has been learned, performance rather than learning is being measured. To pursue issues such as time course of a toxicant's effects on learning, chronic toxicity, or reversibility of toxicant effects, such procedures offer limited utility. Some, however, can be modified to allow repeated measurements of learning. In a discrimination reversal task, for example, acquisition of the original discrimination can be followed by a reversal of the S^+ and the S^-, that is, the stimulus–reward contingency is reversed until the learning criterion is met for the new discrimination problem. Multiple reversals of this sort can be carried out and behavioral adaptation evaluated by measuring the number of trials to criterion on each reversal. After a number of such reversals, however, subjects may acquire the concept of *reversal* and effectively learn the discrimination in a single trial.[138] Bushnell and Bowman[139] found that monkeys exposed to lead showed an increase in the number of trials to criterion and in the number of errors on the first reversal of discrimination problem, but no effect on six subsequent reversals. Likewise, water maze procedures can be modified to permit repeated measurement of learning by moving the location of the submerged platform after the subject has successfully learned its initial location.

An automated paradigm designed specifically to provide a measure of RL was developed for human subjects by Boren.[140,141] This procedure requires the subject to learn a new response sequence or response chain during each experimental session and has since been widely used to study the effects of drugs on learning. In an experiment with pigeons,[142] three stimulus keys in a chamber were all illuminated simultaneously by one of four colors. The pigeon's task was to peck the correct key in the presence of each color—for example, if the key was yellow, peck the left key; if green, peck right; if red, peck center; and if white, peck right. In such a case, if the sequence of light presentations was yellow, green, red, and white, then the correct sequence of responses would be left, right, center, and right. The association between color and key position, however, changed with each successive experimental session, and the subject was required to learn a new four-response sequence. Each correctly completed sequence was followed by food delivery. With training, the number of errors (incorrect responses at any point in the sequence) per session stabilizes, yielding a steady baseline from which drug or toxicant effects on learning can be assessed repeatedly. Thompson and Moerschbaecher[143] have studied the effects of several drugs on the baseline in nonhuman primates.

Paule and McMillan[144] used a variant of this procedure to track the time course of trimethlytin (TMT) effects on learning in rats. In their incremental repeated acquisition procedure, the sequence length was incremented during the course of a session from one- to five-member sequences. By separating certain types of error classes in their analyses, they were better able to understand the particular behavioral processes affected by TMT. Their observations indicated a differential time course for TMT effects on various classes of errors and showed that acquisition of early responses in the sequence was disrupted to a greater degree than the later stages of the sequences, suggesting an effect on learning, while the recall necessary for the longer sequences remained intact.

Another variant of the repeated acquisition procedure devised for rodents by Cory-Slechta and colleagues[145–147] extended the explanatory power of this procedure. Through microanalyses of response patterns and patterns of errors, it could be shown that different drugs could achieve what appeared to be a similar effect (namely, decreases in overall accuracy) through very different patterns of errors. For example, the noncompetitive glutamatergic antagonist MK-801 decreased overall accuracy on the repeated learning (RL) paradigm by increasing the frequency of preservative (repetitive) errors, while scopolamine, a cholinergic muscarinic antagonist, increased the frequency of errors composed of incorrectly skipping forward or backward through the sequence.

Before classifying the effects of a toxicant as one on learning, however, the critical issue of specificity raised earlier must be addressed. Changes in accuracy on learning paradigms may well arise from nonspecific behavioral deficits such as changes in motor activity or function, sensory capacity, motivation, or other unrelated factors, as noted previously. Studies have shown that aging-related impairments in performance by rats in a water maze can be attributed to hypothermia induced by the temperature of the water and inefficient body temperature regulation.[131] Odor trials can likewise affect performance in the water maze.[132] The use

of odor trials as a confounder of learning deficits in conventional mazes is a well-documented phenomenon. Diminished motivation could increase latency in a maze, increasing the delay to reward, which, by itself, would slow the rate of learning, as noted earlier. For the maze procedures described earlier, the potential influence of changes in motor, sensory, and motivational functions and other influences such as temperature-related effects must be ruled out using an independent procedure—that is, by carrying out additional experiments or probes.

One approach that has been widely adopted for assessing the contribution of such nonspecific effects to learning with the repeated acquisition paradigm is to alternate the RL component with a performance (P) component during each experimental session (technically, a multiple schedule of reinforcement; discussed below). The learning or acquisition component, as described previously, requires the organism to learn a new response sequence during each successive experimental session. In contrast, the response sequence reinforced during the P component remains *constant* across sessions, so the organism is simply performing an already learned or rote response sequence. By alternating the RL and P components during each experimental session, such as after every tenth reinforcer delivery, the experimenter can separate, during the same session for each individual animal, drug- or toxicant-induced changes in learning from nonspecific changes in performance or motivation. This is based on the premise that if a compound selectively affects learning, then decreases in accuracy will only be manifest during the learning (acquisition) component of the schedule, as no learning is required in the P component. Because intact motor, sensory, and motivational processes are required in both components, impairments of these functions would result in decreases in accuracy in both the RL and P components.

This approach demonstrated selective effects of lead on learning as illustrated in an extreme case in Figure 38.17,[146] which compares the behavior of a typical control rat to that of a rat exposed to 250 ppm lead acetate from weaning. The particular session depicted began with a performance (P1) component, which was followed sequentially by the learning component (RL1), a return to the P component (P2), and a final presentation of the learning component (RL2), with these components alternating after 25 reinforcer deliveries. Reinforcement followed each completion of a correct sequence. Both rats had received extensive training on the schedule. The control rat (top record) evidenced high levels of accuracy in the first P component, generating a high rate of reinforcement delivery and a relatively low rate of errors, as expected. After the onset of the learning component (RL1), indicated to the subject by a change in illumination in the operant chamber, the rat was required to learn a new three-response sequence. As anticipated, the error rate was initially high, producing a lower rate of reinforcement delivery. By the end of the learning component, however, the rate of errors had begun to decline, and the rat was earning more food deliveries as it gradually began to learn the correct sequence. The acquisition process was even more pronounced during the second presentation of the learning component (RL2), as the rat continued to learn the correct sequence for this particular session. The bottom record of Figure 38.17 shows the rather dramatic impact of lead exposure that was selective for the learning component of the schedule. As can be seen during this particular session, the lead-exposed rat earned virtually no food deliveries during the learning component (RL1 and RL2), emitting hundreds of incorrect responses over the course of both presentations of the learning component, even while exhibiting high-accuracy levels during both presentations of the P component, rapidly earning all 25 available reinforcers. By undertaking a microanalysis of the various patterns of responses and classes of errors, it was determined that the detrimental effect of lead on learning occurred via an increase in response perseveration—that is, repetitive responding on the same lever or repetitive iteration of the same sequence of responses during the learning components.

Any learning assay also must consider the values of the experimental parameters and nature of the problem selected, because such factors influence the sensitivity of the task to disruption by chemical agents. For example, Winneke et al.[148] investigated the effects of lead exposure on the acquisition by rats of both a form and a size discrimination. The form discrimination required rats to distinguish between vertical and horizontal stripes. On the average, only eight training sessions were required by rats to reach criterion accuracy, and the procedure did not differentiate the lead-exposed from the control groups. In contrast, size discrimination, in which a small circle had to be distinguished from a larger circle, proved to be a much more difficult problem, requiring more than 20 training sessions; it revealed a substantial impairment due to lead. A similar effect was reported by Carlson et al.[149] in lead-exposed sheep. Such data demonstrate the important role of task complexity and difficulty in modulating sensitivity to disruption by chemical agents.

Often, the degree of difficulty of the task can be equated with the degree of stimulus control over the performance—that is, the strength of the stimuli controlling the response; for example, Laties et al.[150] required rats to press a fixed number of times on one of two levers, then respond once on the alternate lever for reinforcement. Completion of an insufficient number of responses on the first lever before switching to the alternate lever resets the response requirement. During some parts of the session, a light and tone signaled that the response criterion on the first lever had been met; in other parts of the session, no external stimulus signaled the completion of the response requirement. As would be expected, accuracy of performance was superior during the signaled components of the session, and much higher doses of *d*-amphetamine[150] or toluene[151] were required to disrupt the signaled (S^D) than the unsignaled performance (unlabeled, no S^D). A similar example is exemplified by the data presented in Figure 38.17. Responding on the P component of the multiple RL and P schedule represents a far less difficult discrimination and maintains higher overall levels of accuracy. These findings indicate that behavior strongly controlled by environmental stimuli, such as is the case during the signaled component of

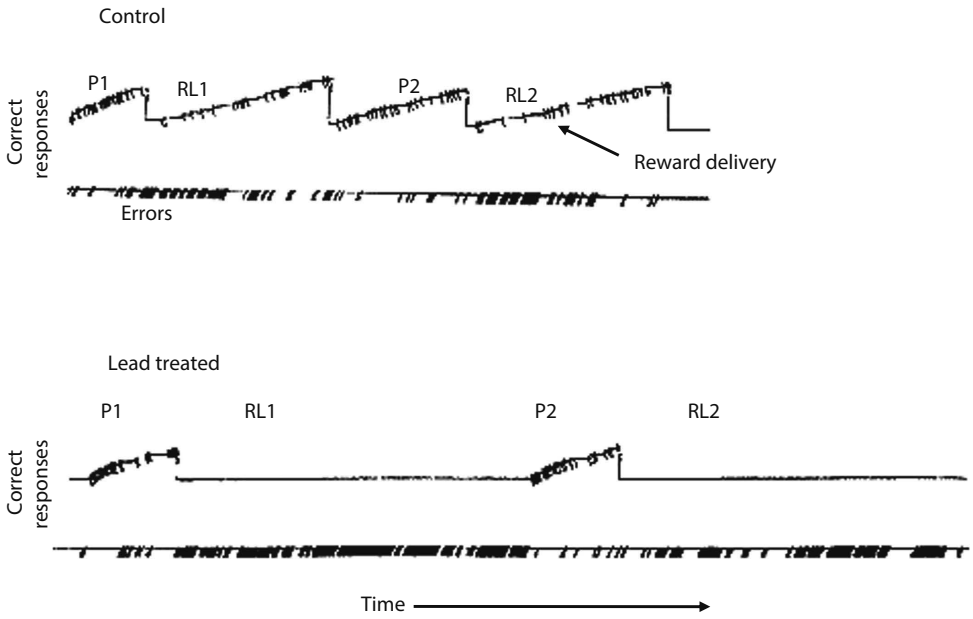

FIGURE 38.17 Cumulative records of performance on a multiple schedule of repeated learning (RL) and performance (P) in a rat exposed chronically to distilled water (top record) versus 250 ppm lead acetate drinking solutions over the course of a behavioral session from left to right. The multiple schedule involved an RL component, which required learning a new three-response sequence during each successive experimental session. These alternated with a P component in which the three-response sequence remained constant across sessions. The top tracing of each record shows the correct responses, which cumulate vertically. Each pip on the correct response curve depicts the delivery of a reinforcer for correctly completing the sequence of three responses required for reward. The pen resets to the baseline with each transition between the performance and RL components. The bottom tracing for each subject shows errors that occurred during the components. The lead-treated rat earned virtually no food deliveries (i.e., completed no correct sequences) during the RL components of the session despite normal performance under conditions where no learning was required (P component). This was not due to a lack of responding, as the rat emitted hundreds of errors during this period. (Adapted from Cory-Slechta, D.A., unpublished data; Cory-Slechta, D.A. et al., *Behav. Brain Res*., 102, 181, 1999.)

Laties et al.,[150] is less easily disrupted than behavior under weaker stimulus control. Thus, the degree of stimulus control over behavior can markedly influence its susceptibility to the effects of drugs of toxicants.

MEMORY

Memory is a term that has been used both to describe and to attempt to account for the behavior of remembering or the influence on behavior of previous events. Experiences are said to be stored in memory, in encoded forms, such as neural engrams or, more recently, as electrical fields, and later recalled from storage by some type of retrieval system. Many theorists have adopted the vocabulary of computer technology to describe memory processes, despite the lack of evidence of operational correspondence. In a behavioral analysis, memory may be best understood and experimentally approached in terms of stimulus control. Remembering is really another way to assert that the probability of certain learned responses is increased. Heise[127] referred to the fact that, while learning is "manifested behaviorally by acquisition, an enduring change in behavior, … memory may be defined as the preservation of the learned behavior over time." Experimentally, memory is indicated by the accuracy of a response after a delay (retention interval) between the occasion for learning and the test for recall. A distinction is typically drawn between short-term memory, occurring over relatively short delay periods, and long-term or virtually permanent memory. Obviously, the temporal parameters of these two subclasses are species dependent.

Novel Object Recognition

A technique that was actually described many years ago, but now increasingly used in neurotoxicology with rodents, is novel object recognition. This paradigm rests on the fact that exposure to a familiar object and a novel object will evoke greater approach and contact with the novel object, and as such is premised on the assumption that the preference for the novel object indicates a memory for the already familiar object. Procedurally, the rodent is initially exposed to two objects in an apparatus for some period of time, after which it is removed. After some time delay, dependent upon experimental conditions, the subject is placed back in the apparatus where one of the familiar objects has been replaced with a new object and the amount of time and/or contacts with each object, the familiar and novel, recorded.[152]

While its simplicity and easy implementation favors it's use, there are several issues that need to be considered in data interpretation. For example, frequently, only data from the second session, that is, that including the familiar and novel object, are presented, precluding the ability to ascertain

whether behavioral differences were also present in the initial session, when both objects are effectively novel, that could have influenced performance in session two (testing of the novel object), for example, side bias or hyperactivity. Other issues related to data interpretation, including that of novelty preference, and involvement of working memory in the paradigm have been described.[153]

Avoidance Behavior

As noted earlier, the various techniques devised to assess memory typically involve the measurement of response accuracy after various delays. An effect of a drug or chemical on memory is suggested by an increased impairment of accuracy with increasing delay values (retention intervals). Avoidance of an aversive stimulus, such as electric shock, is one frequently used measure of both learning and memory. Several different variants of these procedures have been employed; some are discrete trial procedures, and others are free operant procedures. The frequently used passive avoidance paradigm (also called fear conditioning) assesses the tendency of the subject to avoid the site of previous shock delivery. A mouse that avoids returning to a normally preferred dark chamber where it previously has been shocked is said to be exhibiting a memory of that event. Active avoidance paradigms require a specified response to be emitted to postpone an impending shock onset. In some cases, the apparatus used is a two-compartment chamber in which the subject switches compartments at the appearance of a stimulus that signals impending shock (Figure 38.18).

Although useful as a screen for potential memory dysfunction, it is important to note that there are also interpretation issues associated with such approaches, especially the passive avoidance paradigm. As with learning, a drug or toxicant can alter performance in memory paradigms through indirect changes in nonmnemonic functions. For example, motivation to avoid shock can be produced by differences in shock sensitivity prior to the training phase in passive avoidance paradigms. If the toxicant decreases shock sensitivity per se, then treated animals will be less motivated to subsequently avoid the shocked compartment during the memory testing phase, as shock level is an important determinant of subsequent memory. Similarly, in active avoidance paradigms, toxicant-induced decreases in shock sensitivity would diminish response rates to avoid impending shocks. The drug or toxicant may also modify activity levels (e.g., induce hypo- or hyperactivity), thus increasing the probability of the subject returning to the shocked compartment independently of remembering in the passive avoidance paradigm. Furthermore, state-dependent learning may alter subsequent retention for passive avoidance training if the animal is trained during drug or toxicant exposure but retested under nonexposed conditions. In other words, the response may have an altered probability of recurrence during the retest simply because the environmental stimulus conditions (nondrugged) differ from stimulus conditions during training (drugged) and thus may be independent of memory. Such possibilities must then be sorted out in additional experiments that probe these confounding interpretations. Other problems that can be encountered with these simple avoidance paradigms include the fact that variability of response among animals tends to be high, often necessitating large groups of subjects. Additionally, some rats fail to learn such procedures and may be discarded as slow learners, biasing the sample population for unknown reasons.

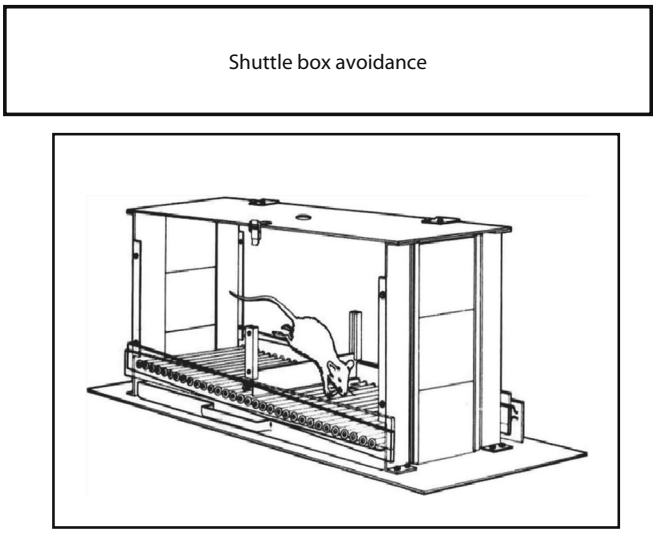

FIGURE 38.18 Shuttle box avoidance apparatus. In this active avoidance paradigm, the rat can avoid impending shock or escape an ongoing shock by shuttling to the other side of the chamber, thus terminating an aversive stimulus.

Delayed Alternation

Delayed alternation requires a subject to alternate responses on each of two response devices such as levers or nose cones for reinforcement (Figure 38.19),[154] that is, a response on device A followed by a response on device B produces a reinforcer, a return to device A, another reinforcer, and so on. After initial training, a delay requirement is interposed between the alternating responses, so only alternations separated by at least the required delay interval are reinforced, rendering this a memory paradigm. Generally, the delay value varies randomly from trial to trial across a series of values designed to include accuracy levels ranging from chance to virtually 100% during an experimental session, allowing the assessment of accuracy by delay (retention interval) information from each experimental session. A response occurring before the end of the delay period typically resets the delay requirement, with the particular delay values specified being dependent on the experimental species. Importantly, on some trials, there is no delay. This no-delay condition is critical for evaluating the contribution of non-memory-related changes in behavior to any presumed memory impairment. Since no memory is required in the absence of a delay, accuracy values should not decline in response to treatment in the no-delay condition. Typically, one also expects to see a greater decline in accuracy with increasing delay values in drug- or

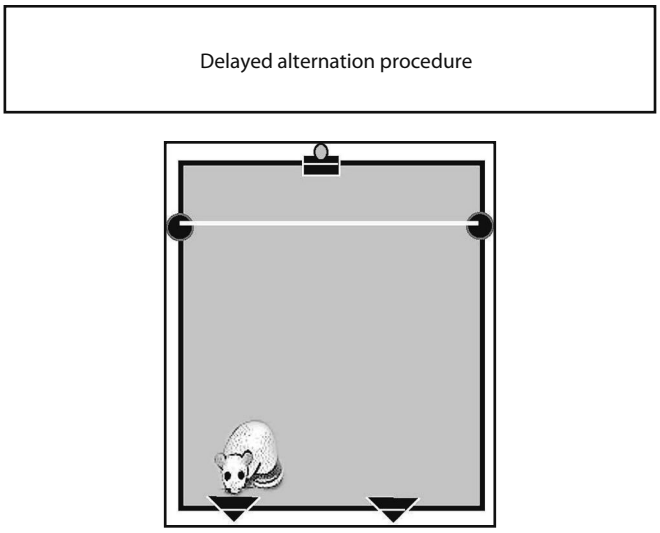

FIGURE 38.19 Schematic of the delayed alternation procedure. This paradigm requires the subject to alternate responses between two response manipulanda for reward (in this case, to nose poke first on the right manipulanda and then on the left manipulanda for reinforcement). The next reinforcement delivery then requires a switch back to the right manipulanda. For the assessment of memory function, a delay between these response opportunities is imposed, requiring the subject to recall on which manipulanda the previous response occurred and thus alternate accordingly. This delay value typically varies from trial to trial during an experimental session so a complete function of accuracy by delay length (retention interval) can be generated for each experimental session.

toxicant-treated groups. Using this procedure, Bushnell[155] reported that TMT could produce deficits in memory processes in rats, with TMT accelerating the decline in the delay interval function relative to control but not affecting accuracy on the zero-second delay trials. These data are consistent with the notion of a selective impairment of remembering.

Delayed Matching to Sample

The matching-to-sample procedure described earlier becomes a memory paradigm when delay intervals are imposed between the presentation of the sample stimulus and the later presentation of the matching stimuli options. As with delayed response procedures, a range of delay values is presented in a semirandom manner throughout the course of an experimental session, allowing the collection of accuracy by delay interval information in every session. Taylor and Evans[156] reported impairments in delayed matching-to-sample performance in pigeons at an exposure concentration of toluene that maintains self-administration behavior (discussed later) in the primate.[157] This impairment was not interpreted as an effect on memory, however, because accuracy was significantly impaired even in the no-delay condition.

As in the case for learning, then, changes in performance on a memory task may have little to do with memory but may instead be indirectly influenced by other nonspecific behavioral effects such as changes in motivation, arousal, sensation, and perception. For example, a toxicant that increased the rate of responding might produce premature responding to the comparison stimuli in a matching-to-sample task and thereby increase error rates. Alternatively, decreased rates of responding might increase the latency to make the response in a choice situation and thus increase the functional delay interval. One efficient way to assess the contribution of nonspecific effects in free operant memory procedures is to examine changes in the rate of responding as well as changes in accuracy in the presence of a no-delay condition. Nonspecific effects on levels of arousal or motivation may be reflected in altered response rates. The no-delay condition permits drug or toxicant effects not related to memory to be determined, as no remembering is required at the zero-second delay. A further condition supporting the interpretation of a true memory impairment is that the magnitude of the decrease in accuracy increases with increasing delay value relative to controls[127] and that similar effects of the toxic agent can be demonstrated in other memory paradigms using other stimulus and response conditions.

SCHEDULE-CONTROLLED BEHAVIOR

Every experimental procedure using operant behavior is based on the principle that behavior is generated, altered, refined, and eliminated by its consequences. Seldom, however, is each and every instance of a specific behavior in the natural environment followed by reinforcement. Continuous or invariant reinforcement is infrequent; instead, intermittent reinforcement is the rule. Paychecks are typically distributed on a weekly, semiweekly, or even monthly basis. Not every visit to the mailbox will be rewarded by the arrival of the letter we are awaiting. Often, a string or chain of responses may be emitted before there is a reward, much as the pianist finishes playing an entire piece of music before the audience applauds. Similarly, the child may correctly put together several puzzle pieces or even the entire puzzle before the parent praises the child. In the wild, predation and foraging behavior are certainly maintained under conditions of intermittent reinforcement. Besides the economy achieved by intermittent presentation of reinforcement, behavior maintained under conditions of intermittent reinforcement is actually considerably more robust than that maintained by continuous reinforcement.[158] For example, a response that has been reinforced on every occurrence declines much more rapidly during an extinction procedure (withholding of reinforcement) than does behavior that has been intermittently reinforced. Put another way, continuously reinforced behavior is much less resistant to extinction than that maintained by intermittent payoff. Many parents have learned, to their distress, how occasional reinforcement of a temper tantrum (failure to ignore it) may subsequently increase the magnitude and persistence of the behavior.[159] The intermittent reinforcement occurring during gambling can sustain high and persistent rates of behavior.

In the human environment, reinforcement schedules—that is, the nature of the rules by which reinforcement is allocated—may be complex. The laboratory offers the

experimenter direct control over these contingencies and thereby allows a more precise analysis of the ways in which the scheduling of reinforcements controls various aspects of responding, including its temporal distribution, force, rate, and resistance to extinction. The study of reinforcement schedules is a discipline in itself.[160–162] Of most relevance to toxicology, an extensive body of literature has accrued describing the effects of a wide variety of central nervous system drugs on schedule-controlled behavior.[8,9,163–168] This permits comparison of toxicant effects on schedule-controlled responding to those of central nervous system compounds whose mechanisms of action are generally well understood. The effects of numerous toxicants on schedule-controlled behavior have since begun to be enumerated.[169–174]

Schedules of reinforcement are especially important to behavioral toxicology, as reinforcement schedules govern the rate and pattern of behavioral responding involved in different behavioral processes.[170] The rate of learning, for example, may well be influenced by the reinforcement schedule according to which the reinforcer is presented. The response may be only slowly acquired if initially reinforced only infrequently. Whether the response is learned at all may depend on the strength of competing responses, the magnitude of reinforcement, and the concurrent availability of competing schedules of reinforcement. In addition, changes in schedule-controlled behavior may actually underlie behavioral changes that are attributed to impairments of other behavioral processes. Decreases in rates of responding produced by a toxicant may be incorrectly interpreted as a decline in the rate of learning in a discrimination procedure. Schedules of reinforcement can also be used as an index of learning processes per se—that is, whether treated subjects learn the behavioral patterns characteristic of the particular schedule under study and whether changes in parametric values of the schedule produce corresponding changes in schedule-controlled performance at that same rate in treated and control subjects. To truly understand the behavioral effects of a toxicant, then, requires an understanding of its impact on schedule-controlled behavior, as behavior occurs at given rates and in particular pattern over time.

Simple Schedules

Although a virtually limitless number of ways to schedule reinforcement delivery are possible, simple schedules are based on either number of responses or time. Four simple schedules have been defined: the fixed interval (FI) and the variable interval (VI), both of which are time-based reinforcement schedules, and the fixed ratio (FR) and the variable ratio (VR), both of which are response-based schedules. Characteristic patterns of performance eventually emerge on each of these schedules, known as steady-state performance.[175] The temporal pattern of responding as well as drug effects on the performance are frequently very similar across species,[165] a feature providing confidence in cross species extrapolation and the continuity of behavioral processes across species. Another advantage of schedule-controlled behavior is that the pattern of performance is often remarkably stable over prolonged periods, a decided advantage for tracking the progression of toxicity and for assessing reversibility.

Typically, after the designated response has been shaped, the schedule of interest is then imposed directly, although it may reach its final parametric value only after a series of gradual changes from the initial parametric values. For example, in studying FR performance in a rat, the experimenter will most likely carry out several sessions at lower FR values before imposing a final value as high as 100. This prevents *ratio strain* (irregular pauses occurring between responses on an FR schedule[160] associated with high FR values) and prevents extinction of the response.

Interval schedules stipulate that a certain amount of time must elapse following a previous response before the next occurrence of the response will be reinforced. On an FI schedule, the time period is constant and typically is measured from the previously reinforced response. For example, an FI 5-min schedule reinforces the first response occurring at least 5 min after the preceding reinforced response; responses during the 5 min interval have no programmed consequence. The FI schedule typically generates a characteristic scalloped pattern of performance, as shown in Figure 38.20, which consists of a pause after reinforcement delivery (designated as the postreinforcement pause time [PRP]) followed by a progressive increase in the rate of responding (running rate) as the time for the next food delivery approaches. In the human environment, studying for a scheduled exam has features resembling performance maintained by an FI schedule, that is, normally, little or no studying occurs early in the semester, but as the time for the midterm approaches, the rate of studying begins to escalate and is highest right before the exam. The species generality of the scalloped pattern of FI performance is amply demonstrated in Figure 38.21 across species, type of response, and type of reinforcer. Human FI performance shows a similar scallop under many, although not all, conditions.[176,177] Sensitivity of the FI schedule to a variety of toxicants has been demonstrated.[171]

The typical, though grossest, measure of schedule-controlled behavior is absolute or overall response rate, which is simply the total number of responses divided by total session time. Often, a full understanding of chemical modification requires a microanalysis to dissect the behavior into more elementary components. Like the separation of various classes of errors in a learning or memory experiment, schedule-controlled performance can be differentiated into component parts, which permits a more precise understanding of the manner in which the schedule controls performance. Such an analysis can suggest the possible behavioral processes that are altered by a chemical and point to directions for further analyses and manipulation.

FI performance provides an example. The schedule has been the focus of much experimental study in part because it exemplifies temporal control over behavior. As previously described, FI performance is characterized by a pause after reinforcement delivery (Figures 38.20 and 38.21). The length

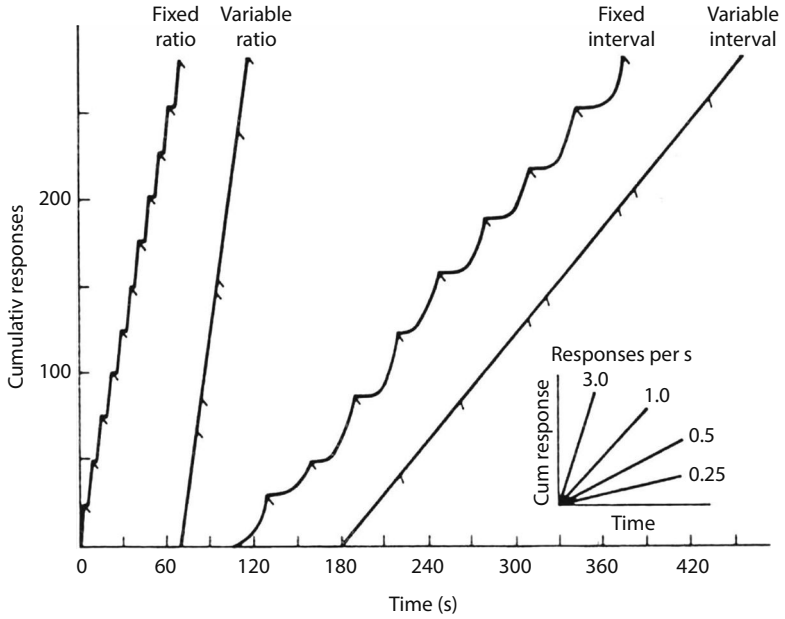

FIGURE 38.20 Characteristic behavior on each of the four simple schedules of reinforcement: the FR, VR, FI, and VI. In these records, responses cumulate vertically, and the slope of the line indicates the rate of responding; examples of slope-rate comparisons are shown in the inset. Each pip on the response curve shows where a reinforcer was delivered according to schedule contingencies. The FR schedule generates a very high rate of responding, with short pauses (indicated by horizontal periods on the curve) following each reinforcer delivery. The VR schedule generates an even higher rate of responding with little or no pausing after reinforcement, as the very next response may produce reward. The FI schedule produces a scalloped pattern of responding characterized by pauses after reinforcement delivery followed by a gradually increasing rate of responding as the time of the next available reinforcer delivery approaches. The VI schedule generates a very stable moderate rate of responding with almost no pausing, as the time to the next available reinforcement opportunity is unpredictable. FIGURE 38.21 Species generality of characteristic FI schedule-controlled behavior. Responses cumulate vertically in these records, and time is represented horizontally. The top panel shows the behavior of an individual pigeon pecking a key for food at three different FI values; the general scalloped pattern persists despite the 100-fold change in time value. Performance on an FI 5 min schedule is shown in the bottom right panel. As can be seen, FI performance is remarkably similar for different species (rat, pigeon, cat) with different responses (lever press, key peck, wheel running, and knob pushing) and different reinforcers (water, food). The bottom left panel shows performance on an FI 10 min schedule of reinforcement; in this case, the pen resets to the baseline after each reinforcer delivery. Again, comparable FI performance occurs across species, response, and reinforcers. (From Kelleher, R. et al., *Ergebnisse der Physiol.*, 60, 1, 1968. With permission.)

of this postreinforcement pause (PRP) time (time from food delivery to the first response in the next interval) depends on the length of the FI[178]: the longer the interval, the longer the pause. The PRP is followed by a long period of shorter pauses, interspersed with short bursts of responding. As the interval progresses, the pauses cease and are replaced by alternating periods of moderate and high response rates until reinforcement delivery.[179] The rate of responding during an interval, after the PRP is subtracted out, is referred to as the *running rate*. With the aid of a computer, the actual times between each successive response, the interresponse times (IRTs), can be collected, a frequency distribution of various length IRTs generated, and sequential patterns of IRTs reconstructed. The characteristic scalloped pattern of performance is usually described by one of two measures. The index of curvature[180] specifies the extent to which the scallop deviates from a straight line (a constant rate of responding throughout the interval), and the quarter-life[181] is defined as that proportion of the interval required for the first 25% of the total responses in the interval. It is these microanalyses that may permit detection of a toxicant effect and understanding of its behavioral mechanism of action. In the case of low-level lead exposure in rats, for example, the proportion of short IRTs (0.5 s or less) is consistently increased by lead exposure, even while increases in overall response rate may be less impressive.[182] A similar effect has been reported in chronically exposed monkeys.[183]

The type of effect produced by lead exposure on FI schedule-controlled behavior might be viewed as a loss of discriminative control by the schedule.[171,184] The behavioral mechanism might be explained as a failure of the FI schedule to exert temporal control over behavior or as a failure to learn to discriminate interval length. This hypothesis earned further support from two additional experiments. In one study,[31] rats were required to hold down the lever for 3 s for each food delivery. Control rat median response durations were between 2.5 and 3 s, while some lead-exposed rats exhibited a much higher proportion of response durations too short to produce reinforcement, even after a tone stimulus was subsequently added to signal that the required duration had been met. In another experiment,[185] reinforcement depended on separation of responses by at least 30 s (a schedule known as DRL or differential reinforcement of low rate). Lead-treated monkeys acquired the performance more slowly than controls, as indicated by a higher frequency of nonreinforced responses during the initial sessions. These findings with lead are consistent with other hypotheses regarding its behavioral mechanisms of action.

In contrast to lead, certain pesticide classes alter both response rate and the temporal patterning of FI behavior, suggesting actions through different behavioral and neurobiological mechanisms.[171] Both organochlorine pesticides[186] and formamidine compounds[187] have been shown to decrease rates of responding on the FI schedule and to disrupt the normal temporal pattern of responding. An example is provided in the cumulative records shown in Figure 38.22.

When relevant information about a toxic agent is scarce, the FI schedule offers several distinct advantages as an early

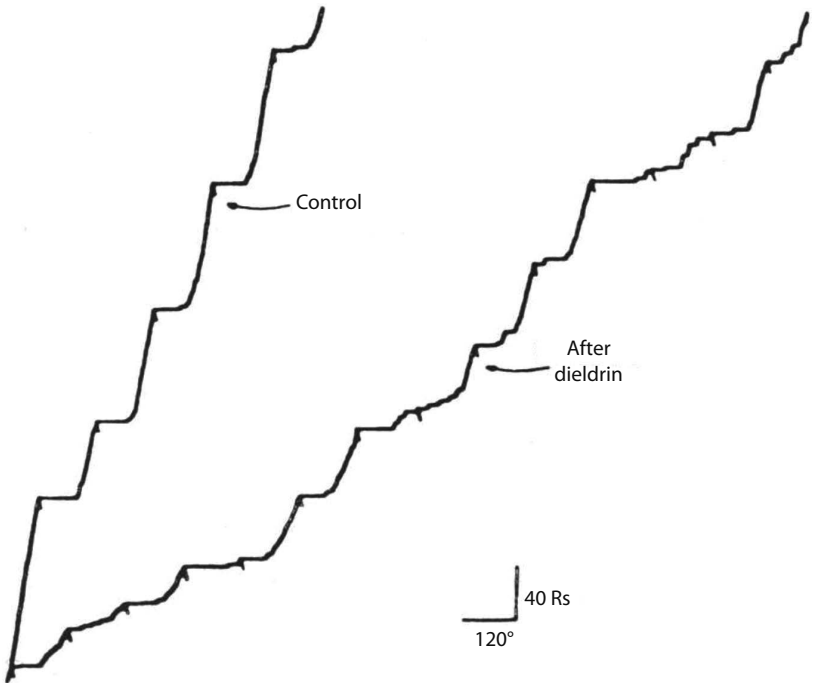

FIGURE 38.22 Cumulative records of the performance of a Japanese quail on an FI, 2 min schedule of reinforcement. Responses cumulate vertically, and time is represented horizontally. Each downward deflection of the pen (pip) indicates food delivery. Performance under control conditions, shown in the left panel, is the typical scalloped pattern characteristic of FI behavior (see Figures 38.20 and 38.21). After 5.0 mg/kg dieldrin treatment (right cumulative record), the response rate is decreased, as indicated by the shallower slope of the curve, and the typical pause after reinforcement delivery is disrupted. (From Burt, G.A., Use of behavioral techniques in the assessment of environmental contaminants, in Weiss, B. and Laties, V.G., eds., *Behavioral Toxicology*, Plenum Press, New York, pp. 241–263, 1975. With permission.)

test for behavioral toxicity. Because the schedule reinforces only the first response after the end of the interval, and because responses during the interval have no programmed consequence, response rates during the interval itself can vary quite broadly before they are sufficient to alter the frequency of reinforcement. This feature may explain in part why FI performance is often more sensitive to drugs than ratio-based schedules of reinforcement[188–190] on which a decrease in the rate of responding necessarily decreases reinforcement frequency (discussed later).

The patterns of behavior by the three other simple reinforcement schedules are shown in Figure 38.20. On a VI schedule, the intervals between reinforcement availability are determined on the basis of time, with the specific value varying from interval to interval and the mean of those values indicated by the schedule parameter value. For example, on a VI 30 s schedule, the specified interval between reinforcement opportunities will vary from one reinforcement delivery to the next, but the average of all the values will be 30 s. As indicated by Figure 38.20, the VI schedule generates a moderate but steady rate of responding, with little pausing evident after the reinforcement, consistent with the lack of predictability of reinforcement availability. Reinforcement may be available immediately after the previous reinforcer delivery or may be delayed. Reynolds[26] cites as an example a busy signal on the telephone, with the caller continuing to make the response that is reinforced (by a ringing sound) on a VI schedule because of the variable length of telephone conversations. The steady persistent pattern of responding on the VI schedule would suggest its utility as a baseline for detecting toxic effects; however, little information in this regard is currently available, even though alterations in VI performance certainly are produced by central nervous system agents.[191]

Ratio schedules require a specified number of responses for reinforcement. On the FR schedule, the requirement remains constant; for example, each completion of 100 responses produces food delivery on an FR 100 schedule. The piecework system used early in U.S. history serves as a classic example; salespeople working exclusively on a commission basis is another. The FR schedule typically generates a pattern of performance in which there is a characteristic pause after reward delivery, the length of which is related to ratio size, followed by a very rapid rate of responding until the ratio requirement is completed. The high, constant response rate on the FR schedule is the result of the relation between rate of reinforcement and rate of responding; the faster the ratio is completed, the sooner reinforcement delivery occurs. As a result, short IRTs tend to be differentially reinforced, amplifying the relationship. As mentioned earlier, the rate of responding on the FI schedule can vary widely before affecting the frequency of reinforcement delivery; however, decreases in response rate on the FR schedule necessarily decrease the rate of reinforcement. It is precisely this difference in the contingencies controlling the two performances that generates the stark contrasts in FI and FR schedule-controlled performance.

Like all schedules, the FR schedule can be analyzed into its component parts, which generally include measurement of the length of the postreinforcement pause and the running rate, as well as an examination of the IRT distribution. Such a microanalysis reveals that the effect of chronic lead exposure on FR performance is to increase the median IRT[169] and thus to decrease response rates. A variety of CNS agents have been shown to alter FR performance,[188,191,192] as have various toxicants, including metals and pesticides.[171] Gentry and Middaugh[193] used simple FR schedules to examine the long-term consequences of prenatal ethanol exposure. In that study, offspring were tested under an FR 1 schedule for 10 sessions, followed by an FR 20 for 9 sessions, and finally an FR 100 for 4 sessions. The increase in response rate across sessions and ratio values was significantly depressed in the groups exposed to ethanol prenatally.

On a VR schedule, the response requirement varies from reinforcement to reinforcement, with the mean of those values designated by the schedule parameter value. On a VR 50, for example, the average response requirement will be 50, but the value will vary from one ratio to the next. One commonly cited example of a VR schedule in the human environment is gambling. The slot machine may pay off on the average once every 100 plays, but the number of plays between payoffs varies unpredictably. Another example includes the sale of real estate. As can be seen with gamblers, the VR schedule generates very high and consistent rates of responding with little or no pausing (Figure 38.20). Both the VR and the FR schedules generate very high rates of responding, but they differ in the characteristic pause after reinforcement, seen only on the FR. This difference in response pattern between the two schedules derives from the fairly constant amount of time required to complete the fixed number of responses on the FR schedule. One hypothesis is that reinforcement delivery on the FR then becomes a stimulus associated with a subsequent period of nonreinforcement or extinction, decreasing response probability, as it represents the earliest part of such a temporal interval. In contrast, reinforcement opportunity on the VR schedule is unpredictable. A reinforcement may follow after any number of responses since the preceding food delivery; thus, reinforcement delivery itself does not become a stimulus that indicates absence of reinforcement availability. The VR schedule is comparable to the VI schedule in that both maintain fairly constant rates of responding with little or no pausing after reinforcement. The VR, however, generally maintains the higher rates of responding of the two because the faster the ratio is completed, the sooner reinforcement delivery occurs. On the VI schedule, higher rates of responding cannot accelerate reinforcement availability. Sensitivity of the VR schedule to toxic agents remains relatively unexplored.

The differences in performance on these four simple schedules of reinforcement thus reflect the very different contingencies of reinforcement. Comparing the effects of a chemical agent on the various schedules can provide a better understanding of the mechanisms by which drugs or toxicants modify behavior or the behavioral mechanisms by which

changes occur. For example, the suppression of response rate on all schedules might suggest a nonspecific effect of a treatment on antecedent factors, such as the motivational level of the subject (i.e., an alteration in functional deprivation conditions). An effect specific to a schedule would implicate the unique contingency of that schedule and its underlying neurobiological substrates for further study.

Several lines of evidence[165,194] indicate that the type of consequence is less important in determining the behavioral effect of a chemical than is the schedule according to which such consequences are presented. Kelleher and Morse[189] found that both amphetamine and chlorpromazine had similar effects on behavior maintained on a given schedule (a multiple FI–FR, described later), regardless of whether it was maintained by food reinforcement or escape from electric shock. Weiss and Laties[195] studied the effects of amphetamine, chlorpromazine, and pentobarbital on the behavioral regulation of temperature. Shaved rats, placed in a cold compartment, could warm themselves by responding on a lever that turned on a heat lamp for a short period of time. Amphetamine increased the frequency of responding even while elevating skin temperature above normal. Despite accelerating heat loss, chlorpromazine decreased the rate of turning on the heat lamp.

Another variable of importance in determining drug or toxicant effect is the baseline rate of responding.[191] Many compounds, including stimulants, barbiturates, minor tranquilizers, and opiates, have been found to increase the length of short IRTs and to decrease the length of long IRTs on certain reinforcement schedules. In other words, many agents increase low rates of responding and decrease higher rates of responding, thus yielding what are called rate-dependent effects. For amphetamine, such effects have been noted in several species and across a wide variety of reinforcement schedules.[196] Thus, on an FI schedule, low rates of responding early in the interval may be increased, while the higher rates of responding occurring just prior to reinforcement may be decreased, leading to a loss of the scalloped pattern of responding characteristic of FI performance. One notable exception to the rate-dependency phenomenon is responding suppressed by punishment, which may be even further decreased by amphetamine.[197] Thus, the baseline rate of responding may be a determinant of toxicant effects.

The designated response to be reinforced can take many forms, depending on the species and the experimenter's goals. For pigeons, pecks on a disk serve as the operant. Tepper and Weiss[198] found that the exposure of rats to concentrations of ozone as low as 0.12 ppm disrupted operant wheel running reinforced under an FI 10 min schedule. Also, the simple lever press can be elaborated into a more complex requirement; for example, the response may consist of holding down the lever for a specified minimum duration, a performance disrupted by chronic lead exposure.[31] A force requirement can also be specified, or the animal may be required to emit a series of responses with different topographies, such as a wheel run followed by a lever press. Another kind of complex response with an extensive literature in behavioral pharmacology specifies that only lever presses separated by a specified interval of time will be reinforced (i.e., the DRL schedule, which makes the pause part of the operant response).

Temporally based schedules of reinforcement also have been used to study processes analogous to retention (memory). Consider the FI schedule of reinforcement. Food delivery is programmed to follow the first response occurring after a specified interval has elapsed since the preceding food delivery. Responses emitted before the end of the interval carry no penalty. The DRL schedule previously described is another type of interval schedule but does prescribe a penalty for early responding in stipulating a minimum interval (and sometimes a maximum) between successive responses. Neither schedule conventionally provides external stimuli, such as lights or tones, to indicate the passage of time. Both schedules generate distinct temporal patterns of responding. FI schedules foster patterns in which little or no responding occurs at the beginning of the interval, which has become a S^D for the absence of reinforcement availability, but as the time of the next food delivery approaches, the rate of responding increases. Subjects experienced on the DRL schedule learn to separate successive responses by enough time to earn a high percentage of reinforcements. Increases in response rate on a DRL schedule, such as found by Colotla et al.[199] to be produced by solvent exposure, then decrease the rate of reinforcement.

One criticism leveled against the use of temporally defined schedules of reinforcement in a memory context is the inability to provide a within-session manipulation of the temporal intervals to be discriminated. Although multiple FI–FI schedules (discussed later) represent an alternative approach,[160] more direct psychophysical techniques for estimation of time intervals are available.[200] In some duration estimation procedures, for example, a stimulus of specified length is presented and the subject makes a choice response to indicate whether the stimulus was short or long. Using a two-key procedure, Stubbs and Thomas[201] presented tone stimuli to pigeons that varied in discrete intervals from 1 to 10 s. Tones 5 s or less were defined as short and were reinforced after a response on a red key, whereas responding on a green key was rewarded after the presentation of long tones. Amphetamine increased the proportion of long tones that were discriminated as short. Using a variant of this procedure, Daniel and Evans[202] reported that acrylamide caused a significant decrement in duration discrimination accuracy, which recovered only gradually.

Complex Schedules

A major advantage of schedule-controlled performance is the flexibility of schedule combinations, so more than one baseline can be studied concurrently in the same subject. This approach compounds the amount of information obtained in an experiment. In a multiple-schedule format, the most common combination, component schedules alternate during the

course of an experimental session. FI and FR schedules have been frequently used as the component schedules because of the marked differences in the contingencies of reinforcement on these two schedules (described earlier). On a multiple FI–FR, the two schedules may alternate either on the basis of time (e.g., every 15 min) or after a certain number of reinforcers have been delivered (e.g., switch to the other schedule after every 10 reinforcer deliveries). Different external stimuli are used to indicate to the organism which schedule component is in effect at a given time; for example, for pigeons, a red light might be illuminated throughout each FI component and a green light used to signal the FR component. After some training, each light serves as a S^D controlling the performance typical of the reinforcement schedule with which it is associated.

The multiple FI–FR schedule of reinforcement has been used by several investigators to study a range of toxicants, such as mercury vapor[203] and methyl *n*-butyl ketone.[204] In those studies, differential sensitivity of the two schedules was not demonstrated, indicating that these toxicants, at the doses used, produced a generalized impairment of performance. In contrast, Levine[205] demonstrated a greater sensitivity of FI than that of FR performance in pigeons exposed to carbon disulfide, a difference similar to that reported for many drugs. A decline in FI rate occurred after a single 8 h exposure (day 1), whereas the concurrent FR performance remained intact. A 2 day, 8 h exposure to carbon disulfide was required to disrupt FR responding. Similarly, Leander and MacPhail[187] studied the effects of the pesticide chlordimeform on a multiple FI 1 min–FR 30 schedule of reinforcement (Figure 38.23) and noted reductions in FI performance at doses lower than those required to disrupt FR performance. Wenger et al.[206] tracked the consequences of TMT exposure in C57B/6N mice responding on a multiple FR 30–FI 10 min schedule of reinforcement. Rates of responding on the FI schedule had increased substantially within 3 h of the administration of TMT, whereas FR performance was as yet unchanged. Markedly divergent effects of TMT on these two schedules were observed 5–9 days after injection, with substantial rate increases on the FI and decreases on the FR. Such divergent drug or toxicant effects reflect the different reinforcement contingencies of

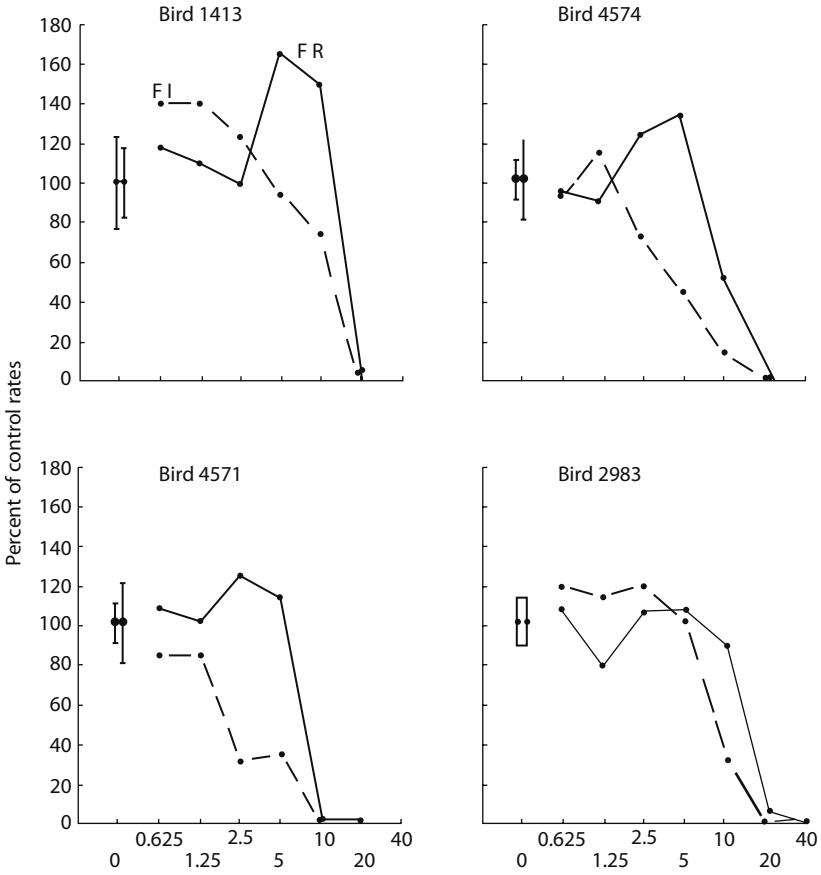

FIGURE 38.23 Effects of acute administration of chlordimeform on a multiple FI, FR schedule of food reinforcement in pigeons. Changes in response rates (total responses divided by session time) are plotted in relation to increasing dose of chlordimeform separately for each component and for each of four subjects. Points and brackets above 0 indicate the mean ± SE under control conditions. As is evident, overall response rates (ordinate) decreased with increasing dose of chlordimeform (abscissa). FI performance was generally more sensitive, however, as it declined at lower doses than those required to disrupt FR performance. (From Leander, J.D. and Macphail, R.C., *Neurotoxicol. Teratol.*, 2, 315, 1980. With permission.)

the two-component schedules and the very different behavioral performances they produce. These examples illustrate how the schedule of reinforcement itself may be a powerful determinant of the effect of a chemical agent.

A mixed schedule of reinforcement operates identically to a multiple schedule, but without external stimuli to indicate which schedule component is in effect.[26,160] The only stimuli available to the subject, then, come from its own behavior in relation to the reinforcement schedule contingencies; thus, comparisons of drug or toxicant effects on multiple versus mixed schedules permit an assessment of the role of S^D control over behavior. In that context, Leander and McMillan[207] compared the effects of chlorpromazine on the performance of pigeons under a multiple FR 30–FI 5 min schedule and a mixed FR 30–FI 5 min schedule of reinforcement. The contingencies of reinforcement were identical on the multiple and the mixed schedules; they differed only in the extent of stimulus control. On the multiple schedule, blue and red key lights were illuminated during the FR and FI components, respectively, while a white key light was illuminated during both components of the mixed schedule. A dose of 3.0 mg/kg chlorpromazine decreased FR response rates on the mixed schedule, whereas a dose of 100 mg/kg was required to produce an equivalent decrease in FR response rates on the multiple schedule. These results again demonstrate the modulation of the effects of a chemical agent by environmental conditions—in this case, the degree and nature of the stimulus control over the performance. A toxicological example is provided by work using a fixed consecutive number (FCN) schedule of reinforcement.[208] On this baseline, pigeons were required to peck eight or nine times on one key and then one time on a second key for reinforcement. Methylmercury exposure shortened the run of responses on the first key below the required level. When an external stimulus was added to signal the completion of the eight to nine required responses, however, the effects of methylmercury were eliminated. A return of the effects of methylmercury on the FCN baseline reemerged when the external stimulus was again removed, a further example illustrating how strong external stimulus control can overcome a toxicant-induced discriminative deficit.

A chained schedule of reinforcement also has different stimuli associated with each component of the schedule, but it requires the completion of the entire sequence of schedule components for reinforcement delivery. For example, on a chained FI 5 min–FR 30 schedule, an external stimulus first signals the FI component and the subject is then required to complete the FI with a response after 5 min has elapsed. This event produces a change in the external stimulus, which acts both as a conditioned reinforcer (S^r) for the FI performance that preceded it and as a S^D for the FR schedule component that will follow. After completing the FR requirement, the reinforcer is delivered, and the chain starts again. A tandem schedule of reinforcement is equivalent to the chained schedule, but no external stimuli indicate which component is in effect.

Wood et al.[151] compared performances on FR 8–FR 1 chained and tandem schedules to determine whether the behavioral effects of toluene were modulated by stimulus control. Both schedules required the completion of the FR 8 on one lever, followed by a single response (FR 1) on the other lever for food delivery. During the chained schedule, the light above the first lever served as the S^D for the FR 8 component. Completion of the FR 8 activated a tone and illuminated the light above the second lever, signaling the subject that a response on the alternate lever would now result in reinforcement delivery. The first of these two stimuli, then, served as the S^D for FR 8 performance, while the second acted as both a conditioned reinforcer for FR 8 performance and the S^D for the FR 1 component, with completion of the latter followed by food delivery. On the tandem schedule, only the house light was illuminated, and it remained illuminated during both the FR 8 and the FR 1 components. Clear differential effects of toluene were observed under these conditions, with performance on the chained schedule, which was under stronger external stimulus control, disrupted far less than the unsignaled tandem performance.

In the complexity of the natural environment, we are routinely faced with many contingent relationships simultaneously, sometimes requiring choices among them. Concurrent schedules, an experimental simulation of such circumstances, facilitate a study of choice by making it possible to select among concurrently operative reinforcement schedules. In an experimental chamber, each such choice would be associated with a separate response device.[209] The choice of component schedules used will, of course, depend on the experimental question of interest. In addition to securing data about preferences for the available reinforcement options, concurrent schedules permit analyses of the behavior of switching between schedule options, a category of responding under the control of the contingencies governing choice. As might be expected, under some conditions,[210] schedule-controlled performance maintained by concurrent schedules differs from the performance observed under conventional schedule conditions.

Despite the wealth of information about complex behavior such as choice yielded by concurrent schedules, few studies of chemical effects on such baselines have as yet been conducted. Newland et al.[57,211,212] used concurrent schedules of reinforcement to examine the effects of in utero exposure to lead, methylmercury, and elemental mercury vapor in squirrel monkeys. Random-interval (RI) schedules were programmed on two response levers, with the reinforcement density always being richer on one of the levers. RI schedules are similar to VI schedules, as the intervals between available reinforcement deliveries are truly random and the RI schedule parameter represents the average of these values. Under steady-state conditions, the behavior of the control monkeys was indeed sensitive to the differences between the two levers in reinforcement density, as indicated by the relative distribution of responses across the levers, that is, monkeys allocated proportionately more time to the response lever associated with the greater reinforcement density. In contrast, the behavior of monkeys exposed to methylmercury and elemental mercury and with blood lead values in excess

of 40 μg/dL was more biased and less sensitive to the differences in reinforcement rates. Further, as exemplified by the results with mercury vapor, when the relative reinforcement densities of the two levers were switched, as shown in Figure 38.24, control monkeys gradually shifted to the new, richer lever, whereas the offspring of females exposed to mercury vapor changed more slowly, or not at all, or even in the wrong direction. These effects led the authors to suggest that one behavioral mechanism by which these exposures altered behavior was by causing insensitivity to alterations in reinforcement contingencies.

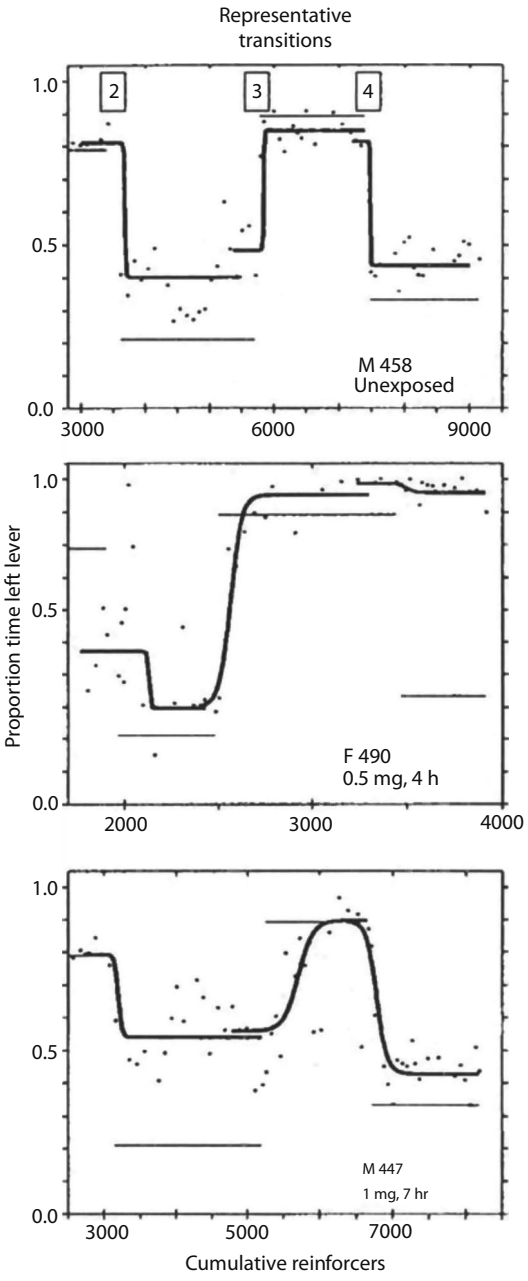

FIGURE 38.24 Plot of transition performance in one control monkey (M 458) and two monkeys whose mothers were exposed to mercury vapor during gestation. Proportion of time on the left lever should track the proportion of reinforcements (shown by the unconnected horizontal lines) on that lever. The response allocations (proportion of time on the left lever) of the control monkey shifted rapidly when the proportion of reinforcers programmed for the left lever was changed. The two exposed monkeys proved less sensitive to the change in contingencies. The heavy black line shows the fit of a logistic equation to the plotted points. (From Newland, M.C. et al., *Toxicol. Appl. Pharmacol.*, 139, 374, 1996. With permission.)

STIMULUS PROPERTIES OF CHEMICALS

Chemical agents or drugs themselves may function as unconditioned stimuli, as discriminative stimuli, and as reinforcing stimuli.[213] These roles correspond to those of conventional exteroceptive stimuli in controlling behavior. As reinforcing stimuli, they may pose the problem of dependence and the allied problem of abuse. Chemicals can function as discriminative stimuli in drug discrimination paradigms to provide information about the central nervous system properties of the agent and its neurochemical mediation. Chemicals have also been shown to have the capacity to act as positive reinforcing stimuli in a drug abuse context, as well as negative reinforcing stimuli that provoke avoidance behavior.

Chemicals as Discriminative Stimuli

The capacity of a chemical to act as a S^D and the neurochemical mediation of its central nervous system effects can be evaluated by a simple discrimination procedure referred to as the *drug discrimination paradigm*. Before an experimental training session, an organism is injected with, or exposed to, a specified dose of an agent (drug, toxicant) or an appropriate vehicle. Subsequently, responding on one of two levers is reinforced if the vehicle was administered prior to the session, but on the alternate lever if drug or toxicant administration preceded the session. The order of administering the chemical or drug versus vehicle across sessions is random, so the organism is not trained to respond to the pattern of chemical and vehicle administration. Typically, responding on the appropriate lever is reinforced according to an FR schedule, such as FR 10 or FR 20. Optimal training parameters of this procedure have been reported.[214] Accuracy of the discrimination within a session is defined arbitrarily (usually about 80%) and measured from the allocation of responses during the first FR completed. This restriction of the accuracy determination to response allocation during the first FR of the session is necessary because the first food delivery itself signals to the subject on which lever responding will be reinforced during the session. The establishment of a discrimination between the drug or chemical and the vehicle is arbitrarily defined, such as 8 of 10 consecutive experimental sessions in which the within-session accuracy criterion was met. The number of sessions required to establish such a discrimination depends on many factors, including parametric aspects of the procedure and training dose of the agent.

Once a discrimination is established—that is, once the subject has learned to accurately report whether it received

a drug or vehicle injection by appropriately responding on the lever consequent to its administration—the dose of the agent administered is varied during special very short–duration test sessions (generalization tests) designed to prevent any training to these other doses of the chemical. This procedure generates a dose–effect function relating the proportion of responding on the drug or chemical lever to the dose of the chemical; the ED_{50} value can then be extrapolated from this function. The procedure can be used to relate toxicant-induced changes in neurotransmitter function to changes at more molecular levels of analysis and to determine the neurochemical basis of behavioral toxicity.[171] For example, Cory-Slechta and colleagues[27,171] used this procedure to evaluate changes in dopaminergic and glutamatergic functions in relation to lead exposures. Rats were trained to discriminate either a D_2 dopamine agonist from saline or a D_1 agonist from saline using standard drug discrimination procedures. When the dose–effect curves depicting the proportion of drug lever responding to various doses of these agonists were determined, the ED_{50} values for postweaning (see Figure 38.25) and postnatally lead-exposed rats were significantly shifted to the left of those of control, consistent with dopaminergic supersensitivity. A previous study also has shown a lead-induced subsensitivity to a *d*-amphetamine drug stimulus.[215]

Chemicals as Positive Reinforcers

Operant techniques for experimentally evaluating the efficacy of drugs as reinforcers were developed in the 1960s for both rat[216] and monkey.[217] Animals are often equipped with intravenous catheters attached to infusion pumps through which specified amounts of the drug are administered when response requirements are met by the organism. The development of such procedures established the capability for an experimental analysis of drug dependence, and the resulting literature demonstrated unequivocally the correspondence between most of the substances self-administered experimentally and those abused by humans. Consequently, these techniques are commonly relied on today to evaluate the abuse liability of newly synthesized compounds. In some cases, animals are first trained to self-administer cocaine. The test compound is then substituted for cocaine, and its efficacy in maintaining responding is determined. Abuse potential is not, however, limited to drugs. Volatile materials and aerosols frequently encountered in occupational settings and also commercially available are likewise subject to abuse by inhalation. Using such procedures in squirrel monkeys, Wood demonstrated self-administration of toluene and nitrous oxide,[157,218] two substances that are also abused by humans. Other toxic compounds reported to engender

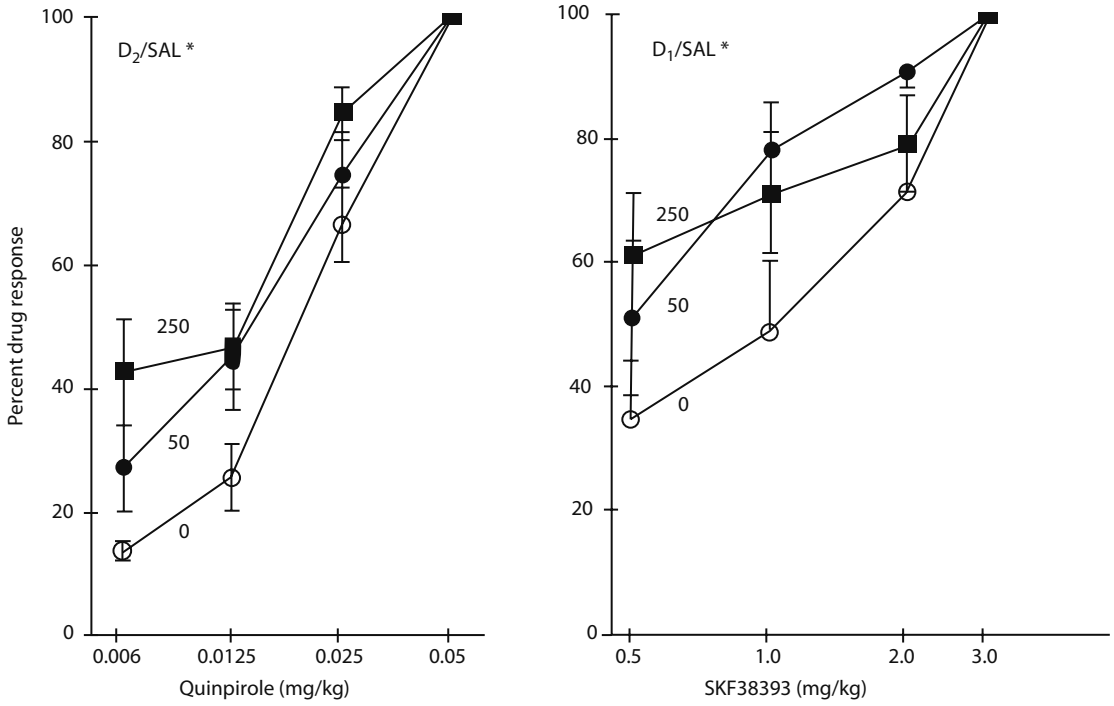

FIGURE 38.25 Generalization dose–effect curves for control (0 ppm; open circles) and 50 (filled circles) and 250 ppm (filled squares) lead-exposed groups trained to discriminate a dopamine D_2 receptor agonist from saline (left panel) or a dopamine D_1 receptor agonist from saline (right panel) using a drug discrimination paradigm that reinforced responding on one lever if the session was preceded by saline administration and on an alternate lever if dopamine agonist administration preceded the session. Test sessions involved administration of lower doses of the agonist. Each data point shows a group mean ± SE based on $n = 10$. The ability to discriminate drug from saline declines with decreasing dose of the drug as expected. These dose–effect curves were shifted to the left following lead treatment, indicating supersensitivity to the dopamine agonists. FIGURE 38.26 Schematic drawing of an exposure chamber used to study the irritant properties of compounds. Panel (a) shows the situation before irritant delivery; panel (b), during irritant delivery. The chamber atmosphere was introduced at the top, and a baffle ensured even mixing. The mouse stood on a perforated stainless steel platform though which the atmosphere exhausted. The irritant was added to the dilution air immediately above the chamber. Delivery of the irritant could be terminated by a nose poke, as shown in panel (b), which interrupted a light beam and was then recorded. Only one of the sensors shown was the active sensor for terminating irritant deliveries; the other served to measure the specificity of any behavioral changes. When the irritant exposure was terminated, either by a response or the end of the trial, a stream of clean humidified air was delivered through each cone to minimize the delay of irritant termination after a response had occurred. self-administration in humans include *n*-hexane, gasoline, vinyl chloride, and other organic solvents and volatile agents.

Chemicals as Negative Reinforcers

Drugs or chemicals may also function as negative reinforcers and maintain escape or avoidance behavior. As shown in Figure 38.26, for example, mice will respond to terminate the flow of ammonia through a chamber.[219] Response latency and incidence are directly related to the concentration of ammonia. In other studies, similar aversive properties of ozone,[220] acetic acid,[20] and formaldehyde[221] have been demonstrated. Also, Tepper and Weiss[198] found that rats working under an FR 20 schedule of reinforcement made fewer responses to release a brake on their running wheels, an avoidance of exercise that increased ozone flow into the lungs. Thus, such techniques can be used to assess both the pleasurable and aversive/irritating properties of a chemical, properties previously considered subjective and consequently barred to experimental evaluation.

BEHAVIORAL TESTING IN INVERTEBRATE ORGANISMS

Increasingly, invertebrate organisms are being added to the arsenal of neurotoxicity testing given the opportunities they afford for more accelerated study and incorporation of genetic variants, among other features. With this has come the development of increasing means of carrying out behavioral testing. While the types of complex cognitive functions described previously cannot be fully encompassed in these species, there are nevertheless mechanisms devised for simple measures, particularly those related to motor function and cognition and in some cases including both respondent and operant conditioning approaches. Multiple reviews have recently been published summarizing such approaches for zebra fish[222–224] and for *Drosophila*.[225–229]

HUMAN BEHAVIORAL TESTING

With the recognition that toxic exposures in the workplace might lead to functional disturbances too subtle to be detected by ordinary clinical or neurological evaluation, a growing body of research based on clinical psychological testing methods began to develop in the early 1970s. Gamberale et al. [230, p. 359] cogently described the rationale for behavioral testing:

> The growing interest in the measurement of performance is most probably due to the sensitivity shown by these methods in unveiling changes in the human organism that otherwise would not be detected. By now, the evidence that these changes are some of the earliest indicators of the occurrence of health effects has become unequivocal. As a consequence, the measurement of performance has come to be regarded by many as a device of major importance for monitoring hazards to health and safety in the work environment.

At the same time, awareness grew that equivalent problems in the community, such as the adverse consequences of excessive lead exposure in children, also required a greater reliance on quantitative behavioral methods rather than clinical examinations.

A salient example of an occupational issue is the claim, advanced most consistently by Scandinavian investigators,

of a syndrome, characterized by behavioral and neurological abnormalities, associated with chronic exposure to organic solvents.[231,232] Because the diagnosis of organic solvent syndrome or toxic encephalopathy makes a worker in those countries eligible for a disability award, official recognition of such a syndrome carries considerable economic implications. A similar point with respect to environmental issues is embodied in the discussion of what constitutes excessive lead exposure in children. If lowered scores on intelligence tests can be detected at blood lead concentrations of 10 or even <10 μg/dL, then sources of environmental lead must be much more stringently controlled.

Testing Approaches

Neuropsychological test methods, confined previously to clinic or laboratory settings, have been increasingly adapted to serve in both field and population studies. Although in principle both clinical neuropsychology and experimental psychology flow from common tenets, there are marked differences in history and tradition. Laboratory animal testing is based on the traditions of experimental psychology and the technology refined by behavioral pharmacology. Much of human psychological testing is rooted in questions of clinical diagnosis. Many of the tests that were most widely applied in occupational settings were designed to originally classify subjects or patients into various diagnostic categories or to characterize areas of deficit. The assessment of brain damage was the major focus of the specialty of neuropsychology.

Both standard clinical neuropsychological methods and those developed in experimental psychology have now come to be used in occupational and environmental studies. Advanced tests of sensory and motor function in humans, as described earlier, are closer in design to those devised for animals, and in fact, many of the laboratory animal methods are direct analogs of those created originally for humans; however, most techniques currently used for assessing and predicting what is designated as *achievement*, such as the acquisition of specialized knowledge, still come from the neuropsychological tradition, such as intelligence tests that partly attain such aims and may serve diagnostic functions as well. Disturbances of subjective state, such as depression and irritability, are frequently assessed using neuropsychological tools. Not only may they sometimes foreshadow overt toxicity, but they can also constitute important data in themselves. As elaborated in the succeeding text, as the questions being pursued become more focused on more specific behavioral deficits, reliance on experimental psychology approaches suited to both human and nonhuman subjects and to single behavioral domains is increasing.

Certain functional variables have assumed a special role in human testing, partly because of the frequency with which they have been reported, partly because tools for their assessment are available, and partly because they are deemed critical qualities. Only a few of the methods are reviewed here, and they are meant to serve as illustrations.

Clinical Neuropsychological Test Batteries

Early studies of occupationally and environmentally exposed populations largely involved the utilization of screening batteries,[233] with multiple different tests available to ascertain a range of behavioral functions based on the uncertainty about the correlations between specific effects and specific agents. Criteria for test selection, whether in batteries or used individually, include standardization, clinical evidence of sensitivity, selectivity, and test validity, that is, the degree to which a test score reflects what the test was designed to measure. Validity can be determined in different ways because of its many dimensions, but each is defined essentially by the criterion just described. Sensitive tests reflect earlier manifestations of toxicity or efficacy at low doses; tests with a high degree of specificity are less responsive to conditions not relevant to those the test was designed to detect. Another criterion is reliability or reproducibility. A test that fails to yield consistent results from one administration to the next will bury true differences in excessive variability. A related problem is standardization, which refers to the population from which the norms for certain kinds of tests are derived. The original Stanford–Binet intelligence test, for example, was developed and standardized on a white, middle-class sample of children, so the intelligence quotient (IQ) scores calculated from it probably are misleading when the test is given to black children from other sociocultural strata. The mode of framing the experimental question will also help guide choice. If the aim is screening or determining whether toxicity is detectable at a particular exposure level, functional breadth is accorded more importance than selectivity. If the aim is to clarify the nature of the functional deficits or their mechanisms, selectivity will receive greater emphasis.

It is important to note that sensitivity cannot be judged on an absolute scale in human studies, however. Only relative sensitivity, derived from a comparison of different measures, is within our grasp. Unlike the situation in animal studies, we rarely are in a position to exert control over exposure levels, studies with human volunteers being the exception. If one test instrument discriminates an exposed from an unexposed population more definitively than another, we may term it more sensitive. Such results do not indicate whether it could identify a population with even lower exposures. Further, the exposure level at which the effects are observed is not necessarily the lowest level of effect. One approach, advocated by Kennedy et al.,[234] calibrates the test battery by relating deficits in computerized performance tests to graded doses of alcohol.

Accumulated experience, coupled with theory and tradition, has led most investigators to select neuropsychological tests for batteries that encompass a fairly common set of behavioral domains. These may include tests of memory, of simple motor function, of complex cognitive performance, of attention and vigilance, and of mood or subjective state. Not all categories may appear in any single study, because some investigations are directed at one or a small cluster of functions. A common choice for inclusion in a test battery

TABLE 38.6
Subtests of the WAIS—Revised

Verbal	
Information	Questions of a general nature
Comprehension	Interpretation, judgment
Arithmetic	Numerical calculations
Similarities	Comparisons of nouns
Digit span	Repetition of digit sequences
Vocabulary	Word definitions
Performance	
Digit–symbol	Symbol–number coding
Picture completion	Identify missing portions
Block design	Duplication of patterns
Picture arrangement	Construct narrative sequence
Object assembly	Assemble jigsaw puzzle

has been the Wechsler Adult Intelligence Scale (WAIS), an attractive feature of which is its relatively careful standardization[235] and large body of accumulated experience. The WAIS is actually a battery of tests in itself and was designed to assess a broad sample of functions. It consists of 11 subtests assigned to verbal and performance categories to yield two major subscores (Table 38.6). This division is somewhat arbitrary because the two categories show considerable functional overlap and high correlations. Many investigators have chosen certain WAIS subtests rather than the complete assemblage for incorporation into their own repertoire of tests.

Vocabulary tests are examples of the verbal category. An example of the performance category is the digit–symbol substitution test of the WAIS, which requires entering symbols that are paired with numbers (digits) according to a specified code into appropriate blanks on a form. All of the subscales can be combined to yield a full-scale IQ score that correlates highly with academic achievement. The full-scale score, because it is a global score composed of the 11 subscale scores, is unlikely to provide much information about the precise areas of impaired function arising from exposure to a particular toxic agent. For this reason, some investigators have simply adopted certain subscales of the WAIS to assay-specific functions; however, the pattern itself is often useful for diagnosis, and techniques have been developed to explicitly relate the profile of performance to diagnosis.[236]

Two of the more widely used test batteries in worksite research are shown in Tables 38.7 and 38.8. The WHO neurobehavioral core test battery consists of a small number of components selected because of broad use and because they were not reliant on instruments or techniques that would be unavailable in developing countries. To verify the applicability of the WHO battery in different settings, Anger[233] compared performance in ten countries representing diverse populations. In general, the results from country to country were remarkably consistent. A major objection to the WHO battery[230] is that its emphasis on traditional manual and paper-and-pencil tests, largely to avoid complicated technical

equipment, especially computer-based administration and scoring, diminishes its sensitivity to neurotoxic effects.

One development in computerized testing, pioneered by Anger and colleagues,[237] uses both computer technology and operant behavior principles to deliver instructions to subjects in novel ways. Reliance upon language to deliver instructions can be an impediment to the use of neurobehavioral tests internationally because of the problem of translation. To avoid such problems, a set of preliminary instructions is provided so the subject's responses are operantly shaped by techniques such as successive approximation to the criterion response to conform to the test requirements. After the subject masters the test procedure, he or she is then ready for the actual test. Even under these circumstances, which are designed to minimize educational and cultural contributions, such variables still exert a pronounced effect. Another study[238] compared subjects of European descent with American Indian, African-American, and Latin-American populations on two consensus neurotoxicity test batteries. One was the WHO collection (Table 38.7), and the other one was assembled by the Agency for Toxic Substances and Disease Registry (ATSDR). Education accounted for the most variance in the tests studied, followed by cultural group. Years of education and cultural group had 13%–25% shared variance on the cognitive tests, suggesting that these factors should be controlled during the design phase of a study rather than in the statistical analysis. The authors stress that failure to adequately control and analyze these variables could lead to inaccurate conclusions about the association between poor performance and neurotoxic insult.

The neurobehavioral evaluation system (NES), devised originally by Letz and Baker[239] to exploit the potential of computer administration and scoring,[71] has been among the most widely used of the current batteries (Table 38.8). It embodies three main categories of tests: psychomotor, memory and learning, and cognitive (executive function). It is a much more ambitious battery than the WHO collection and has been translated into several languages other than English. In its current form (NES3), it includes 18 tests of functions such as reaction time, motor coordination, and simple cognition.[240] Other groups have devised batteries of their own, based on personal preferences, theories, or unique aims, but the NES and WHO formats offer the most extensive databases.

Experimental Psychological Batteries

Experimental psychological-based tests based on approaches that can be used widely across species have gained increasing use in behavioral evaluation. One such example is the Cambridge neuropsychological testing automated battery (CANTAB), a computer-automated battery of neuropsychological tests designed for accurate, sensitive cognitive assessment.[241] It includes tests of memory, attention, and executive function administered via a touch screen, many identical to those used in the experimental psychology domain. Studies carried out to date have shown its sensitivity to a variety of neurodegenerative diseases and behavioral dysfunctions, including Alzheimer's, Parkinson's, and Huntington's diseases, attention deficit disorder, autism, depression, and schizophrenia, as well as age-related deficits in cognition. Moreover, its utility extends from children as young as 4 years old through seniors, and its potential for use in neurotoxicology has been suggested.[241] Studies demonstrate the sensitivity of CANTAB in revealing deficits in spatial memory and reversal learning in lead-exposed children as young as 4–5 years of age.[242] Indeed, this battery has great utility for elaborating specific behavioral deficits related to chemical exposures in human studies. The fact that many of these tests are the same as those used in an extensive experimental animal literature allows extrapolation from a rich base of experimental studies that includes neurobiological and neurochemical substrates of specific functional deficits. In addition, definition of specific deficits in human populations in response to neurotoxicant exposure using more specific and precise tests of behavioral domains can also be used to refine animal models and for the development of behavioral therapeutic approaches.

Memory

Complaints of impaired memory surface frequently in workers exposed to neurotoxic agents and, according to a survey by Anger,[233] are the functions most often assessed in worksite research. Memory disorders also appear in adults with focal brain damage and in patients suffering from degenerative neurological diseases. Given the prominence of such complaints in patients and the central role accorded memory in psychological theory and in neuroscience, it is not surprising that numerous tests and techniques are available for the study of this function. A frequent distinction is made between immediate or working or short-term memory and remote or reference or long-term memory. Such distinctions, and the more elaborate ones offered by current workers, often are difficult to apply to specific experimental conditions, and it has even been argued that the term *memory* itself has grown too vague to be useful scientifically. Often, terms borrowed from computer technology, such as *storage* and *retrieval*, are alleged to account for memory. But, if memory, as noted earlier, is defined by responses based on earlier experiences, this more neutral and empirical definition is a better platform from which to launch useful experiments, and the examples that follow are presented from an empirical standpoint for that reason.

One widely used test is the WAIS assay of short-term memory known as *digit span*. Traditionally, the examiner calls out a series of numbers that the patient or subject is asked to repeat. Smith et al.,[243] like many other current investigators, adapted the digit-span technique to the computer and presented the numbers, one at a time, on a display terminal. Their subject population consisted of workers from two mercury-cell chloralkali plants whose urinary mercury concentrations had been monitored repeatedly. The lists of digits were presented with ascending length, beginning with three digits. If the worker then recited the list correctly, a list with four digits was presented, and so on. Errors on two successive presentations of the same list length halted the test, and the worker's score was noted as the length of the previously correct list. No relationship with mercury excretion was observed, primarily because the standard WAIS procedure proved to be unreliable, yielding a correlation between successive administrations of 0.36. To overcome this inherent flaw, the investigators modified the procedure so they could use probit analysis to estimate the 50% threshold span. With this procedure, the reliability coefficient rose to 0.85, and regression analysis showed a significant correlation between this measure of digit span and urinary mercury concentration.

Hanninen[70] also noted that the digit-span subtest of the WAIS can produce ambivalent results; however, Baker et al.,[244] in a study of foundry workers exposed to lead, obtained a significant relationship between blood lead values and performance on a version of the digit-span test that required the subjects to repeat the list backward. It is possible that this result arose not so much from the inability of workers to remember the list but from intruding factors such as the fatigue, depression, and confusion detected by an inventory of subjective state. Complaints of cognitive difficulties and lowered scores on memory tests may also stem from sources such as depression and the inability to concentrate.[245] These potential confounds need to be addressed in interpreting behavioral outcomes. Variations of the digit-span procedure that are said to test verbal memory include letter span and word span. One contribution made possible by computer-based batteries is a restructuring of tests such as digit span

to offer adaptive procedures in which the presentation of test items is contingent on the performance of the subject, as in programmed instruction.

In the Benton visual retention test, a test of nonverbal memory, a common component of many neuropsychological test batteries,[246] the subject is asked to reproduce a three-figure design. Scoring systems have been developed to quantify fidelity and to correlate types of distortions with different kinds of brain damage. The test is sensitive to brain lesions that lead to neglect of one side of the body,[247] but such deficits are uncommon in neurotoxicology. Another variant, the Graham–Kendall memory-for-designs test,[245] consists of a series of 15 geometric designs presented to the patient one at a time for 5 s. The patient is then asked to copy the design, and the reproduction is scored for various kinds of errors.

The ability to memorize lists of words or nonsense syllables is commonly assessed in neuropsychological test batteries. The Wechsler Memory Scale®[248] contains a paired-associate learning task consisting of 10 word pairs. Some, such as baby–cries, are relatively simple; others, such as cabbage–pen, are less transparent. The list is read three times. After each repetition, a test trial is conducted during which the examiner calls out the first word and the subject is required to say the second word of the pair. This kind of learning paradigm has a long history in experimental psychology, and many different kinds of items, including pictures and nonsense syllables, have been used as materials. Adverse effects of food dyes on young children were demonstrated by the paired-associate learning of number and zoo (animal) combinations.[249]

As part of their performance battery used to test lead workers, Williamson and Teo[250] also examined paired-associate learning of five pairs of three-letter words. The subject was required to write down the second member of the pair after the first member of the pair was presented. This sequence was repeated until the subject was able to identify all five pairs. Lead-exposed workers recalled fewer items than controls after the first presentation (mean of 0.72 vs. 2.19), required more trials to reach criterion (mean of 3.74 vs. 2.81), and had a higher incidence of individuals failing to reach criterion (64.2% vs. 13.8%).

Although it may have been sensible in the beginning to choose methods for assessing memory function that were based on widespread diagnostic acceptance, new concepts, data, and techniques are emerging at a rapid rate, including the efficacy and utility of experimental psychology approaches. Sahakian et al.[251] relied on complex delayed matching-to-sample stimuli, presented by computer displays in the CANTAB battery and described earlier, to evaluate memory deficits in Alzheimer's disease. In this paradigm, subjects are first shown a *sample* stimulus, which is then removed. The subject must choose the sample from among several stimuli subsequently presented after a delay that matches the original sample. Since then, such techniques have been increasingly used to determine sensitivity for detecting Alzheimer's disease and mild cognitive impairment, thought to be a precursor to Alzheimer's disease. An accumulating literature has continued to demonstrate the sensitivity and specificity of the CANTAB delayed matching-to-sample paradigm in such cases.[252] Recently, using multiple linear regression analyses adjusted for age, education, and smoking status, a significant association of higher calcaneal bone lead levels with increasing memory impairments on the CANTAB delayed matching-to-sample paradigm was reported in a cohort of 47 healthy subjects ranging from 55 to 67 years of age.[253] In addition, the CANTAB version of episodic memory, paired-associate learning, has likewise been shown to be sensitive to these impairments.[252,254,255] In this paired-associate learning test, the subject is shown a screen on which a set of boxes are displayed (up to 8). The boxes are opened, one at a time, and contain a stimulus pattern. After all the boxes have been opened, each of the stimulus patterns is presented to the subject, one at a time, and the subject must recall the location of the box that contained that stimulus pattern. As previously noted, these emerging trends are bound to influence behavioral toxicology and eventually to displace or augment the traditional approaches that so far have dominated the literature.

Attention

Attention is a behavioral construct that includes three diagnostic categories: hyperactivity, inattention, and impulsivity, all of which require different behavioral approaches. Reaction time measures, frequently used to measure sustained attention, are relatively simple to implement and generate straightforward values that do not require elaborate clinical interpretation. Basic reaction time paradigms can be modified to provide an immense range of complexity in the assessment of many kinds of stimulus variables. A frequent variation is to compare reaction times under conditions where alterations in responding are required in accordance with the location or other properties of the stimulus. Reaction time measures seem to reflect both acute and subchronic toxicities resulting from volatile organic solvent exposure. Experiments with workers exposed to styrene, a solvent widely used in fabricating fiberglass boat hulls, called for the experimenters to visit the plant on Friday, familiarize the workers with the reaction time situation, and deliver a questionnaire about work history and personal habits.[256] On the succeeding Monday, simple reaction times were measured with a portable device at the beginning and end of the shift, and urine was collected by each subject until bedtime. Blood samples were drawn at the end of the shift. Following the suggestions of Gamberale and Kjellberg,[257] the rate of stimulus presentation was fairly high (16 trials per minute), a decision based on findings that such high rates lead to a quicker decline in performance.

Men exposed to styrene began the shift with slower reaction times than did men in a reference group, but by the end of the day, the groups did not differ. Within the exposed group, however, those men with the highest blood levels of styrene showed no improvement and displayed the greatest deterioration in ratings of alertness and exhaustion. In a subsequent study, the investigators observed substantial correlations between urinary mandelic acid (a styrene metabolite) and

reaction time performance on Monday morning, indicating that, even with a 60 h period away from the plant, the effects of exposure were still evident in performance. Exposure levels, it should be noted, did not exceed the British TLV® of 100 ppm.

Needleman et al.[258] demonstrated the sensitivity of reaction time measures to an index of cumulative lead exposure in children by comparing levels of dentine lead in the highest and lowest deciles of a distribution obtained from two Boston suburbs based on more than 2000 children. They used simple reaction times but varied the interval between the ready signal, which alerts the subject to the next stimulus, and the presentation of the stimulus. On two blocks of trials, the interval was specified as 3 s; on two other blocks, it was specified as 12 s. These values were chosen to probe for the possible influence of distractibility. The longer interval produced longer reaction times in both groups, but for both intervals, the children with the higher lead levels responded more slowly than those with the lower levels. A subsequent study by Yule et al.[259] confirmed these results in British children with even lower lead levels, while a study from Germany adds another dimension of support to these findings.[148] In addition to confirming the relationship between tooth lead and reaction time performance, these investigators also observed that, when the children were categorized by social class, the data of those from the less-advantaged group showed an even greater correlation with tooth lead than the group as a whole.

Despite a large number of publications featuring or including such measures, however, the power of reaction time measures to detect neurotoxicity remains only superficially exploited. Gamberale et al.[230] and Iregren and Gamberale[260] demonstrated that, with computerized testing and analysis, the sensitivity of such measures can be enhanced and can even contribute to the differentiation of various diagnostic groups, such as those suffering from solvent-induced deficits. One of the limitations of reaction time measures is the common practice of ignoring stimulus properties such as intensity. Almost never is the brightness of a stimulus light or the properties of a stimulus tone reported, even in studies of agents known to affect vision or hearing. Because reaction time is sensitive enough to stimulus intensity to be used as a psychophysical measure,[261] ignoring stimulus characteristics can lead to the suspicion of confounding.

Several different measures have been used to examine sustained attention. The most frequently used is the continuous performance test or some variant thereof, which is a more complex version of reaction time that can be made to be relatively complex and tasking and utilized in a parametrically appropriate fashion across species. Basically, the subject is instructed to watch for the occurrence of specific targets over time using computerized presentation. These can range from a single number or tone or may require detection of a sequential series of digits. Further, they include measures beyond simple reaction time, including accuracy of detection, omission errors, and commission errors as well as the ability to use measures of signal detection theory. Such tests have been found to be influenced by low-level lead exposure in children, leading to decreases in number of correct detections and increased numbers of omission errors,[262,263] findings consistent with studies in experimental animals.[264]

Highway driving and piloting aircraft are situations that require competence in motor performance and in attention and are often stated to require *vigilance*. Some examples are provided by power stations and chemical process plants where remaining alert enough to respond to infrequent or slowly changing signals is critical and is challenged by shift-work schedules that induce chronic sleep disruption. In the laboratory, these functions can be examined in detail because of the available instrumentation and time. In field testing, where simpler, often portable equipment is mandated, and where workers must be allowed time from their jobs, performance assessment is usually directed toward global screening for adverse effects rather than determining definitive answers about the parameters of dysfunction.

A prototype vigilance task is the clock test devised by Mackworth, which has served as the criterion task in many studies with drugs.[265] It is arranged so a pointer on a clock face moves 1° every second, except for occasional deflections of two steps. The subject's task is to respond to these infrequent events by pressing a key. Typically, the frequency of detections falls sharply after the first 30 min but can be counteracted by administering drugs, such as the amphetamines, that promote alertness. Dick et al.[266] included the clock test in a battery to evaluate experimental exposures to toluene, methyl ethyl ketone, and ethanol. Exposure to 100 ppm toluene (the TLV) for 4 h lowered the proportion of correct detections. Ethanol also impaired performance at a dose of 0.8 mL/kg.

More complex vigilance performance, which may demand a certain amount of coordination skills, also offers unexplored potential. In a series of classic studies, Payne and Hauty[267] reported the effects of various drugs and parametric variations on the school of aviation medicine multidimensional pursuit test,[268] which was designed originally as a tool for pilot selection. The subject was seated in a simulated aircraft cockpit and asked to monitor four dials. The pointers on the dials drifted irregularly from their null positions, and the subject's task was to restore them to null by manipulating a control stick, rudder pedals, and a throttle control. With a typical group of subjects, total time at null reached asymptotic values after about 1 h of practice, but with further testing began a gradual decline. The rate of decline was enhanced by drugs with sedative actions and retarded by drugs such as the amphetamines, even at remarkably low-dose levels. The unusual sensitivity of this task to drugs suggests that it, or a contemporary analog based on computer technology, deserves to be evaluated in behavioral toxicology.

The multidimensional pursuit test is not simply watchkeeping, because it also embodies the type of visually directed motor performance called tracking. Mackay et al.[269] examined the acute effects of carbon monoxide on a tracking task. Subjects controlled the position of a cross displayed on an oscilloscope screen by moving a joystick and were required to maintain the cross within a square target that

moved continuously around the screen in random patterns. During a single test session, they performed on five 1 min trials. Carbon monoxide significantly increased error amplitude and decreased time on target during the 2 h exposure period. Tracking tasks are now included in a number of test batteries; for example, one of the tests used in studies of methylmercury-exposed children required the subjects to follow a sine-wave display by appropriate movements of a joystick.[270]

More typically than not, performance demands occur in settings requiring more than one task to be monitored and responded to concurrently. Driving, piloting, air traffic control, and scanning and adjusting medical monitoring equipment provide examples. Most neurobehavioral test systems strive to examine one function at a time, making extrapolation to multitasking situations somewhat uncertain. A study conducted by Rahill et al.[271] employed a multitasking scheme to evaluate the performance effects of exposure to 100 ppm of toluene (see Figure 38.27). Significantly lower composite performance scores were obtained by the subjects during toluene exposure.

A third domain of attention deficit is impulsivity, also referred to as inability to manage delayed gratification and loss of self-control. Delay of reward paradigms is one measure of impulsivity and has been used across species. These paradigms essentially provide the subject with a choice between a small reward following a short delay and a large reward but only after a longer delay. Surprisingly, although validated for ADHD,[272] such paradigms have yet to be frequently employed in neurotoxicology. Another connotation for impulsivity is inability to inhibit responding. This is frequently evaluated using time-based schedules of reinforcement (see Figures 38.20 and 38.21), again with applicability across species, although to date used primarily with experimental animals. For example, on a DRL schedule, responses must be separated by *t* seconds in order to obtain a reward; thus, impulsive or premature responding will impair performance and decrease total number of rewards obtained. Such studies have revealed impairments in response inhibition in response to lead exposures as well as polychlorinated biphenyls (PCBs).[264]

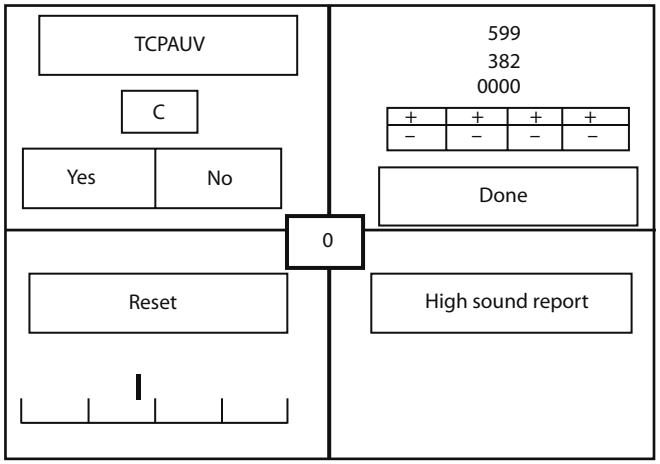

FIGURE 38.27 Multitasking performance test (SYNWORK). (Top left) A series of letters appears on the screen, then it is removed. In the following box, letters are flashed in sequence, and the subject is required to indicate whether or not the letter belongs to the original set. (Top right) The subject calculates the sum of the two upper numbers and, using the mouse, scans through the numerals 0–9 to place them in the appropriate positions in the third number. (Lower left) The cursor drifts toward the end of the scale, and the subject is required, by mouse clicks, to prevent it from reaching the end. (Lower right) A series of tones is presented through a headset. Intermittently, a louder tone is inserted. The subject is asked to respond when the louder tone is detected. The box in the center of the screen displays the subject's numerical score for that session. The SYNWORK task proved sensitive to toluene exposure. (From Rahill, A.A. et al., *Aviat. Space Environ. Med.*, 67, 640, 1996. With permission.)

Subjective State

Certain clusters of symptoms seem to be characteristic of different toxic exposures. Mercury vapor induces a cluster so well known that it earned the label *erethism* (Table 38.9). Chronic solvent exposure is associated with complaints of tiredness, depression, and confusion. Roels et al.[52] and Mergler and Baldwin[273] found excessive fatigue to dominate the list of subjective complaints among manganese workers. Measurement of such vague symptoms is not a task to be undertaken without an appreciation of the principles of psychometrics. The earlier discussion of validity and reliability probably applies more directly to symptom measurement than to almost any other criterion because accessory criteria are so difficult to define. Memory, for example, can be assessed by enough different techniques to provide some index of consistency. A complaint of depression is not as readily confirmed. To simply construct a questionnaire based on what the investigator believes are the most conspicuous symptoms associated with a particular exposure is a virtual guarantee of uninterpretable data. For this reason, neuropsychologists rely on standardized instruments such as the Beck depression inventory.[274]

An example of the arduous process required to design and develop a quantitative measure of specific symptoms is described by Goldberg,[275] who aimed to construct a scale sensitive to minor psychiatric illness. The evolution of the questionnaire proceeded through several steps: selection of items, including careful editing of wording; decisions about the form of the response (i.e., whether to ask for a *yes–no*

response or to ask for some form of rating such as a scale from *infrequent* to *always*); selecting criterion groups and then determining which items of the inventory discriminate among them (a measure of validity); and assessing the consistency of responses within individuals (reliability). Some of these stages may be repeated and items added, deleted, or modified. Some items may carry an excessive burden of social desirability and may not be answered with total candor. Several other well-designed inventories of subjective state are available that also offer considerable data about validity and reliability. Some were constructed, such as the Goldberg questionnaire, to detect mild psychiatric dysfunction.

Some were developed to measure the acute effects of drugs or to follow the course of drug therapy. The profile of mood states (POMS) is a self-rating scale designed to measure subjective responses to various therapeutic or experimental maneuvers.[276] It consists of 65 adjectives that the subject judges on a 5-point rating scale that has been tested on both psychiatric patients and normals. A factor analysis yielded the following major factors: tension–anxiety, depression–dejection, anxiety–hostility, vigor–activity, fatigue–inertia, and confusion–bewilderment. Baker et al.[244] included the POMS in a battery given to lead foundry workers and observed marked elevations in several of these factors in workers with the higher blood lead levels. The SCL-90[277] was devised as a self-report rating scale for psychiatric outpatients and, like those already referred to, provides a set of dimensions (factors) extracted from the entire 90-item scale. Its designers cite it as particularly useful in clinical drug trials undertaken to evaluate psychoactive agents. Anyone contemplating the framing of an ad hoc questionnaire should note the care taken in the construction of the SCL-90. For example, to make the wording of the items accessible to the widest variety of subjects, the designers of the inventory turned to the Thorndike–Lorge *word book*, which provides frequency counts obtained from materials such as newspapers for 30,000 words. It allowed them to equate the vocabulary levels of the nine factors and to select the most basic word levels to express the item accurately.

One example of the data that may be extracted with a properly designed inventory was provided by Levin et al..[278] They compared 24 control subjects matched by age and education with 24 subjects who had been exposed to organophosphate insecticides in recent weeks. The subjects were evaluated by a structured interview, a depression inventory, and the Taylor manifest anxiety scale consisting of 50 true–false items derived from the Minnesota multiphasic personality inventory, which enjoys wide use in psychiatric diagnosis. These items include both psychological and somatic manifestations of anxiety. The structured interview and the depression scale yielded no differences between the two groups, but several items on the Taylor scale provided a clear separation. These are listed in Table 38.10 and support the view that organophosphate exposure may induce subclinical psychological effects that would not be detected by conventional medical surveillance or even by inventories and questionnaires that did not contain specific kinds of symptom items. The 13 commercial applicators in the exposed group (the others were farmers) accounted for the bulk of the difference; their plasma cholinesterase levels, however, fell within the normal range, suggesting that this exposure measure is not an accurate reflection of central cholinergic status.

TABLE 38.10
Items on the Taylor Manifest Anxiety Scale Sensitive to Differences in Organophosphate Insecticide Exposure

I work under a great deal of tension.
My sleep is fitful and disturbed.
I have periods of such restlessness that I cannot sit long in a chair.
I believe that I am no more nervous than most other people.
I feel anxiety about something or someone almost all the time.
I am usually calm and not easily upset.
It makes me nervous to have to wait.
I practically never blush.

TABLE 38.11
Persistent Neurological Sequelae of Acute Organophosphate Poisoning

Test Name	100 Cases	100 Controls	p-Value
WAIS verbal IQ	105.40	111.86	0.001
WAIS performance	108.41	110.13	0.242
WAIS full scale	107.50	111.77	0.001
Impairment rating	1.07	0.91	0.001

Pegboard	148.34	137.96	0.002
Card sorting	17.07	12.91	0.001

A more ominous legacy of organophosphate exposure is now undergoing examination. Earlier probes of the aftermath of acute organophosphate poisoning had suggested persisting neurotoxic consequences, but Savage et al.[279] were the first to combine well-documented exposures and neuropsychological measures. They reported on 100 individuals who had experienced a poisoning episode 1 year earlier and on 100 matched controls. Although clinical chemistries and medical examinations indicated normal function in the exposed group, psychological testing indicated residual deficits as measured by several WAIS subtests and other indices (Table 38.11). Subsequent reports by others have confirmed these findings.[280]

Developmental Assessment

Most of the tests described earlier were devised to assess adults. Many questions about behavioral toxicity, however, arise from the possible impact on early development and involve testing during infancy or childhood, which has been the domain of behavioral teratology. Methylmercury, lead,

and PCBs are examples of substances closely connected with developmental disturbances. Although the essential functions that should be evaluated remain the same throughout the life cycle, early developmental stages can pose several unique problems. One is that young children have not yet acquired or developed the full behavioral and functional repertoire of adults. Another is that early childhood is a period of rapid change with marked individual differences in rate of development, one of the factors that dilutes the ability of tests administered at that time to predict later capacities. For these and associated reasons, investigations of developmental toxicity have to adopt approaches that sometimes differ markedly from those suitable for adults. Infancy is the most difficult stage to evaluate because of the plasticity of infant behavior.

The most common scale of infant development is the Brazelton Neonatal Behavioral Assessment Scale,[281] which usually is administered within the first 3 days after birth. It consists of two subscales. One includes items reflecting habituation, motor activity and control, stimulus responsiveness, and similar responses among 27 behavioral items. The other is comprised of 21 neurological items based on elicited reflexes. Although Brazelton scores are not highly correlated with tests of later function, they have proven capable of reflecting the effects of obstetrical medications.[282]

One of the best examples of how the Brazelton scale might be used in a study of developmental toxicology is provided by Streissguth et al.,[283] who reported their findings on a cohort of about 500 children, selected at birth, to determine the consequences of various levels of maternal alcohol consumption. The mothers of these children were interviewed during the fifth month of pregnancy to obtain data on this and other relevant drug practices, as well as on social, educational, and demographic variables. Habituation in the infant was a special focus of this investigation because of observations indicating that neonates with a clinically overt fetal alcohol syndrome failed to display a response decrement to repeated auditory stimulation. A factor analysis of scores (a procedure that reduced the 27 original Brazelton scores to a smaller number of dependent variables) yielded 6 independent factors. After a multiple-regression analysis, which adjusted for possibly confounding contributions from smoking, caffeine, maternal nutrition, and so on, maternal alcohol consumption during pregnancy remained a significant determinant of poorer habituation and increased low arousal in the infants. The care taken by these investigators to ensure that the examiners were kept uninformed of the other data and the efforts made to train and preserve consistency in examiner ratings can serve as a model for such studies.

The ultimate question for investigators is how well measures obtained during infancy predict later outcomes such as intelligence test scores or school status. One of the more promising techniques, the Fagan test of infant intelligence, measures visual recognition memory.[284] The infant is held so it faces a display with two screens, behind which an observer can record the amount of time the infant's gaze is directed to each screen. On an individual trial, a particular visual stimulus, such as a face, is projected on one of the screens. After the infant has had time to examine the stimulus and after a brief interval, the previous stimulus and a new one are presented simultaneously. The observer measures the amount of time spent by the infant in examining the novel stimulus compared to the one displayed earlier. The novel object recognition test described earlier and used in rodents represents an analog of the Fagan test. Infants who score higher on later developmental tests such as the Stanford–Binet tend to spend less time viewing the old stimulus. In studies exploring the developmental neurotoxicity of PCBs, the Fagan test revealed a significant relationship between umbilical cord PCB levels (attributed to maternal consumption of tainted Great Lakes fish) and psychological development.[285] Gunderson et al.[286] found that infant monkeys exposed prenatally to methylmercury spent more time than controls gazing at the previously displayed stimulus.

For later stages of infancy, encompassing a range from 2 to 30 months of age, the Bayley Scales of Infant Development[287] are among the most popular because of the care taken in their standardization and their ability to be used for repeated testing. The Bayley items are arranged chronologically and divided into three subscales: mental, motor, and behavioral. The mental scale is composed of 163 items, ranging from responses to visual and auditory stimuli to abilities such as naming objects. A notable application to toxicology was suggested in studies relating cord blood lead concentrations to performance, summarized by Bellinger and Needleman.[288] At 6, 12, 18, and 24 months of age, even after correcting statistically for many potential confounding variables such as maternal age and intelligence, a significant relationship between cord blood lead and scores on the mental development index emerged. Children in the group with the highest cord blood lead values (a mean of 14.6 μg/dL, compared to 6.5 for the middle group and 1.8 for the low group) attained the lowest scores at all ages tested. At 24 months of age, the difference between the lowest and highest groups reached 8%, although by that time, all three groups had converged toward the same mean blood level of about 7 μg/dL. Similar findings have since emerged from other prospective studies in Cincinnati[289] and Australia.[290]

At later ages, the number and variety of instruments available for psychological assessment are overwhelming. Most investigators choosing a battery of tests will typically include one of the intelligence tests designed for children. The Wechsler Intelligence Scale for Children–Revised (WISC-R)[291] is the dominant choice for children older than 6 years of age. In addition to its demonstrated reliability, it is attractive because, like the WAIS, it provides separate verbal and performance subscales that include several individual tasks. These offer a profile of the child's abilities across a variety of functional components. For younger children, the Wechsler Preschool and Primary Scale of Intelligence (WPPSI)[292] yields the same subscale advantages as the WISC and is basically an extension of the WISC for ages 4–6.5 years. Another instrument suitable for younger children, the McCarthy Scales of Children's Abilities,[293] also extends into

early school years, spanning 2.5–8.5 years of age. It provides five separate scales that can be combined into what is called a *general cognitive index*, similar to an IQ. All three of these, plus the older Stanford–Binet, have been used to assess the effects of lead. Needleman et al.[258] included the WISC-R in their landmark study, which indicated lowered performance on IQ tests in those children whose tooth lead concentrations fell at the upper portions of the distribution. Their results have since been confirmed by other investigators, including some from outside the United States who also used the WISC-R or an adaptation of it to measure intellectual function. This is one illustration of how reliance on a standardized test allowed different investigations to be combined with some degree of confidence.

Needleman[294] and Bellinger and Needleman,[288] in two companion articles, discuss the strategy for using such scores in a context where many potential confounding variables should be considered. Some examples, besides obvious factors such as race, birth weight, and length of gestation, are maternal age, birth order, parental education, family social class, and quality of the rearing environment. Even when these and other variables were compensated for in the statistical analysis, cord blood lead values remained significantly associated with reduced scores on the mental development index of the Bayley scales. Parallel conclusions have been drawn by other groups.

As in adult epidemiological studies, most investigations try to assemble comprehensive test batteries to try to determine relationships between neurotoxic exposure across a broad spectrum of functional outcomes. For the evaluation of the cohort of another large prospective methylmercury study,[270] in the Faroe Islands of the North Atlantic, investigators chose a neuropsychological test battery for 7-year olds consisting of the following components: finger tapping, hand–eye coordination, tactual performance test (shape discrimination when blindfolded), continuous performance test (vigilance and reaction time), WISC-R (digit spans, similarities, and block designs), bender visual motor gestalt test, Boston naming test, California verbal learning test (children), and a pictorial analog of the POMS survey. They also included a chart that is used to measure visual contrast sensitivity and several neurophysiological measures. Their analyses pointed to mercury-related deficits primarily in the domains of language, attention, and memory, but they also observed deficits in visuospatial and motor functions. Subsequent studies of this cohort have indicated that coexposures to PCBs from consumption of whale blubber[295] could be contributing to these deficits.

Evaluations of the Seychelles cohort, where PCBs are not present, have so far failed to demonstrate any adverse developmental outcomes due to methylmercury.[296] For this assessment, the test battery has included the McCarthy Scales of Children's Abilities (the general cognitive index), the Preschool Language Scale for measuring expressive and receptive language, two subtests of the Woodcock–Johnson series designed to measure reading and arithmetic achievement, the Bender–Gestalt test, and the Child Behavior Checklist designed to assess social and adaptive behaviours.

Contrast sensitivity pretest	Verbal cancellation
Vibration II	Story memory delay

These two groups of investigators selected somewhat different arrays of instruments for these two parallel investigations because they were pursuing somewhat different questions and because they were evaluating different age ranges and stages of maturity. All investigators agree that no one test battery will be suitable for all purposes or populations. Selection will be guided by the questions asked, the population studied, and the investigator's inclinations. Often, designers of test batteries attempt to provide researchers with a menu of tests, so to speak. One example is the battery assembled[225] to assist the ATSDR, which is responsible for evaluating health risks at hazardous waste sites in the United States. The prototype test battery consists of the components shown in Table 38.12. The entire battery, because it is designed for screening populations rather than for the intensive appraisal of small groups or individuals, requires only about 1 h for children. The first five items refer to information secured from the parent.

Emerging Issues

Like other components of contemporary toxicology, behavioral toxicology is undergoing almost continuous change. Its literature has grown almost exponentially, and the range of techniques applied to its problems has expanded over a broader spectrum of behavior and neuroscience. Compare, for example, the first U.S. book on the topic[297] with a comprehensive survey published almost 20 years later.[298] The range of topics is not only broader but now more firmly based on a comprehensive literature. Especially for human assessment, however, greater efforts are necessary to extend the range, relevance, and specificity of test procedures. Although standardization and an extensive history of use are advantages, they should not limit investigators. Advances in test development are at least as crucial to behavioral toxicology as the analysis of toxic effects themselves. Contrast, for example, the relative crudeness of sensory and motor testing in most test batteries with the precise, elegant methods described in earlier sections of this chapter that have been applied to animals.

Even cognitive function, which has received the bulk of attention from neuropsychology, is only superficially addressed in most test batteries. Among the more promising advances in this area are those stemming from the translation of rigorous

laboratory test procedures into practical test methods suitable for clinical and even field evaluations, such as CANTAB, described previously,[241,254,255] and an operant battery for measuring complex performance in children[299] that, like the items on intelligence tests, reflects developmental maturity. Both have the advantage of direct comparability with the techniques used for assessment in animals with the associated literature on neurobiological substrates. In addition, because of the flexibility afforded by computer technology, both can introduce increasingly difficult versions of the same basic test to avoid ceilings on performance. Finally, because they do not require verbal responses, problems of language translation and illiteracy can be bypassed. As more data have become available, the ability to more precisely specify hypotheses with respect to predicted functional deficits should become possible, allowing the use of increasingly sophisticated and specific methods in both human and experimental studies.

QUESTIONS

38.1 New behavior can be generated in two basic ways: operant conditioning and respondent conditioning. They differ in (1) the type of response, (2) the conditioning procedure, and (3) the criteria for judging the strength of the conditioned response. How would you use each type of conditioning to evaluate impaired learning capacity? What potential confounds must be considered?

38.2 As a test of memory difficulties, design a procedure to test whether a rat can remember which of two levers (a left and a right, say) it had pressed 10 s earlier.

38.3 Workers in a machine shop, where tools are constantly being degreased, have been complaining that, away from work, their friends and families are telling them that they are confused about identifying colors. Could there be some validity to their complaints? How would you test them?

38.4 The Food Quality Protection Act of 1996 is a product of growing concern over vulnerability of children to environmental chemicals. What components of a neuropsychological test battery might be used to evaluate whether children living in a community located near a waste dump might be suffering adverse neurobehavioral effects?

KEYWORDS

Behavior, Operant conditioning, Respondent conditioning, Motor function, Sensory function, Learning, Memory, Attention, Schedule-controlled behavior, Screening batteries, Stimulus properties of chemicals

39 Organelles as Tools in Toxicology
In Vitro and In Vivo Approaches

Bruce A. Fowler, Joseph R. Landolph, Jr., Kathleen Sullivan, and A. Wallace Hayes

CONTENTS

INTRODUCTION

As the interdisciplinary science of cell biology has evolved, it has become clear that not only are cells composed of discrete organelle systems that carry out essential functions for cellular survival but also these organelle systems interact with each other in a cooperative manner. Toxic chemicals that preferentially damage specific organelle systems may also damage cellular homeostasis and viability in a secondary manner by disrupting the relationships between intracellular organelle systems, thus further exacerbating cell injury processes leading to cell death or neoplastic transformation. Prior versions of this chapter[1] have focused on chemical toxicity to major target organelles and available methods for measuring these events. The present chapter takes a more *organelle systems toxicology* approach and, wherever possible, also examines chemically induced disruption of physical and functional relationships that must exist between organelle systems for maintaining homeostasis and that are disrupted by chemically induced toxicity and contribute to processes of cell injury and cell death. Data from both in vivo and in vitro studies will be considered in an effort to show how inclusion of an integrated organelle systems approach adds further insights into understanding basic mechanisms of cell injury/cell death and the central role of organelles in these processes. It is also important to note the recent appreciation from cell biology studies that organelles such as mitochondria are not only physically dynamic on an individual basis to divide and fuse but also appear to move about in the cytoplasm of the cell, suggesting a more macrointernal dynamic organization that contributes to interorganelle cooperation. Disruption of interorganelle cooperation during the initiation of toxic cell injury undoubtedly contributes to subsequent deleterious events ultimately resulting in cellular demise or neoplastic cell transformation. Understanding these phenomena is a complex task, but fortunately the advent of computer-assisted models[2,3] should help to better document and appreciate the dynamic nature of the subcellular organization and interorganelle interactions.

IN VITRO AND IN VIVO TEST SYSTEMS: GENERAL CONSIDERATIONS

It is important to consider the source and state of cells from which organelles are evaluated. Factors such as the composition of cellular growth medium for in vitro studies and nutritional status, age, and gender for in vivo studies need to be considered and documented, since these factors may influence the responses of intracellular organelles and systems regulating those organelles to insults from toxic chemicals.

In Vitro Systems

There are many commercial cell culture systems available to investigators, and it is important to consider constituents in the cell medium for chemical exposures. For example, responses to chemical exposures in media containing fetal calf serum versus media containing only basic salts may be very different due to differences in cellular uptake of the chemical under study.

In Vivo Systems

Similarly, responses of animals on semipurified diets to chemicals may be very different to those on general laboratory animal chow, due to differences in chemical uptake and the potential presence of contaminating chemicals, antibiotics, and excess nutrients in the general laboratory chow that may vary from batch to batch. The degree to which such dietary differences may impact cellular responses to toxic chemicals will depend on a number of factors, such as experimental design and study endpoints. Similar cautions should be made concerning strain, age, and gender of the animals from which organelles are derived. As with any experiment, the parameters of study should be specified in the greatest detail possible since these differences may impact organelle responsiveness.

INTRACELLULAR ORGANELLES

Cell Membranes

In order for toxic agents to produce intracellular toxicity, they must be transported across the cell membrane that is a dynamic structure whose characteristics vary with cell type. This organelle is not a static structure but plays an important role in the transport of toxic agents. For example, methylmercury by amino acid transporters,[4] lead by pinocytosis following external membrane surface coat binding,[5] and endocytic vesicular uptake of protein/ligand-bound toxic molecules such as cadmium bound to metallothionein or incorporated into nanomaterials[6] are common mechanisms of uptake and lead to intracellular accumulation of toxic agents. It is important to note that the cell membrane itself is not an inert organelle and may itself become a target for chemical exposures to agents such as glyphosate[7] and phospholipase A_2[8] that disrupt cell membrane permeability and hence cellular ability to regulate both essential and nonessential chemical entities leading to cell injury and cell death. Techniques for assessing alterations in cell membrane integrity include transendothelial monolayer electrical resistance (TER)[8,9] and dextran Transwell permeability assay[8,10] (please see the following). Acute exposure to agents such as mercury ion[11] and chromate (Cr^{6+})[12] appears to damage directly this organelle via oxidation of essential membrane proteins and other types of molecules.[13,14] The point to this discussion is that the cell membrane is a dynamic organelle that plays a number of essential roles in maintaining the viability of the cell by regulating the uptake of both essential and toxic chemical entities. Disruption of this organelle by chemical toxicity can lead to cell death by a number of mechanisms including altered maintenance of electrolyte balance, uptake of essential molecules, reduced excretion of metabolites, and activation of the FAS receptor, leading to induction of the caspase system and cell death via apoptosis.[14–17]

Selected Techniques

TER is a summary adaptation from Garcia et al.[10] The reader is referred to this primary reference for further details:

1. Artery endothelial cells (ECs) are grown to confluency in standard EC growth media at 37°C and in a 5% CO_2 atmosphere.
2. Gold counter electrodes (1 cm^2) are attached to a phase lock-in amplifier.
3. TER is measured with an electrical cell–substrate impedance sensing system from Applied Biophysics Inc., Troy, New York.
4. A current is applied across the electrode by a 4000 Hz ac voltage source (AMP 1 V, 1 M Ω, 1 μA).
5. Measurements are conducted for 30 min.
6. Increased TER is observed if cells spread out across the electrodes and reach a maximal value at confluence.
7. If the cells round up, lose attachment, or contract, there is a loss of TER.
8. Values of TER are pooled at regular intervals and plotted against time.

Dextran Transwell permeability assay is a summary adaptation from Dudek et al.[9] The reader is referred to this primary reference for further details:

1. ECs are grown to confluence under standard conditions as described previously on confluent polycarbonate filters—vascular permeability assay kit from Millipore (Billerica, MA).
2. Cells are exposed to the agent of interest for 1 h.
3. FITC-labeled dextran (60 kDa) is loaded into the luminal compartment of the kit Transwell inserts for 2 h.
4. The movement of labeled dextran across the filter to the external compartment is monitored by relative fluorescence (485 nm) excitation/530 nm emission and data reported as arbitrary FUs.

Mitochondria

Ultrastructural Techniques

The various ultrastructural techniques for evaluating mitochondria have been described in the fifth edition of this book[1] to which the reader is referred for details.

Biochemical Procedures

In recent years, there have been a number of advances to the biochemical procedures described in the fifth edition of this book,[1] including high-throughput automation and computer analyses of combined metabolic measurements of mitochondrial function, which link mitochondrial respiration[18] with glycolytic parameters (Seahorse Biologicals). In addition, great progress has been made in understanding the roles of mitochondria in apoptosis, as discussed in the following.

Combined Metabolic Measurements

Seahorse Biochemicals[19] applied this technology for screening a number of inhibitors of mitochondrial respiration in relation to nephrotoxic potential.

High-Throughput Mitochondrial Toxicity Screening with Fluorescent Probes

High-throughput mitochondrial toxicity has also been evaluated by the use of fluorescence probes (A65N-1)[11] and high-throughput 96-well plates with automated fluorescent plate reading systems, which compared favorably with conventional polarographic techniques. Altered mitochondrial respiratory function rates[20] including respiratory control[21] are important elements in mitochondrial generation of reactive oxygen species (ROS) from damage to essential components of the mitochondrial respirome complexes, such as cytochrome *c* oxidase[22] that may further damage other cellular components and exacerbate cell death processes[21] as discussed in the following. The central roles of mitochondria as generators of ROS and the regulatory roles of ROS in guiding redox-regulated cellular signaling processes[22–24] and cross talk with other intracellular sources of ROS, such as the NADPH oxidases, have only recently been appreciated. The implications of the understanding of these complex systems are obvious from the perspective of mechanistic toxicology and highlight the need to revisit reductionistic molecular data in a broader context.

Mitochondria and Programmed Cell Death (Apoptosis)

One of the major outcomes of mitochondrial toxicity is the central role this organelle plays in triggering the apoptotic response. Studies by Jeong and Seol[25] have highlighted the central role of regulating intracellular calcium (Ca^{2+}) in relation to Ca^{2+} signaling and the roles of the apoptotic regulatory proteins in the Bcl-2 protein family in regulating the dynamic Ca^{2+} relationships between mitochondria and the endoplasmic reticulum (ER). In addition, these authors noted the importance of mitochondrial morphology in relation to mitochondrial fission and numbers of mitochondria in the development of the apoptotic response. Studies by Chacko et al.[26] have shown that the outer mitochondrial membrane voltage-dependent channel-1 (VDAC-1) plays a major role in regulating the TRAIL-mediated apoptosis via control of mitochondrial caspase-8 activation. Martel et al.[27] studied fatty liver disease in ob/ob mice fed high-fat diets and reported altered outer mitochondrial membrane permeability, posttranslational modification of VDAC, and alteration of NADH oxidase as early mitochondrial effects leading to a number of alterations in mitochondrial functions, including phosphorylation of VDAC by GSK3. The level of VDAC phosphorylation correlated with the severity of steatosis in patients. The authors conclude that VDAC can act as an early marker for lipid toxicity, since its phosphorylation

status controls the permeability of the outer mitochondrial membrane. Kavanagh et al.[28] reported that control of the actin cytoskeleton dynamics by the $p57^{KIP2}$ protein played a major role in the proapoptotic effect on the mitochondria. Bhattacharyya et al.[29] also studied hepatocytes and reported iron induction of hepatocyte death by MAPK activation and a mitochondria-dependent apoptotic pathway, which was attenuated by addition of glycine to the cell culture medium. Hussain et al.[30] demonstrated that cerium dioxide nanoparticles induced apoptosis and autophagy in human peripheral blood monocytes with hallmark effects on BAX, loss of mitochondrial membrane potential, and DNA fragmentation. Other recent studies by McGill et al.[31] on acetaminophen liver toxicity in mice and humans showed that this drug produced both mitochondrial damage and nuclear DNA fragmentation without increases in serum caspase-3 or cleaved caspase-3 activities but that these activities were elevated in TNF-induced apoptosis. These data suggested that although APAP produced liver toxicity including mitochondrial damage and DNA fragmentation, cell death in humans was most likely by mechanisms involving necrosis. The involvement of other caspases in this model was not evaluated.

Mitochondrial Fission and Fusion Processes in Cell Injury

In recent years, there has been a growing appreciation of the importance of mitochondrial fission and fusion processes and the molecular signaling pathways regulating these physical changes as well as mitochondrial motility in mediating cell injury and mitochondria-based diseases. Indeed, from the perspective of toxicology, swollen and pleiomorphic mitochondria have been noted in liver cells of mice exposed to arsenic in drinking water[32] (Figures 39.1 and 39.2) and ethanol-fed rats.[33] Mitochondrial motility has recently been evaluated in living vascular ECs[34] and associated with mitochondrial fission and linked to mitochondrial bioenergetics. Taken together, these studies provide further support for the intrinsic linkage between dynamic changes in mitochondrial structure and biochemical function following chemical exposures.

Studies in neuronal cell systems have highlighted differences in swelling responsiveness in mitochondria from astrocytes and cortical neuronal cells in culture in situ[35] using optimized spatial filtering of mitochondrial fluorescence to assess changes in membranes as a function of swelling, fission, or fusion. This technique generates a *thinness ratio* (TR) for the mitochondrial membrane fluorescence in which measurements were sensitive to mitochondrial swelling but not fission or fusion of mitochondria. The technique demonstrated marked differences in mitochondrial swelling during uncoupling between astrocytes and neuronal cells. The balance between mitochondrial fission and fusion appears to be an important factor in defining a new mechanism of neurodegeneration from a variety of insults related to Alzheimer's disease, Huntington's disease, and stroke.[36] Studies point to the role of dynamin-related GTPases and the protein Drp1

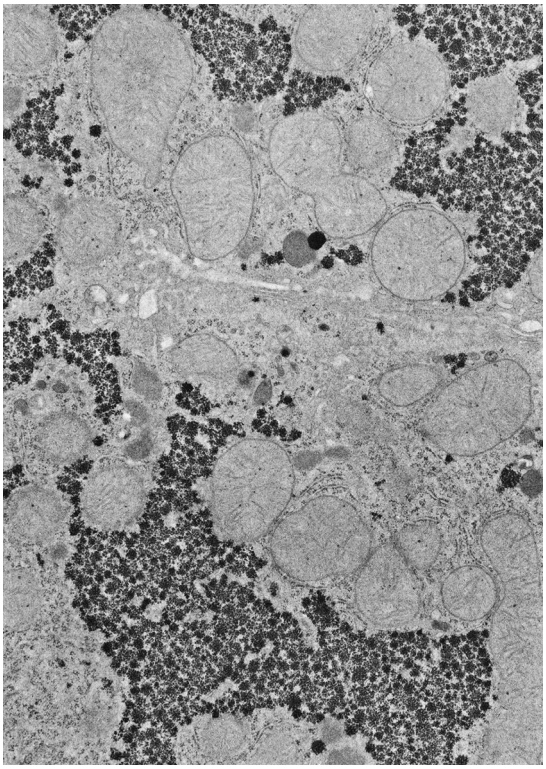

FIGURE 39.1 Hepatocyte from a mouse given the 40 ppm arsenate dose level showing swollen mitochondria. (From Fowler, B.A. and Woods, J.S., *Toxicol. Appl. Pharmacol*., 50, 177, 1979.)

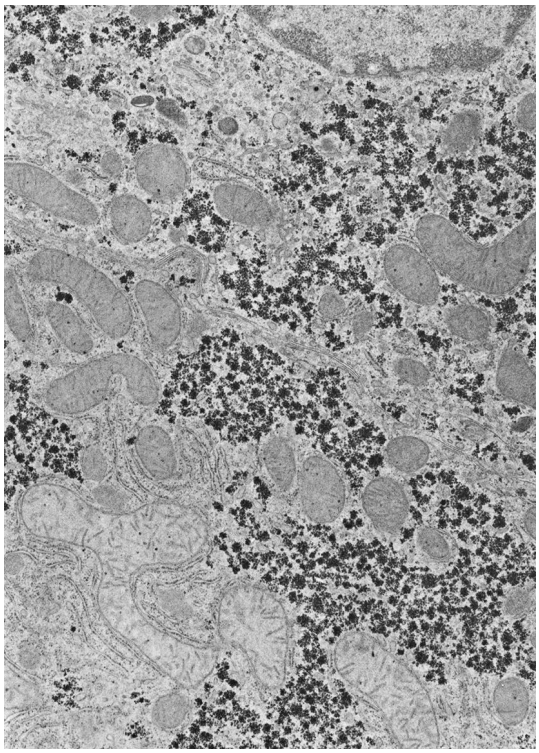

FIGURE 39.2 Hepatocyte from a mouse given the 85 ppm arsenate dose level showing mitochondria with normal appearance and swollen polymorphic mitochondria. (From Fowler, B.A. and Woods, J.S., *Toxicol. Appl. Pharmacol*., 50, 177, 1979.)

in particular in mediating mitochondrial fission processes. In neuronal cells, Drp1 appears to be positively regulated by Bcl-xL to affect mitochondrial function with regard to formation of synapses.[37] Other work[38] has demonstrated that Drp1 activity could be increased by the binding of a mutant Huntington protein resulting in increased mitochondrial fragmentation, altered mitochondrial transport processes, and neuronal cell death. By studying inhibition of mitochondrial energy production associated with fragmentation, the physical structure of mitochondria has been demonstrated to increase formation of ROS and lead to cell death of neuronal cells by an NMDA/ROS-dependent pathway.[39] The release of proapoptotic factors such as cytochrome *c* from physically altered mitochondria[40] may result in the triggering of the caspase cascade, resulting in apoptotic cell death.[41–43]

From the previous discussion, it is clear that the mitochondria are dynamic organelles, both structurally and biochemically, that perform a number of functions for the cell that are highly sensitive to perturbations by chemical agents. The consequences of these disturbances may be profound on many levels and may ultimately lead to cell death via apoptosis.

Biochemical Procedures

There are a number of new biochemical assays for evaluating the biological activities of mitochondria.

In Situ Swelling and Contraction Assays

This biophysical procedure is a summary adaptation from Gerencser et al.[35] and the reader is referred to this chapter for in-depth details:

1. Rat neuronal astrocyte and neurons are placed in cell culture on cover slips under standard culture conditions.
2. Time-lapse fluorescence microscopy is conducted on astrocyte and neuronal cell cultures in a medium containing 5.4 mM KCl, 150 mM NaCl, 1 mM $MgCl_2$, 1.8 mM $CaCl_2$, 0.9 mM NaH_2PO_4, and 5.6 mM glucose in a 20 mM HEPES buffer (pH 7.4) at 37°C.
3. Astrocytes are evaluated using a Nikon Diaphot 200 inverted microscope with a 75 W xenon arc lamp. This basic system is augmented with a 535/20 exciter, 570LP emitter, and a 560LP dichroic mirror. Photographs are taken with a cooled digital camera operated by MetaFluor 3.5 software from Molecular Devices, Downingtown, PA.
4. Primary neuronal cultures are evaluated using a laser scanning confocal microscope and studies conducted with the 543 line of a 5 mW HeNe laser at <7% power fitted with an HFT 488/543 dichroic mirror and 560LP emission filter.
5. Studies on mixed neuronal cultures are conducted using an inverted microscope with a lambda LS Xe arc light source (175 W and ND of 0.3).
6. Data are collected using a cooled digital CCD camera.
7. Z-stacks of seven planes with 0.8 μM spacing are recorded at 1 min intervals and time points of 0, 5, and 90 min.
8. The studies are conducted with the entire microscope stage at 37°C in an air environment. Acquisition of images is managed by a computer program (MetaMorph 6.3 from Molecular Devices).
9. The TR is calculated as the ratio of average fluorescence intensities for organelle regions from HBP-filtered images and LBP-filtered images.

Lysosome/Proteasome Systems

As with other intracellular systems, a better understanding of lysosome structure and function has emerged over the last decade and is now expanded to include the concept of the proteasome, which involves tagging of damaged or dysfunctional proteins by ubiquitin for degradation and recycling of amino acids in autophagosomes. There is growing evidence that autophagosomes have some unique functional properties and may produce constitutive ROS that exacerbate oxidative stress-mediated cell injury.[44,45] Studies by Dogra and Mukhopadhyay[46] have shown that the drug methyl *N*-(phenyl sulfanyl-1H-benzimidazol-2-YI) carbamate produces a marked inhibition of the ubiquitin–proteasome pathway, which can produce a strong inhibitory effect on cancer cells in vitro. The cell killing effect was associated with induction of stress on the ER, decreased mitochondrial membrane potential, increased formation of ROS, release of cytochrome *c*, and death of the cells by apoptosis. Other recent studies by Ivanova et al.[47] demonstrated apparent lysosomal destabilization in Caco-2 cells by the mycotoxin enniatin B, resulting in cell death by a nonapoptotic cell death pathway that occurred prior to cell cycle arrest in the G2/M phase and attendant increased production of ROS and development of apoptosis or necrosis.

The biogenesis, cargo selectivity, and directional movement of autophagosomes are also highly regulated by intracellular signals and the ubiquitin tagging of targets. The movement of autophagosomes within the cell may be driven by the motor protein dynein[48] and directionally controlled by the cellular cytoskeletal components of microtubules and F-actin.[49]

As with the other organelles discussed in this chapter, lysosomes play a number of roles in normal biology of the cell but may also become intracellular targets for toxicity by accumulating toxic materials, damaged organelles via autophagocytosis, and generation of ROS during degradative processing of deposited materials by lysosomal proteases. Inhibition of lysosomal function by agents such as cadmium[6] can have profound physiological consequences due to altered intracellular processing of proteins.

Ultrastructural Techniques

The ultrastructural techniques used to visualize and quantify lysosomes in situ have been extensively described in the 5th edition of this book.[1] The reader is referred to this source for details.

Measurement of ER Stress and ROS Activity

The following methods are adapted and summarized from Dogra and Mukhopadhyay[46] and the reader is referred to this primary publication for further details.

Measurement of ER Stress Using the Secreted Alkaline Phosphatase Assay Method

1. For these studies, 293 T cells are placed in 96-well plates and transfected 1 day later with pSEAP-con-plasmid obtained from Clontech (Palo Alto, California). This plasmid constitutively expresses secreted alkaline phosphatase (SEAP).
2. At 24 h posttransfection, cells are either left unexposed or treated with the chemicals of interest in fresh media containing 1% fetal bovine serum.
3. After 24 h, 10 μL of the culture media is extracted and incubated with 4-MUP as the substrate according to the Clontech protocol.
4. This protocol involves mixing 10 μL of culture media with 15 μL of 5× SEAP assay buffer containing 0.5 M Tris at pH 9.0 containing 0.5% bovine serum albumin (BSA) in a final volume of 50 μL in a 96-well plate and incubated for 30 min at 65°C to inactivate endogenous SEAP.
5. The plate is placed on ice for 2 min and then 25 μL of 1 mM 4-methylumbelliferyl phosphate substrate is added to each well.
6. The assay mixture is incubated for 2 h at 37°C and SEAP activity is monitored using a PE-fluorescent plate reader with excitation at 355 nm and emission at 460 nm.
7. Analyses are conducted in triplicate.

ROS Activity

1. A549 cells are grown on cover slips in 35 mm culture dishes and exposed to the chemical of interest, or 10 μM MG132 for 4 h with NAC added 2 h prior to addition of the chemical of interest.
2. In measurement of ROS after incubation, the cells are washed and incubated with 1 μM dichlorofluorescein-DA at 37°C for 1 h in serum-free media without phenol red dye.
3. The cells are washed twice and then illuminated with a 100 W mercury lamp for viewing with a Nikon fluorescent microscope with a FITC filter or using a PE fluorimeter with excitation at 485 nm and emission at 530 nm for quantitative studies.

Endoplasmic Reticulum

Ultrastructural Techniques

Visualization of the ER of both rough (RER) and smooth (SER) ER by electron microscopy including ultrastructural morphometry[50] has been extensively described in the fifth edition of this volume. Only a few recent publications related to toxicology are described here.[51–53] Ultrastructural alterations of the ER in hepatocytes in animals or cell cultures exposed to carcinogens[51] and pancreatic cells[52] from animals treated with ethanol have demonstrated similar structural changes with regard to degranulation/fragmentation of the RER, proliferation of SER, and dilation of ER membranes. Similar effects have also been reported for acridine cholinesterase inhibitors following in vitro exposures. It is important to note that these structural changes in the ER are commonly associated with alterations in biochemical functions such as those described in the following.

Biochemical Procedures for Phase I and Phase II Microsomal Metabolism

A number of new assays and biochemical procedures have been developed in recent years that have helped to further elucidate the intimate relationships between the structure of the ER and various aspects of biochemical functionality, including Phase I cytochrome P-450-based enzymatic processes, Phase II conjugation/deconjugation enzymatic reactions, and more recently the roles of acid hydrolase proteasomal degradation of ubiquitin-tagged proteins.

Preparation of Human Liver Microsomes

The separation of SER- and RER-enriched membrane fractions by differential centrifugation techniques has been previously described in the fifth edition of this book,[1] and the reader is referred there for details.

Microsomal Activation/Deactivation Systems

Microsomal Flavin-Containing Monooxygenases

Microsomal Cytochrome P-450

There is an extensive literature[54–57] on chemical-induced effects on the activities of cytochrome P-450 monooxygenases that is outside the scope of this chapter, but this literature is reviewed in an article by Guengerich[58] as described in the following.

P-450-dependent (Phase I) enzymes[58] have been demonstrated over the last 50 years to play a number of important roles in chemical toxicology, including both the bioactivation of organic molecules to more toxic chemical species and the detoxification of organic molecules into less toxic chemical species. As noted by Guengerich,[58] there is still much to be learned about this important cellular metabolic system, including characterization of *orphan* cytochrome P-450s, kinetics, animal–human extrapolations, and other aspects of these molecules related to chemical toxicity risk assessments and development of cancer. In this regard, Mohutsky et al.[54] discuss the issue of induction of hepatic drug-metabolizing enzymes in relation to preclinical and clinical risk assessments. This aspect of the cytochrome P-450s is clearly important for preventing interactions between drugs where more than one drug is being administered in a clinical setting,

which is often the case. There are a number of approaches to dealing with this issue from a risk management perspective, including altered dose levels of the drugs involved, dose timing, consideration of the age, gender, genotyping of the patient, and discontinuation of one of the drugs. The situation is complex but not without promise as we move toward more personalized medical treatments.

Evaluating Microsomal Function

Microsomal Conjugative Enzymes

In addition to the cytochrome P-450 enzyme activities associated with the ER, there are a number of linked conjugating enzyme activities that deal with reactive metabolites from cytochrome P-450 action for excretion. These enzyme functions have been studied in a wide variety of toxicology studies.[59–61]

Phase II Enzyme Systems

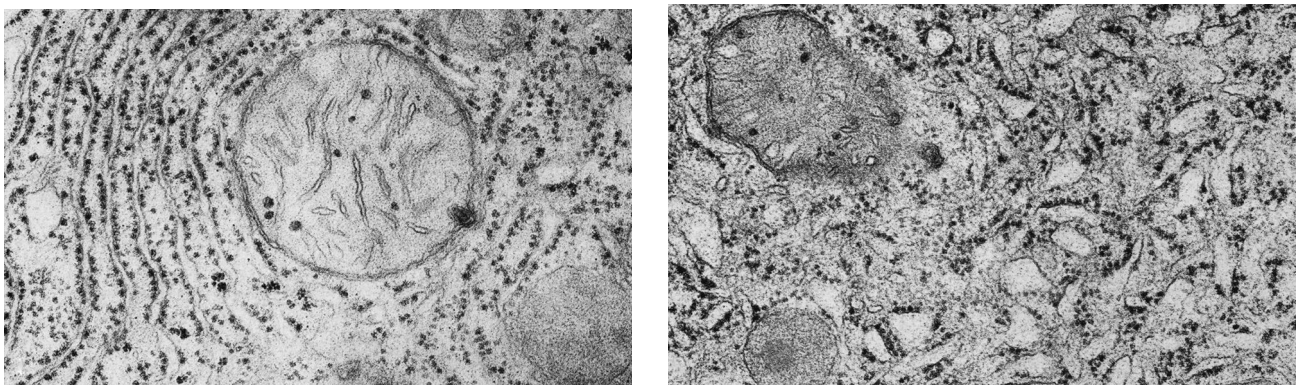
The presence of conjugation/deconjugation enzymes in the ER that further metabolize products of Phase I metabolism so they can be more readily excreted has been appreciated for many years (see fifth edition[1] for discussion).

These include a number of conjugating enzymes like glucuronyl transferase but also hydrolytic enzymes, such as acid phosphatase, beta glucuronidase, and sulfatases, and a number of proteases such as the cathepsins. In recent years, a great deal of interest has been focused on the roles of ER-based proteases, known collectively as the proteasome, and lysosomes in the recycling of amino acids from damaged proteins as part of both normal protein turnover and the impact of chemically induced cell death pathways on these processes. Proteasome degradation of ubiquitin-tagged proteins has been a major focus. It is important to note that damaged ER proteins can also be dislocated from the ER membranes into the cytosol[62] for degradation by the proteasomes and visualized by live cell imaging techniques. The mechanisms by which proteins move to and from the ER are highly complex with a number of specific chemical (cholesterol content) and molecular factors, such as chaperone proteins and dibasic amino acid regions of transported protein involved.[63–65]

As with the other organelles discussed in this chapter, there is an ever-increasing understanding of the dynamic nature and complexity of functions performed by this organelle system, both directly and in concert with other organelles, such as the mitochondria and cellular proteasome/lysosome systems. It should be noted that a close physical relationship is frequently observed between the ER and organelles, such as the mitochondria (Figure 39.3), which would facilitate transport of essential metabolic products, such as heme, produced by the mitochondria for incorporation into ER hemoproteins such as cytochrome P-450 and proteins/enzymes synthesized by the ER and chaperoned into the mitochondria. Chemically induced disruption of these physical linkages between the ER and organelles such as the mitochondria (Figure 39.3) has profound and differential consequences on biochemical functions in these organelle systems.[50]

Peroxisomes

The peroxisomes are single-membrane-bound organelles that have been studied by electron microscopy and are known to contain catalase, D-amino acid oxidases, and lipid oxidases. The morphology of these organelles varies by animal species, and a crystalline structure is sometimes observed in peroxisomes of some species. In recent years, induction of peroxisomes via the peroxisome proliferator pathway receptor (PPAR) has been linked to the development of certain types of cancers. Hence, there is extensive scientific interest in the biological function of these organelles in mediating carcinogenic processes. Kudo et al.[66] demonstrated that peroxisome proliferation in livers of mice fed 8–2 telomer alcohol produced peroxisome proliferation in a dose- and time-dependent manner, which was associated with perfluorooctanoic acid (PFOA), a metabolite of 8–2 telomer alcohol. The authors conclude that the metabolite PFOA is responsible for the observed peroxisomal proliferation effects in mice from 8–2 telomer alcohol exposure. Other studies[67] have demonstrated that the peroxisome proliferator-activated



(a) (b)

FIGURE 39.3 Higher magnification of hepatocyte from control rat (a) and indium-injected rat (b) (40 mg/kg) after 16 h showing fragmentation and dilation of ER with loss of ribosomes into cytoplasm. (From Fowler, B.A. et al., *Lab Invest*., 48, 471, 1983.)

receptor (PPAR) in mucosal cells can be regulated in part by a CCAAT/enhancer-binding protein homologous protein (CHOP) under cellular translational stress. CHOP was shown to have increased expression and nuclear translocation in human intestinal epithelial cells following exposure to ribotoxic agents such as deoxynivalenol and anisomycin. CHOP is a positive regulator of IL-8, but this effect was inversely related to expression of the PPARy. PPARy is a negative regulator of IL-8 mRNA, which is in turn linked to the mRNA protein HuR. CHOP is a positive regulator of HuR protein translocation from nuclei. The overall conclusion is that functional interrelationships between CHOP and PPARy may be important mechanistic linkages between ribosomal toxic stresses and proinflammatory production of cytokines such as IL-8.

The metabolic activity of the peroxisomes generates ROS[68] in relation to lipotoxicity, but the presence of catalase in this organelle also suggests that it may play a role in protecting the cellular processes from ROS damage as well. On the other hand, peroxisomes are also known to be generators of ROS, which are presumably usually neutralized by the action of catalase. However, this balance may be altered by exposure to some chemicals or drugs. The proliferation of peroxisomes in cells has been linked to the development of certain kinds of cancer.

The role of peroxisomes in mediating chemical toxicity and carcinogenicity is a currently active area of research.[68–70]

Fluorescent Hydrogen Peroxide-Sensitive Proteins

Application of HyPer proteins[69] for analysis of H_2O_2 generation from peroxisomes and mitochondria is a relatively new approach[68] for localizing H_2O_2 generation in an organelle-specific manner and involves some interesting molecular biology approaches. The following is a summary adaptation of the methods from Elsner et al.[68] for this purpose. The reader is referred to this primary reference for further details:

1. HyPer vector cloning is conducted using the cDNA for the H_2O_2-sensitive protein (HyPer protein–pHyPer-dMito obtained from Evrogen, Moscow, Russia). The cDNA is subcloned into a viral transfer plasmid (pLenti6/V5-MCS obtained from Invitrogen). The cDNA is excised from the pHyPer-dMito plasmid using the NheI and NotI restriction sites. The cDNA is then blunted and ligated into the EcoRv site of the pLenti6/V5 protein. In order to construct expression vector for the HyPer-peroxisome protein, PTS1 is connected to the 3′ end of the HyPer cDNA via a polymerase chain reaction (PCR) using a composite primers as expression of the HyPer-peroxisome proteins is conducted as previously reported[68] by transfecting lentivirus particles and harvesting the virus particles by ultracentrifugation for 2 h at 70,000 ×*g*. Virus titers are confirmed via TaqMan qPCR as specified in reference[68] and the pHyPer-dCyto plasmid as a template. The HyPer-peroxisome cDNA is subcloned in the Xbal/Bsp site of the plasmid pLenti6/V5-MCS.
2. Rat primary tissue culture cells are infected with lentivirus using an MOI of 10:1. The cells are selected for expression of the HyPer proteins using blasticidin at 1 μmol/L.
3. HyPer protein analysis of intracellular hydrogen peroxide generation is conducted using RINm5F cells, or primary rat cells that overexpress the HyPer are seeded onto black 24-well glass-bottom plates (Greiner, Frickenhausen, Germany).
4. The cells are cultured for 24 h and then exposed to palmitic acid for an additional 24 h.
5. Live cells are imaged using an inverted microscope fitted with a CFP–YFP dual filter with excitation bands at 427 and 504 nm and an emission band at 520 nm.
6. The microscope is fitted with CellR software for analytical imaging.
7. H_2O_2 production is measured via changes in the fluorescence ratios of the RINm5F, RINm5F-Cr, RIMm5FMitoCat, and INS-1E cells that overexpress the HyPer proteins and are quantified with a spectrofluorimeter. The fluorescence ratios are measured before and after treatment with palmitic acid or the chemical/drug of interest for 24 h.

Nuclei

The nuclear compartment of the cell is a primary repository of the cellular genome. In addition, it performs a number functions for the cell and as such may become an intracellular target for toxicity. This organelle may also show dynamic changes in size and shape, such as the formation of giant nuclei in response to agents such as ectoposide,[71] which was associated with G2/M arrest and severe DNA damage. In addition, these organelles may become intracellular storage sites for aggregated or damaged proteins such as amyloid fibrils[72] and intranuclear inclusion bodies from lead (Figure 39.4),[73] bismuth,[74] and mercury–selenium-containing complexes (Figure 39.5a and 39.5b),[75] which are formed as metal–protein structures. An important point is that nuclei as structures can be target organelles for chemical toxicity. Like the other organelles discussed previously, they play a number of dynamic roles in the biology of the cell, including acting not only as repositories for genetic materials and physical sites of DNA replication but also as dynamic intracellular storage sites for drugs, metals, and damaged proteins.

Recently, using live cell imaging techniques, transient ruptures of the nuclear envelope have been reported in human cancer cells during interphase.[76] The observed biological/structural consequences of these effects were incorrect localization of nuclear and cytoplasmic proteins. Formation of micronuclei-like structures and loss of chromatin material from the nuclei was observed and incorrect formation of intermediate support filaments in the nuclei. The overall effect of these physical changes would be an alteration of the cancer cell genomic structure, which could impact the behavior of the cancer cells.

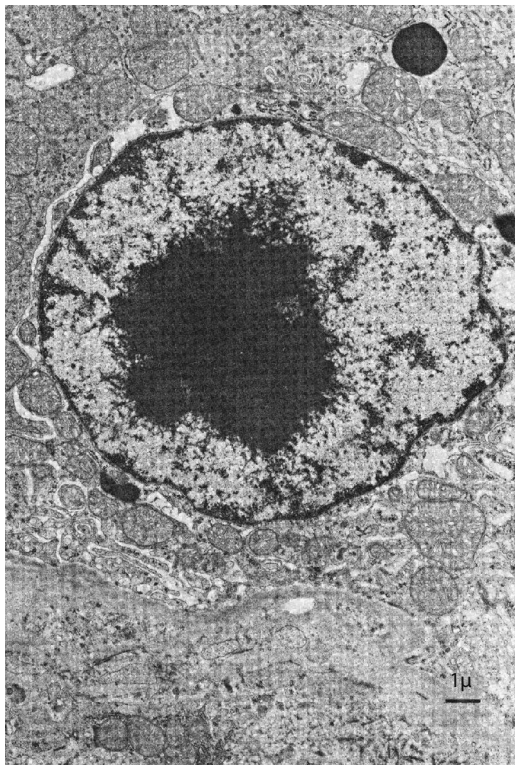


FIGURE 39.4 Proximal tubule cell from a rat exposed to lead in drinking water, showing large intranuclear inclusion body. (From Fowler, B.A., Ultrastructural and biochemical localization of organelle damage from nephrotoxic agents, in Porter, G.A., ed., *Nephrotoxic Mechanisms: Drugs and Environmental Toxins*, Plenum Press, New York, 1982, pp. 315–330.)

Increasingly, sophisticated approaches have evolved in recent (e.g., postgenomic) years for tracking altered genomic elements,[77] including automated image modeling approaches for the subsequent subcellular localization patterns of gene products[78] or sophisticated proteomic techniques[79] and statistical evaluation using image analysis databases.[80] The point is to highlight the ever-increasing sophistication and integration of scientific approaches, including bioinformatics, to generate more holistic answers to complex scientific problems. The application of these approaches for addressing pressing toxicological issues and translating information for risk assessment purposes is now a major area of focus in the toxicology community.

Cytoplasm

The cytoplasm is the overall milieu in which the various organelle systems reside, but it also is a dynamic compartment that is the site of numerous molecular functions and processes. From the perspective of toxicology, localization of antioxidant cellular defense systems, such as reduced glutathione (GSH), which is inducible and usually present in millimolar concentrations, is an important feature in preventing ROS-induced cell injury. For toxic metals such as cadmium (Cd), inducible metal-binding proteins such as metallothionein (MT) have been shown to play a central role in the biological transport, cellular uptake, and toxicity of the element. A global conceptual diagram is presented that attempts to link some known aspects of MT handling of Cd with possible linkages to mechanisms of cell death via apoptotic pathways. This framework may be particularly useful in helping to explain some of the low-dose effects of Cd in target cell populations

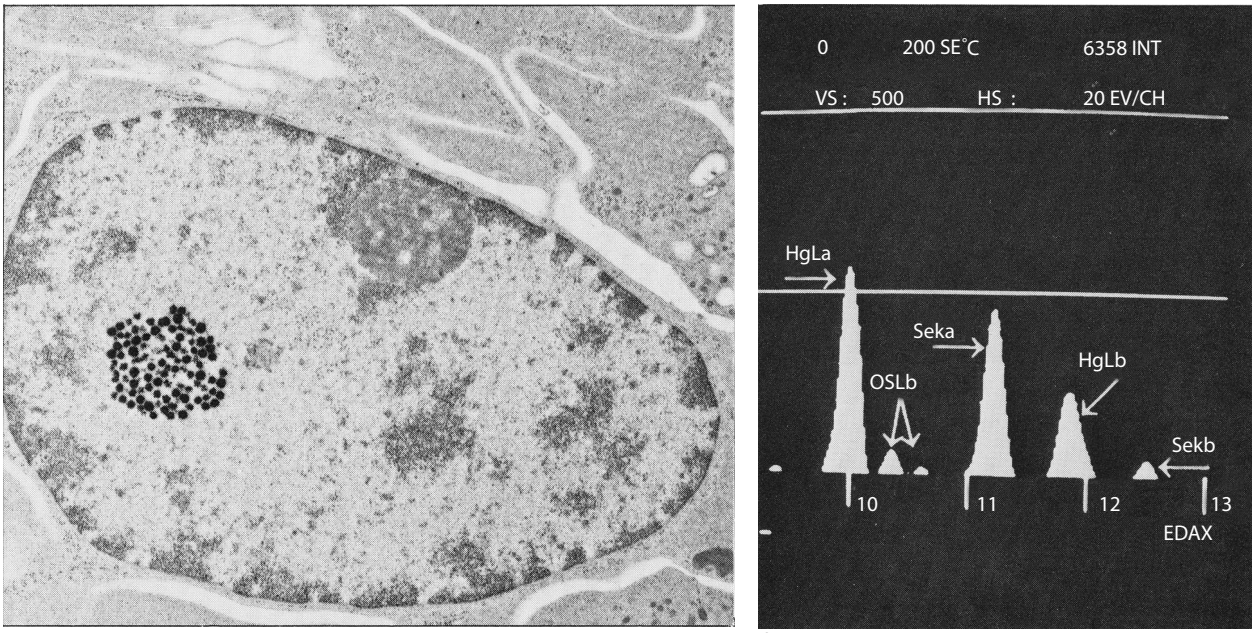

FIGURE 39.5 (a) Electron micrograph of nuclear inclusion in a proximal tubule of a rat following $HgCl_2$ and Na_2SeO_4 treatment. (b) Energy dispersive x-ray microanalysis spectrum of inclusion similar to (a). Peaks visible are HgLα, OsLα, and SeKα. (From Carmichael, N.G. and Fowler, B.A., *J. Environ. Pathol. Toxicol.*, 3, 399, 1980.)

with apparently limited metallothionein synthesis capabilities, such as ECs of the blood vasculature.[81–83] It may also be helpful in understanding the effects of low-dose Cd exposure on multiple cell types in relation to the roles of Cd in the aging process.[82] The importance of MT as a protective regulatory molecule, which is largely localized in the cytosol, is not to be underestimated. Other protective proteins, which are largely localized in the cytosol, are able to enter or be present inside the subcellular organelles, such as the stress or (HSP) proteins. They play a number of roles in mediating cell injury/cell death, chaperoning newly synthesized proteins into organelles such as the mitochondria and peroxisomes, and refolding or transporting damaged proteins to the proteasome/lysosome system for degradation or transport out of the cell (Figure 39.6).[84] Ubiquitin tagging of proteins for proteasomal degradation is a particular aspect of this general phenomenon.

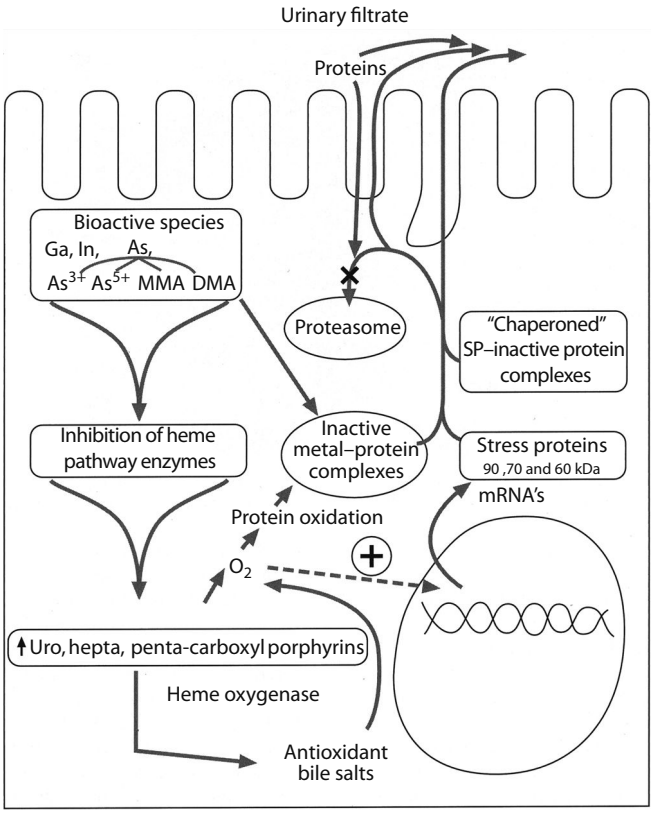

FIGURE 39.6 The hypothesized mechanisms by which GaAs and InAs produce cell injury in renal proximal tubule cells are shown in relation to alterations in the heme biosynthetic pathway and proteotoxicity and proteinuria. These findings are shown in relation to the stress protein response and the hypothesized decrease in chaperoning of reabsorbed proteins from the urinary filtrate for proteasomic degradation and export of damaged intracellular proteins into the urinary filtrate to produce the observed GaAs- and InAs-specific proteinuria patterns. The magnitude of the tubular proteinuria may be due to decreased reabsorption of filtered proteins, but the observed specificity may be the result of damaged intracellular proteins chaperoned out of the tubule cells at the apical membrane surface perhaps by ubiquitin. (From Fowler, B.A. et al., *Toxicol. Appl. Pharmacol.*, 206, 121, 2005.)

The cytosolic compartment plays an important and dynamic role in mediating fundamental processes of chemical toxicity. A full, detailed discussion of these functions is beyond the scope of this chapter. However, it can be anticipated that as tools of modern toxicology evolve, a better understanding of the complex pathway from chemical insult at the cellular level to overt cell death will continue to emerge.

Alterations in the Cytoskeleton during Chemically Induced Cytotoxicity to and Morphological and Neoplastic Cell Transformation of Mammalian Cells

The development of antibodies to cytoskeletal components, which are conjugated to fluorophores, now allows investigators to visualize cytoskeletal components of mammalian cells. Specifically, microtubules can now easily be decorated and visualized by staining cells with antibodies to α-tubulin or to β-tubulin, which are then conjugated to fluorescein isothiocyanate, and then visualizing the cells by confocal microscopy. In this manner, one can visualize disruption of microtubules when cells are treated with various toxic or carcinogenic chemicals that disrupt microtubules.[85] In addition, microfilaments in cells can be decorated and visualized when the cells are stained with phalloidin, a fungal toxin that binds to microfilaments, which has been conjugated to fluorophores, and visualized by confocal fluorescent microscopy.[85] In this way, damage to the microfilaments by specific chemical toxins can also be demonstrated.

Secondly, a number of cell culture systems now have been developed in which investigators can study chemically induced morphological and neoplastic cell transformation. In one of these, C3H/10T1/2 Cl 8 (10T1/2) mouse embryo cells, carcinogenic insoluble nickel (Ni) compounds—nickel subsulfide, green nickel oxide, black nickel oxide, and crystalline nickel sulfide—and samples of Ni refinery dust have been shown to induce morphological and neoplastic transformation.[86,87] Foci of Ni-transformed cells have been ring-cloned from these experiments, biologically characterized, and expanded into transformed cell lines.[86,87] The techniques of decorating microtubules with fluorophores conjugated to antibody directed against α-tubulin or β-tubulin and visualizing microtubules by confocal microscopy have been used to show that in transformed 10T1/2 mouse embryo cell lines derived from nickel (Ni) compound–induced transformed foci, there are higher steady-state levels of microtubules,[85] due to the amplification of the ect-2 proto-oncogene and overexpression of ect-2 mRNA and protein.[88–90] Amplification of the ect-2 oncogene and overexpression of ect-2 mRNA and protein in Ni-transformed and in 3-methylcholanthrene (MCA)-transformed 10T1/2 mouse cell lines[90] will lead to higher steady-state levels of the protein complex, RhoA–GTP, which binds to the caps of microtubules, and will lead to higher steady-state levels of RhoA–GTP-microtubule cap complexes.[85,90] This, in turn, will lead to synthesis of more microtubules, which in turn will lead to higher steady-state levels of microtubules in the Ni^{2+}- and MCA-transformed

cell lines. Higher steady-state levels of microtubules in chemically transformed cells next lead to larger cells with aberrant shapes and nonhomogeneous distribution of microtubules in the transformed cell lines.[85] This in turn will lead to changes in gene expression in the Ni^{2+}- and MCA-transformed cell lines (DeSilva-Pehl and Landolph, manuscript in preparation).

Further, due to the silencing of the β-centaurin-2 gene that our Joseph R. Landolph's (JRL's) laboratory found in Ni^{2+} ion-transformed 10T1/2 cell lines,[85,91] signals that should ordinarily be sent to the ADP-ribosylation factor (ARF) protein, which ordinarily causes the microfilaments to disaggregate,[85] are not sent to the ARF. Hence, the microfilaments in Ni^{2+} ion–transformed 10T1/2 mouse embryo cell lines lacking expression of β-centaurin-2 protein will fail to disaggregate. Since additional microfilaments will continue to be synthesized, this leads to higher steady-state levels of microfilaments in Ni-transformed cell lines[85] (DeSilva-Pehl and Landolph, manuscript in preparation). Again, this leads to a nonhomogeneous distribution of microfilaments in the Ni-transformed cells, to larger cells, and to cells with aberrant cell shapes.[85] These consequences of overexpression of the microfilaments will contribute to alterations in gene expression in the Ni-transformed cell lines[91] (DeSilva-Pehl and Landolph, manuscript in preparation).

Use of mRNA Differential Display to Analyze Aberrations in Gene Expression in Chemically Induced Morphological and Neoplastic Cell Transformation

Our JRL's laboratory has recently been using random access primer (RAP)–PCR mRNA differential display to study the alterations in gene expression that occur in transformed cell lines derived from Ni compound–induced foci and MCA-induced foci in 10T1/2 mouse embryo cell lines. With RAP–PCR mRNA differential display, we found that 10 genes are differentially expressed in Ni-transformed and in MCA-transformed 10T1/2 cells compared to nontransformed 10T1/2 cells when 8% of the total mRNA was analyzed.[88,89] Therefore, by extrapolation, in 100% of the mRNA, 130 genes would be differentially expressed between nontransformed 10T1/2 cells and Ni^{2+} ion–transformed or in MCA-transformed 10T1/2 cell lines.[88,89] Among these differentially expressed genes, we found that the epithelial cell transforming factor 2 (ect-2) proto oncogene, the calnexin gene, and the Wdr1 stress response gene were overexpressed in the transformed cell lines compared to their expression in nontransformed 10T1/2 cells.[88–90] The ect-2 proto-oncogene was amplified, and higher steady-state levels of ect-2 mRNA and protein were expressed in Ni^{2+} ion–transformed and in MCA-transformed 10T1/2 cell lines compared to their expression in nontransformed 10T1/2 cell lines.[90] In addition, we found that the vitamin D receptor-interacting protein (DRIP80), the β-centaurin-2 gene, the insulin-like growth factor receptor gene #1 (IGFR1), and the flavin adenine dinucleotide (FAD) synthetase gene were expressed in nontransformed 10T1/2 cells but were not expressed at detectable levels in Ni^{2+} ion transformed and MCA-transformed 10T1/2 cell lines.[88,89,91] The small nuclear RNA activating complex protein (SNAP C3) was expressed in nontransformed 10T1/2 cells but was significantly underexpressed in Ni^{2+} ion–transformed and in MCA-transformed 10T1/2 cells lines.[88,89]

Our current working model is that approximately 15 primary genes are altered in expression in Ni^{2+} ion–transformed and in MCA-transformed 10T1/2 cell lines. For each gene altered in expression, this will cause further nine genes (130/15) to be altered in expression.[88] Approximately 3/8 of these genes will be either mutated or amplified and/or overexpressed, and this will lead to overexpression of $3/8 \times 15 \times 9 = 50$ additional genes. Five-eighths of these primary genes will become quiescent transcriptionally in the transformed cell lines. This will lead to loss of expression of, or underexpression of, $5/8 \times 15 \times 9 = 84$ additional genes. Therefore, alterations (mutations or methylations of the promoters/inactivating mutations) in 15 primary genes will lead to aberrations in expression of 130 genes total.[88,89] This will substantially perturb gene expression and cellular physiology, leading to induction and maintenance of morphological and neoplastic cell transformation.[88,89] Hence, the use of RAP–PCR mRNA differential display can lead to significant insight into the carcinogen (Ni^{2+} ion and MCA)-induced perturbations in gene expression that lead to induction of and maintenance of the transformed phenotypes of morphological transformation, anchorage independence, and tumorigenicity in Ni^{2+} ion–transformed and in MCA-transformed 10T1/2 mouse embryo cells.[88,89,91]

QUESTIONS

39.1 How can an increase of appreciation organelle interactions improve the quality of scientific answers to pressing questions in toxicology?

39.2 How is understanding on the basic processes governing interorganelle interactions or trafficking of value to mechanism or mode of action risk assessment improved?

39.3 How can modern image analysis tools of intracellular organelles within intact cells provide improved interpretation of data from putative genomic, proteomic, and metabolomic biomarker suites?

39.4 What information does use of fluorescent antibodies to microtubules and microfilaments give us into the alterations in physiology that occur in chemically transformed cell lines?

39.5 What insight does use of RAP–PCR differential display give into perturbations in gene expression and cellular physiology of Ni^{2+} ion- and MCA-transformed 10T1/2 cell lines?

39.6 How can alterations in expression of 15 genes lead to further alterations in 130 genes in chemically transformed cell lines?

40 Analysis and Characterization of Enzymes and Nucleic Acids Relevant to Toxicology

F. Peter Guengerich

CONTENTS

INTRODUCTION

More than 30 years have elapsed since I prepared this chapter for the first edition.[1] The book has been very successful, and the original chapter has been revised five times since then.[2–5] Many things have changed since the first version. Toxicology has become a more mechanistic field. In this sixth edition, the general discussion has been extensively modified. Some of the basic methods have been retained, because they are still utilized widely, without extensive changes, or they serve as prototypes for other assays. Several of the procedures have been changed in this sixth version, in order to reflect perceived needs in readers' laboratories. In some cases, detailed protocols have been deleted because commercial manufacturers routinely supply detailed instructions; in those cases, some general guidance about the basis of the system will be provided. Readers are also referred to some details previously covered in earlier editions of the chapter and book.

BIOACTIVATION AND DETOXICATION

What can be learned by studying enzymes? A general paradigm for the relationship of enzymes to toxicology issues is shown in Figure 40.1. A chemical can be directly transformed to an inactive product. An alternative enzymatic reaction is conversion to a *biological enzymatic intermediate*, such as the epoxide shown in the example. This reactive compound can be hydrolyzed or conjugated (possibly enzymatically in either case), yielding detoxicated product. Some of the reactive product may also react with tissue nucleophiles. Most of the reactions are with *nontargets*, which is good, although these products obscure the searches toward understanding mechanisms. The reactions with *targets* for toxicity are the detrimental ones. Sixty-five years have elapsed since the concept of ultimate toxic forms was first developed.[6] Such activation is now widely accepted as the first step leading to the toxic and carcinogenic effects of many chemicals.

The classification of the enzymes of interest is somewhat subjective, but the list provided in Figure 40.2 would probably be generally agreed on, with some possible changes. The list is based on the original work of Jakoby[8] and was utilized in two later monographs.[7,9] The reader is referred to this list. Many of these enzymes exist in medium to large gene families and are inducible. This chapter will focus on the P450 enzymes as general models for many of these enzymes, and many of the assays presented should, at least in principle, be useful for many of these enzyme systems.

The basic principles of the chemistry involved in toxicity are relatively straightforward. Most bioactivation reactions (*reactive intermediates*) can be explained in terms of either (1) the irreversible reaction of an electrophile with a tissue nucleophile or (2) propagation of free radicals (Figure 40.3). The enzymatic steps leading to the generation of electrophiles are myriad but have been extensively studied.[10,11] The following principles govern these reactions.[12,13] (1) The basic reactions involve simple chemistry, for example, reactions of electrophiles with nucleophiles and free-radical propagation. (2) The first metabolic product or the most obvious chemical prospect may not be the reactant. (3) The stability of reactive products influences sites and patterns of damage. A short time ($t_{1/2}$ of 1 s) may be considerable in a cell, and some reactive

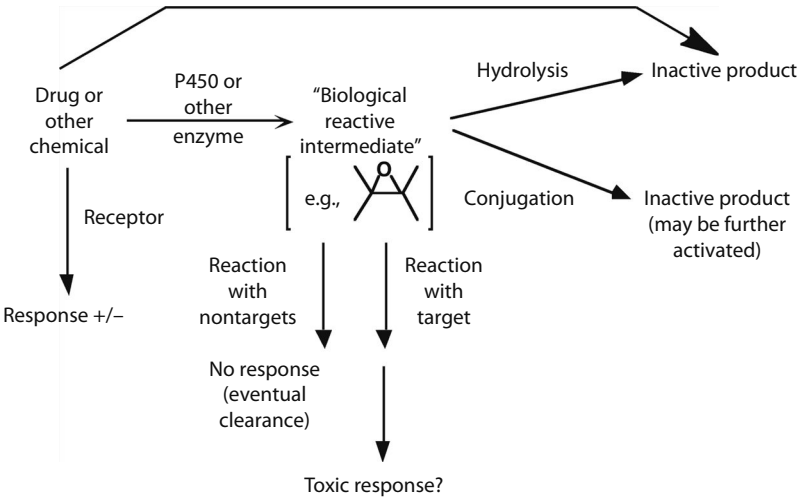

FIGURE 40.1 General paradigm for the role of enzymatic bioactivation and detoxication.

molecules are long lived ($t_{1/2}$ of min to h). (4) In vitro systems are models, good for elucidating details. However, only some results, not all, apply in vivo. (5) The dose is an issue or more properly, *the* issue, a concept traced to Paracelsus.[14] (6) Covalent binding can be an index of toxicity, but exceptions exist even after considerations of dose. Other issues (in addition to covalent binding) are receptor-mediated events (esp. signaling), ability to repair (DNA and protein) damage, cell proliferation, and immune responses.

Events leading to radical initiation involve some type of one-electron chemistry, and radical propagation is often the result of free metal ions in biological systems. An important component of the radical chemistry is oxidative damage, resulting from the production of partially reduced oxygen species. In many cases, the effects of oxidative damage are not readily distinguished from alkylation and reactions of electrophiles. These and other events, including direct interactions of either parent chemicals or products with cellular

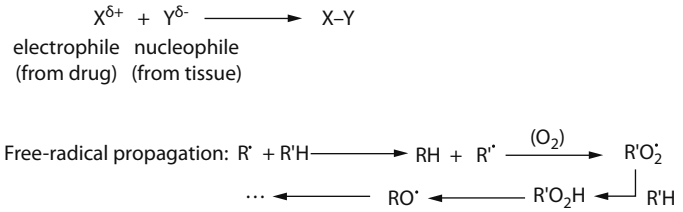

FIGURE 40.3 Basic chemical reactions involved in chemical toxicity: reaction of an electrophile with a nucleophile; free-radical propagation.

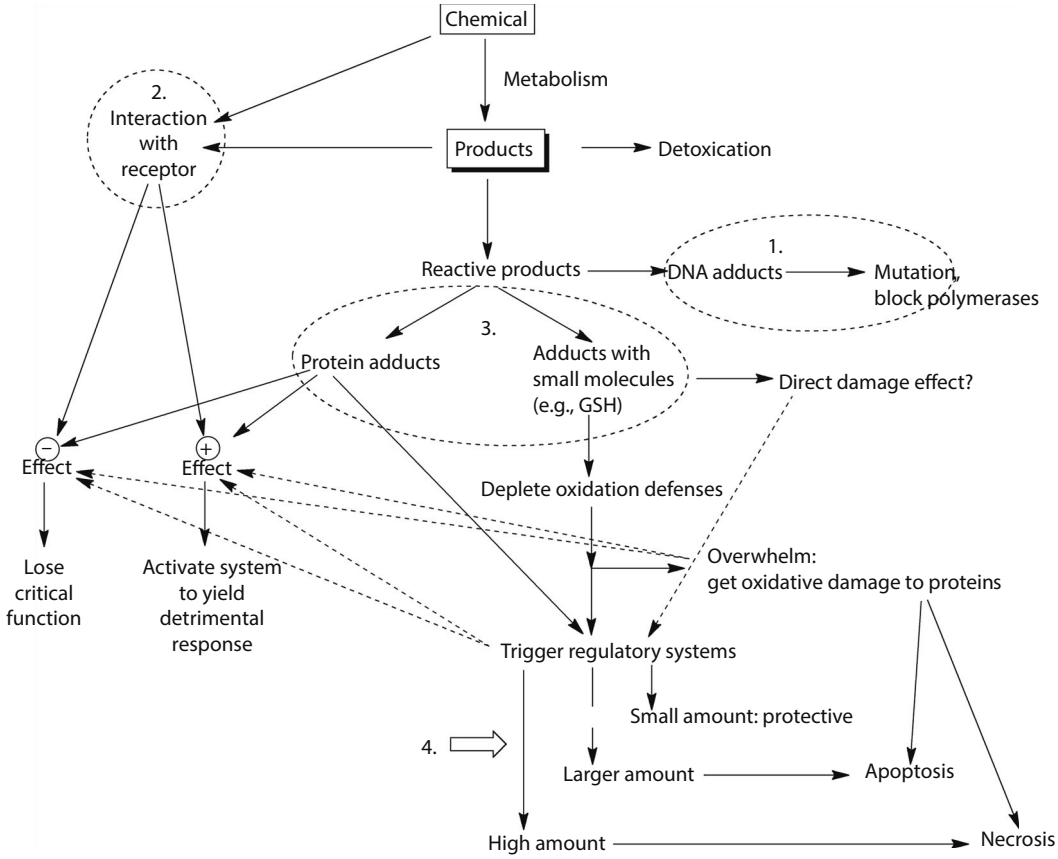

FIGURE 40.4 Cellular events related to the potential toxicity of chemicals.[13] See text for discussion. The steps indicate points for medium- to high-throughput assays: (1) genotoxicity, (2) interaction with known receptors, (3) covalent binding to proteins or surrogate nucleophiles, and (4) events related to disruption of normal cellular function.

receptor systems, are elaborated in the complex global view of the present knowledge of events related to toxicity in Figure 40.4.[13,15] Covalent binding of metabolites is only one of the ways of disrupting the networks in a cell. Some direct effects on receptors can produce similar outcomes. The numbers indicate the events that would be useful to monitor: (1) Genotoxicity tests are relatively well established and have been used in preliminary screening for >30 years. (2) Many receptor assays are now routinely done (e.g., AhR, PPARα). Most of the guilt is by association, in that most of the details related to toxicity are still vague. (3) Recently, assays have been developed to monitor the reaction of electrophiles with small thiols, with the hope of predicting toxicity in medium- to high-throughput assays.[10] (4) The real goal is to develop biomarkers and assays that will prevent events in this area related to toxicity. Some assays are in use, but this area would appear to have the greatest potential.[16]

Some examples of bioactivation processes follow. The first is the classic case of acetaminophen (paracetamol). Although this analgesic and antipyretic is used safely every day by many people, overdoses (accidents, attempted suicides) result in a large fraction of the cases of acute liver failure.[17] The chemistry related to acetaminophen is rather simple (Figure 40.5). Small amounts are efficiently conjugated by uridine glucuronosyl transferases (UGTs) or sulfotransferases (SULTs) to yield products that are readily eliminated. However, cytochrome P450 (P450) enzymes are involved in minor oxidation pathways. The catechol product does not appear to be a

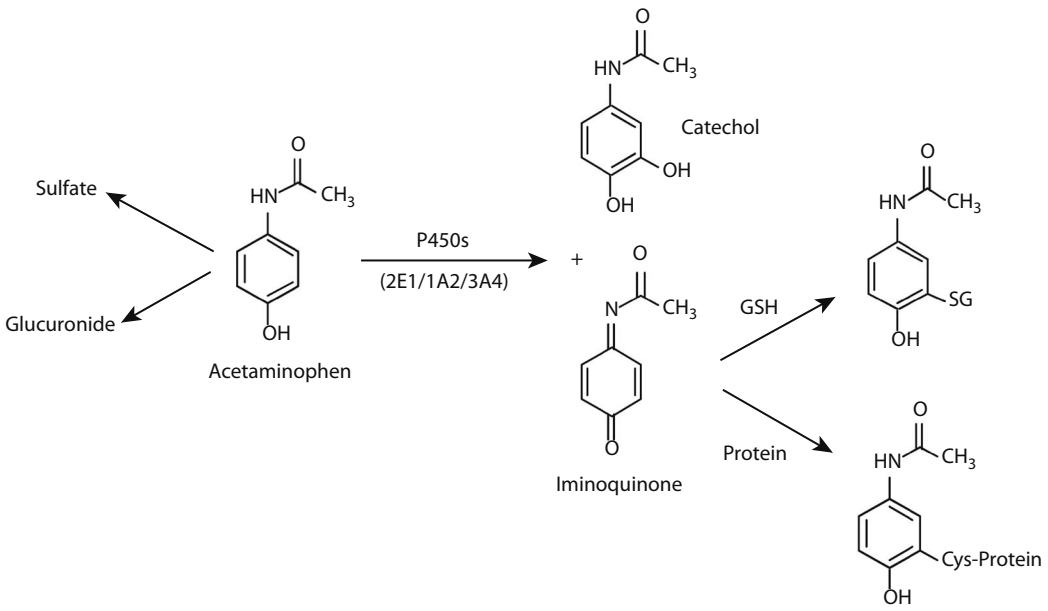

FIGURE 40.5 Pathways involved in metabolism of acetaminophen. The conjugates are formed by the action of SULTs and UGTs. For reference to the oxidations, see[18,19].

problem but the iminoquinone is. GSH reacts with the iminoquinone and blocks its reaction with proteins. Thus, at low concentrations of acetaminophen, very little tissue damage results. When the concentration of acetaminophen increases, the sulfation and glucuronidation pathways are overwhelmed and, in some cases, GSH is depleted and more of the iminoquinone reacts with tissues.[20] The extent of covalent binding is well correlated with parameters of toxicity.[21] Interestingly, the *meta* isomer of acetaminophen is much less toxic but gives the same level of total covalent binding.[22,23] The protein targets for the two isomers are not identical,[24] but exactly which targets for acetaminophen are most relevant to toxicity, if any are, is still not clear. Recently, a number of pharmaceutical companies have utilized in vitro (and in vivo) screens for covalent binding.[10] Although a strong case can be made for the role of bioactivation and covalent binding in the toxicity of many drugs—for example, [25,26]—exactly what the impact of these screens has been is not easy to discern. Several recent studies have involved analyses of the covalent binding of older drugs of established hepatotoxicity (and lack of toxicity).[27–30] The results show generally higher levels of covalent binding with known hepatotoxins, but there is wide variability, even after making appropriate corrections for dose, other rates of metabolism, etc. An overall conclusion, perhaps not surprising, is that the level of covalent binding is one contributor to toxicity but not the only one. The possibility exists that covalent binding to a very select set of proteins may be most reliable in making predictions, but that remains to be established and can be considered in the context of biomarkers.[31] One point to keep in mind is that a number of useful marketed drugs function by covalently binding their targets.[32]

The second example is the prototypic polycyclic aromatic hydrocarbon (PAH) benzo[*a*]pyrene (Figure 40.6). This carcinogen, known since the 1930s,[33] is oxidized to an epoxide. This first epoxide is not unusually reactive and is readily hydrolyzed by microsomal epoxide hydrolase to yield a dihydrodiol. The dihydrodiol is an excellent substrate for some P450s (i.e., human P450s 1A1 and 1B1). The resulting diol epoxide is quite reactive and can either react with H_2O directly, be conjugated by GSH transferases, or react with DNA.

One example, provided in Figure 40.7, is the metabolism of aflatoxin (AF)B_1. Over the course of a decade of research in this and other laboratories, the enzymes involved in nearly every step of AFB_1 metabolism have been identified, and the numerical value of the k_{cat}/K_m is given in Figure 40.7 (for nonenzymatic processes, the estimated second-order rate constant is given). These are the parameters that should be operative at the low AFB_1 concentration encountered in relevant human exposures, although some caveats must be considered when substrate concentrations begin to approximate the enzyme concentrations. As we consider this work in a global text, P450s can activate or detoxicate AFB_1 (Figure 40.7). GST M1 has a protective role, although not being as effective as in some species (e.g., mice). Some aldo-keto reductases (AKRs) protect against protein (but not DNA) damage. Epoxide hydrolase is too inherently slow to provide much catalytic protection of DNA from the 8,9-*exo* epoxide, although enough of the enzyme might scavenge the epoxide, acting as a reagent.[36]

An analysis of interest is the activation of chemical carcinogens (Figure 40.8A).[37] The most striking aspect is the dominant role of the P450 enzymes. Interestingly, beyond these, the AKR enzymes have a role that exceeds that of any other enzyme group, driven by their reported roles in PAH activation to quinones.[38] Of the P450s, six P450s—1A1, 1A2, 1B1, 2A6, 2E1, and 3A4—account for 77% of the reported activations (Figure 40.8B).[37] The Family 1 enzymes are prominent in the activation of PAHs and heterocyclic amines, plus arylamines and a variety of other compounds. The values for

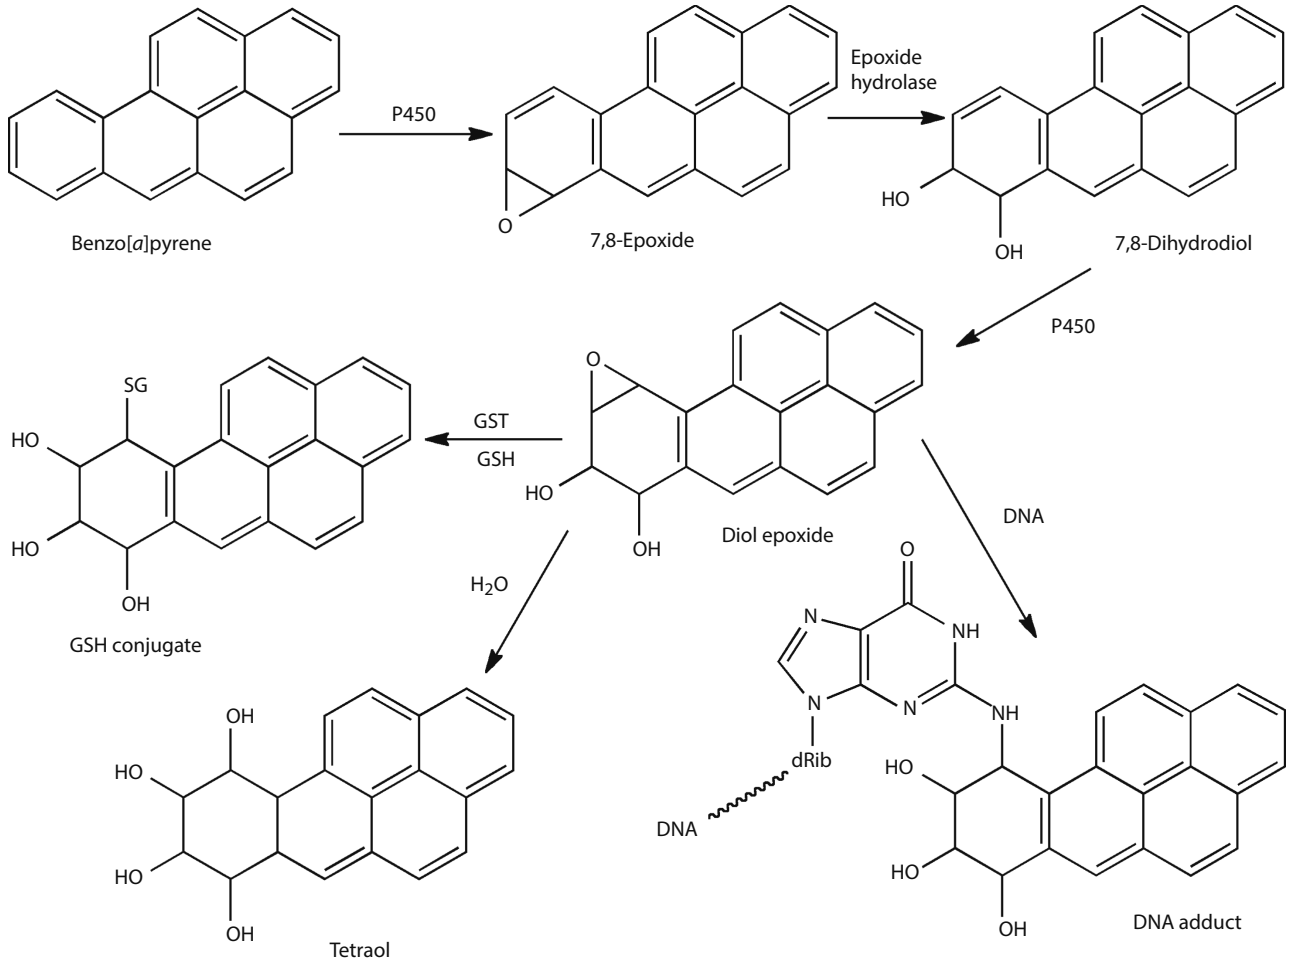

FIGURE 40.6 Major reactions involved in the conversion of the PAH benzo[*a*]pyrene to a reactive diol epoxide, plus reactions of the diol epoxide, plus reactions of the diol epoxide with H_2O, DNA, and GSH.

P450s 2A6 and 2E1 are driven by their roles in the metabolism of *N*-nitrosamines and a variety of low M_r commodity chemicals, including several vinyl monomers.[39] Another analysis involves the type of reactions involved in bioactivation reactions (Figure 40.9). As seen there, 11 reactions account for 94% of the total, each representing 5%–15%. The *O*-acetylation and *O*-sulfonation conjugations collectively account for 22%. Reductions constitute 16%. Most of the other reactions are oxidations, together accounting for ~56%. Of these, *N*-hydroxylation was the most prominent.[37]

Knowledge about the overall pathway can lead to logical intervention strategies. For instance, chlorophyllin can be used to absorb AFB_1, the initial substrate.[40] Oltipraz inhibits P450 oxidation.[41] Oltipraz and other antioxidant response (ARE) inducers (Keap1 modifiers) induce GSTs and AKR enzymes involved in detoxication.[42]

P450 AS A PARADIGM FOR ENZYMES INVOLVED IN TOXICOLOGY

By far the most common mechanism for bioactivation of chemicals is mixed-function oxidation by P450. This enzyme system was really discovered in the late 1950s and has attracted a great deal of interest ever since. A number of enzyme forms exist within each species; some are tissue specific as well as species specific. The different forms preferentially oxidize different substrates, and this specificity contributes to the preferential bioactivation and detoxication of chemicals by different enzyme forms.

With a general catalytic mechanism involving abstraction of electrons or hydrogen atoms followed by oxygen rebound,[43] one can explain the apparently diverse oxidative reactions catalyzed by P450, which can be classified as carbon hydroxylation, heteroatom oxygenation, heteroatom release (dealkylation), epoxidation, oxidative group migration, and other related events (Figure 40.10).[11,44] These basic mechanisms can also explain the suicidal inactivation observed with substrates such as olefins, cyclopropylamines, and aminobenzotriazole; variation of structural features has allowed the selective inactivation of individual enzymes by mechanism-based (suicide) inhibitors.[45,46] P450 also reduces some compounds such as azo dyes, CCl_4, and *N*-oxides.[11,47]

The total number of P450 substrates easily runs into the thousands.[37,47] The broad specificity is due in part to the existence of multiple forms, but even a single purified form

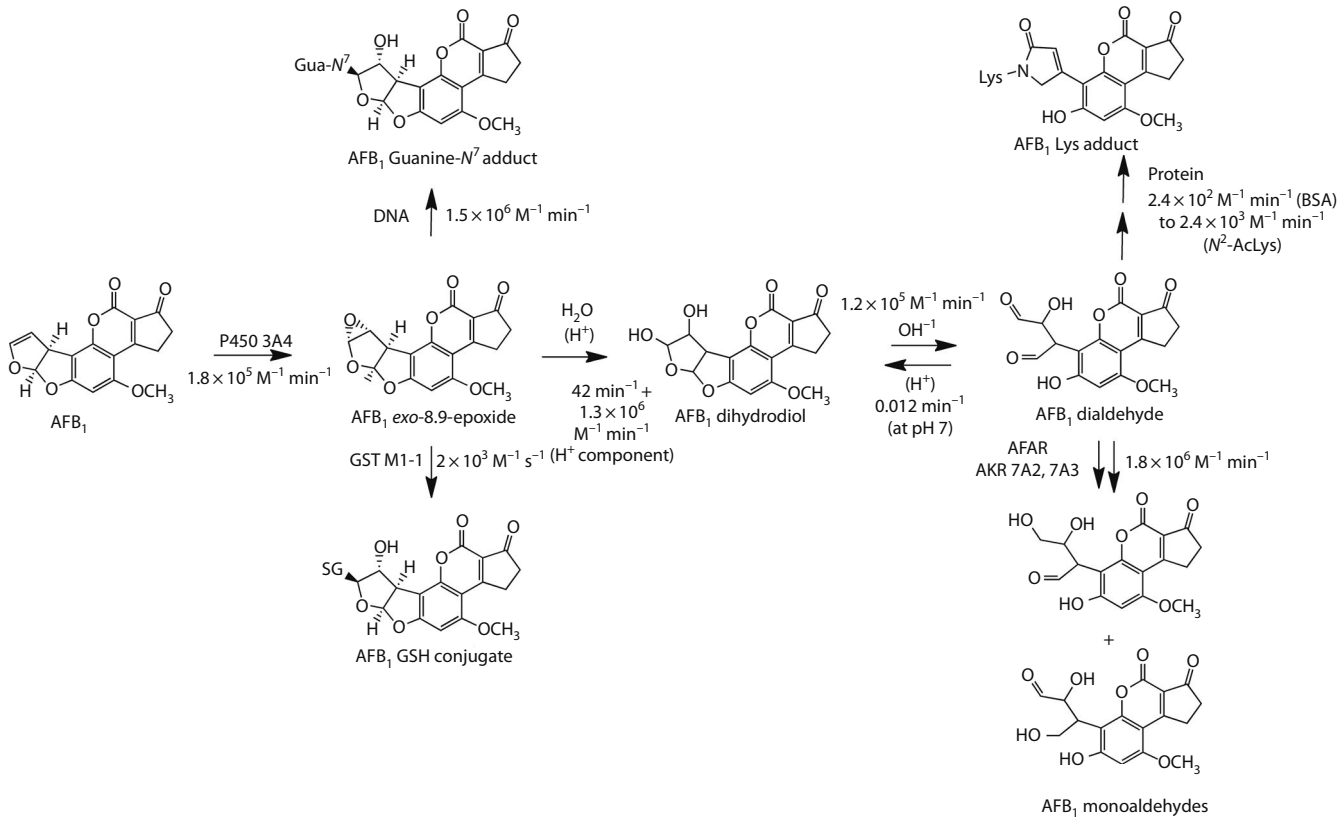

FIGURE 40.7 Reactions involved in the metabolism of AFB_1 in the human liver. The major human enzymes involved in each step are indicated. The values indicated are either second-order rate constants (for chemical reactions) or k_{cat}/K_m values for the purified enzymes. (From Guengerich, F.P. and Johnson, W.W., *Drug Metab. Rev.*, 31, 141, 1999; Guengerich, F.P. et al., *Chem. Res. Toxicol.*, 15, 780, 2002.)

(e.g., human P450 3A4) has been shown to oxidize >1000 different substrates.[48,49] The active site must be large enough to accommodate all of these. However, a number of larger substrates such as warfarin, testosterone, and debrisoquine and other drugs are stereo- and regioselectively oxidized, indicating that the binding sites do really have some distinct features. The smaller substrates apparently fit into these sites and the sites of oxidation on them are maybe governed more by chemical than spatial (physical) properties, although this hypothesis needs to be tested further.

One view is that most P450 enzymes exist for the metabolism of specific endogenous substrates such as fatty acids, steroids, and eicosanoids; however, others believe that the purpose of these enzymes is the clearance of ingested foreign chemicals (terpenes, alkaloids, pyrolysis products, etc.).[50] There is validity in both viewpoints and good cases for individual enzymes with each function may be found (Table 40.1).

One of the major reasons for the widespread study of P450 is that these enzymes are involved in the activation and detoxication of xenobiotics. However, much of the early evidence was circumstantial. The literature is filled with examples in which one can directly demonstrate covalent binding of a chemical to protein or DNA with a P450 or produce mutagenesis in bacterial strains. Known P450-generated metabolites can be found bound to macromolecules in vivo, and in some cases, administration of known products of P450 oxidation

TABLE 40.1
Classification of Human P450s Based on Major Substrate Class[a]

Sterols	Xenobiotics	Fatty Acids	Eicosanoids	Vitamins	Unknown
1B1	1A1	2J2	4F2	2R1	2A7
7A1	1A2	4A11	4F3	24A1	2S1
7B1	2A6	4B1	4F8	26A1	2U1
8B1	2A13	4F12	5A1	26B1	2W1
11A1	2B6		8A1	26C1	3A43
11B1	2C8			27B1	4A22
11B2	2C9				4F11
17A1	2C18				4F22
19A1	2C19				4V2
21A2	2D6				4X1
27A1	2E1				4Z1
39A1	2F1				20A1
46A1	3A4				27C1
51A1	3A5				
	3A7				

[a] This classification is somewhat arbitrary, for example, P450s 1B1 and 27A1 could be grouped in either of the two different categories.[51]

TABLE 40.2
Marker Activities for Some Human P450s Involved in Toxicology Studies

P450	Tissue Sites	Typical Reaction
1A1	Lung, several extrahepatic sites, peripheral blood cells	Benzo[*a*]pyrene 3-hydroxylation
1A2	Liver	Caffeine N^3-demethylation
1B1	Many extrahepatic sites, including lung and kidney	17β-Estradiol 4-hydroxylation
2A6	Liver, lung, and several extrahepatic sites	Coumarin 7-hydroxylation
2A13	Nasal tissue	Activation of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)
2B6	Liver, lung	(*S*)-Mephenytoin *N*-demethylation
2C8	Liver	Taxol 6α-hydroxylation
2C9	Liver	Tolbutamide methyl hydroxylation
2C19	Liver	(*S*)-Mephenytoin 4′-hydroxylation
2D6	Liver	Debrisoquine 4-hydroxylation
2E1	Liver, lung, other tissues	Chlorzoxazone 6-hydroxylation
3A4	Liver, small intestine	Testosterone 6β-hydroxylation
3A5	Liver, lung	Testosterone 6β-hydroxylation
3A7	Fetal liver	Testosterone 6β-hydroxylation
4A11	Liver	Fatty acid ω-hydroxylation

Source: Guengerich, F.P., Human cytochrome P450 enzymes, in: Ortiz de Montellano, P.R., ed., *Cytochrome P450*: *Structure, Mechanism, and Biochemistry*, 3rd edn., Kluwer Academic Publishers, New York, pp. 377–530, 2005.

can produce the toxicity observed with the parent substrate (e.g., fluoroxene and trifluoroacetic acid).[52] Often, the administration of chemicals that are known to induce (or inhibit) forms of P450 can increase or decrease the toxicity of a certain chemical in experimental animals. The usefulness of this approach is limited because of the ability of these chemicals to alter the levels of several cytochromes P450 concomitantly, alter the content of other enzymes, and affect physiological parameters (e.g., blood flow) that contribute to endpoints under consideration. The problem of not knowing exactly *how* metabolites exert toxic effects also obfuscates the problem. While P450s do appear to play a role in the generation of ultimate toxicants and carcinogens, efforts to show the importance of changes in the composition of individual forms on the effects are more difficult.

Today, no doubt exists concerning the existence of distinct forms of P450 in experimental animals or man. At this time, 83 gene products have been characterized in rats and 57 in humans (Table 40.1).[53] See the Internet sites http://drnelson.uthsc.edu/cytochromeP450.html (Cytochrome P450 Homepage) and http://www.imm.ki.se/CYPalleles/ (The Human Cytochrome P450 (CYP) Allele Nomenclature Database) for more current information regarding P450 genes and sequences. All of the human P450 genes are known from the Human Genome Project. The purified proteins differ in electrophoretic properties, immunochemical aspects, primary sequence, and other criteria, including catalytic specificity (Table 40.2). The genomic sequences of >18,000 P450 enzymes in different species are known. In addition, many genomic DNA sequences have been established. There is no evidence to support an earlier view that gene translocations have made P450 a huge supergene family like the immunoglobulins.

In some cases, considerable conservation of P450 structure is found between species. Small differences among the P450 proteins, however, can generate large differences in catalytic activity and substrate specificity, as shown in several notable examples. Lindberg and Negishi[54] showed that the change of a single residue (209) of mouse P450 2A5 could alter its catalytic selectivity quite dramatically.

Some human P450 enzymes were purified,[48,55] and many more have been characterized using recombinant methods.[51] These have been shown to have specificity in catalyzing the oxidation of drugs and other chemicals. In every case, some structural similarity with certain P450 forms isolated from experimental animals has been shown; however, this similarity can be misleading in ascertaining catalytic specificity in some cases.[56] As in the case of experimental animal models, immunochemical methods have been of use in establishing the roles and catalytic specificities of the human P450s.

There are several levels at which overall catalytic activity can be influenced.[57,58] Cofactor supply can be important: NADPH levels can be altered by starvation, and oxygen gradients exist in the liver. The different P450 forms also are localized preferentially in different regions of the liver (and in different cell types in liver and extrahepatic tissues). Heme is necessary as a prosthetic group for P450 and a deficiency

can lower activity. NADPH–P450 reductase is present at a level an order of magnitude lower than P450 and is needed for activity. While reconstituted P450 systems are stimulated by phospholipids, in vivo changes in lipid composition probably do not have any significant effect in most cases,[59] with the notable exception of the P450 3A family enzymes.[60,61]

In experimental animals, the major way in which activities, or at least rather specific catalytic activities, are modulated is via changes in the amounts of individual P450 forms present.[62,63] Such changes have been clearly demonstrated to involve de novo synthesis and often involve specific increases in rates of nuclear DNA transcription. The list of P450 inducers is nearly as long as the list of substrates. Only in a few cases does one see induction of only one P450; more commonly, several are induced. In some cases, the level of one of these proteins is depressed, while others are induced.[64,65] Several of the rodent liver cytochromes P450 are also regulated by steroid hormones.[66,67] Most of the P450 proteins have similar half-lives (about 24 h); however, some evidence exists for a stabilizing effect of certain classic *inducers* on mRNA stability. In the case of most cytochromes P450, evidence exists for intracellular receptors that bind the inducing ligands.[68]

Another aspect of regulation is polymorphism, which is observed with certain catalytic activities in both experimental animals and man. While most of the catalytic activities associated with P450s are affected at least somewhat by environmental factors, genetic polymorphisms are distinct and not so readily influenced by other factors. These can be produced by variations in structural genes (coding or regulatory regions) or by variations in other proteins that regulate expression. Polymorphisms have been mapped to chromosomes in rats and mice, and structural details underlying the polymorphisms have been elucidated in many cases. In humans, genetic polymorphisms related to the metabolism of certain drugs have been identified. Correlations have been made between individuals expressing individual phenotypes (or genotypes) and susceptibility to chemical carcinogenesis. Low activity of the steroidogenic P450s can lead to lethality or debilitating diseases.[51,69,70] Still another issue with human P450 is inhibition, which can be a major issue in drug–drug interactions (Table 40.3).

While the cytochromes P450 have received considerable attention, one should realize that the existence of *isozymes* (or more appropriately, *enzymes*) in a family is not unusual nor is a multigene family. These probably occur with many gene families, including some others that are involved in other aspects of metabolism of xenobiotic chemicals. For instance, at least 19 different forms of human glutathione (GSH) S-transferase (GST) exist and have been shown to be distinct gene products.[75] Again, the catalytic specificities of these enzyme forms differ and many are under differential regulatory control. Considerable evidence supports the view that many forms of UGT exist,[76] and the epoxide hydrolases are distinct gene products.[77] Distinct forms of microsomal flavin-containing monooxygenase (FMO) are found in different tissues, specifically the liver and lung.[78] However, in some of the other instances, only one gene appears to be involved, for example, NADPH–cytochrome P450 reductase.[79]

Res. Toxicol*., 11, 1048, 1998; Newton, D.J. et al., *Drug Metab. Dispos*., 23, 154, 1994.

ROLES OF P450S IN RELATIONSHIP TO OTHER ENZYMES IN BIOACTIVATION AND DETOXICATION

As mentioned earlier, P450-catalyzed oxidation can result in either the bioactivation or detoxication of a potential toxicant. In general, reduction reactions catalyzed by either P450 or NADPH–P450 usually lead to more reactive products. Oxidations by other enzymes (i.e., FMOs, alcohol, and aldehyde dehydrogenases) can also result in either bioactivation or detoxication. For instance, oxidation of allylic alcohols by alcohol dehydrogenase yields acrolein derivatives, which react rapidly with *soft* nucleophiles. In classical drug metabolism, oxidation–reduction reactions have been termed *Phase I*, and conjugation reactions, which usually follow after oxidation or reduction, are termed *Phase II*.[80] However, this classification is outdated and frankly misleading[81] and it will not be used here. The majority of these conjugation processes detoxicate chemicals, and therefore, increases in the concentrations of the proteins that catalyze these reactions, or increases in the concentrations of cofactors (cosubstrate), tend to render an organism at decreased risk to protoxicants. However, many exceptions to this generalism can be found. For example, epoxide hydrolase action on benzo[*a*]pyrene 7,8-oxide leads to formation of a substrate that is efficiently converted to 7,8-dihydroxy-7,8-dihydro-9,10-oxo-benzo[*a*]pyrene (the dihydrodiol),

which reacts rapidly with DNA and is a potent mutagen and carcinogen (Figure 40.6). GSTs can activate *vic*-dihaloalkanes to yield DNA damage (*vide infra*). Glucuronides are formed by action of UGTs on hydroxylamines, which can break down in the acidic environment of the bladder to release nitrenium ions to alkylate DNA. Thus, we see that metabolic transformations must be viewed in a global manner to put the importance of individual steps into context.

What can studies on metabolic transformations tell us about the toxicity of chemicals? Comparison of the actions of a series of small industrial compounds provides some examples:

$$CH_2{=}CH{-}CN$$

$$CH_2{=}CH{-}Cl$$

$$Br{-}CH_2{-}CH_2{-}Br$$

The first, acrylonitrile, is acutely toxic and also causes several types of general toxicity problems when administered at high doses in chronic studies (i.e., nausea, weight loss, gastric disturbances). The compound is not particularly carcinogenic, causing only tumors of the forestomach, brain, and Zymbal's gland at high doses. These actions can be understood when the various pathways for acrylonitrile are measured using in vitro assays. Acrylonitrile reacts rapidly and nonenzymatically with sulfhydryls, both in proteins and in GSH (Figure 40.11). Conjugation with GSH is the major fate of acrylonitrile and renders it innocuous. Reaction with proteins is considerable and probably accounts for the toxic effects of acrylonitrile. About 10% of acrylonitrile is oxidized by P450 to its epoxide, which can (1) release cyanide (which does not appear to play a role in most toxicity), (2) be conjugated with GSH, (3) alkylate proteins, or (4) alkylate nucleic acids. The extent of the latter reaction does not appear to be very great, consistent with the relatively low tumorigenic potential of acrylonitrile.[82–84]

Vinyl chloride appears similar in structure to acrylonitrile at first glance but behaves quite differently. Only very high doses are acutely toxic and this toxicity is probably unrelated to metabolism. However, vinyl chloride is carcinogenic, causing a peculiar hemangiosarcoma that is almost unique to vinyl chloride production workers and can be reproduced in laboratory animals. Unlike acrylonitrile, vinyl chloride does not react directly with thiols and its metabolism proceeds strictly through oxidation. The epoxide 2-chlorooxirane (2-chloroethylene oxide) can react with nucleic acids to form several lesions, including 1,N^6-ethenoadenine, N^3,4-ethenocytosine, 1,N^2-ethenoguanine, 7-hydroxy-1,N^2-ethanoguanine (5,6,7,9-tetrahydro-7-hydroxy-9-oxoimidazo[1,2-*a*] purine), N^2,3-ethenoguanine, and N^7-(2-oxoethyl)guanine.[85] Which of these is most intimately related to tumorigenesis is yet unclear, although evidence favors the etheno adducts.[86,87] The epoxide also spontaneously rearranges to form 2-chloroacetaldehyde,[88–90] which is more like acrylonitrile, reacting rapidly and nonenzymatically with GSH and protein thiols. It reacts only slowly with nucleic acids and is probably not relevant to tumor initiation. The major site of vinyl chloride oxidation is the parenchymal cells of the liver. However, hepatic tumors originate in the reticuloendothelial cells, which have little, if any, oxidation capacity. A possible explanation is that the epoxide is formed in the parenchymal cells and is stable enough to migrate to other cells (some experimental evidence supports this view)[91]; the differential susceptivity to the alkylating agent may be explained by variations in rates of DNA adduct repair among the cell types.

The next compound to consider in this series is ethylene dibromide (1,2-dibromoethane). This compound causes kidney toxicity and is carcinogenic at a number of sites. Oxidation by P450 (esp. P450 2E1)[39] yields 2-bromoacetaldehyde, which behaves in the same way as 2-chloroacetaldehyde (*vide supra*) and depletes sulfhydryls. GSH transferase-catalyzed conjugation of ethylene dibromide with GSH also occurs; the ratio of ethylene dibromide metabolized through the oxidative and conjugative pathways is ~4:1 in rats.[92] In this case, the GSH conjugate is unstable, however, because of the leaving group still present (Br) (Figure 40.12). Nonenzymatic dehydrohalogenation produces an episulfonium (thiiranium) ion,[95,96] which also has several fates. If it is hydrolyzed, *S*-(2-hydroxyethyl)GSH is formed and this innocuous product is degraded and excreted. The putative

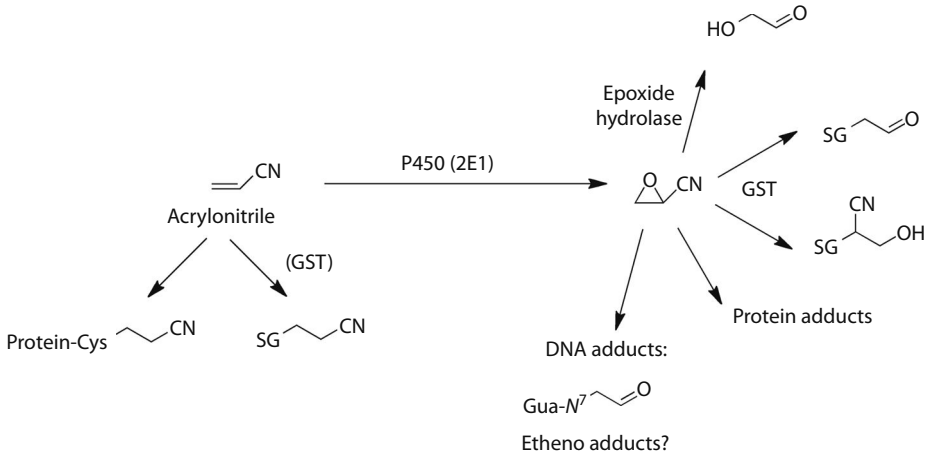

FIGURE 40.11 Proposed scheme for metabolism of acrylonitrile. (From Geiger, L.E. et al., *Cancer Res.*, 43, 3080, 1983.)

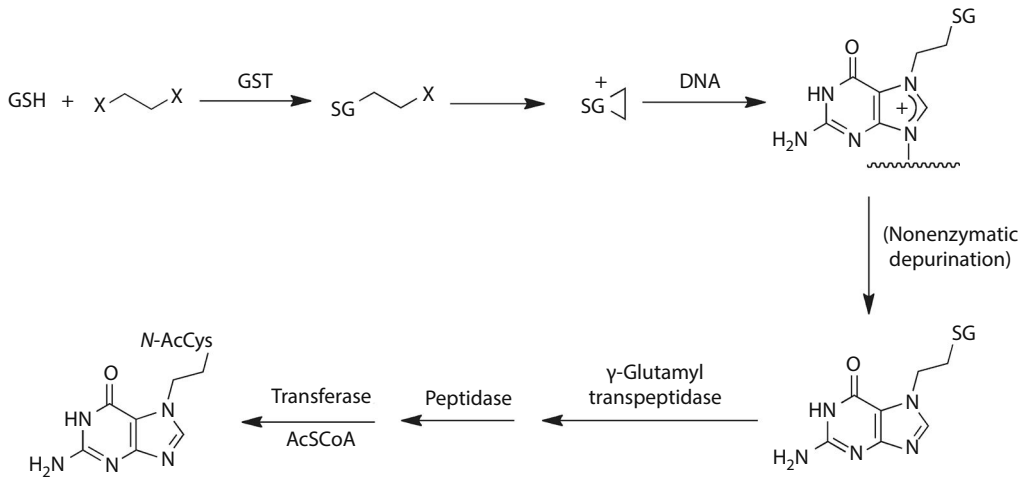

FIGURE 40.12 Scheme depicting formation of the major DNA adduct from ethylene dihalides and the degradation of the adduct. (From Inskeep, P.B. et al., *Cancer Res.*, 46, 2839, 1986; Kim, D.H. and Guengerich, F.P., *Cancer Res.*, 49, 5843, 1989.)

episulfonium ion can also react with another GSH to form the ethylene-bis GSH adduct, which is also innocuous. Another possibility is elimination to yield GSSG (oxidized GSH) plus ethylene, another mode of detoxication.[97] However, another reaction (of the episulfonium ion) occurs with DNA to yield *S*-[2-(*N*^{7}-guanyl)ethyl]GSH as the major product.[98] This GSH pathway appears to be related to carcinogenesis because in vitro DNA binding and mutagenesis are much more dependent upon cytosolic than microsomal enzymes, and in vivo studies also support this view.[93,99] Thus, we see here that GSH conjugation can become a major bioactivation pathway.

The aforementioned three compounds share some apparent features of similarity, yet further analysis indicates that they differ widely in terms of their chemical properties, the manner in which they are handled by the body and the biological effects that are exerted. Much of our understanding of these chemicals has come from in vitro studies using assays of the type that are described here. But what can we learn from studies that focus on identification and quantitation of individual enzymes?

One example involves the suppression of a particular P450 in rat liver. PAHs (e.g., 3-methylcholanthrene), β-naphthoflavone, and isosafrole induce increased synthesis of at least two forms of P450 in rat liver, P450 1A1 and P450 1A2. Increases in microsomal catalytic activities following administration of such compounds have generally been held to support the involvement of these inducible forms in a particular transformation, and in many in vivo studies alterations in acute toxicity of compounds by these inducers have been interpreted in the same terms. The levels of a particular form of P450, P450 2C11 (measured with a specific antibody), are decreased when compounds are given to rats that induce P450 1A1 and P450 1A2 (also measured immunochemically).[65] The decrease is as much as 10-fold when certain polybrominated biphenyl congeners are administered to rats.[64] P450 2C11 is male specific[66,67] and is responsible for the bulk of certain catalytic activities, including testosterone 2α-hydroxylation[67] and (in rats) generation of the most toxic products of AFB_1.[100] If formation of a reactive metabolite is mediated by P450 2C11 and neither P450 1A1 nor P450 1A2 act on the parent compound, then one might (without knowledge of the complexity of the situation) conclude that if administration of PAHs such as 3-methylcholanthrene to rats decreases toxicity and total P450 levels, P450 must have a detoxicating role in metabolism. As we see here, that view could be totally erroneous and lead to unsound predictions for other situations. The basic information underlying the phenomenon presented here, that is, the suppression of individual forms of P450, could only have been obtained with the use of purification, enzyme reconstitution, and immunochemical techniques.

Does the identification and assay of individual enzyme forms have any relevance in clinical settings? The answer is yes, and several examples will be given from the realm of drug toxicity and therapeutic effectiveness. The antituberculosis drug rifampicin is a potent enzyme inducer and appears to increase the P450 form(s) that catalyzes the A ring hydroxylation of 17α-ethynylestradiol, the major estrogenic component of oral contraceptives. Such oxidation renders the drug ineffective, and cases have been reported where rifampicin administration to women has led to unanticipated pregnancies.[101] In other clinical cases, genetic deficiency in P450 2D6 has led to the accumulation of certain drugs and the production of undesirable side effects, such as the neuropathy associated with perhexiline and captopril-induced agranulocytosis.[102] The suggestion has been made that dangers associated with chemicals in the environment may be affected by some of the same factors that influence drug clearance; for instance, individuals lacking P450 2D6 have been suggested to be less prone to tumors related to AFB_1 and cigarette smoking,[103,104] although the findings are controversial. The molecular basis of the P450 2D6 polymorphism is now known.[105] We can now understand some interindividual variations in response to potentially toxic chemicals at the level of specific sequence changes. Toward this end, methods in enzymology can be applied in the field of toxicology.

For many of the enzymes under consideration here, a number of purification and heterologous expression techniques have been developed independently, and the reader is referred to the original literature for details. In describing the general assay procedures for use with microsomal and purified fractions, an effort has been made to deal with some of those most commonly used in the author's and other laboratories. Selected examples of different types of assay procedures are given, and many of these can be adapted to other uses.

ANALYTICAL AND PREPARATIVE PROCEDURES

Preparation of Microsomal and Cytosolic Fractions

Microsomal fractions have been prepared from a variety of tissues using procedures developed for use with rat liver. The following procedure[106,107] has been found to be useful in this laboratory for the preparation of microsomes and cytosol from a variety of animal and human tissues.

Reagents (All should be at 0°C–4°C for storage and use):

1. 1.15% KCl (w/v).
2. Buffer A: 0.10 M Tris–acetate buffer (pH 7.4) containing 0.10 M KCl, 1.0 mM EDTA, and 20 mM butylated hydroxytoluene (BHT).
3. Buffer B: 0.10 M potassium pyrophosphate buffer (pH 7.4) containing 1.0 mM EDTA and 20 mM BHT.
4. Buffer C: 10 mM Tris–acetate buffer (pH 7.4) containing 1.0 mM EDTA and 20% glycerol (v/v).

Rats are killed by CO_2 asphyxiation in a closed container, in line with current animal care regulations. Livers are excised and placed in cold 1.15% KCl. All subsequent steps are carried out at 0°C–4°C. The livers are trimmed of debris and washed with 1.15% KCl; if one desires, hemoglobin contamination can be lowered by perfusing livers with KCl via the portal vein. The livers are blotted and weighed, placed in four times that weight of buffer A, and minced with a scissors. The method of homogenization depends upon the scale of the preparation. If only a few livers are used, a mechanically driven Teflon-glass homogenizer (4–5 vertical passes) is preferred. For larger preparations, two 40 s bursts in a Waring blender are more efficient.

The homogenate is centrifuged at $10^4 \times g$ for 20 min and the supernatant is saved. If the yield of microsomes is a factor, the precipitate can be homogenized in buffer A again and recentrifuged to obtain additional supernatant. The supernatant is submitted to centrifugation at $10^5 \times g$ (3.5×10^4 rpm in a Beckman 45 Ti rotor) for 60 min to yield a microsomal pellet. After discarding the supernatant, a volume of buffer B equal to that of the discarded supernatant is added and microsomes are removed from the clear glycogen pellet by gentle swirling or, if necessary, with the use of a rubber policeman. The suspended microsomes are homogenized with four passes of a mechanically driven Teflon-glass homogenizer and recentrifuged at $10^5 \times g$ for 60 min; the resulting pellets are homogenized and recentrifuged (60 min at $10^5 \times g$). The pellet is homogenized (with four strokes of the Teflon-glass system) in a minimum volume of buffer C (to give 20–50 mg protein mL^{-1}) and stored at –20°C or –70°C (the latter is preferable).

Several comments are in order. BHT and EDTA are added to retard lipid peroxidation, and the pyrophosphate buffer is useful in removing hemoglobin and nucleic acids.[107] If proteases are a potential problem, as is often the case in extrahepatic tissues, phenylmethylsulfonyl fluoride (PMSF) or other protease inhibitors can be used. PMSF is unstable in water; a stock 0.10 M solution should be prepared in absolute ethanol or *n*-propanol, stored at –20°C, and added to buffers to give a final concentration of 0.10 mM immediately prior to their use. The use of dithiothreitol (DTT) has also been reported to be useful in the preparation of functional rat colon microsomes.[108]

Buffers containing 0.25 M sucrose can be substituted for buffers A and B in the procedure. Some older procedures can be applied if an ultracentrifuge is not available. Precipitation of microsomes can be done at much lower speeds when 8 mM $CaCl_2$ is added to buffers.[109] Alternatively, microsomes have been isolated using gel exclusion chromatography.[110,111] More sophisticated techniques are available for the separation of rough and smooth endoplasmic reticulum and Golgi apparatus fractions. Some workers prefer to store microsomes as frozen pellets. For many enzyme activities, microsomes are functional for at least several months when stored frozen, either as pellets or homogenized in buffer C.

Essentially identical procedures are routinely used to prepare microsomes and cytosol from livers of other animals, including humans.[112] In work with human samples, it is advisable to have individual samples tested for HIV and hepatitis B (and other forms of hepatitis) if at all possible before proceeding. Personnel should be immunized against hepatitis B and C. In handling tissues, personnel should handle samples as if viruses such as HIV or hepatitis might be present, that is, that even a viral test could be in error. Good hygiene is essential, and some key practices used in this laboratory include the following: (1) delivery of all residual tissue materials to the infectious diseases division of the institution for incineration or other disposal; (2) carrying out early steps that produce aerosols (homogenization, balancing of tubes containing crude fractions) in a fume hood; (3) *absolutely no* mouth pipetting; (4) prompt disposal of blotters over which all work has been done; (5) use of disposable plastic gloves and other protective clothing; (6) disinfection of glassware, knives, etc., in an appropriate detergent (e.g., Decon LopHene Detergent Disinfectant, Fisher Scientific, Pittsburgh, PA—containing phenols); and (7) above all, use of common sense in handling potentially dangerous material.

The same procedures used for livers of various animals may be adapted to extrahepatic tissues,[113] although these are usually more resistant to homogenization. Cutting devices (e.g., Tissue-mizer) may be used, although caution is advised if catalytic activity is to be measured in samples. The effects of such procedures should be checked.

Assay of P450

The most generally used method is that of Omura and Sato,[114] which utilizes the reduced-CO versus reduced difference spectrum. The procedure used in this laboratory is outlined in the succeeding text.

Reagents:

1. 0.10 M potassium phosphate buffer (pH 7.4) containing 1.0 mM EDTA, 20% glycerol (v/v), 0.50% sodium cholate (w/v), and 0.40% Tergitol NP-10 (Sigma–Aldrich Chemical Co., St. Louis, MO), Emulgen 913 (Kao-Atlas, Tokyo, Japan), or equivalent detergent (w/v)
2. $Na_2S_2O_4$ (sodium dithionite, sodium hydrosulfite), reagent grade (keep bottle tightly closed when not in use)
3. CO gas (in pressurized tank), reagent purity; *store and use in fume hood*

Microsomes (or other preparations) are added to buffer to give a final concentration of 0.05–5 μM P450, mixed, and divided into two 1.0 mL glass or (disposable) polystyrene cuvettes (10 mm pathlength). The sample cuvette is saturated with 40–60 bubbles of CO at a rate of about 1 bubble s^{-1}. A baseline is recorded between 400 and 500 nm using a split-beam spectrophotometer. A few crystals of $Na_2S_2O_4$ (1–2 mg) are added to each cuvette; the cuvettes are covered with parafilm, inverted several times to mix the $Na_2S_2O_4$, and placed in the spectrophotometer again after checking for liquid on the sides of the cuvettes (alternatively, a *plumping* device [*add-a-mixer*, from NSG Precision Cells, Farmingdale, New York] can be used to mix the contents, without removing the cuvette from the chamber). Spectra are recorded (400–500 nm) until the 450 nm peak reaches a maximum.

The A_{490} (isosbestic point) serves as a reference point. P450 content is determined as follows (Figure 40.13):

$$\frac{\left(\Delta A_{450}-A_{490}\right)_{\text{observed}}-\left(\Delta A_{450}-A_{490}\right)_{\text{baseline}}}{0.091}=\text{nmol P450 mL}^{-1}$$

Cytochrome P420 represents denatured forms of P450 and is determined using the following formulae:

$$\left(\text{nmol P450/mL}\right)\times\left(-0.041\right)=\left(\Delta A_{420}-A_{490}\right)_{\text{theoretical}}$$

$$\frac{\left(\Delta A_{420}-A_{490}\right)_{\text{observed}}-\left(\Delta A_{420}-A_{490}\right)_{\text{theoretical}}-\left(\Delta A_{420}-A_{490}\right)_{\text{baseline}}}{0.110}$$

$$=\text{nmol cytochrome P420 mL}^{-1}$$

The extinction coefficient ($\Delta\varepsilon_{450-490}$) of 91 mM^{-1} cm^{-1} has been verified using highly purified rat and rabbit liver P450 preparations.[115,116] The second set of formulae is based upon the observation that P450 has an extinction coefficient of −41 mM^{-1} cm^{-1} ($\Delta\varepsilon_{420-490}$) in the difference spectrum

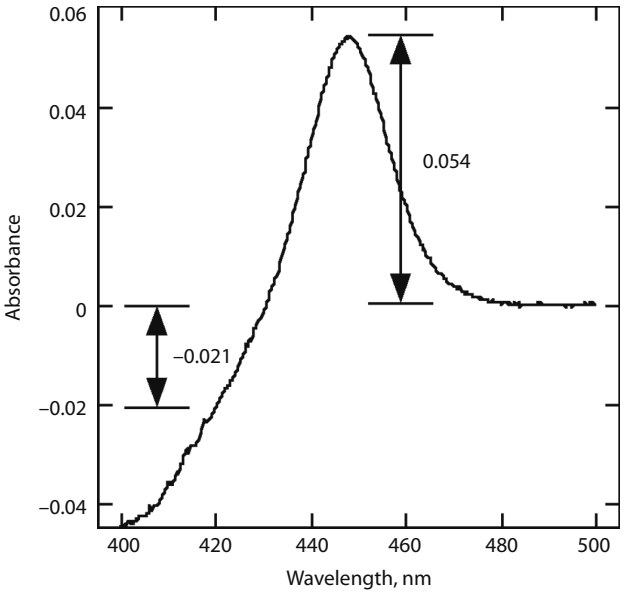

FIGURE 40.13 Calculation of P450 and P420 concentrations. A sample of rat liver P450 1A1 was diluted 10-fold with 0.1 M potassium phosphate buffer (pH 7.7) containing 1 mM EDTA, 20% glycerol (v/v), 0.2% Emulgen 913 (w/v), and 0.5% sodium cholate (w/v). The sample was divided into two cuvettes, and one was saturated with CO gas. The two cuvettes were balanced in an Aminco DW2a/OLIS spectrophotometer using the automatic baseline correction mode. The corrected baseline was recorded. After addition of $Na_2S_2O_4$ as indicated in the text, the final difference spectrum was obtained. The calculations are as follows: 0.054/0.091 = 0.59 nmol P450 mL^{-1}, 0.59 × (−0.041) = −0.024 (A_{420}), −0.024 − (−0.021) = 0.003, 0.003/0.110 = 0.03 nmol cytochrome P420 mL^{-1}, 0.59 × 10 = 5.9 nmol P450 mL^{-1}, and 0.03 × 10 = 0.3 nmol cytochrome P420 mL^{-1}. See text for further discussion.

(i.e., the A_{420} of the reduced-CO complex is less than the A_{420} of the reduced P450).[117]

While rat liver microsomes can be routinely prepared with minimal hemoglobin contamination, this is not the case for extrahepatic preparations. The basic procedure of Matsubara et al.[118] for assaying P450 in liver homogenates is then useful. In this method, two cuvettes are prepared as before but both are equilibrated with CO and the baseline is recorded. $Na_2S_2O_4$ is added *only* to the sample cuvette to obtain a reduced-CO versus oxidized-CO difference spectrum; the extinction coefficient ($\Delta\varepsilon_{450-490}$) is 106 mM^{-1} cm^{-1}. Distinguishing between methemoglobin and cytochrome P420 is difficult, although Johannesen and DePierre[119] have reported that methemoglobin can be specifically reduced by ascorbate and phenazine methosulfate.

Detergents are routinely used in the assay of P450 in this laboratory, as these solubilize the microsomal membranes to reduce light scattering and do not denature P450 in the presence of glycerol.[107] The buffer also helps prevent settling of any insoluble particles. However, some particular P450 proteins may not necessarily be stable in the presence of these detergents.[60] If one desires to carry out determinations in the absence of detergents, a spectrophotometer should be used that is capable of handling turbid solutions. The limit of

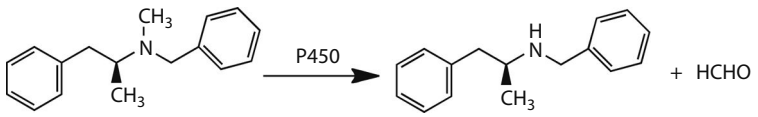

FIGURE 40.14 *d*-Benzphetamine *N*-demethylation.

detection of P450 in extrahepatic tissues is influenced more by the presence of hemoglobin than instrumental considerations. In our own laboratory, we have used Varian 635M and Cary 14, 210, and 219 spectrophotometers for such measurements in the past. Other instruments are also suitable. The Aminco DW-2a instrument has historically been popular among investigators, and we currently use a computer-updated version (On-Line Instrument Systems, Bogart, GA) in our own laboratory; this is particularly useful with bacterial cells (e.g., heterologous expression) because of the ability to handle turbid samples.

Assay of NADPH–Cytochrome *c* Reduction

This enzyme is conveniently measured by its NADPH–cytochrome *c* reduction activity.[120]

Reagents:

1. Horse heart cytochrome *c* (0.50 mM) in 10 mM potassium phosphate buffer (pH 7.7)
2. 0.30 M potassium phosphate buffer (pH 7.7)
3. 10 mM NADPH (fairly stable for <7 days at 4°C in the dark; however, for the most accurate work, solutions should be prepared fresh daily)

Pipette 80 µL of cytochrome *c* solution, the enzyme sample, and sufficient 0.30 M phosphate buffer in a 1.0 mL cuvette (10 mm pathlength) to bring the total volume to 0.99 mL. The components are mixed and preincubated at 30°C (room temperature is also acceptable for most measurements) in a recording spectrophotometer; the recorder is adjusted to zero absorbance at 550 nm (full scale 1.0; slit width 1.0 nm if possible, because of the narrow band being observed). After recording the baseline for 3 min, 10 µL of NADPH is added and the A_{550} is followed for about 3 min. Activity is calculated as follows:

$$\frac{\Delta A_{550}\,\text{min}^{-1}}{0.021} = \text{nmol cytochrome } c \text{ reduced min}^{-1}$$

An amount of enzyme should be used such that the initial ΔA_{550} does not exceed 0.2 min^{-1}. The assay is an indirect measure of NADPH–P450 reductase activity; measurement of the actual reduction of P450 activity requires anaerobic conditions and rapid reaction techniques.[120] The hydrophobic N-terminus of the reductase is required for efficient reduction of P450 but not cytochrome *c*; if no proteolysis has occurred, the two activities are closely correlated.[121]

NADPH–cytochrome *c* reduction activity is stimulated by the high salt concentration used in the assay.[120] If activity is assayed in the presence of mitochondria (or in bacteria), KCN (1.0 mM) may be added as a precautionary measure to block nonmicrosomal activity. The reduction of several other compounds, such as dichlorophenolindophenol, ferricyanide,[121] or a tetrazolium dye,[122] may also be used to assay activity. Spectrophotometers with automatic sample positioners or plate readers may be used to carry out multiple assays simultaneously.

Assays of P450-Linked Activities

Some classic and typical assays will be presented, along with prototypes of different types of methods and approaches.

Benzphetamine *N*-Demethylation

The assay of this activity (Figure 40.14) has been very popular because of its ease and sensitivity, especially with microsomes prepared from animals treated with barbiturates or similar inducers. At least three assays can be used. HCHO is released during the reaction and forms the basis for the first two of the assays.

Colorimetric Measurement of HCHO

For studies on colorimetric measurement of HCHO and other carbonyls, see Nash et al.[123–125]

Reagents:

1. 1.0 M potassium phosphate buffer, pH 7.7.
2. 10 mM $NADP^+$.
3. 1 mg = 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.7] containing 1.0 mM EDTA and 20% glycerol [v/v]).
4. 0.10 M glucose 6-phosphate.
5. NADPH-generating system: Mix 25 parts Reagent 2, 1 part Reagent 3, and 50 parts Reagent 4, in an amount sufficient to supply 0.15 mL (mL of total reaction)$^{-1}$; store on ice during the day of use and then discard. This mixture may need to be preincubated to the reaction temperature prior to addition; otherwise, keep on ice during the day of use, then discard. *Note*: The system may be easily checked before use, which is a good idea when using new reagents or doing a large number of experiments: add 0.10 mL of the reaction buffer, 0.05 mL of Reagent 2, 0.10 mL of Reagent 4, and 0.75 mL H_2O to a cuvette and mix. Place this in a spectrophotometer and adjust the baseline to zero. Add 2 µL of Reagent 3, preferably using a plumping device (see P450 assay given earlier), and record the change in A_{340}. The system should reach an A_{340} of 1.0–2.0 within 60 s.

6. 10 mM *d*-benzphetamine · HCl.
7. 17% aqueous $HClO_4$ (w/v, 1/4 dilution of conc. $HClO_4$).
8. Nash reagent [300 g $NH_4CH_4CO_2$, 4.0 mL acetylacetone (2,4-pentanedione), and 6.0 mL glacial CH_3CO_2H L^{-1}].

Incubations are carried out in 1.27 mL total volume and include 0.5–2 mg microsomal protein, 50 mM phosphate buffer, and 1.0 mM benzphetamine·HCl (this should be added after the other components from a 10 mM aqueous stock). Tubes are preincubated for 3 min at 37°C and then 0.23 mL of Reagent 5, the NADPH-generating system, to start incubations. After shaking the tubes (150 rpm) for 10 min at 37°C, the incubations are stopped by the addition of 0.50 mL of 17% $HClO_4$ (w/v) and chilled on ice for 5–10 min. (Because of the short incubation time, it is convenient to start and stop individual tubes every 10 s.) Tubes are centrifuged at $3 \times 10^3 \times g$ for 5 min and 1.0 mL of each supernatant is transferred to a new tube. To each of these tubes is added 0.40 mL of Nash reagent. The tubes are heated at 60°C–70°C for 20 min in a water bath (covered with aluminum foil to prevent evaporation). The tubes are cooled in a bath of tap water and A_{412} values are read versus a water blank. Both minus benzphetamine and minus NADPH-generating system blanks should be included; the A_{412} values for these should be similar and are subtracted from the experimental values. A standard curve can be prepared using HCHO; we find that such curves routinely yield factors of 460–480, which, when multiplied by net A_{412}, give the total nmol of HCHO produced. If microcuvettes are used for reading A_{412}, the entire procedure can be scaled down 10-fold if an appropriate spectrophotometer is available. The same procedure is generally applicable to many substrates that release HCHO as a consequence of oxidation by P450.

Radiometric: Extraction of $H^{14}CHO$

This procedure necessitates the use of [*N*-methyl-^{14}C]-benzphetamine but offers increased sensitivity.[116,126] This material can be synthesized from *d*-benzylamphetamine. The synthesis has been carried out in this laboratory.[127]

Assays are set up as in the colorimetric procedure, but the volume is reduced to 0.75 mL and the protein concentration may be reduced to fit the situation. Incubations are stopped by the addition of 0.25 mL 1 M NaOH and 5.0 mL $CHCl_3$ (or CH_2Cl_2). Tubes are mixed using a vortex device and centrifuged ($3 \times 10^3 \times g$ for 5 min). The aqueous upper layer is transferred to a clean tube, 5.0 mL of $CHCl_3$ is added, and the mixing, centrifugation, and transfer steps are repeated. The aforementioned step is repeated once more, and a 0.50 mL aliquot of the aqueous phase is transferred to a miniscintillation vial. The contents are neutralized by the addition of 0.50 mL of 0.10 M sodium citrate buffer (pH 6.5) to which has been added 0.060 M HCl; 5 mL of a water-miscible liquid scintillation cocktail is added. Vials are capped, mixed, and counted (10 min will usually produce satisfactory counting deviation). Blanks contain all components except NADPH or protein.

The efficiency of extraction is >95%. HCHO remains in the aqueous phase and residual substrate is extracted in the $CHCl_3$ layers at the basic pH. A similar procedure may be used in the assay of any substrate that can be labeled with a labeled methyl group that is released following oxidation. An alternate method involves trapping the labeled HCHO product as the dimedone derivative[128] or as the 2,4-dinitrophenylhydrazone or dansylhydrazone derivative and analysis by HPLC (detection with UV, fluorescence, or mass spectrometry).[129,130]

Enhancement of NADPH Oxidation or O_2 Uptake

Because of high rates of endogenous oxidase activity, these procedures are more commonly used with reconstituted enzyme systems than with microsomes.[131,132] In the oxygen electrode procedure, experiments are set up as before and a background rate of O_2 uptake is observed. The differences in the rates obtained with substrates are measured; each nmol of O_2 consumed corresponds to one nmol of substrate oxidized.[132]

The NADPH oxidation assay is carried out in a similar way. The NADPH-generating system is deleted. Incubations, containing all components except NADPH, are preincubated for 3 min at 37°C in 1.0 mL cuvettes in a recording spectrophotometer set at 340 nm (1.0 full scale absorbance). NADPH (15 μL of a 10 mM solution, prepared the same day) is added and the rate of decrease in A_{340} is observed. Blank incubations contain all components except benzphetamine. Rates are determined by dividing net ΔA_{340} min^{-1} by 0.00622 to obtain nmol NADPH oxidized min^{-1}.

The NADPH oxidation and O_2 uptake rates are higher than the rate of oxidation of the substrate because some of the electrons are used in the abortive reduction of O_2 to H_2O_2 and H_2O. The stoichiometry can be calculated.[133]

Fluorescence

7-Ethoxycoumarin O-Deethylation

This reaction (Figure 40.15) is an example of a fluorescence assay involving extraction; it is very sensitive, convenient, and applicable to a wide variety of samples.[134,135]

Reagents:

1. 30 mM 7-ethoxycoumarin (Sigma–Aldrich Chemical Co., St. Louis, MO), dissolved in CH_3OH (avoid exposure to light, store in amber glass).
2. 1.0 M potassium phosphate buffer (pH 7.4).
3. 10 mM $NADP^+$.
4. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.7] containing 1 mM EDTA and 20% glycerol [v/v]).

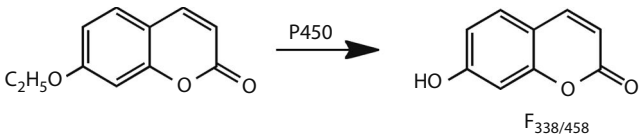

FIGURE 40.15 7-Ethoxycoumarin *O*-deethylation.

5. 0.10 M glucose 6-phosphate.
6. NADPH-generating system: Mix 25 parts Reagent 2, 1 part Reagent 3, and 50 parts Reagent 4 in an amount sufficient to supply 0.15 mL (mL of total reaction)$^{-1}$; see "Benzphetamine *N*-Demethylation" section regarding checking the system.
7. 0.20 M sodium borate (pH 9.6).
8. 1.0 mM 7-hydroxycoumarin (Sigma–Aldrich), dissolved in an aqueous solution of 0.10 N NaOH and 0.10 M NaCl (prepare fresh solution each day; avoid exposure to light).

An appropriate amount of enzyme is placed in a test tube along with 50 mM phosphate buffer, 0.30 mM 7-ethoxycoumarin, and water to bring the volume to 0.90 mL. After 3 min preincubation at 37°C, 0.15 mL of Reagent 6, the NADPH-generating system, is added per mL to start incubations. (As in the case of benzphetamine, reactions are conveniently started and stopped each 15 s.) After 5–10 min, incubations are stopped by the addition of 0.10 mL of 2.0 M HCl and 2.0 mL $CHCl_3$. Tubes are mixed and centrifuged for 5 min at $3 \times 10^3 \times g$. One milliliter of the lower $CHCl_3$ phase (containing both substrate and product) is transferred to a clean tube and 2.0 mL of 0.20 M sodium borate buffer is added. The tubes are mixed and centrifuged 5 min at $3 \times 10^3 \times g$. The upper phase, containing the phenolic product, is transferred to a new tube and fluorescence is read versus a standard curve in a fluorimeter with the excitation wavelength set at 338 nm and the emission wavelength set at 458 nm.

Benzo[a]pyrene Hydroxylation

This assay has been widely used because of its sensitivity, the widespread occurrence of this activity, and the interest in carcinogenic aspects of benzo[*a*]pyrene. This substrate is carcinogenic, light sensitive, and gives rise to many metabolites. The following procedure measures primarily the 3-hydroxy derivative (Figure 40.16) and, to a lesser extent, 9-hydroxybenzo[*a*]pyrene.[136]

Reagents:

1. 1.0 M potassium phosphate buffer (pH 7.4).
2. 10 mM $NADP^+$.
3. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.7] containing 1.0 mM EDTA and 20% glycerol [v/v]).
4. NADPH-generating system: Mix 25 parts Reagent 2, 1 part Reagent 3, and 50 parts Reagent 4 in an amount sufficient to supply 0.15 mL (mL of total reaction)$^{-1}$; see "Benzphetamine *N*-Demethylation" section regarding checking the system.
5. 8.0 mM benzo[*a*]pyrene, dissolved in $(CH_3)_2CO$.
6. 6.0 mM quinine, dissolved in 0.10 M H_2SO_4.
7. 1.0 mM 3-hydroxybenzo[*a*]pyrene (this material can be obtained from the National Cancer Institute Chemical Carcinogen Reference Repository, c/o Midwest Research Institute, Kansas City, MO).

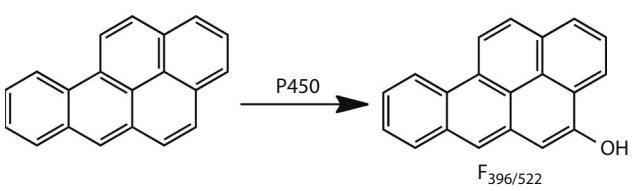

FIGURE 40.16 Benzo[*a*]pyrene 3-hydroxylation.

An appropriate amount of enzyme is placed in a test tube along with 50 mM phosphate buffer (pH 7.4), 80 μM benzo[*a*]pyrene, and sufficient water to bring the total volume to 1.0 mL. (All procedures should be carried out in dim light [or under yellow light]. Alternatively, reactions may be done in amber glass vials. Appropriate precautions should be taken to prevent exposure of skin to benzo[*a*]pyrene or its metabolites. When solid material is being handled, precautions should be taken to avoid breathing dust.) After 3 min preincubation at 37°C, 0.15 mL of Reagent 4 (NADPH-generating system) is added per mL to initiate reactions (this is conveniently done every 10–15 s). After 5–10 min, reactions are stopped by the addition of 1.0 mL of cold acetone and mixed. Hexane (3.25 mL) is added and mixing is repeated. An aliquot of the upper layer (2.0 mL) is transferred to a clean tube with a pipette and 4.0 mL of 1.0 M NaOH is added to this. After vortex mixing and centrifugation for 5 min at $3 \times 10^3 \times g$, the aqueous phase is carefully transferred to a clean tube.

Fluorescence is read with an excitation wavelength of 396 nm and emission wavelength of 522 nm. A standard curve is prepared in 0.10 M NaOH using 3-hydroxybenzo[*a*]-pyrene. Since solutions of the standard are unstable, a convenient method involves setting up the standard curve, changing the wavelength settings to 350 nm (excitation) and 450 nm (emission) without adjusting other settings and preparing a standard curve using serial dilutions of quinine sulfate. The quinine sulfate can then be used as a secondary standard in subsequent experiments and levels of 3-hydroxybenzo[*a*]pyrene can be calculated by reference to the original curves.

An alternative fluorescence procedure devised by Dehnen et al.[137] is comparable in terms of convenience and sensitivity. Other benzo[*a*]pyrene metabolism assays can be carried out with radioactive substrate to measure total polar metabolites,[138] individual metabolites (after separation by high-pressure liquid chromatography [HPLC]),[139,140] or metabolites covalently bound to protein or added nucleic acids.[141]

HPLC

Nifedipine Oxidation

A description of this assay is added to serve as an example of how HPLC methods may be utilized very effectively. Nifedipine is a widely used calcium channel blocker and oxidation by P450 renders it inactive.[142]

Nifedipine oxidation (from the dihydropyridine to the pyridine product [Figure 40.17]) is measured in the following manner. *All incubation, extraction, and other handling of samples are done in amber vials because of the light sensitivity of nifedipine solutions.* Amber glass vials

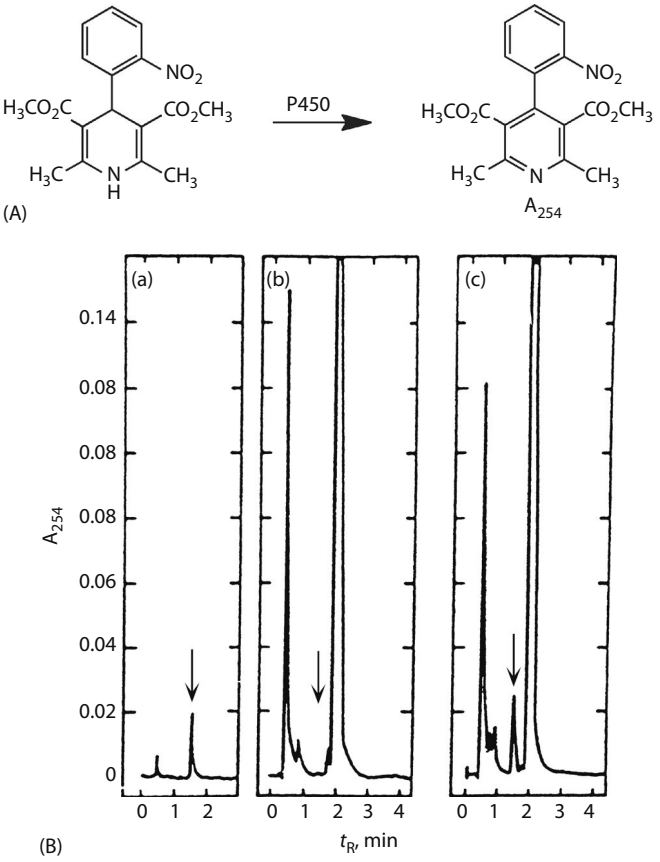

FIGURE 40.17 (A) Oxidation of nifedipine to the pyridine derivative.[142] (B) HPLC separation of the oxidized (pyridine) product of nifedipine oxidation from human liver microsomes. A typical 10 min incubation with 100 pmol of human liver microsomal P450 was done and 20 µL of the total extract was chromatographed as described. The t_R of the nifedipine oxidation product is indicated with an arrow. (a) Authentic standard of the metabolite (200 ng), (b) extract of an incubation devoid of NADPH, and (c) complete incubation. (From Guengerich, F.P. et al., *J. Biol. Chem.*, 261, 5051, 1986.)

are available from Fisher Scientific (Pittsburgh, PA). The use of aluminum foil is not a substitute (here or in other light-sensitive applications), in that it only acts as a mirror. Typical incubations include liver microsomes containing 10–100 pmol of P450, 0.10 M potassium phosphate buffer (pH 7.85), and 0.20 mM nifedipine (added from a stock solution of 20 mM in CH_3OH) in a final volume of 0.50 mL. The components are equilibrated for 3 min at 37°C and the reaction is initiated by the addition of an NADPH-generating system consisting of (final concentrations) 10 mM glucose 6-phosphate, 0.50 mM $NADP^+$, and 1.0 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (see "Benzphetamine *N*-Demethylation" section regarding using and checking the system). The reaction proceeds for 10 min at 37°C and is then quenched by the addition of 2.0 mL of CH_2Cl_2. One hundred microliters of 1 M Na_2CO_3 buffer (pH 10.5) containing 2.0 M NaCl is added to each vial. The contents of each vial are mixed using a vortex device and the two layers are separated by centrifugation at $3 \times 10^3 \times g$ for 10 min. From each lower organic layer, 1.4 mL is transferred to an amber *Reactivial* (Fisher Scientific, Pittsburgh, PA). The total extract is reduced to dryness at 23°C under an N_2 stream. The residue is dissolved in 50 µL of CH_3OH and 20 µL is injected onto an octadecylsilane (C_{18}) reversed-phase HPLC column (e.g., 6.2 mm × 80 mm; Mac-Mod, Chadds Ford, PA,[142] or suitable alternative) placed in series following an octadecylsilane guard column and 0.2 mm filter. The column is eluted with an isocratic mixture of 64% CH_3OH–36% H_2O (v/v) at a flow rate of 3.0–4.0 mL min^{-1}. Detection is at 254 nm (found to be optimal by previous scanning). Quantitation is usually done with external standards and by the use of peak heights. Alternatively, nitrendipine or another dihydropyridine[143,144] can be used as an internal standard. Typically, a 20 ng sample of the metabolite (59 pmol) yields a maximal A_{254} of about 0.015 under these conditions (in the HPLC effluent). A typical chromatogram resulting from injection of a human liver microsomal incubation extract is shown in Figure 40.16.

Assay conditions were optimized with a human liver microsomal sample.[142] Product formation was linear up to a time of 20 min, the pH optimum was 7.85 (Tris–HCl yielded lower rates than did potassium phosphate buffer), the rate of product formation per unit enzyme was constant over a range of 5–1000 nM P450, and a substrate concentration of 200 µM was optimal (K_m ~ 10 µM; substrate inhibition observed at concentrations >500 µM; no evidence for multiphasic behavior observed over the concentration range of 2–1000 µM).

When purified P450 fractions are assayed for activity, the microsomes are replaced with 20–100 pmol of P450, 250 pmol of rabbit NADPH–P450 reductase, 250 pmol cytochrome b_5, and 15 nmol of L-α-1,2-dilauroyl-*sn*-glyceryl-3-phosphocholine. These components are mixed and then incubated for 10 min at 23°C prior to addition of other materials. Examination of experimental conditions indicated that the NADPH–P450 reductase, substrate, and phospholipid concentrations used are optimal. However, product formation is not linear for more than 5 min. The use of alternate phospholipids has been found to improve the activity.[61]

The separation of the product from the substrate is very efficient with the reversed-phase system used. The only solvent components needed are CH_3OH and H_2O, thus eliminating any problems with salts. The product elutes before the substrate, enhancing sensitivity of the assay. There is no need to have more than baseline separation, and interfering peaks are absent. Thus, a short column can be used with a high flow rate and low back pressure. The total HPLC time for each assay can be <3 min. The efficiency of analysis could also be improved with the use of an automated injection system. Analysis time can also be reduced if incubations are only deproteinized and not extracted prior to HPLC analysis, but the sensitivity would be reduced.

Chlorzoxazone 6-Hydroxylation

Another HPLC-based assay of P450 activity involves measurement of the 6-hydroxylation of chlorzoxazone (Figure 40.18).

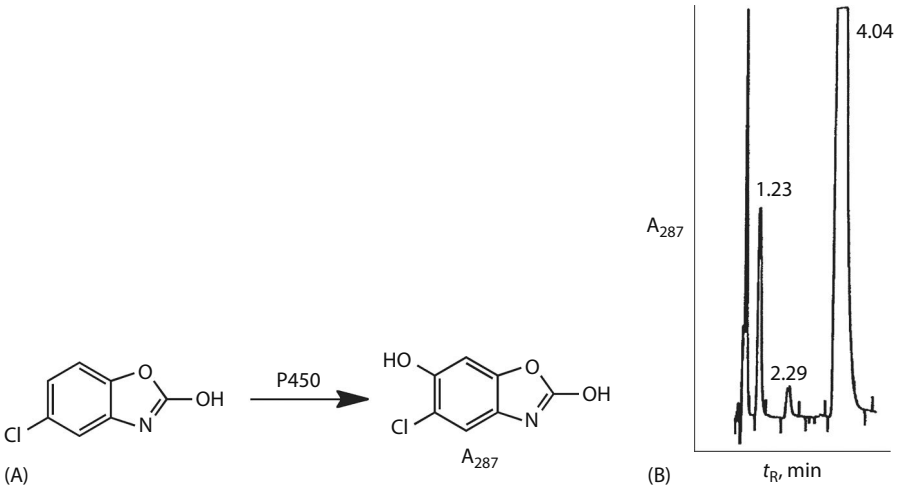

FIGURE 40.18 (A) Chlorzoxazone 6-hydroxylation. (B) HPLC separation of an extract of a chlorzoxazone incubation. See text for details. In this particular assay, 0.27 nmol of human P450 (in liver microsomes) was incubated for 10 min with 0.5 mM chlorzoxazone. The t_Rs of the individual peaks are designated: 1.23 min, 6-hydroxychlorzoxazone; 2.29 min, 5-fluorobenzoxazolinone; and 4.04 min, chlorzoxazone. (From Peter, R. et al., *Chem. Res. Toxicol.*, 3, 566, 1990.)

This reaction has been reported to be highly selective for P450 2E1 in human liver.[39,145] The assay presents considerable advantages of sensitivity, reliability, and specificity over many other traditional assays for the function of P450 2E1, for example, *N*,*N*-dimethylnitrosamine *N*-demethylation and 4-nitrophenol 2-hydroxylation. Chlorzoxazone is used as a drug ([145] and references therein) and this general procedure can be used to measure pharmacokinetic parameters in humans to assess their relative levels of P450 2E1.[146,147]

Reagents:

1. 1 M potassium phosphate buffer (pH 7.4).
2. $NADP^+$, 10 mM.
3. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.4] containing 1 mM EDTA and 20% glycerol [v/v]).
4. 0.1 M glucose 6-phosphate.
5. NADPH-generating system: Mix 25 parts Reagent 2, 1 part Reagent 3, and 50 parts Reagent 4 in an amount sufficient to add 0.15 mL (mL of total reaction)$^{-1}$; see "Benzphetamine *N*-Demethylation" section regarding checking the system.
6. 50 mM chlorzoxazone in 60 mM KOH (prepare fresh daily and store on ice: dissolve 51 mg chlorzoxazone [Sigma Aldrich, St. Louis, MO] in 0.36 mL 1.0 N KOH by vigorous mixing with a vortex device or sonic bath, add 0.64 mL H_2O, continue mixing until dissolved, and then add 5.0 mL H_2O). Avoid introduction of organic solvents, because they are inhibitors of P450 2E1.[148,149]
7. 6-Hydroxychlorzoxazone [standard product; see Peter et al.[145] for synthesis].
8. Either 2-benzoxazolinone (Sigma Aldrich) or 5-fluorobenzoxazolinone[145] dissolved in 2.0% aqueous propylene glycol 400 (internal standard [optional]).

An appropriate amount of enzyme is placed in a test tube along with 50 mM potassium phosphate buffer (pH 7.4) and 0.50 mM chlorzoxazone (final incubation volume 0.50 mL). After 3 min preincubation at 37°C, 0.15 mL of Reagent 5 (the NADPH-generating system) is added per mL to start incubations. After 10–20 min at 37°C, reactions are stopped by the addition of a 25 µL of aqueous 43% H_3PO_4 (w/v). An appropriate amount of the internal standard (5.0 nmol) is also added to each tube, followed by 2.0 mL of CH_2Cl_2. The contents of each tube are mixed using a vortex device and the layers are separated by brief centrifugation ($3 \times 10^3 \times g$, 10 min). An aliquot (1.6 mL) of each lower (CH_2Cl_2) layer is transferred with a pipette to a clean test tube or conical vial (Reacti-vial, Fisher Scientific, Pittsburgh, PA) and the solvent is removed under an N_2 stream of 23°C. The residue is dissolved in 50 µL of CH_3CN (mixing on a vortex device) and 20 mL is injected onto a 6.2 mm × 80 mm Zorbax octylsilane (C_8) HPLC column (3 µm, Mac-Mod, Chadds Ford, PA)[145] (or equivalent) utilizing a solvent mixture of 32% CH_3CN (v/v) and 0.5% H_3PO_4 (w/v) in H_2O, with UV detection at 287 nm (flow rate 3.5 mL min^{-1}) (Figure 40.18). Under these conditions, each assay requires ≤5 min HPLC time. For more complex samples, the CH_3CN concentration may need to be decreased to move the produce peak away from the solvent front. It is reasonable to use as little as 5 pmol of microsomal P450 in this assay and obtain reliable results.

GC–Mass Spectrometry

N,N-Dimethylaniline N-Demethylation

Amine *N*-dealkylations are catalyzed by a number of different oxidases and are important in the disposition of drugs and other chemicals. The P450-dependent reactions have historically been of the most interest, although such reactions can also be catalyzed by peroxidases, flavoproteins, and other enzymes as well.[150] The mechanism of the reaction has been a matter of considerable interest and the reader is

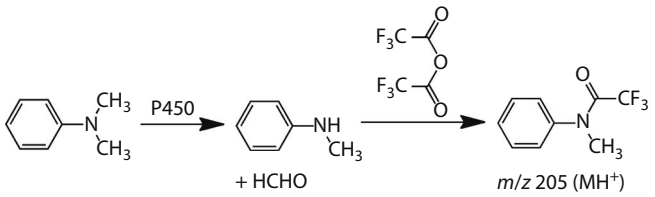

FIGURE 40.19 *N*,*N*-Dimethylaniline *N*-demethylation assay. (From Okazaki, O. and Guengerich, F.P., *J. Biol. Chem*., 268, 1546, 1993; Miwa, G.T. et al., *J. Biol. Chem*., 258, 14445, 1983.)

referred to work on this topic.[151,152] The *N*-demethylation of *N*,*N*-dimethylaniline (Figure 40.19) can be assayed by measurement of HCHO by other procedures (*vide supra*), but the assay is typical of many used for GC and GC–mass spectrometry. It was specifically used in our work to measure kinetic deuterium isotope effects.[151]

Incubations contained an enzyme, an NADPH-generating system (consisting of final concentrations of 0.50 mM $NADP^+$, 10 mM glucose 6-phosphate, and 1.0 IU glucose 6-phosphate dehydrogenase mL^{-1}; see "Benzphetamine *N*-Demethylation" section regarding checking the system), and 1.0 mM *N*,*N*-dimethylaniline in a final volume of 1.0 mL. Reactions proceed for 10 min in vials sealed with Teflon liners (to prevent evaporation of substrate) and are quenched by the addition of 0.40 mL of 17% $HClO_4$ (w/v). After 0.10 mL of 270 μM [N^2-H_3, *ring*-$^2H_5$]*N*-methylaniline is added as an internal standard, the pH is made alkaline and the substrate, products, and perdeuterated internal standard are extracted into 2.0 mL of CH_2Cl_2 by mixing with a vortex device (the internal standard may be prepared by reaction of [*ring*-$^2H_5$]aniline with C^2H_3I[151]). The layers are separated by centrifugation ($3 \times 10^3 \times g$, 10 min) and the (lower) CH_2Cl_2 layer is removed, dried by adding anhydrous Na_2SO_4 and mixing, and then transferred to a clean vial. $(CF_3CO)_2O$ (50 μL) is added to each vial, and the vials are sealed with caps and Teflon liners and allowed to stand overnight at 4°C to form trifluoroacetanilide.

Most of the CH_2Cl_2 is removed under a stream of N_2 (≤30°C), and aliquots (~2 μL) are injected onto a 0.5 mm × 3 m SPB-1 capillary GC column connected to a mass spectrometer operating in the chemical ionization mode with He as the carrier gas and CH_4 as the ionization gas. The column temperature is programmed from 100°C to 280°C at 20° min^{-1}. The ions at *m/z* 205 and 214 (both [M+H$^+$]) are monitored for the product and internal standard. Mixtures of varying ratios of trifluoroacetanilide and the perdeutero derivative are used to prepare a standard curve.

Another example of a procedure involving derivatization of product and GC–mass spectrometry involves the conversion of ethanol to acetaldehyde by human P450 2E1 and derivatization as the oxime.[154] Another example, without derivatization, is presented for ethyl carbamate (EC) (*vide infra*). In some cases, it is impractical to use a heavy isotope as an internal standard, and product analogs must be considered. There are many procedures for GC-based methods involving flame ionization, electron capture, and other means of detection. Electron capture can be a very sensitive assay procedure when halides or nitro groups are present. The use of capillary GC columns has made packed columns nearly obsolete because of the superior resolution. However, the need to use very small injection volumes requires the need for internal standards except in cases where head space analysis is done.

Ethyl Carbamate Desaturation

Ethyl carbamate (urethane) desaturation is presented as another example of a reaction with an assay involving GC–mass spectrometry. The desaturation of EC to vinyl carbamate (VC) (Figure 40.20) had been suggested by Dahl et al.[156,157] but direct evidence for this view had been difficult to obtain. It is now realized that the oxidation of EC to VC is a very slow process and that the succeeding step, epoxide formation, is ~400 times faster (and is catalyzed by the same P450 enzyme).[155] Thus, the steady-state level of VC is very low. The procedure described in the succeeding text can be used to estimate levels of several EC metabolites—VC, 2-hydroxyethyl carbamate, and *N*-hydroxyethyl carbamate.[155] In the reference cited, a major aspect was the qualitative demonstration of these products. With this procedure, it was possible to detect one part product in 10^4 parts substrate.

Reagents:

1. 1.0 M potassium phosphate buffer (pH 7.4).
2. $NADP^+$, 10 mM.
3. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.4] containing 1.0 mM EDTA and 20% glycerol [v/v]).
4. 0.10 M glucose 6-phosphate.
5. NADPH-generating system: Mix 25 parts Reagent 2, 1 part Reagent 3, and 50 parts Reagent 4 in an amount sufficient to supply 0.15 mL (mL of total reaction)$^{-1}$; see "Benzphetamine *N*-Demethylation" section regarding checking the system.
6. 0.10 M EC (urethane, Sigma Aldrich Chemical Co., St. Louis, MO; purify by sublimation—use house vacuum or a water aspirator to achieve ~15 mm Hg).
7. 2-Hydroxyethyl carbamate (formerly Pfaltz and Bauer, Stamford, CT; now listed as available from AKos Building Blocks, Steinen, Germany).

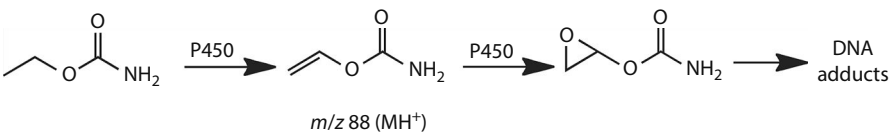

FIGURE 40.20 Desaturation of EC and epoxidation of VC. (From Guengerich, F.P. and Kim, D.-H., *Chem. Res. Toxicol*., 4, 413, 1991.)

8. *N*-Hydroxyethyl carbamate (Sigma–Aldrich, St. Louis, MO).
9. VC.[156,158]
10. Methyl carbamate (Sigma–Aldrich; purify by sublimation before use).

Note: These carbamates, particularly ethyl and vinyl, should be handled with care. They are carcinogenic and volatile. Use fume hoods, closed vials, and appropriate protective clothing.

The oxidation of EC is catalyzed primarily by P450 2E1, so care should be taken to avoid adding organic solvents, which are inhibitory.[148] The reaction is slow and a high concentration of microsomal protein is needed, so it is useful to remove glycerol (or sucrose) from microsomes by dialysis for 1–2 h versus 0.10 M potassium phosphate buffer (pH 7.4) at 4°C just prior to use. Microsomal protein (10–15 mg protein mL^{-1}) is mixed in a vial with 100 mM potassium or an equivalent amount of a reconstituted P450 system, 10 mM EC, and an NADPH-generating system consisting of (final concentrations of) 0.50 mM $NADP^+$, 1 IU glucose 6-phosphate dehydrogenase mL^{-1}, and 10 mM glucose 6-phosphate (see "Benzphetamine *N*-Demethylation" section regarding checking the system). The total volume is 1.0 mL. Each vial is sealed with a cap and Teflon liner and incubated for 2 h at 37°C.

Methyl carbamate is then added as an internal standard and the products are extracted twice into 1 mL of CH_2Cl_2 by mixing on a vortex device and the layers are separated by centrifugation ($3 \times 10^3 \times g$, 10 min). The (lower) CH_2Cl_2 layer is removed and concentrated to ≤0.1 mL under an N_2 stream at ≤23°C, with care taken to avoid concentration to dryness. This extract can either be analyzed directed by GC–mass spectrometry or, if a cleaner sample is required (e.g., for obtaining scans of individual compounds), the products can be extracted from the ~0.1 mL CH_2Cl_2 sample into 1 mL of H_2O. The products are then extracted from the 1 mL of H_2O into 2 mL of CH_2Cl_2, and the CH_2Cl_2 layer is evaporated again to ~0.1 mL. Thus, the water solubility of EC and its products can be used to advantage in this case. An aliquot (1–2 mL) of the extract is injected onto a 0.1 mm × 9 m Carbowax 20M capillary GC column with the effluent directed into a mass spectrometer operating in the chemical ionization mode with CH_4 as the carrier gas. The selectivity and sensitivity are enhanced in the chemical ionization mode, relative to electron impact, in this case. Total ion current and the ions at *m/z* 74, 88, and 106 are monitored as the column is heated with a linear temperature gradient. The actual t_R values depend upon the rate of heating, gas flow rate, etc. Under typical operating conditions, methyl carbamate (*m/z* 74) is eluted at ~4 min, VC (*m/z* 88) at 6.8 min, EC (*m/z* 90, not monitored) at 8.0 min, ethyl *N*-hydroxycarbamate (*m/z* 106) at 10.4 min, and 2-hydroxyethyl carbamate (*m/z* 106) at 12.9 min.[155] Standard curves may be prepared by plotting the ratio of detector response relative to methyl carbamate versus the concentration of each product; such curves were linear over several orders of magnitude for each of the oxidation products under consideration.[155]

The steady-state concentration of VC can be expressed as a function of the EC concentration:

$$[\mathrm{VC}] = \frac{(k_1 K_2)[\mathrm{EC}]}{V_2}$$

where

k_1 is the rate constant for oxidation of EC to VC

V_2 and K_2 are the parameters V_{max} and K_m for the oxidation of VC to form the epoxide (estimated from the rate of formation of 1,N^6-ethenoadenosine)[155]

Thus, the steady-state concentration should be relatively independent of the concentration of enzyme, if both desaturation and epoxidation are catalyzed by the same enzyme (i.e., P450 2E1 in this situation).[155]

HPLC-Fluorescence Assay: 1,N^6-Ethenoadenosine Formation

Fluorescence assays have long been regarded for their high sensitivity.[159] The discrimination of compounds provided by the use of selective excitation and emission wavelengths may be further enhanced by coupling to HPLC. In many cases, the enzyme product has intrinsic fluorescence and may be monitored. In other cases, postcolumn derivatization can be used to render products' fluorescence. The situation described here is somewhat different. A compound is present in the enzyme mixture (adenosine) that does not impede the reaction but reacts with the reaction product to generate a fluorescent product, that is, 1,N^6-etheno(ε)adenosine (Figure 40.21). The procedure has a deficiency in that it probably does not serve as a quantitative trap for any of the compounds under consideration. On the other hand, it is of considerable relevance to studies in toxicology and chemical carcinogenesis in that the same reaction serves to modify DNA to introduce a potentially mutagenic lesion. The procedure described here is based upon our own use[39,155] of methods described earlier by Leithauser et al.[158] and Rinkus and Legator.[160]

Reagents:

1. 1.0 M potassium phosphate buffer (pH 7.4).
2. 50 mM adenosine, dissolved in H_2O (heat in a bath of hot tap water or sonicate to dissolve).
3. Appropriate substrate, dissolved in H_2O (not organic solvent at ~10 × the concentration used in the assay.
4. 10 mM $NADP^+$.
5. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.7] containing 1.0 mM EDTA and 20% glycerol [v/v]).
6. 0.1 M glucose 6-phosphate.
7. NADPH-generating system: Mix 25 parts Reagent 4, 1 part Reagent 5, and 50 parts Reagent 6 in an amount sufficient to supply 0.15 mL (mL of total reaction)$^{-1}$; see "Benzphetamine *N*-Demethylation" section regarding checking the system.
8. Standard solutions of 1,N^6-ε-adenosine dissolved in H_2O.
9. 0.60 M $ZnSO_4$ (in H_2O).

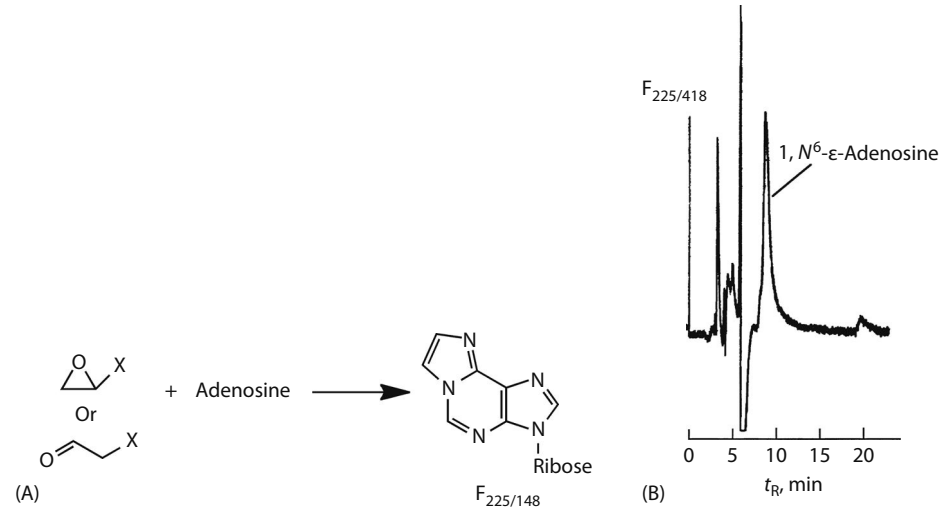

FIGURE 40.21 (A) Reaction of bifunctional electrophiles with adenosine. (B) Formation of 1,N^6-ethenoadenosine in a microsomal incubation. The incubation included 5 mg liver microsomal protein (prepared from isoniazid-treated rats) mL^{-1}, 2.0 mM *N*-methyl,*N*-vinylnitrosamine, 10 mM adenosine, and an NADPH-generating system. After an incubation time of 120 min, a 100 µL aliquot was analyzed as described in the text. (From Guengerich, F.P. et al., *Chem. Res. Toxicol.*, 4, 168, 1991.)

An appropriate amount of microsomes or purified enzyme system is placed in a glass vial (generally to provide ~2 mg microsomal protein mL^{-1}). Reagents are added to give 50 mM potassium phosphate buffer (pH 7.4), 0.50 mM $NADP^+$, 1.0 IU glucose 6-phosphate dehydrogenase mL^{-1}, and the substrate. Most of the substrates that generate products reacting with adenosine to produce 1,N^6-ε-adenosine are small organic compounds (e.g., ethylene dibromide, ethylene dichloride, vinyl chloride, vinyl bromide, acrylonitrile, VC, EC, and some nitrosamines).[39] These are usually substrates for P450 2E1 enzymes; because organic solvents are competitive inhibitors, they should be avoided.[148,149] Although these compounds are considered to be organic solvents, most are actually reasonably soluble in H_2O[39] [see Merck Index and various handbooks of physical constants of chemicals]. Many of these are rather volatile, so the vials may have to be sealed with screw caps and Teflon liners (rubber septa absorb these chemicals and should be avoided). Gases such as vinyl chloride can be added directly to the head space of such vials.

Incubations are initiated by the addition of 0.15 mL of Reagent 7, the NADPH-generating system, which is added per mL, and proceed with shaking at 37°C for a specified period of time. With some of the slower reactions (e.g., EC), Guengerich and Kim[155] and Leithauser et al.[158] have found, surprisingly, that reactions can proceed in a linear manner for up to 3 h. Reactions are stopped by the addition of $ZnSO_4$ to 30 mM. The protein is precipitated by centrifugation at $3 \times 10^3 \times g$ for 10 min, and aliquots of the supernatant are injected onto an HPLC system (octadecylsilane [C_{18}], equilibrated with 11% CH_3CN [v/v] in 50 mM $NH_4CH_3CO_2$ [pH 5.0]). With a 4.6 mm × 250 mm or a 6.2 mm × 80 mm column, as much as 250 µL of material may be injected; at a flow rate of 1.0 mL min^{-1}, the t_R of 1,N^6-ε-adenosine is typically ~8 min. The effluent passes through the flow cell of a spectrofluorimeter, with the excitation wavelength set at 225 nm and using a 418 nm emission filter. The 1,N^6-ε-adenosine peak follows a large negative peak of residual adenosine (Figure 40.21). If enough separation is not seen, then the concentration of CH_3CN should be reduced. As little as 0.5 pmol of 1,N^6-ε-adenosine can be detected using this method.

Continuous Assays

Two examples of P450-based assays are provided as examples, coumarin 7-hydroxylation and 4-nitroanisole *O*-demethylation. The continuous monitoring of a reaction, when possible, allows the investigator to determine exactly what part of the enzyme assay data to establish linearity, that is, when the enzyme is functioning under steady-state conditions and before substrate depletion, product inhibition, etc., are issues. The change in absorbance is used to calculate a rate, using the known extinction coefficient for the product. In the case of fluorescence, a known amount of the product must be used to calibrate the instrument.

4-Nitroanisole O-Demethylation

This is an assay that has been used in P450 assays for many years and uses the (yellow) absorbance of the product as the basis (Figure 40.22).[161,162]

Reagents:

1. 1 M potassium phosphate buffer (pH 7.7)
2. 10 mM $NADP^+$
3. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.7] containing 1.0 mM EDTA and 20% glycerol [v/v])
4. 0.10 M glucose 6-phosphate
5. 10 mM 4-nitroanisole (in CH_3CN)

In this assay, the product 4-nitrophenol has a broad absorbance band at 400 nm. The absorbance is only seen for the

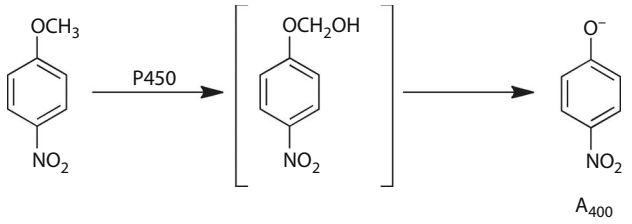

FIGURE 40.22 4-Nitroanisole *O*-demethylation.

anionic form of the product (unprotonated), so the apparent extinction coefficient is pH sensitive.

An enzyme system containing P450 and NADPH–P450 reductase is incubated in 1.0 mL of 0.1 M potassium phosphate buffer (pH 7.7), along with 100 μM 4-nitroanisole, 10 mM glucose 6-phosphate, and 150 μM $NADP^+$, in a glass or plastic cuvette in a spectrophotometer and equilibrated at 37°C (for 5 min). Absorbance can be recorded at 400 nm to be sure that no change in A_{400} occurs during this period due to turbidity, or refractive index changes. In a typical experiment, 0.25 μM rabbit P450 1A2, 0.50 μM NADPH–P450 reductase, and 50 μM L-α-dilauroyl-*sn*-glycero-3-phosphocholine were used as the enzyme system.[162] The assays can also be done with microsomes.[161] The reaction is started by the addition of 2 μL of the glucose 6-phosphate dehydrogenase solution. A convenient means of adding the last reagent to start the reaction is with a *plumping* device (see P450 determination section previously mentioned), that holds up to 50–100 μL of a reagent and can be used to add materials to cuvettes in a spectrophotometer, without withdrawing the cuvette. Doing this minimizes the *dead* time and also avoids errors due to repositioning the cuvette in the chamber. A_{400} is monitored for 1–2 min, recording the trace in the instrument. Under these conditions, $\Delta\varepsilon_{400}$ = 12.0 mM^{-1} cm^{-1}, so an A_{400} change of 0.012 corresponds to 1 nmol of product formed (in a 1.0 mL cuvette, with an optical pathlength of 10 mm).

A convenient means of analyzing the results is to do the experiments in a spectrophotometer connected to a computer. In this laboratory, the assays are usually done with a Cary 14-OLIS instrument (OLIS, Bogart, GA). The collected data can be handled to use only the linear portions of the traces and to fit the lines with regression analysis. The disappearance of substrate can also be monitored at 314 nm ($\Delta\varepsilon_{314}$ = 10.4 mM^{-1} cm^{-1}).[162]

Coumarin 7-Hydroxylation

The principle of the assay is similar to that described for the 7-ethoxycoumarin *O*-deethylation assay. Coumarin has some fluorescence, but the product 7-hydroxycoumarin has much stronger fluorescence (Figure 40.23). The fluorescence

FIGURE 40.23 Coumarin 7-hydroxylation.

($F_{390/460}$) is much stronger for the anionic form of the product, so it is pH dependent (a 390 nm wavelength is used for excitation to avoid interference from the NADPH at 340 nm). Among the human P450 enzymes, the reaction is selectively catalyzed by P450 2A6.[163,164]

Reagents:

1. 1 M potassium phosphate buffer (pH 7.7)
2. 10 mM $NADP^+$
3. 10^3 IU yeast glucose 6-phosphate dehydrogenase mL^{-1} (dissolved in 10 mM Tris–acetate buffer [pH 7.7] containing 1.0 mM EDTA and 20% glycerol [v/v])
4. 0.10 M glucose 6-phosphate
5. 5 mM coumarin, dissolved in H_2O
6. 100 μM 7-hydroxycoumarin, dissolved in H_2O

An enzyme system containing P450 2A6 and NADPH–P450 reductase is incubated in 3.0 mL of 0.10 M potassium phosphate buffer (pH 7.7) and equilibrated at 37°C for 3–5 min in the compartment of the spectrofluorimeter, along with 50 μM coumarin, 10 mM glucose 6-phosphate, and 150 μM $NADP^+$. The fluorescence excitation wavelength is set to 390 nm and the emission wavelength is 460 nm. The reading can be adjusted to zero with some instruments at this point, and the fluorescence output should be stable. The reaction is initiated by the addition of 3 μL of the glucose 6-phosphate dehydrogenase solution, and fluorescence ($F_{390/460}$) is monitored continuously for 2–3 min (Figure 40.24). The data are calibrated by adding a known amount of 7-hydroxycoumarin (also using a plumping device) and recording the change in $F_{390/460}$. A computer-linked spectrofluorimeter is useful for recording and analyzing the data. In this laboratory, an OLIS DM-45 instrument is routinely used.

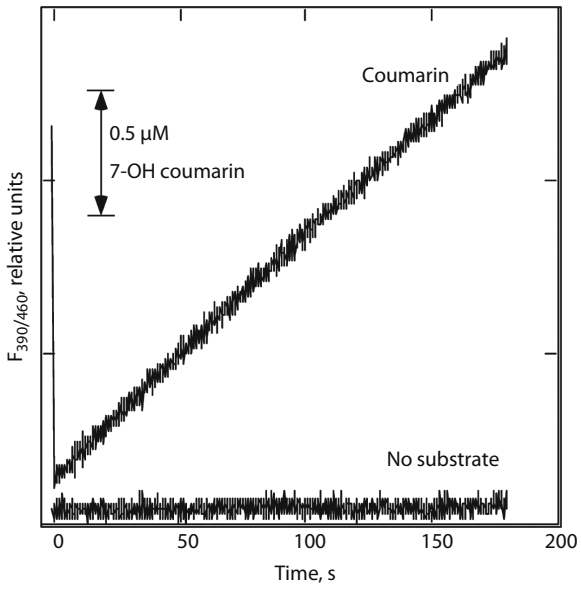

FIGURE 40.24 Continuous fluorescence traces for 7-hydroxylation of coumarin by P450 2A6.[165] An NADPH-generating system was used in both cases.

HPLC–Mass Spectrometry: Midazolam Hydroxylation

Midazolam has been increasing used as in vivo probe for P450 3A4 activity because its metabolism is essentially complete and is totally mediated by P450 3A4.[166] The directions here are for plasma samples but can be modified for in vitro assays, in that the chromatography is the same.

Reagents:

1. β-Glucuronidase type H1 from *Helix pomatia* (if sample is plasma) (Sigma–Aldrich, St. Louis, MO)
2. Diazepam
3. 2 M bicine buffer saturated with NaCl, pH 9.3
4. Methyl-*tert*-butyl ether containing 10% ethyl acetate, v/v
5. 20 mM $NH_4CH_3CO_2$
6. 20 mM $NH_4CH_3CO_2$ in CH_3CN

Midazolam and the 1′-hydroxy product (Figure 40.25) are determined via HPLC–tandem mass spectrometry. One milliliter (200 units) of β-glucuronidase type H1 from *H. pomatia* is added to 1.0 mL of plasma, diluted with 0.55 mL of H_2O containing 50 ng of diazepam. Diazepam is used as the internal standard for the study. The mixture is incubated at room temperature for 20–24 h. Add 1.0 mL of 2 M bicine buffer saturated with NaCl, pH 9.3. The mixture is extracted with 6 mL of methyl-*tert*-butyl ether containing 10% ethyl acetate (v/v). After centrifugation, the organic layer is evaporated to dryness under an N_2 stream at 60°C. Samples are dissolved in 250 µL of an equal mixture mobile phase A and mobile phase B. Samples are then mixed briefly with a vortex device, incubated for 60 s, and filtered through 2 µm Spin-X Costar centrifuge filters. A 60 µL aliquot is chromatographed, using an autosampler for injections. Gradient chromatography is performed with a 4.6 mm × 50 mm Zorbax XDB C_8 octylsilane column, using a flow rate of 0.35 mL min^{-1}. Mobile phase A consists of 20 mM $NH_4CH_3CO_2$ in H_2O and mobile phase B is 20 mM $NH_4CH_3CO_2$ in 90% CH_3CN (v/v). The gradient is initiated with equal parts of both phases and then linearly changed over 6 min to 10% phase A/90% phase B (v/v). Then the gradient is returned to the original 50:50 mixture (v/v) and equilibrated for 2 min prior to the next injection.

LC–MS–MS analysis can be performed with the use of a Finnegan 7000 TSQ or equivalent instrument with an atmospheric pressure chemical ionization (APCI) source interfaced with a Waters HPLC system. APCI settings are as follows: capillary temperature 200°C, vaporizer temperature 500°C, and current 5 µA. Collision energy is 27 eV with a collision gas pressure of 2.5 mTorr for MS–MS. Selected reaction monitoring (SRM) and retention characteristics of the various compounds are as follows: [$^{15}N_0$]-midazolam, 326–291 *m/z* and 4.4 min; [$^{15}N_0$]-1′-hydroxymidazolam, 342–324 *m/z* and 3.2 min; diazepam, 285–193 *m/z* and 5.4 min; [$^{15}N_3$]-midazolam, 329–294 *m/z*; and [$^{15}N_3$]-1′-hydroxdymidazolam, 345–327 *m/z* and 3.2 min.[166] A sample chromatogram is shown in Figure 40.25B.

Covalent Binding

Binding of Metabolites to Protein

The irreversible binding of reaction products to protein was observed 65 years ago.[6] Although no consensus is presently clear about the importance of individual targets or how such modification of proteins actually leads to death of cells, in vitro binding of chemicals to protein provides an index of bioactivation processes and can be useful in the characterization of reactive intermediates.

In general, the enzyme system under investigation is incubated with the radioactive substrate for a fixed amount of time, during which the rate of production of species binding covalently should remain constant. In practice, this is usually <1 h. Incubations are terminated and binding to protein is measured. Several approaches are available for measuring binding.

One method involves precipitation of the protein with organic solvent (C_2H_5OH or CH_3OH, >2 volumes) or aqueous Cl_3CCO_2H (5% final concentration, w/v) and collection of the pelleted material after centrifugation in any case ($10^4 \times g$, 15 min). The sensitivity of the residual substrate (and the protein adduct) to the solvent must be considered, as well as the solubility. The supernatant is decanted and more acid or solvent is added; the protein pellet is washed by vigorous mixing or homogenization. We have found that carrying out the entire procedure in stainless steel centrifuge tubes is convenient because the vessels can be centrifuged in a (Sorvall SS-34 or SA-600 or equivalent) rotor and homogenized (with a Sorvall Omni mixer) (Thermo Scientific) without the need to transfer contents. The process of homogenization, centrifugation, and decantation of supernatant is repeated several times until significant radioactivity no longer appears in the wash fractions. At that point, the protein samples are dried by heating at 60°C for 2 h. The protein is dissolved in 1.0 M NaOH (about 1–2 mL) for 1 h at 60°C. Insoluble material is removed by centrifugation and the protein in an aliquot of each sample is measured by the Lowry et al.[167] or bicinchoninic acid method (*vide infra*), [168] because the recovery is variable. A larger aliquot of each sample is added to 5–10 mL of a scintillation cocktail capable of holding H_2O, and chemiluminescence is allowed to decay overnight at room temperature in the dark prior to counting. The results are expressed in terms of nmol adduct/mg protein, with subtraction of values obtained with an inactive enzyme (e.g., without NADPH in the case of mixed-function oxidases).

Another approach is extensive dialysis of protein samples against buffer containing sodium dodecyl sulfate (SDS).[169] We have utilized this method with hydrophilic materials such as acrylonitrile[82–84] but have not obtained as reliable results with more hydrophobic materials.

A third method, currently preferred, involves the adsorption of protein to glass fiber filters, such as those used for in vitro protein translation experiments.[170] These disks can be washed with organic solvents in a shaking device to remove unbound material. We have usually used 5–8 changes of the wash solvent, with wash times of 30 min per cycle (usually

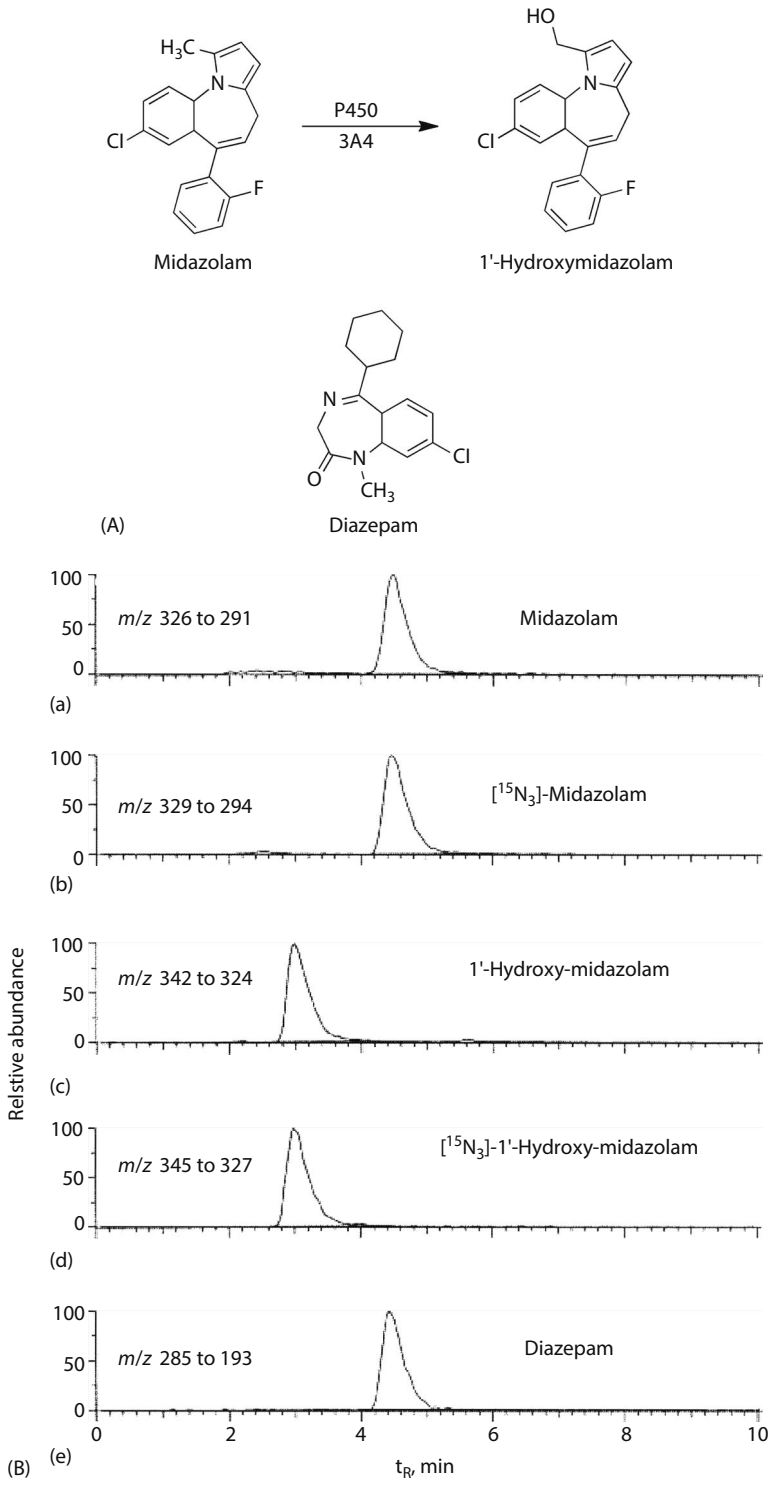

FIGURE 40.25 LC–MS scheme.[166] (A) Midazolam hydroxylation by P4503A4 to yield 1′-hydroxymidazolam and the structure of the internal standard diazepam. (B) A sample chromatogram of the midazolam hydroxylation assay with P450 3A4.[166] SRM combined with liquid chromatography gives the following retention characteristics: (a) midazolam, *m/z* 326–291 and 4.4 min; (b) [$^{15}N_3$]-midazolam *m/z* of 329–294; (c) 1′-hydroxymidazolam, *m/z* 342–324 and 3.2 min; (d) [$^{15}N_3$]-1′-hydroxymidazolam, *m/z* 345–327; and (e) diazepam (internal standard), *m/z* 285–193.

with C_2H_5OH as the solvent).[39,90] The capacity of these filters is limited, so that such an approach may not be satisfactory if considerable amounts of protein must be used. However, if satisfactory sensitivity can be achieved with the use of submilligram amounts of protein, then the method is considerably easier than the other approaches. In our experience with trichloroethylene, we have found that recovery of protein on the filters is nearly quantitative when ≤1 mg protein is used (checks on binding can be done with radiolabeled proteins).[39,90]

Binding of Metabolites to DNA

Like the binding of reaction products to protein, binding to DNA provides an index of bioactivation. One must remember that binding to naked DNA in such a system may be much higher than in vitro or in cells. Binding to protein is not to be equated with nucleic acid binding; notable examples demonstrate that different enzymes and pathways can be involved in the generation of the various types of adducts (cf. acrylonitrile, ethylene dibromide—*vide supra*).[12,171]

Calf thymus DNA has been used in many in vitro binding experiments. Herring sperm DNA is considerably cheaper and much more soluble; its fragmented nature should not cause a problem in this type of work unless one attempts to use SDS sedimentation (*vide infra*). In general, DNA is added to incubations, containing a radioactive substrate, at a concentration of ~2 mg mL^{-1}, with other components as used in standard procedures (*vide supra*).

Several methods can be used to purify the DNA for measurement of bound adducts, and the choice depends upon the situation.

One approach involves initial extraction of the aqueous solution with H_2O-saturated butanol to remove small compounds. Centrifugation ($3 \times 10^3 \times g$, 10 min) is used to separate the layers after each step. The DNA solution is mixed with an equal volume of phenol solution: (liquid phenol is first washed sequentially with equal volumes of 1.0, 0.50, and 0.02 M Tris–HCl [pH 7.4] and then 1 g of 8-hydroxyquinoline is added per liter of phenol). After mixing (with a vortex device), the layers are separated by centrifugation; DNA remains in the lower phase. The step is repeated one or two more times. NaCl is added to the DNA layer to a concentration of 0.10 M (NaCl). The DNA is precipitated by the addition of 5 volumes of cold (–20°C) C_2H_5OH and recovered by centrifugation; the material, dried under a N_2 stream, can be dissolved in any of a number of low ionic strength buffers, although shaking or other agitation may be necessary.

Another procedure that has been used as an alternative to the butanol and phenol extractions involves the sedimentation of DNA by ultracentrifugation.[172] This process is usually done following the enzymatic incubation: SDS is added to a final concentration of 1% w/v (from a stock 10% solution). The incubation buffer should not contain potassium ions because potassium dodecyl sulfate is rather insoluble. The preparations are centrifuged at $10^5 \times g$ for 16 h at 20°C to pellet the DNA. The recovery is generally good (>80%) and most proteins remain soluble and are decanted in the supernatant. Although the procedure is limited by availability of rotor places in the ultracentrifuge, the effort involved in manipulations is minimal. (*Note*: This method is not effective if herring or salmon sperm DNA is used, due to the fragmented nature. It works well with calf thymus DNA.)

Sometimes these procedures do not completely remove unbound materials. A useful procedure for further purification is hydroxylapatite chromatography. A method used in this laboratory is outlined: for a sample containing 1 mg of DNA, 1 g of dry hydroxylapatite (DNA grade, formerly Calbiochem, San Diego, CA; now EMD Chemicals, San Diego, CA) is suspended in 5 mM sodium phosphate buffer (pH 6.8) and swirled to hydrate the particles. The suspension is evacuated (at 40°C) to remove gas bubbles, using an aspirator, and poured into a column (1.6 cm diameter), where 5 mM sodium phosphate buffer (pH 6.8) is pumped through the column at a flow rate of ~2 mL min^{-1} using a peristaltic pump. The DNA is applied to the column (using the pump) and the column is sequentially eluted with 100, 200, and 300 mM sodium phosphate buffers (pH 6.8). The eluate is monitored at 260 nm and the elution buffer is not changed until A_{260} has decreased nearly to the baseline (eluted fractions are collected). Proteins are eluted with 100 mM phosphate, RNA with 200 mM phosphate, and DNA with 300 mM phosphate. Aliquots of fractions can be assayed for radioactivity after mixing with a cocktail containing a detergent and designed for aqueous samples. When large volumes of water and high phosphate concentrations are used, the conditions needed for formation of a stable gel should be checked carefully beforehand.

If concentration of peak fractions is necessary, this is conveniently achieved by removal of the salt from the pooled samples by extensive dialysis and subsequent lyophilization. In some cases, further treatment of DNA with RNase (heating at 80°C for 10 min prior to use to destroy DNase) or pronase may be desired, with subsequent recovery of DNA by phenol extraction and ethanol precipitation. Analyses for RNA can be done using the basic orcinol procedure.[173] Protein can be measured with any of several assays or, if necessary, by amino acid hydrolysis[84] (*Note*: purine decomposition leads to abnormally high levels of glycine). DNA itself can be estimated with the diphenylamine procedure,[173] with Hoechst 33258 dye using a fluorimeter,[174] or by UV spectroscopy using the approximate relationship of $E^{1\%}_{260} = 200\,cm^{-1}$.

If major DNA adducts have been identified for a particular substrate, then the best approach is to hydrolyze the DNA and measure the adduct by a specific method, for example, chromatography or immunoassay.

Other Enzyme Assays

Many of the types of enzyme assays have been covered in the list of examples. The reader is referred to Table 35.1 of an earlier version of this chapter[4] for more. Other types of assays that are not covered here include the use of a bacterial mutagenic or other genotoxicity endpoint[175,176] and radioisotope characterization (i.e., adding a radiolabeled compound to derivatize the product).[177,178]

Structural Elucidation of Enzyme Reaction Products and Development of Assays

One common problem that occurs when an enzyme acts on a drug or other chemical is that a new, undefined compound results. Of course, this can happen not only with a purified enzyme but also with crude systems. In the past, the elucidation of the structure of a new metabolite was often a heroic task and a considerable amount of material was required.

Today, the process is much more efficient, and in many situations, there are demands to identify new products quickly and develop assays for further quantitative analysis. Such situations are now routine in the pharmaceutical industry, and in our own experience, we are of the opinion that the rapid identification of reaction products will gain even more importance in academic laboratories.

A very typical situation is one in which a research incubates a chemical with an enzyme and analyzes the extracted products by HPLC, finding one or more new products, often as judged by the appearance of UV response. The challenge is to identify these.

First, consider the HPLC system. The majority of work is done with reversed-phase systems (C_8, C_{18}, phenyl, cyano, etc.) but not all. The effluent from most systems can probably be used with online UV–visible detection, but the system may be incompatible for other spectroscopy. Therefore, there is a preference for avoiding normal-phase, ion-exchange, and ion-pairing systems. Some of the salts and organic solvents may be incompatible with a mass spectrometer. The researcher will also need to decide if spectra will be acquired online or offline. In the latter case, the peaks of interest are collected manually and processed. Manual collection (*by hand*) is preferable to use of a fraction collector, unless major separations are achieved. If manual collection is done, it works best with a detector having a rapid response, for example, a simple detector with a strip-chart recorder, because many computer-based detectors have time delays for averaging and processing signals. Early in the work, the researcher will also have to decide what scale will be needed for the separation and accumulation. If a semipreparative HPLC column is needed (typically 10 mm × 250 mm), then the change should be made immediately in order to define the operating conditions. Typically, the flow rate for a 10 mm × 250 mm reversed-phase HPLC column is ≥4 mL min^{-1}, which will give a separation similar to a classical analytical column (4.6 mm × 150–250 mm) operating at 1.5–2 mL min^{-1}. In some cases, we have used 25 mm × 250 mm columns, operating at ≥10 mL min^{-1}.[179] The analytical columns are usually very appropriate for doing online UV–visible spectroscopy and mass spectrometry. If fractions are to be collected offline for NMR, then the larger columns may be in order.

Online UV–visible spectroscopy is reasonably straightforward. In this laboratory, we utilize both diode array (Hewlett-Packard, Agilent) and rapid-scanning monochromator (Thermo)-based systems. The two systems each have their own advantages in handling and displaying data. With both, the software can be used to subtract the solvent absorbance and also any peaks contributed by other eluting chemicals, for example, not completely resolved. If the sample is too concentrated, the spectrum will not be valid (e.g., if the absorbance is >1 or 2), and a more dilute sample should be analyzed. With regard to the interpretation of spectra, there are some general rules that can be of use in the interpretation of spectra.[180–182] The data should be stored in files on the hard drive of the computer, backed up (preferably to a compact disk, DVD, or flash drive rather than a magnetic diskette), and printed to a version that can be appropriately saved in a notebook. As always, all relevant information needed to repeat the work should be recorded.

Online LC–mass spectrometry is similar, in terms of the HPLC. In contrast to HPLC/UV–visible spectroscopy, HPLC columns larger than analytical cannot be used unless there is a splitter. In some cases, microbore columns are preferred. A review of mass spectrometry and complete description of all relevant aspects is beyond the scope of this review. However, almost all work of this sort will begin with either electrospray or APCI, in either the positive or negative ion mode. The preferred solvents are those composed of H_2O, CH_3OH or CH_3CN, and some $NH_4CH_3CO_2$ or a similar compatible volatile buffer. With a new compound, one will have to collect *full-scan* data because the *m/z* values are unknown. To monitor the presence of all eluted chemicals, one should follow either a UV absorbance signal (from an in-line detector) as the total ion current as a function of timed. The detected peaks can then be scrutinized to recover full spectra.

The interpretation of mass spectra is beyond the scope of this chapter. One should have some intuition as to what *m/z* values are realistic from the knowledge of the substrate. The molecular ion will be manifested as $[M+H]^+$ or $[M-H]^-$ in electrospray (M is the molecular mass), depending upon whether the positive or negative ion mode is used. One simple guide for chemicals containing the common atoms dealt with in this type of research is that an odd number for M indicates an odd number of nitrogen atoms (1, 3, 5,…) and an even number indicates either none or an even number (2, 4, 6,…). It is possible to utilize a higher-resolution instrument to acquire more mass accuracy, but linking such instruments (e.g., magnetic sector, Fourier transform ion cyclotron) to HPLC is not as common. With a resolution of $>1/10^4$, four decimal places are recorded and the atomic composition of a molecule can be established. It is possible to collect samples and submit them for such *elemental analysis* or *exact mass* determination.

In some cases, the structure of a compound can be established with reasonable certainty just from the fragmentation pattern. Modern mass spectrometers allow the fragmentation of individual ions, which can be quite useful. However, with complex molecules and in the absence of work done with stable isotopes, establishing structures of unknown compounds only by UV–visible and mass spectrometry methods is usually not a definitive process.

NMR spectroscopy is a very powerful approach to determination of chemical structures. Two basic types of information can be obtained: through-bond coupling (which atoms are attached to each other) and through-space coupling (for our purposes, stereochemistry). The simplest through-based method is a simple 1D ^1H NMR spectrum. More complex 2D methods require more sample or longer acquisition times. Some of these establish the linkages of protons and ^{13}C atoms, in a manner based on the protons and thus much more sensitive than direct analysis of the ^{13}C signals. Examples we have utilized in this laboratory include COESY, HSQC, HMBC, and CIGAR methods. The

2D through-space methods we have utilized with small molecules are NOESY and ROESY.[183,184]

NMR spectra of small molecules are usually run in deuterated solvents to avoid artifacts introduced by signal suppression methods. If HPLC peaks are collected offline, then the chemical of interest can often be extracted from the (aqueous) elute into an organic solvent (e.g., CH_2Cl_2) and concentrated for NMR analysis. If compounds cannot be extracted (e.g., nucleosides), one approach is to use a *volatile* combination of buffer salts (e.g., NH_4HCO_2, $NH_4CH_3CO_2$, *N*-ethylmorpholine) and remove the buffer by repeated lyophilization. Removing solvents and H_2O as rigorously as possible should be done in order to avoid interfering peaks. With small amounts of a chemical, the limitation to sensitivity is usually not the amount of the chemical itself but the extent of contamination by solvents, H_2O, grease, and other contaminants. Spectra are usually recorded on instruments with field strengths of 300–600 MHz. The inherent sensitivity increases as a function of the square of the field strength, so an 800 MHz instrument should provide fourfold more sensitivity than a 400 MHz system. Other factors for sensitivity are the sample volume (smaller is better) and the probe temperature. *CryoProbe* technology provides more sensitivity because of a square root relationship with the absolute temperature.

A relatively recent development is the implementation of combined LC–NMR systems (Figure 40.26). In true online systems, one of the two HPLC buffers is usually deuterated and the elution is paused when peaks are eluted (into the NMR probe) to collect spectra for longer time periods. A new development involves automated robotic systems for collecting designated HPLC peaks (detected by UV–visible or mass spectral measurements). The designated effluent is directed onto a solid-phase extraction (SPE) cartridge. (The run can be repeated to apply a multiple load.) Each SPE cartridge, loaded with a peak from the HPLC run, is then washed with solvent to remove any salts and the HPLC solvent; then a small amount of deuterated organic solvent is applied to each SPE cartridge to elute the bound compound into a 30 μL capillary tube. These capillaries, all filled offline, are then moved to the NMR spectrometer, where spectra can be recorded for the desired length of time.

The amount of material required to obtain useful spectra in each of these approaches is dependent upon the particular compound and its physical characteristics. UV–visible spectra can be collected with absorbance maxima of <0.01, and the sensitivity will depend upon the dimensions of the HPLC column and the detector cell. Subnanomolar amounts can be characterized in many cases, depending on the chromophore. Mass spectrometry has a similar detection limit, depending upon the ionization characteristics of the compound, the HPLC column bore, and the details of the specific mass spectrometer. Our own experience has been with ThermoFinnigan electrospray instruments, with the newer TSQ series having ~50-fold greater sensitivity than the older 7000 series.

NMR is usually the limiting factor in analyses of this type, depending upon the situation. If only a 1D ^1H NMR is needed, then, in principle, the UV–visible, mass, and NMR spectra can be collected with samples in the low microgram range.

One powerful approach to spectral analysis is the use of online systems, that is, liquid chromatography coupled to spectroscopy. An example from this laboratory is presented in Figure 40.26 and involves the characterization of an unknown oxidation product of testosterone by recombinant P450 3A4. Testosterone was incubated with 0.1 nmol of the P450 (plus NADPH–P450 reductase) for 5 min and the substrate and products were extracted and applied to an HPLC column. The effluent was split, with a minor fraction directed to a UV detector and a mass spectrometer. On the basis of the UV profile, fractions were collected (robotically) on small SPE cartridges. In this work, three HPLC runs were pooled before further processing. The SPE columns were switched and washed, to elute solvent and any salts, and then eluted with a small amount of deuterated solvent into small capillary tubes. All of this processing can be done offline from the NMR spectrometer. The capillary tube containing the peak of interest was then used for NMR analysis, in this case 1D (^1H), COSY (^1H–^1H), HSQC, and NOESY (^1H). In this case, most of the ^1H and ^{13}C resonances were already known from the literature on testosterone.

The UV spectrum (not shown) was very similar to that of testosterone, suggesting no change in the double bonds that constitute the chromophore (Figure 40.26). The mass spectrum confirmed the addition of one oxygen atom (+16). The chemical shift (δ) of the proton(s) associated with the new product (relative to the substrate testosterone) suggested that it was adjacent to either an allylic carbon or a carbon α to a carbonyl, that is, C-1 or C-7. Inspection of the COSY spectra indicates a lack of connection to C8, arguing against a hydroxyl at C-7 and thus in favor of C-1. The HSQC spectrum supports this view. The stereochemistry was easily established as 1β with the NOESY spectra, after considering the 3D possibilities for the molecule (Figure 40.28). If the H-7 proton were in the β-position, it would be expected to show a very strong cross peak with the (three) protons of the C-19 methyl group. It does not, and therefore the H-7 proton is α (and the hydroxyl group is β). The NOESY spectrum shows the expected coupling to H-2α,β, H-9, and H-11 (Figure 40.26). Thus, the structure was established as 1β-hydroxytestosterone with ~6 μg of the product.[184]

In some cases, the aforementioned information may not be sufficient to assign the structure. Other spectroscopy may be in order. Infrared (IR) spectra can be useful, particularly if the presence of certain diagnostic groups is suspected.[181] Circular dichroism (CD) spectra can be useful in assigning stereochemistry.[185,186] In the example shown here with 1β-hydroxytestosterone, an *exact* mass was obtained. As mentioned earlier, this is not always done as a first course to characterizing a molecule but can be very important in distinguishing among possibilities after obtaining a lower-resolution spectrum. High-resolution mass spectrometry is becoming much more important in such situations.[187] Another approach needed sometimes involves use of more NMR spectra, especially 2D spectra.[183,188]

A common next step in work of this type is development of an assay. One preferred approach is to synthesize

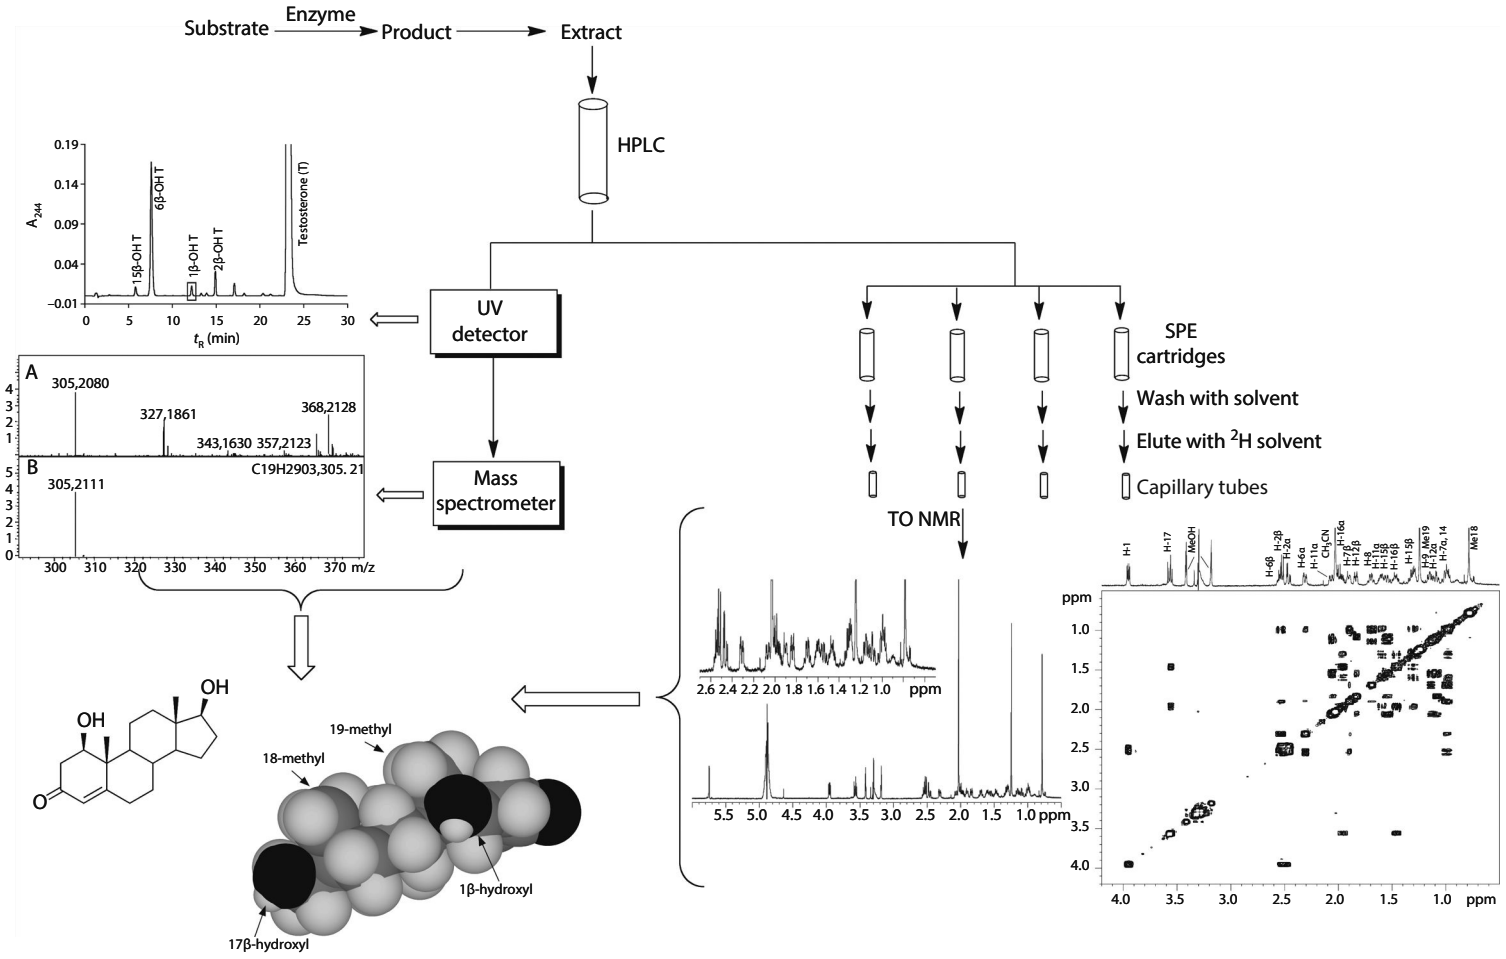

FIGURE 40.26 Determination of a structure of a reaction product by online LC–SPE–MS–NMR. The UV detector can also be used to obtain the UV spectrum of the peak of interest (indicated with box, spectrum not shown). The data are from the characterization of 1β-hydroxytestosterone as an oxidation product of testosterone by P450 3A4. (From Krauser, J. et al., *Eur. J. Biochem.*, 271, 3962, 2004.)

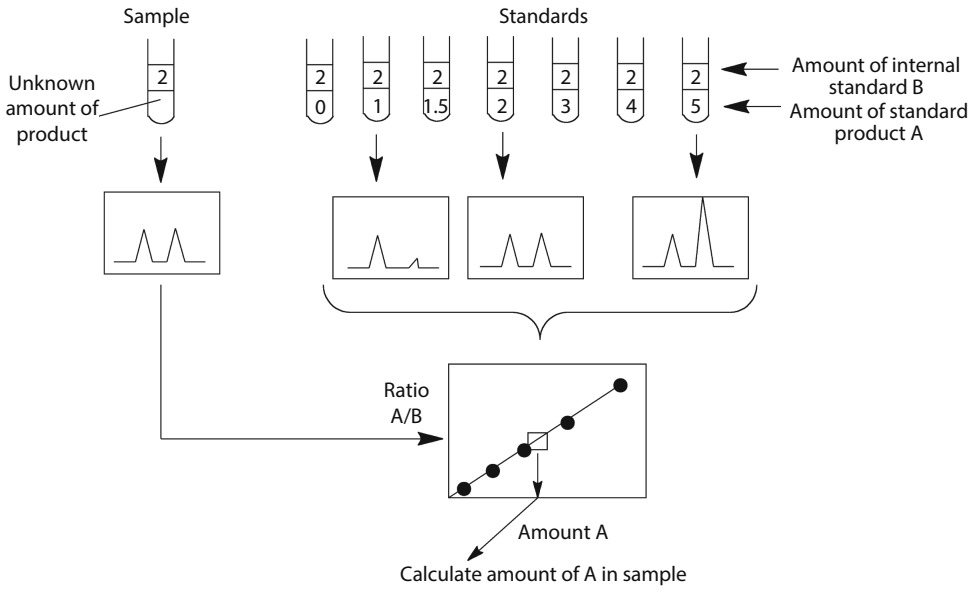

FIGURE 40.27 General approach to use of an internal standard (closely related compound) for quantitative HPLC analysis.

the reaction product and use it as a standard, preparing stocks by gravimetric methods. Typically, an assay would be set up using HPLC (in that in the case cited here [Figure 40.26], the product was first separated by this method). Detection could be by UV or fluorescence spectroscopy or mass spectrometry. A common approach is to use an internal standard, that is, a closely related compound that is still distinguished. This is added after the enzyme reaction, prior to the extraction step, in order to control for product recovery. If the analysis utilizes mass spectrometry, then ideally, the internal standard will be the same compound with heavy atoms (≥2 preferred) covalently attached (^{13}C, ^{18}O, and ^{15}N are preferred) to avoid isotopic (^{2}H) effects on HPLC t_R. In other cases, a compound differing slightly but having similar physical properties (extraction, ionization) is derived. The principal of internal standard curves is presented in Figure 40.27.

One problem that arises in many cases is that of quantifying a very small amount of a product that cannot be synthesized; also, the amount available may be too low for accurate gravimetric determination. One option is the use of a sensitive microbalance. Another, depending on the structure, is the use of the UV–visible extinction coefficient of a similar molecule with the same basic chromophore, in the absence of interference problems. Another method of quantifying small amounts of source materials is to use ^{1}H NMR spectra, which are absolute in their signal intensity. The choice depends upon the interfering signals; a choice used compound devoid of signals in the aliphatic region is CH_3CO_2H, which gives a sharp singlet (δ 1.91 in DMSO)[189,190] (Figure 40.28).

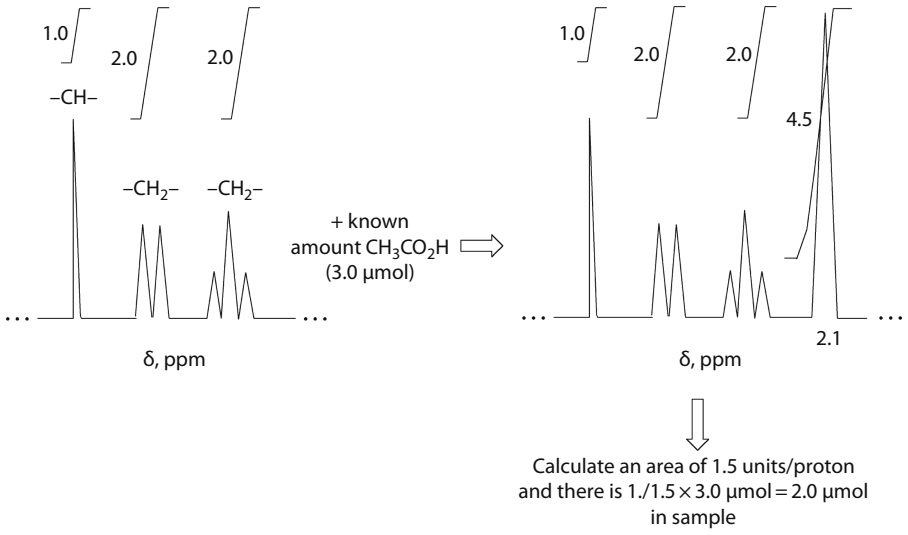

FIGURE 40.28 Use of NMR and an internal standard (CH_3CO_2H, δ 2.1) to establish the concentration of a small amount of a new product. (From Gottlieb, H.E. et al., *J. Org. Chem.*, 62, 7512, 1997; Wu, Z. et al., *Chem. Biodivers.*, 2, 51, 2005.)

An extensive discussion of all possible assays is beyond the scope of this article, and some representative assays are mentioned earlier. If interference is a problem (due to contaminating ions at the *m/z* of interest), a suitable assay may be set up by monitoring the loss of a specific fragment characteristic of the analyte of interest.

Heterologous Expression of Enzymes

The overall approach to handling enzymes has changed dramatically since the chapter published in the first edition of this book.[1] In today's world, the genomes of humans and many principal experimental animals are known. In such systems, the isolation of a new enzyme from a tissue or a microorganism is rare. Most enzymes are now prepared by heterologous expression methods. The advantages are simple: (1) The amount of enzyme that can be obtained is much less of an issue. (2) The expression system is usually cheaper to work with. (3) In principle, all human enzymes are accessible. (4) Individual amino acids can be replaced to study their roles. (5) Purification is easier, because (a) the starting concentration of the enzyme of interest is much higher, (b) the presence of interfering, closely related enzymes (e.g., other P450s) can be avoided, and (c) many proteins can be expressed with innocuous tags that will facilitate isolation.

A thorough treatment of heterologous expression is beyond the scope of this test, and the reader is referred to other work, including some compilations,[191–193] original work, and commercial literature. However, the point should be made that most practicing biomedical scientists (and certainly all enzymologists) must be able to utilize recombinant DNA methods and heterologous expression in today's scientific environment.

Considerations

Many methods for expression are available, and many scientists have personal favorites. What are some of the issues in deciding which system to use? Here are some issues to consider:

Amount Needed

Some scientific problems require large amounts of enzyme. For instance, x-ray crystallography and some physical techniques require considerable amounts, at least mg amounts of highly purified protein.

Posttranslational Modification

If the protein of interest is known to require posttranslational modification (other than incorporation of heme, flavin, metal ions), then eukaryotic expression systems are in order. The disadvantage is that these systems generally have lower yields. Another issue is that some posttranslational systems differ in lower and higher eukaryotes.

Difficulty of Reconstitution

Multiprotein systems can be difficult to reconstitute. However, if a protein has multiple subunits, coexpression of the components in a single system may facilitate the interaction, and the proteins may be isolated as a complex.

Needs for a Specific Cellular System

In some applications, the interest is not in using a purified enzyme but in doing studies within the context of a cellular environment because of the endpoints to be examined. For instance, in this laboratory, we have utilized bacteria to report genotoxicity, both in analysis of chemicals[176,194] and in doing random mutagenesis/molecular breeding.[195] Others have used mammalian cell systems to evaluate toxicity.[196] Thus, the complexity of the system depends upon the project.

An extension of this question is whether a transgenic animal will be used instead of a cellular system. Obviously, many mammalian responses can be detected only in such complex settings.

Use of Protein Tags

The purification of proteins is facilitated by the attachment of tags to either ends of the protein. In work in this laboratory, we have often employed a $(His)_5$ tag at the C-terminus.[197,198] N-terminal tags can be employed in some cases,[199] although that is the first end of the protein synthesized and it may be less tolerant to modification, particularly in bacteria.[200] In bacteria, the N-terminus can often be modified to improve protein expression, if there is no effect on the properties of the protein.

An alternate approach is to add larger peptide units to expressed proteins and utilize chromatography systems that will bind the tag. Some of the larger tags can be removed with selective proteases, if interference is a potential problem.

Heterologous Expression Systems Available for Use

As indicated earlier, these will be described only briefly, mainly in terms of the advantages and limitations of each, moving from the simplest to the more complex.

In Vitro Translation

A simple, low-cost instrument can be purchased (e.g., Roche) and this approach can be very useful if only small amounts of protein are required. The need to optimize organisms for expression efficiency is avoided. The reagents (aside from the cDNA) are commercially available and are expensive for large-scale work but reasonable for small projects.

Bacteria

Bacteria have many advantages and remain the preferred vehicle in this laboratory.[193] Most work is with *Escherichia coli*, although sometimes *Salmonella typhimurium*[201–203] and *Bacillus subtilis*[191] have applications. Bacterial expression is generally fast (1–2 days culture), relatively inexpensive, and gives high yields. Many vectors are available. The systems can be employed for various screens done in the cells.[193,201,202] Scale-up to high-volume production in fermentors is most easily accomplished with bacterial systems.

The limitations for bacterial expression are the need for posttranslational modification and problems in the proper

folding of source proteins. In addition, many proteins express better if the N-terminus is modified, for various reasons.[193,204] Thus, some are usually necessary with several constructs before proceeding with productive expression.

If expression of proteins is too rapid in bacteria, then misfolding can occur. Sometimes the misfolded proteins are accumulated in inclusion bodies, which are particles of damaged protein (devoid of prosthetic groups). Several approaches can be used to minimize this problem, including use of weaker promoters, lower incubation temperatures, and coexpression of chaperone proteins. For expression of human P450s in *E. coli*, the addition of chloramphenicol and ethanol has been helpful in some cases.[205] For the P450s that are more difficult to express, the addition of heme precursors has been helpful, probably by providing a prosthetic group for the protein to *wrap itself around*.

Yeast

Most work is done with *Saccharomyces cerevisiae* but other yeasts have some advantages.[206] Yeast expression of P450s has been done in this laboratory in the past[207] and is still done in other groups.[208,209] In addition to yeasts, some expression has been done in the *false yeast Pichia pastoris*, for example, with monoamine oxidase.[210,211]

Yeasts are eukaryotes and have advantages in terms of posttranslational processing capability and capacity for proper protein folding. Numerous vectors are available for expression, and generally, less manipulation of sequences is necessary for expression. *S. cerevisiae* does have an NADPH–P450 reductase (and cytochrome b_5), which couple with some mammalian P450s but not all.[212,213]

The expression levels achieved in yeast are generally lower than in bacteria. The recombinant DNA manipulations needed to prepare vectors are done in bacteria and then transferred to yeast. The expression times are longer than in bacteria. A major disadvantage of yeast expression is the difficulty in breaking yeast cells for enzyme purification.[207] Breaking cells with only (strong) mechanical methods is not very inefficient, and enzymes such as yeast lytic enzymes are required.

Insect Cell Systems

Systems based on baculovirus infections are useful.[214,215] The advantages and limitations of these systems are similar to yeast. Enzymes are not required to break the cells, but the costs of media are considerable. High levels of expression can be achieved, although the expression volume is usually a limitation because of the cost of media. As with yeast, posttranslational modification occurs; it may or may not be identical to what occurs in mammalian systems. Baculovirus-based expression of P450s and other heme proteins does require the addition of heme. As a general rule, baculovirus is a reliable means of expression proteins that are recalcitrant to expression in other systems.

These expression systems are usually used in *spinner* cultures, which do not require rigorous aseptic conditions. Insect cell culture is possible in shaking cultures (i.e., Fernbach flasks) although such methods have been used less. Large-scale cultures are possible although expensive.

Mammalian Cell Culture

COS-1 cells have a monkey kidney origin and have been used extensively for many proteins.[216] Other systems used for enzymes of relevance to toxicology include TKK lymphoblasts and V79 cells, which have been used in toxicity and mutation assays. Human embryonic kidney (HEK) cells have been used for higher level expression, usually in roller bottles. In some cases, these latter systems have been used to generate enough material for structural biology studies, although this is not a trivial or inexpensive process.

Another variation is vaccinia virus systems, which are used to produce proteins in mammalian cells.[217,218] These systems have been used for synthesis of drug-metabolizing enzymes and transporters, with higher levels of expression than some of the other mammalian systems.

The mammalian cell systems have the advantages of not requiring much optimization and rather faithfully doing post-translational modification. They also provide good models for cell-based assays. The disadvantages are the need for cell culture facilities, cost, and difficulties in large-scale work.

Transgenic Animals

A detailed discussion is far beyond the scope of this chapter.[219] Transgenic animals can be considered one type of heterologous expression, although they are usually not used to harvest the protein except in certain commercial settings with large animals and biopharmaceuticals (proteins used as drugs). However, transgenic mice are commonly used to address hypotheses in in vivo settings, both in terms of gain and loss of function (gene knock-in and knock-out animals, respectively). Transgenic rats are not very common, in that the technology is not as developed. Obviously, these are expensive experiments. The ease of developing transgenic mice has improved in recent years; the cost of maintaining the animals is still an issue. Transgenic animals do provide a reasonably appropriate setting for analyzing the functions of proteins in vivo.

Use of Purified P450 Enzymes

Many individual forms of P450 have now been purified and characterized from a number of species, including humans. A complete discussion of these preparations is beyond the scope of this article and the reader is referred to other references.[55,62,63,65,220,221] For a discussion of the current recommended nomenclature for the P450 families and subfamilies, see Ref. [222] and the website <http://drnelson.utmem.edu/CytochromeP450.html>. One of the reasons for purifying individual forms of P450 is to determine which individual forms are involved in particular reactions. This task has been made somewhat easier in the light of current knowledge available concerning cytochromes P450.

With rat liver systems, the first step is the development of an in vitro assay for the particular activity under consideration. This has to be developed with liver microsomes and the sensitivity should be optimized, along with conditions such as pH, time, and protein and substrate concentrations.

The next step involves comparison of rates of oxidation with microsomes isolated from (untreated) male and female rats and male rats treated with various inducing agents. A considerable body of knowledge now exists concerning the effects of gender and inducing agents on individual P450 forms and this information can be used to advantage.[63,65–67,223] For example, male rats (adult) contain P450 2C11 and P450 3A2 but not P450 2C12. Phenobarbital administration induces P450 2B1, P450 2B6, P450 2B2, and P450 3A1. Pregnenolone 16α-carbonitrile and dexamethasone induce P450 3A1. Levels of P450 2C11 are suppressed by administration of any of several of the typical inducers, particularly PAHs. From information obtained in such experiments, one can begin to suggest which forms are involved.

The next step involves examination of the relative abilities of individual forms of P450 to catalyze the reaction, if these are available. Reconstitution conditions are described elsewhere.

When specific inhibitors are known for individual forms of P450 (e.g., 7,8-benzoflavone [α-naphthoflavone] for rat P450 1A1 and P450 1A2), these can also be used to advantage (*vide infra*).[46,224]

Another step involves using specific antibodies with microsomal preparations to determine which will inhibit the reaction. This approach is discussed later in this chapter. These results should agree with and confirm those obtained in the aforementioned experiments.

The strategy is slightly different for studies with human enzymes, since induction and gender patterns are not involved. If some results are available on the catalytic selectivity of rat or other animal P450 enzymes, this information may be of some use in predicting human enzymes, although there are many cases of catalytic selectivity jumping subfamilies when making such comparisons, particularly in the P450 2C family.[56,225]

One way to proceed is to first use diagnostic chemical inhibitors[46,224] (Table 40.3). Because human samples are known to vary considerably in their P450 composition, it is risky to rely on a single human sample, particularly if there is little prior knowledge about its characteristics. Usually, several samples (≥3) should be used in initial screens. An alternative is to use a single experiment with microsomes pooled on the basis of protein content (≥10 samples). The same strategy applies to human hepatocytes (here, the number of samples available may be low).

Another useful strategy with microsomes is correlation analysis.[226,227] A set of microsomal samples is compared for the new activity under consideration and also marker activities diagnostic of individual P450 enzymes (Table 40.2 and Figure 40.29). In general, ≥10 samples should be used. Correlation analysis can be done with either linear or Spearman rank methods.[226,229] In principle, the parameter r^2 estimates the fraction of the variation accounted for by the relationship between two variables. Values of $r^2 \geq 0.5$ are generally judged to be significant (but the significance, p, is dictated by sample size).

An additional approach is to utilize purified or, more likely, recombinant enzymes to assay the activity. If this is done with a chemical, there should be some appreciation of the plasma or tissue concentrations relevant to the problem under consideration when a substrate concentration is selected. An improved approach involves measuring activity at several substrate concentrations and estimating V_{max} (or more appropriately k_{cat}, which is V_{max} divided by the enzyme concentration) and K_m.

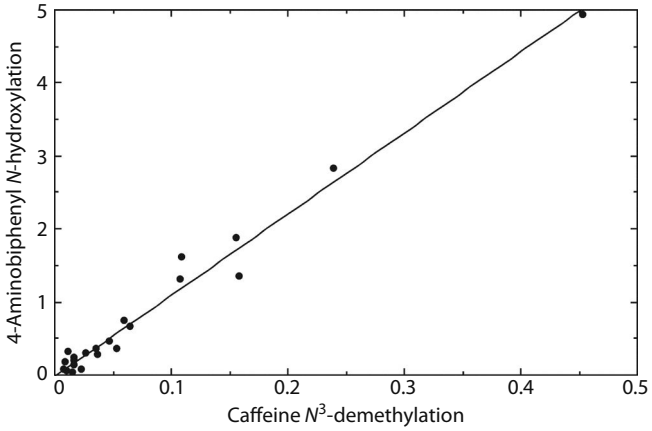

FIGURE 40.29 Correlation of caffeine N^3-demethylation and 4-aminobiphenyl *N*-hydroxylation in different human liver microsomal samples, indicative of P450 1A2 variability and involvement in both reactions.[228] All rates are expressed in nmol product formed/min/mg microsomal protein.

Inhibitory antibodies can also be useful. In principle, the fraction of inhibition one sees when one adds an antibody (to a particular P450) to microsomes is the fraction of that reaction catalyzed by the P450 to which the antibody was raised (Figure 40.30). There are several confounding problems. One is that antibodies generally do not distinguish between P450 subfamily members, unless extensive cross adsorption is done with the antibody. Despite early success in the area,[230,231] not all anti-P450 antibodies are inhibitory. Further, even antibodies raised against recombinant P450 proteins have sometimes showed reactions with similar epitopes in different P450 families.[232] This cross-reactivity can vary with individual rabbits. Although polyclonal antibodies raised against purified P450 enzymes have been highly useful in development of the field, there are two prospects for improvements. One is the use of monoclonal antibodies, which have already been exploited for some uses.[233–235] The other, more recent, is the use of antipeptide antibodies. Some of these have shown impressive specificity[236,237] although immunoinhibitory potency may still be a problem. A new development in this area is phage-display methods (*vide infra*).[238]

Two general points need to be made about use of such information (some points are also made later regarding heterologous expression systems). First, many of the parameters often cited for the in vitro systems used today are inappropriate, particularly with the recombinant systems. The expression of an activity of a recombinant system in terms of mg protein is not particularly helpful because no information is available about the level of expression. The concentration of the enzyme under consideration should be determined and used

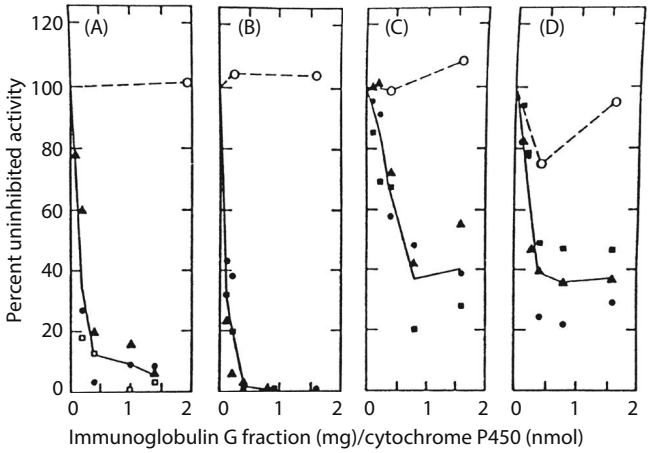

FIGURE 40.30 Inhibition of mixed-function oxidation of debrisoquine, sparteine, encainide, and propranolol in human liver microsomes by antirat P450 2D1. Incubations were carried out with microsomes prepared from liver samples 17 (△), 25 (□), 31 (●), 32 (▲), 34 (■), 72 (◊), and 86 (◆), which contained 0.32, 0.55, 0.77, 0.50, 0.55, 0.61, and 0.30 nmol P450 (mg protein)$^{-1}$, respectively. The microsomes were incubated with indicated amounts of anti-P450 2D1 (IgG fraction) for 30 min at 23°C in the appropriate buffer and other incubation components were then added. Results are expressed as percent of the control activity (obtained in the absence of antibody) for debrisoquine 4-hydroxylation (A), formation of Δ^5-dehydrosparteine from sparteine (B), encainide *O*-demethylation (C), and propranolol 4-hydroxylation (D). The solid lines are drawn connecting the means of the values obtained with the various samples, and the broken lines connect the means of the values (○) obtained with IgG prepared from preimmune antisera (individual values not shown). Control activities of debrisoquine 4-hydroxylation were 0.16, 0.060, and 0.19 pmol min^{-1} (nmol P450)$^{-1}$ for samples 25, 31, and 32, respectively. Control activities of Δ^5-dehydrosparteine formation were 26.6, 20.4, and 2.0 pmol min^{-1} (nmol P450)$^{-1}$ for samples 31, 32, and 34, respectively. Control activities of encainide *O*-demethylation were 0.044, 0.072, and 0.039 nmol min^{-1} (nmol P450)$^{-1}$ for samples 31, 32, and 34, respectively. Control activities of propranolol 4-hydroxylation were 0.17, 0.12, and 0.081 nmol min^{-1} (nmol P450)$^{-1}$ for samples 31, 32, and 34, respectively. (From Distlerath, L.M. and Guengerich, F.P., *Proc. Natl. Acad. Sci. USA*, 81, 7348, 1984.)

in the normalization. Such an analysis may be difficult if an immunochemical method is needed, since apoprotein or inactive enzyme will also be measured. Another common problem in P450 work (and with most of the other enzymes of interest here) is the attachment of too much significance to the K_m value itself. Contrary to what is often conveyed in toxicology and pharmacology texts, K_m does not generally note substrate affinity, unless specifically proven to be. The parameter K_m is an operational term, simply denoting the substrate concentration at which half-maximal velocity occurs.[239,240] It is a complex collection of microscopic rate constants, which are usually not known. In the case of P450 2E1, K_m can even be considered a function with k_{cat} appearing as a dependent variable.[154]

Second, the ratio of k_{cat}/K_m (or V_{max}/K_m) is considered the most appropriate estimate of enzyme efficiency by enzymologists.[240,241] In a plot of v versus S for an enzyme, this is the tangent to the plot at low substrate concentrations and has units of M^{-1} s^{-1} (or the equivalent). However, k_{cat}/K_m (or V_{max}/K_m) is *not* intrinsic clearance (nor *in vitro clearance*). Clearance is an in vivo parameter with a distinct meaning. If blood flow is not rate limiting and there are no complicating factors due to transport, then intrinsic clearance within a given organ might be a direct function of k_{cat}/K_m.[242] However, the more proper term for the ratio k_{cat}/K_m is simply *enzyme efficiency*. This is not to demean efforts at physiologically based pharmacokinetic modeling, which can be very useful.[241,243] However, these models must not make inappropriate assumptions about what they incorporate in the way of meanings of parameters, any more than they would incorporate the wrong pathways.

Purification of P450 from Bacterial Recombinant Expression Systems

Overview

A procedure is outlined that is used for purification of P450 3A4 from *E. coli* membranes in this laboratory. Details of construction of the expression plasmid (NF14) are presented elsewhere,[244,245] including the addition of the C-terminal pentahistidine ($(His)_5$) tag.[197,246] This chapter is an updated version of an earlier procedure published in this series.[247] The major change has been the incorporation of the $(His)_5$ tag and the use of metal-affinity chromatography (Figure 40.31).

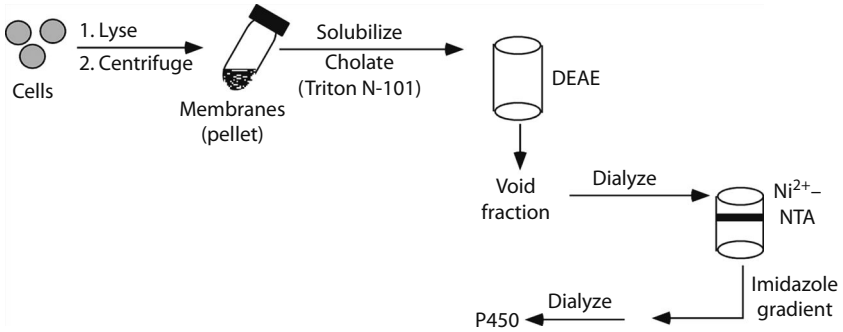

FIGURE 40.31 Purification of recombinant human P450 from *E. coli* membranes utilizing nickel affinity chromatography. (From Guengerich, F.P. and Martin, M.V., Purification of cytochrome P450: Products of bacterial recombinant expression systems, in: Phillips, I.R. and Shephard, E., eds., *Methods in Molecular Genetics, Cytochrome P450 Protocols*, Academic Press, Orlando, FL, pp. 31–37, 2006.)

Attachment of an oligo-His region, usually at the N- or C-terminus, has been used to facilitate protein purification.[248] The free His residues (usually $(His)_4$, $(His)_4$, or $(His)_6$) can chelate Ni^{2+} and similar metal ions; thus, a Ni^{2+}-chelate affinity column can be used for rapid purification.[249] Such approaches have been used with P450s, with His tags at either the C[250,251]- or N[199,252]-terminus. Detergent is needed to solubilize the membranes and keep the proteins disaggregated during chromatography, and the detergent must be removed in a subsequent step.

In our early work on the purification of *E. coli*-expressed human P450s, the procedures consisted mainly of ion-exchange chromatography methods.[244,245,247,253–256] The change to metal-affinity methods was made for two reasons: (1) the metal-affinity approaches can be used to reduce the need for nonionic detergents or to facilitate removal of these (nonionic detergents can yield artifacts and are even substrates[257]) and (2) some P450 mutants are relatively unstable and their purification requires more rapid methods.[258–260]

An example is provided in which an ion-exchange step is used prior to metal-affinity chromatography.[197] In some cases, the step can be omitted and solubilized P450 preparations can be used directly for metal-affinity chromatography (e.g., P450s 1A2 and 2D6[199,258,259,261,262]). In these cases, highly purified P450s can be prepared without the need for earlier steps.

Reagents:

1. 1.0 M Tris–acetate buffer (pH 7.6).
2. Sucrose.
3. Sodium EDTA, 0.10 mM in H_2O, adjusted to pH 7.5.
4. Lysozyme, 50 mg mL^{-1}.
5. 1.0 M potassium phosphate buffer (pH 7.4).
6. Magnesium acetate.
7. Glycerol.
8. 2-Mercaptoethanol.
9. PMSF, 0.1 M in *n*-propanol (stored at −20°C).
10. Leupeptin, 0.20 mM in H_2O.
11. Bestatin, 0.1 mM in H_2O.
12. Aprotinin, 4 U mL^{-1}.
13. 3-[(3-Cholamidopropyl)dimethylammonio]-1-propanesulfonic acid (CHAPS), Sol-Grade (Anatrace, Inc., Maumee, OH).
14. Sodium EDTA, 0.10 mM in H_2O, adjusted to pH 7.5.
15. Diethylaminoethyl (DEAE)-Sepharose, adjusted to pH 7.4 (GE Healthcare, Piscataway, NJ).
16. Nitrilotriacetate (Ni-NTA) agarose (QIAGEN, Valencia, CA). An alternative is a Co^{2+}-based matrix, for example, the Talon® system (Clontech, Mountain View, CA) although we have not used this in our own work.
17. DTT.

Preparation of Bacterial Membranes

Bacterial cells are recovered by centrifugation ($4 \times 10^3 \times g$, 15 min) and resuspended in 0.10 M Tris–acetate buffer (pH 7.6) containing 0.50 M sucrose and 0.5 mM EDTA at a concentration of ~70 mg wet cells mL^{-1}. The suspension is diluted twofold with H_2O and lysozyme is added to 0.1 mg mL^{-1}. The suspension is gently shaken and incubated on ice for 30 min in order to hydrolyze the outer membranes. The resulting spheroplasts are recovered by centrifugation at $4 \times 10^3 \times g$ for 15 min; the pellet is resuspended in buffer at a concentration of ~0.5 g mL^{-1}. This buffer for contains 0.10 M potassium phosphate (pH 7.4), 6 mM magnesium acetate, 20% glycerol (v/v), and 10 mM 2-mercaptoethanol. At this point, the preparation can be stored frozen at −70°C until further use.[245]

The frozen spheroplasts are thawed in a water bath at room temperature. During the thawing process, protease inhibitors are added to the spheroplasts to the following final concentrations: PMSF, 1.0 mM; leupeptin, 2.0 μM; bestatin, 1.0 μM; and aprotinin, 0.04 U mL^{-1}. Cells, in a Rosette cell packed in ice, are lysed for approximately 15 min (at ~70% full power) using a Branson sonicator or until the cell lysate is void of clumps. The lysate is subjected to centrifugation ($10^4 \times g$, 20 min) and the pellet is discarded. The supernatant is then centrifuged at $10^5 \times g$ for 90 min (e.g., 3.5×10^4 rpm in a Beckman 45 Ti rotor). The pelleted membranes are resuspended in a minimum volume of 100 mM potassium phosphate buffer (pH 7.4) containing 20% glycerol (v/v), 6 mM magnesium acetate, and 10 mM 2-mercaptoethanol. The suspension is quickly frozen in liquid N_2 and stored at −70°C (unless further purification is started immediately).

The *E. coli* membranes prepared as earlier are diluted to a 20 mM potassium phosphate concentration by addition of 4 volumes of a solution of 20% glycerol (v/v), 1.25% CHAPS (w/v), and 10 mM 2-mercaptoethanol. Buffer, containing 20 mM potassium phosphate (pH 7.4), 10 mM 2-mercaptoethanol, 20% glycerol (v/v), and 1.0% CHAPS (w/v), is added, as necessary, to dilute to a protein concentration of ~2.0 mg mL^{-1}. Some P450s are not solubilized well with only an ionic detergent (CHAPS, cholate, etc.) and require the addition of a nonionic detergent (e.g., Triton N-101, Emulgen 911 or 913, Tergitol NP-10).[247] P450s in this category that we have encountered in this laboratory include P450 2A6 and 2D6. The mixture is stirred gently for 2–4 h and centrifuged at $10^5 \times g$ for 30 min; the pellet is discarded.

The resulting supernatant is applied to a 2.5 × 10 cm column of DEAE-Sepharose (suitable for ~1000 mL of solubilized membranes) that has been equilibrated with 20 mM potassium phosphate buffer (pH 7.4) containing 10 mM 2-mercaptoethanol, 20% glycerol (v/v), and 1.0% CHAPS (w/v) and 10 mL fractions are collected. After all of the sample has been applied, the column is washed with ~2 bed volumes of the equilibration buffer and the fractions containing red color (P450) are pooled. KCl (solid) is added to the pooled fractions to achieve a 0.5 M concentration. A spectral assay is done[114] to estimate recovery, and it may be useful to also monitor the progress of purification at this point by SDS–polyacrylamide gel electrophoresis.[263]

The pooled material is applied directly to a 1.5 × 5 cm column of Ni-NTA agarose that has been equilibrated with 20 mM potassium phosphate buffer (pH 7.4) containing 20%

glycerol (v/v), 0.5% CHAPS (w/v), 0.5 M KCl, and 10 mM 2-mercaptoethanol, at a flow rate of ~1 mL min^{-1}. Most of the brown color should be adsorbed to the column. The column is washed with 10 column volumes of the equilibration buffer. The column is then washed with 10 bed volumes of 20 mM potassium phosphate buffer (pH 7.4) containing 20% glycerol (v/v), 0.5 M KCl, and 10 mM 2-mercaptoethanol. The protein (P450) is then eluted from the column with 20 mM potassium phosphate buffer (pH 7.4) containing 20% glycerol (v/v), 0.5 M KCl, 10 mM 2-mercaptoethanol, and 400 mM imidazole, collecting 5 mL fractions. The pH of the elution buffer is rechecked after addition of the imidazole and is adjusted to 7.4 with 43% (or more dilute) H_3PO_4. The fractions are analyzed for A_{417} and by SDS–polyacrylamide gel electrophoresis, taking care to dilute samples to avoid potassium dodecyl sulfate precipitates. The P450 fractions (as judged by A_{417}) that are homogeneous (>95%) as judged by SDS–polyacrylamide gel electrophoresis are pooled and dialyzed extensively (4×, >6 h each time) with 100 mM potassium phosphate buffer (pH 7.4) containing 20% glycerol (v/v), 0.1 mM EDTA, and 0.1 mM DTT, either before or after concentration with an Amicon ultrafiltration system and a PM-30 membrane. The concentration of P450 is estimated spectrally[114] (*vide supra*).

NADPH–P450 Reductase

Affinity procedures have been described by Yasukochi and Masters[264] and Strobel and Dignam[265] for purification of this enzyme from rat and hog livers using detergent extraction from microsomes, DEAE-cellulose chromatography, and 2′,5′-ADP- or $NADP^+$-agarose affinity chromatography. 2′,5′-ADP-agarose is commercially available from Sigma–Aldrich. Ion-exchange chromatography, or some other initial purification procedure, is often used to facilitate binding of the reductase to the affinity column.[264] Alternatively, the *n*-octylamino-Sepharose 4B reductase fraction from rabbit, rat, or human liver P450 purification procedures[135,266–271] can be directly applied to the affinity column. In our own laboratory, we now produce the rat or human reductase in *E. coli* and isolate it from the membranes, using the methods of Hanna et al.[272] These expression vector systems are freely available upon request.

The column is washed with 0.25 M potassium phosphate buffer (pH 7.7) containing 0.10 mM EDTA, 20% glycerol (v/v), and 0.20% Triton N-101 (w/v) (or other nonionic detergent) to remove other proteins. The detergent is then removed by washing the column with 30 mM potassium phosphate buffer containing 0.10 mM EDTA, 20% glycerol (v/v), and 0.10% sodium cholate (w/v). The reductase is eluted with the latter buffer containing 10 mM 2′-AMP or $NADP^+$ (and 0.10 mM PMSF) and dialyzed (48 h) versus 100 volumes of 10 mM Tris–acetate buffer (pH 7.4) containing 0.10 mM EDTA and 20% glycerol (v/v) to remove cholate and 2′-AMP (or $NADP^+$).[65,268,273]

This procedure has been used to obtain NADPH–P450 reductase in yields as high as 50%; specific activities for cytochrome *c* reduction range from 40 to 70 mmol min^{-1} (mg protein)$^{-1}$.[264,265,273] Spectra show the absence of nonflavin components; the A_{455}/A_{380} ratios are 1.10–1.15.[268,273] The apparent monomeric M_r is 74 kDa (the protein sequence has been deduced from cDNA and the actual mass is somewhat different[264]). Sometimes, proteolysis is a problem and results in cleavage of a peptide necessary for activity toward P450 (but not cytochrome *c*). This problem can be avoided by adding PMSF (from a stock ethanolic solution) to 0.10 mM to buffers immediately prior to use to inhibit serine-active proteases. Some preparations appear to lose some flavin mononucleotide (FMN), as evidenced by stimulation by 10 mM FMN. This problem can be minimized by including 1 mM concentrations of FMN in buffers and minimizing exposure to light during dialysis (use of amber glass).[269]

Methods for Use of Enzymes

Estimation of Protein Concentration

Estimates of protein concentrations are useful in a number of settings, ranging from standardization of crude assays, for the purpose of repeatability, to precisely establishing the amount of an enzyme being used in a reaction.

In the course of monitoring proteins during purifications, following the absorbance at 280 nm (due mainly to tryptophan) is a reasonable approach. However, even this can be a nontrivial issue if absorbing materials are present in buffers. For instance, alkyl phenyl ether detergents (Triton, Emulgen, etc.) are problems.

At least five methods are used to estimate protein concentrations in individual samples. The first three are colorimetric assays and are used widely.

The Lowry method is based on the use of Folin–Ciocalteu reagent[167] and yields a blue color, based on reactions with tryptophan and tyrosine (which still remains vague after all these years). A detailed protocol was published in this chapter in a previous edition.[4] The assay is reasonably rapid and sensitivity. A major limitation is the sensitivity to interference by contaminating materials (e.g., detergent, buffer salts).

The biuret assay is an older method, using complexation of Cu^{2+} ions with the amide bonds. Compared with the Lowry assay, this method has less interference by buffer anomalies but is also much less sensitive.

The Bradford method involves a color change of the dye Coomassie Brilliant Blue G upon binding to protein.[274] This assay is convenient and has sensitivity comparable to the Lowry method. However, as might be suspected, any extraneous hydrophobic material will interfere (esp. detergents).

Another method, the bicinchoninic acid, or *BCA* assay,[168] is even more sensitive than the Lowry method and generally has fewer interference problems. The reagents can be purchased (Thermo Scientific) and the manufacturer provides a detailed description of the method. It is technically simpler than the Lowry assay in that only a single reagent is used and the timing of additions is less critical; this makes the procedure more adaptable in microassay systems. The sensitivity

is increased at higher temperatures (e.g., 50°C), and detection of sub microgram amounts of protein is not unrealistic.

All of the aforementioned four systems are based on phenomena that are not well understood, and even if the basis were established, a real issue is the protein-to-protein variability of the colorimetric response. Thus, an assay used to establish the concentration of a protein by one of these methods can often show a twofold error. This inaccuracy may not be an issue in some settings but could be critical in others, such as establishing the stoichiometry of binding of a substrate or prosthetic group or the extent of a kinetic burst measurement.[275]

Two methods are accurate when the concentration of an individual protein must be known with great accuracy. One approach is to calculate the expected extinction coefficient (ε_{280}) from the content of tryptophan and aromatic amino acids in the sequence. The websites <http://www.biomol.net/en/tools/proteinextinction.htm> and <http://www.basic.nwu.edu/biotools/ProteinCalc.html> can be utilized. This approach can provide a reasonable value. Extinction coefficients at the lower UV wavelengths (i.e., 210, 215 nm) are based on the amide bonds and might be expected to be accurate. They are more sensitive[276]; however, the far UV absorbance is also very sensitive to interference by contaminants, including some buffer components.

The other accurate method is probably the best, although it is more laborious and expensive enough to restrict use to critical applications. The method is a throwback to a method called *quantitative amino analysis*, which has been used in protein chemistry. The protein is carefully hydrolyzed (usually 6 M HCl, 24 h at 110°C) to its component amino acids. These are derivatized, usually with phenyl isothiocyanate, and analyzed by HPLC. The amounts of each amino acid are determined by comparisons with external standards processed in the same way (using the integrals of the A_{254} peaks). Alternatively, the derivatization can be done with a fluorescent reagent to increase the sensitivity. The hydrolysis yields of tryptophan and cysteine are not ideal but the deviation due to these rarer amino acids is usually not significant enough to limit the application. The amount of the protein can be calculated from knowledge of the amounts of each amino acid and the known sequence of each protein.[275] In one application, three component DNA polymerase δ protein subunits were resolved by SDS–polyacrylamide gel electrophoresis and the amounts of each were determined by quantitative amino acid analysis.[277]

Methods for the Determination of Enzyme Purity

As in the case of other chemicals, no single technique can be used to establish purity; moreover, purity is always defined as a limit of given impurities in a given analytical system, and one can argue that nothing is really *pure*. However, some techniques are more useful than others in ruling out heterogeneity and will be discussed here. Some of the classical considerations about purity have been relaxed by the ability to express in recombinant systems, in that related enzyme family members are not expressed. However, for some purposes, proteins must still hold to strict criteria (e.g., antibody production, certain enzymology experiments):

1. An obvious criterion of homogeneity is the absence of suspected contaminants. For instance, P450 preparations should be devoid of NADPH–cytochrome *c* reduction activity and epoxide hydrolase preparations should be devoid of heme. Of course, such impurities must always be defined in terms of detectable limits of contamination. A point to be considered here is that an experimental situation may call for the absence of lipid or detergent contamination as well as protein contamination, and the limit of such impurity must be determined. Phospholipid can be determined by thoroughly dialyzing the enzyme versus Tris buffer and then H_2O to remove soluble phosphates; lipids are extracted as described by Bligh and Dyer[278] and phosphate content is determined according to Chen et al.[279] Ethylene oxide–based detergents (including Emulgens 911 and 913, Renex 690, Tergitol NP-10, Triton N-101, and Lubrol PX) can be extracted and assayed as described.[280,281] Alternatively, detergents can also be assayed by HPLC.[257]
2. Specific activity or specific content of the isolated enzyme is a guide to follow in purification. For instance, P450 preparations should contain *x* nmol of P450 (mg protein)$^{-1}$, where $x = 10^6$/subunit M_r (i.e., x = 16–22), NADPH–P450 reductase preparations should catalyze the reduction of 40–70 mmol cytochrome *c* min^{-1} (mg protein)$^{-1}$ under optimal conditions. However, such measurements are dependent on the accuracy of the protein estimation, which may be a problem. Specific activities are sometimes more variable than expected. In the case of P450, some forms may exist in vivo without a full complement of heme[282] (these are issues regarding prosthetic group loss that involve expressed proteins as well as those purified from tissues). These general guidelines about activity, and prosthetic group content are useful in evaluation of purity.
3. SDS–polyacrylamide gel electrophoresis[263] is routinely used as the main criterion for homogeneity. This technique has been quite useful in determination of homogeneity; moreover, the subunit M_r estimates appear to be reasonably valid for P450[127,135] and NADPH–P450 reductase.[79] The reader should remember, however, that even this powerful technique has its limitations. Evidence has been presented that different microsomal enzymes cannot always be distinguished by this technique.[65,283] Furthermore, the results obtained with this technique are rather dependent upon the exact procedure used, and the methods vary in resolving abilities.[65,135] Finally, apparent M_r values also vary depending upon the procedure and the standards used, and the reader is cautioned to compare results

from different laboratories carefully and allow for as much as 3–4 kDa differences. Further, it is well established that in some cases, such a change may result from a single amino acid replacement regardless of the effect on the true M_r.

Isoelectric focusing can provide resolution of enzymes and has been used in studying cytochromes P450. However, a number of artifacts can be encountered in the use of this methodology, at least when used without specialized procedures.[220,284–287]

Staining of electrophoretograms is usually done with protein stains. In the absence of SDS, NADPH–P450 reductase can be stained using tetrazolium dyes[288] and P450 can be stained using benzidine derivatives and H_2O_2.[289,290] The latter method has also been used to tentatively identify P450 in SDS–polyacrylamide gel electrophoresis. However, much of the heme leaves the enzyme, even in the absence of reducing agents. While others have claimed that heme does not bind to other proteins, Thomas et al.[290] found that heme was bound to albumin; thus, one must be cautious in interpreting data involving such a technique. Immunochemical techniques have been developed for the identification of P450 separated from microsomal membranes by SDS–polyacrylamide gel electrophoresis; these methods proved useful in answering a number of questions about P450 induction (*vide infra*).

Reconstitution of Enzyme Activity

Early work on reconstitution of mixed-function oxidase activity was reviewed by Lu and West.[125] The following general statements can be made. The optimum rate of enzyme activity, based upon P450, is obtained when NADPH–P450 reductase is present at an equimolar concentration or excess. Phospholipid enhances the rates of most activities; this phospholipid can be in the form of a microsomal extract or synthetic L-α-1,2-dilauroyl-*sn*-glyceryo-3-phosphocholine. Some nonionic detergents will partially replace phosphatidylcholine at low concentrations.[291,292] The activity toward some substrates can be further enhanced by small amounts of cholate or deoxycholate.[125] The role of phospholipid is not completely understood, but a dual role has been postulated[293]: L-α-1,2-dilauroyl-*sn*-glycero-3-phosphocholine increased the affinity of a rabbit liver P450 for *both* organic substrate and NADPH–P450 reductase; all four components are complexed during catalysis. Several investigators have studied synthetic liposomal systems; however, no such system has been prepared to date that is more active in hydroxylation than a system reconstituted in the presence of subcritical micelle concentration levels of phospholipid. Neither cytochrome b_5 nor NADH is required for activity in many reactions, although some are definitely enhanced considerably by cytochrome b_5. The effect of the phospholipid appears to be kinetic and can, at least in some cases, be overcome with high protein concentrations and extended preincubation conditions.[59] However, see also Halvorson et al.[60] and Imaoka et al.[61]

A basic procedure for reconstituting mixed-function oxidase activity is outlined in the succeeding text. Equimolar concentrations of P450 and NADPH–P450 reductase (both of which have been stripped of excess detergent by treatment with polystyrene beads and/or calcium phosphate gel or hydroxylapatite)[107] are first mixed in the presence of 40 mM sonicated L-α-1,2-dilauroyl-*sn*-glyceryo-3-phosphocholine, and after 5 min, an appropriate buffer (i.e., 50–100 mM potassium phosphate or other buffer, pH 7.0–7.7) is added plus a sufficient volume of H_2O. The substrate is then added, preferably in H_2O if possible. If not, the substrate should be dissolved in $(CH_3)_2CO$, $(CH_3)_2SO$, or CH_3OH such that the final concentration of organic solvent is ≤1% (v/v) for the enzymes. Some forms of P450 oxidize these compounds or are inhibited by them (e.g., P450 2E1) and caution must be exercised.[148,149] The system is preequilibrated at 37°C for 3–5 min and the reaction is initiated by the addition of NADPH (0.15–0.5 mM) or, preferably, an NADPH-generating system. (The organic substrate should not be the last addition, as prior addition of NADPH will result in generation of H_2O_2, which can destroy P450.)[273] The length of the time for which the reaction is linear depends upon the substrate; in general, rapidly metabolized substrates do not give long periods of linearity and some substrates are converted to metabolites that destroy P450 rapidly. The addition of catalase (~800 U mL^{-1}, dialyzed before use to remove the preservative/inhibitor thymol) and superoxide dismutase (40 μg mL^{-1}) may be useful in avoiding heme destruction due to the generation of reduced oxygen species.[273,294]

FMO activity requires only the single protein, of course, but the enzyme is dramatically less heat stable than others.[295–297] The enzyme is stabilized by pyridine nucleotides, so NADPH should be added to the enzyme before incubation at 37°C, and then the organic substrate should be added. NADPH–P450 reductase has other enzyme activities in the absence of P450; many of these require no special conditions but may be stimulated, as is the case for lipid peroxidation, by high salt concentrations.

Use of Selective P450 Inhibitors

Chemical inhibitors offer considerable potential in the discrimination of enzymes involved in reactions. Unlike antibodies, they can readily be obtained by many laboratories by chemical synthesis or, in many cases, purchased directly. Further, they have the advantage that they can be used in vivo in many cases, even in humans. The approach of using chemical inhibitors with crude enzyme preparations to discern catalytic specificity has been most highly developed for the P450 enzymes (Table 40.3). P450 inhibitors have been known for some time but many of the early compounds (e.g., SKF-525A [*N*,*N*-DEAE-2,2-diphenylvaleric acid] and metyrapone) are only partially selective. Newer and more specific compounds are now available. A list of those used for human P450 enzymes is presented in Table 40.3.[46,72]

A few comments are in order. First, the specificity tends to carry over within each enzyme family (1A, 2A, 2B, 2C,…) between species, although some differences can be noted. For instance, quinine is a better inhibitor of rat P450 2D enzymes than its diastereomer quinidine, while the opposite

is true in humans. Some inhibitors are highly effective with more than one enzyme (e.g., diethyldithiocarbamate). Some inhibitors are irreversible and act by modifying the protein and/or prosthetic group. Ketoconazole is able to inhibit several P450 enzymes but many of its in vivo effects can probably be attributed to P450 3A4. The same is probably true of cimetidine.[298]

Immunochemical Techniques

Antibodies have been raised to P450, NADPH–P450 reductase, epoxide hydrolase, and many of the other enzymes considered here. For instance, these antibodies have been used to show the involvement of P450[229–231,299–302] and its reductase[288,303] in a number of reactions. Antibodies have also been used to examine the homogeneity of isolated enzyme fractions, the multiplicity of enzymes in microsomes, and the amounts of individual enzyme forms in microsomal preparations.[64,65,283,304–308] The topical location of the enzymes in microsomal membranes has also been studied with immunological techniques[230,309] as have several aspects of enzyme biosynthesis. Antibodies have also been used to study the localization of the enzymes in various sections of individual organs.[310,311]

Preparation of Antibodies

All three of the aforementioned enzymes are rather antigenic, and antibodies have been raised in rabbits using <50 μg of protein. Sheep, goats, and guinea pigs have also been used for antibody production. A number of different immunization schedules can be used, depending upon the animal and the dose. Antisera can be used in some procedures, but immunoglobulin G (IgG) fractions are needed in some applications.[231,299] To prepare these fractions, antisera are heated 20 min at 56°C and centrifuged at $10^4 \times g$ for 10 min. The supernatants are mixed with equal volumes of 50% $(NH_4)_2SO_4$ (w/v) and recentrifuged. The pellets are washed with 25% $(NH_4)_2SO_4$ (w/v) to remove most of the color and then dissolved in 10 mM potassium phosphate buffer (pH 8.0) and dialyzed against the same buffer (at 4°C). The dialysates are passed through columns of DEAE-cellulose equilibrated with the same buffer. The void volume fractions (measured by absorbance at 280 nm) are pooled, retreated with $(NH_4)_2SO_4$ as earlier to remove color if necessary, concentrated by ultrafiltration (up to 50 mg mL^{-1}), and stored at –20°C. There are a number of alternative procedures available using commercial Protein A or Protein G affinity columns.

An alternative approach to using the purified protein of interest is to utilize peptides to generate antibodies. This approach has become more popular with P450s, as well as many other enzymes, for several reasons. First, the intact protein does not have to be expressed do isolated, although it may be necessary for use as a standard in either defining specificity or quantifying the protein. Second, the ability to use only part of the protein provides an opportunity to choose sequences that are specific for a particular protein compared to closely related forms. Some caution (and experimental work) is necessary because antibodies can show reactivity with less closely related proteins, for example, some antibodies recognize P450 proteins from multiple gene families.[232] Finally, the purification of peptides is generally more straightforward than proteins, in that they are smaller and can be readily subjected to methods such as reversed-phase HPLC with organic solvents and acidic conditions. Thus, the prospects of including contaminating antigens are less. Many commercial vendors supply peptides already purified. The quality of these peptides is important, and the purity and identity can be readily confirmed by methods such as capillary electrophoresis and matrix-assisted laser desorption ionization/time-of-flight mass spectrometry. Peptides are generally conjugated to a carrier protein (e.g., keyhole limpet hemocyanin) before injection into animals.

Another approach involves the production and use of monoclonal antibodies. This methodology, originally developed by Milstein,[312] involves initial injection of animals and utilization of spleen cells, either in in vitro or intact animals for the hybridoma production. An advantage of using a monoclonal antibody is that it is only one of a complex mixture of antibodies that normally is generated in the polyclonal response. Therefore, no problems should result from the variability one often sees with polyclonal antibodies, that is, with variation in the individual antibodies produced among different animals and at different times.[232]

Another approach avoids the need to use animals and has other advantages. Large phage-display libraries exist (e.g., 10^9 antibody molecules). These systems are bacteria based and can be readily screened. For instance, blots containing the protein of interest (e.g., a particular P450 and other proteins that one wishes to avoid recognition of) can be used with such a library. The phage that selectively binds can be recovered and cultured in bacteria. Recovery can be expedited using epitope tags. Further, such approaches can be used to select antibodies using unpurified systems, for example, one can screen an existing phage-display library for antibodies (or, more correctly, F_c chains) with a set of cells that is hypothesized to contain a specific protein and another set is not. If a difference is observed, in terms of which F_c chains are selected, then that F_c chain can be recovered and used as a reagent to either monitor purification of the protein or to immunopurify the protein directly.

The list of immunochemical techniques that can be used with such antibodies is quite lengthy and the reader is referred to texts on the general subject[313]; the procedures include double-diffusion analysis, inhibition of enzyme activity, radioimmunoassays (RIAs) and enzyme-linked immunoassays, immunoprecipitation, immunoaffinity column chromatography, and immunohistochemical localization. These techniques continue to be useful in studies of the roles of individual forms of these microsomal enzymes in various processes.

Immunoinhibition of Catalytic Activity

In this approach, one adds an antibody to an enzyme preparation and determines if that antibody preparation can block

catalytic activity (Figure 40.30). This approach is most useful with a crude enzyme system, such as a subcellular organelle preparation. Thus, one can ask what fraction of total activity is the result of the enzyme specifically recognized by the antibody (if the antibody completely inhibits the activity of the antigen itself). Such an approach has been useful in a number of cases in our own laboratory[220,229,314,315] as well as many others.

Antibodies to some proteins tend to be more inhibitory than others. In general, polyclonal antibodies raised against cytochromes P450 are often, but not always, inhibitory. However, inhibitory antibodies have not been reported for microsomal FMO and only occasionally has inhibitory anti-epoxide hydrolase been prepared.[316] Apparently, antibodies raised against GSTs are not inhibitory. Some of the difference may be due to the size of the substrate or accessory protein that interacts with the antigen in catalysis. Thus, one would expect binding of an antibody to block binding of very large substrates (viz., other proteins) more readily than smaller compounds. In support of this view, anti-NADPH–P450 reductase blocks reduction of cytochrome *c* but not ferricyanide or neotetrazolium blue.[288] Another general trend is that only a limited fraction of monoclonal antibodies are inhibitory.[317,318]

Analyzing for antibody inhibition is a relatively straightforward process. In general, the enzyme preparation of interest is mixed with the antibody and incubated for 20 min at room temperature. Other components are then added and catalytic activity is measured in the usual manner.

A general way to properly assess enzyme inhibition is to run several incubations, varying the amount of antibody and holding the amount of enzyme constant. Parallel assays should be done in which a nonimmune antibody preparation prepared in the same way is added at the same levels to the enzyme preparation of interest (Figure 40.30). (Alternatively, one can mix varying ratios of immune and nonimmune antibodies with each aliquot of enzyme, maintaining a constant *total* amount of antibody added.)

Most assays of this type are done with IgG antibody fractions. Serum and ascites fluid contain other materials that can cause nonspecific inhibition. However, if the antibody titer is very high (with regard to inhibition) or if the catalytic assay is so sensitive that little antibody is needed for inhibition, then such crude materials may be used.

In general, little can be said about inhibition <15% of the total unless enough careful replicates are done, and the difference between immune and nonimmune serum incubates is reproducible, concentration dependent, and statistically significant. To a first approximation, the percentage of inhibition is a reflection of the fraction of the total catalytic activity in the preparation that is due to the protein that reacts with the antibody. The antibody should completely inhibit the purified enzyme itself, however, for this analysis to be valid, for the possibility exists that noninhibitory antibodies may hinder the binding of inhibitory antibodies and total inhibition might never be achieved.

Quantitation of Proteins by Immunoblotting

In many cases, the absolute concentration of a particular protein in a sample is desired, apart from its catalytic activity. A direct way to obtain such measurements is with the use of specific antibodies. A variety of immunochemical techniques are available for use, including various types of RIAs and enzyme-linked immunosorbent assays (ELISAs).[319] However, knowledge concerning the specificity of the antigen–antibody reaction must be available. Probably the single most reliable technique for evaluating specificity is coupled SDS–polyacrylamide gel electrophoresis/immunoperoxidase staining, or immunoblotting (which often goes by the slang term *Western blotting*), where a crude mixture of protein is separated by electrophoresis and the resolved proteins are transferred to a thin sheet of nitrocellulose paper where they can be detected after binding antibodies and antibodies coupled to enzymes with chromogenic substrates. In our early studies with this system, we found that the intensity of the staining of protein bands was proportional to the amount of antigen applied and that such a procedure could be utilized in making quantitative measurements (Figure 40.32). We still continue to use such a system to quantify many proteins,[320] for several reasons. Under appropriate conditions,

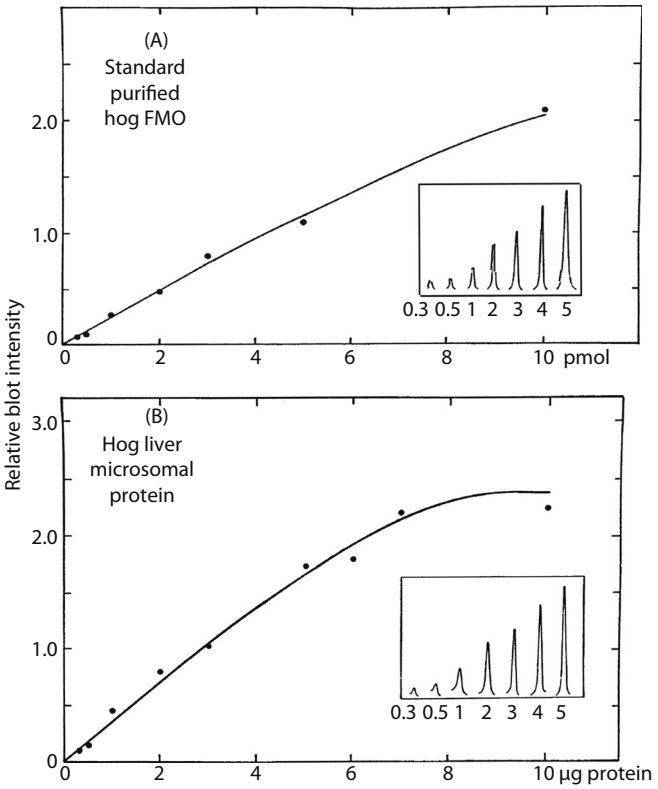

FIGURE 40.32 Immunoelectrophoresis and densitometry of FMO in purified samples and porcine liver microsomes.[283] (A) Area under the densitometric peak as a function of the amount of purified porcine liver FMO used for electrophoresis. The *inset* shows the actual densitometric traces. (B) Area under the densitometric peak as a function of the amount of porcine liver microsomal protein used for electrophoresis. The *inset* shows the actual densitometric traces.

the method is accurate and quite sensitive. It provides a check on the specificity of antigen–antibody interaction in each individual antigen sample and provides data even when cross-reactive materials are present (if they can be resolved in a single electrophoretic dimension). The method is relatively rapid and straightforward, even when new systems are explored little optimization is required.

Samples of roughly 5 μg of microsomes or cellular homogenate protein are solubilized by heating with SDS and 2-mercaptoethanol. The samples are electrophoresed in a typical system based on the procedure of Laemmli[263]—a slab gel is used with up to 25 samples. Five or six lanes are used to prepare a standard curve for each gel: the lanes contain, for example, 0.5, 1, 2, 3, 5, and 10 pmol of the purified antigen. Crude protein samples to be analyzed are loaded into the wells for the other lanes. Typically, 1–50 μg of microsomal protein might be loaded per well for analysis of P450 proteins. Protein samples are dissolved in a mixture of 63 mM Tris–HCl buffer (pH 6.8) containing 10% glycerol (v/v), 1.0% SDS (w/v), 0.001% pyronin Y (w/v), and 5.0% 2-mercaptoethanol (v/v) and heated for 60 s at 95°C. Aliquots are loaded into the wells of a 1.5 mm × 16 cm × 20 cm gel (e.g., Bio-Rad, Richmond, CA). The separating gel is poured from a mixture of 0.375 M Tris–HCl buffer (pH 8.8) containing 7.5% acrylamide (w/v), 0.03% tetramethylethylenediamine (TEMED) (w/v), 0.10% SDS (w/v), and 0.0425% $(NH_4)_2S_2O_8$ (w/v) and the stacking gel, in which the wells are formed, is poured from a mixture of 0.14 M Tris–HCl buffer (pH 6.8) containing 3.5% acrylamide (w/v), 0.057% TEMED (v/v), 0.65% sucrose (w/v), 0.11% SDS (w/v), and 0.045% $(NH_4)_2S_2O_8$ (w/v). The electrode buffer (pH 8.3) contains 190 mM glycine, 25 mM Tris, and 0.10% SDS (w/v). Power is applied to the system at a constant current setting of 25 mA per gel to move the samples through the separating gel. The electrophoresis takes ~4 h. When the pink dye front has moved to within about one cm of the edge of the gel, the power is turned off and the system is separated. One of the glass plates on the gel is removed and water is sprinkled on the surface. A wetted piece of nitrocellulose paper (0.45 mm, Whatman) is laid over the wet gel. Care should be taken (and enough water used) to avoid trapping air bubbles. Two sheets of Whatman #3 paper, prewetted with water, are laid over the nitrocellulose. The glass plate is removed from the other side of the gel and replaced by a wet sheet of Whatman #3 paper. The entire *sandwich* is placed between two wet sponges and then enclosed between the two electrode baffles of an electrotransfer apparatus, with the nitrocellulose closer to the anode than the cathode. The apparatus, with the gel and nitrocellulose between the baffles, is filled with 25 mM Tris–HCl buffer (pH 8.2) containing 190 mM glycine and 20% CH_3OH (v/v). Constant current (400 mA for 1 h or 200 mA for 2 h) is applied to the system.

After the blotting operation, the polyacrylamide gel and the filter papers are discarded and the nitrocellulose sheet is placed in 25 mL of a solution of PBS (phosphate-buffered saline: 10 mM potassium phosphate buffer [pH 7.4] plus 0.9% NaCl [w/v]) containing 0.50% Tween 80 (w/v). The sheet is conveniently placed in a plastic box of only slightly larger dimensions (13 × 18 × 3 cm) with a lid. The gel is shaken in a 37°C water bath for 30 min to block reactive sites on the nitrocellulose sheet with serum proteins so that antibodies will not be bound in subsequent steps. After the blocking step, the nitrocellulose sheet is washed twice with 60 mL of PBS at room temperature. In practice, the box is rocked on a platform rocker (Bellco Glass, Vineland, NJ) for 5 min, the buffer is decanted, and 60 mL of fresh PBS is added each time.

In the next step, 25 mL of PBS containing 0.50% Tween 80 (v/v), and an appropriate dilution of the antiserum of choice, is poured into the box over the nitrocellulose sheet. The system is shaken (or rocked) at 37°C for 30 min and then overnight at 4°C; alternatively, 37°C for 2 h is usually satisfactory. Typical antisera dilutions range from 1/100 to 1/2000 (some monoclonal antibodies have been successfully used at $1/10^6$ dilutions of ascites fluid). Then the nitrocellulose sheet is washed six times (5 min each, room temperature) with 60 mL of PBS. The next addition is 25 mL of PBS containing 0.50% Tween 80 (w/v) and 0.20% (v/v) goat antirabbit IgG antiserum (if the primary antiserum was made in rabbits). This solution is rocked or shaken with the nitrocellulose sheet at room temperature for 30 min, and the sheet is then washed again six times with PBS as before. The next addition to the sheet is 25 mL of a solution of PBS containing 0.50% Tween 80 (w/v), and 0.20% (v/v) horseradish peroxidase/rabbit anti-horseradish peroxidase complex (Promega, Madison, WI). The sheet is rocked in this solution at room temperature for 30 min and washed six times with PBS as before.

Development of the stain is done in the following manner. 4-Chloro-1-naphthol (32 mg) is dissolved in 12 mL of CH_3OH and diluted with 60 mL of PBS. H_2O_2 (120 mL of a 30% solution) is added and the solution is poured over the nitrocellulose sheet; bands usually appear within a few minutes. The solution is removed; the nitrocellulose sheet is washed three times with PBS and twice with H_2O. Sheets can be dried between two layers of Whatman #3 filter paper, with a uniform weight applied.

When the gel is dry (within 1–2 h), the bands can be scanned using a densitometer. The integrals are used to construct standard curves and estimate the amount of antigen in each sample (Figure 40.31).

In practice, a standard curve is constructed on each nitrocellulose sheet. An additional way to reduce error is to include an internal standard in each protein sample. Equine alcohol liver dehydrogenase can be used for this purpose, adding 0.2 mg to each sample prior to electrophoresis. The buffer containing the primary antisera is fortified with a 1/500 dilution of rabbit antisera raised against equine alcohol dehydrogenase. When the nitrocellulose sheets are visualized, the P450 band in the 50–60 kDa region is accompanied by a second band migrating with apparent M_r of 43 kDa. The integrals of both bands are obtained from the densitometer. The ratio of the areas of the two bands can be compared to the ratios found with the standard antigen samples.

Even if the antigen–antibody system is not specific enough to visualize only a single electrophoretic band, useful

information can be obtained, if the different antigens are electrophoretically separable. For instance, rat P450s 1A1 and 1A2 usually cross-react but can be separated and quantified.[64,321] The same situation exists with human P450 2C enzymes.[315]

Since the original immunoblotting work was done,[322] a number of variations of the procedure have been reported. Many of these are cited in subsequent reviews.[323,324] For instance, different additives can be used in the buffers for blocking the sheets. Nylon membranes, such as Zeta-Probe (Bio-Rad, Hercules, CA), have increased capacity and can be used to increase the sensitivity of the methods. *Staphylococcus aureus* protein A conjugates can be bound to the primary antibody. Other enzymes such as alkaline phosphate can replace peroxidase; alternatively, ^{125}I-labeled antibodies can be used with autoradiography, as described in the original Towbin et al.'s paper.[322] Another alternative is the use of IR fluorescent reagents (e.g., LI-COR system), which works very well for quantitation (LI-COR, Lincoln, NE).[320] If monoclonal antibodies are used, the methods must be adapted by including a step with rabbit antimouse immunoglobulin G[317,318]; many monoclonal antibodies give poor responses in this system because the individual epitopes do not have sufficient affinity constants.

In our own laboratory, we have applied this approach to rat and human microsomal epoxide hydrolase, rat NADPH–P450 reductase, several different forms of rat and human P450, and FMO. The method can be utilized with cells[325] or tissue homogenates[283] as well as with subcellular organelles.

One related new alternative to determining concentration of proteins in tissues and other crude samples is the use of proteomics.[326,327] No antibodies are needed, and the method makes use of peptides within the proteins of interest. A crude sample is cleaved with trypsin (or another protease), and the crude mixture of peptides is analyzed by LC–mass spectrometry, quantifying an individual peptide or set of peptides. The method is sensitive and we have used it with studies of DNA polymerases in *Sulfolobus solfataricus*. The sensitivity is comparable to that of immunoblotting and the time, and the cost of raising antibodies is eliminated.

Recombinant DNA Techniques

mRNA Isolation

Analysis of mRNA levels provides insight into regulatory mechanisms. In many cases, regulation of enzymatic activity occurs primarily at the level of transcription and mRNA levels are well correlated with protein levels. However, this is not always the case, and notable exceptions have been documented with some P450 enzymes.[328,329] Techniques of mRNA isolation and handling have become routine and may be mastered without considerable difficulty. Moreover, the generation of highly specific probes can be easily achieved by synthesis of oligonucleotides or long probes developed by polymerase chain reaction (PCR) technology, in contrast to the production of antigens and antibodies for analysis of protein levels (*vide supra*). The most widely used procedure for RNA isolation is that of Chomczynski and Sacchi.[330] It is rapid, reliable, and useful with large numbers of samples.

First and foremost, one of the critical aspects of working with RNA is to avoid RNase. Any traces of this protein on glassware, dust, or fingertips will be devastating. Disposable gloves must be worn during all steps and all glassware and plasticware should be treated as described in the succeeding text and stored specifically for RNA procedures. Several commercial kits for total RNA isolation are currently available based on the guanidine method. These kits do offer the ease of ready-made reagents or a single monosolution combining all the initial reagents but at much higher costs.

Reagents for RNA Isolation:

1. Stock guanidine thiocyanate: 250 g of guanidine thiocyanate (Sigma–Aldrich) is dissolved (at 65°C) in a mixture of 293 mL H_2O, 18 mL of 0.75 sodium citrate buffer (pH 7.0), and 26 mL of 10% sarkosyl (w/v). This solution can be stored ≥3 months at room temperature.
2. Denaturing solution: add 0.36 mL of β-mercaptoethanol per 50 mL of the solution just described (add before use—can be stored 1 month at room temperature if necessary).
3. Water-saturated phenol: nucleic acid grade phenol, saturate with H_2O. Once made, the solution may be stored for <1 month at 4°C. This may be purchased ready-made from a variety of sources.
4. 2 M sodium acetate (pH 4.0).
5. $CHCl_3$/isoamyl alcohol (49:1, v/v) or bromochloropropane.[331]
6. 100% isopropanol.
7. 75% C_2H_5OH.
8. All glassware and plasticware to be utilized should be previously treated with a solution of diethylpyrocarbonate (DEPC) and autoclaved, preferably in individually self-sealed pouches. Autoclaving does not inactivate all RNases. Alternatively, glassware can be baked at 300°C for 4 h. Some types of plasticware may be washed with $CHCl_3$ as an alternative to DEPC.[332]
9. If possible, solutions should be shaken with 0.1% DEPC (w/v) and then autoclaved to destroy excess DEPC, which can react with nucleic acids. For chemicals that react with DEPC (e.g., Tris buffers) or that cannot be autoclaved, sterile filtration through 0.2 μm Nalge filters may reduce potential RNase contamination. Presterilized disposable pipettes, pipette tips, filter units, and such may be used directly if individually wrapped as supplied.
10. Whenever possible, all chemicals to be used in RNA work should be reserved for this purpose only and weighed out only with the use of DEPC-treated spatulas.

This procedure may be used for 100 mg of tissue or an equivalent amount of cells, 10^7 cells.[332] The tissue is removed

from the animal and minced on ice. If frozen material is utilized, the tissue should be ground with a mortar and pestle in liquid nitrogen. It is important to note that substantial RNA degradation may occur during this step. Homogenize the material in 10 mL of denaturing solution per g of tissue with either a glass Teflon homogenizer or a Tissue-mizer (Cole Palmer, Vernon Hills, IL). Transfer the homogenate to either a 25 mL glass Corex tube or a smaller polypropylene centrifuge tube. To this are added, sequentially, per 1.0 g of tissues 1.0 mL of 2 M sodium acetate (pH 4.0) and mix thoroughly by inversion, 10 mL of H_2O-saturated phenol and repeat mixing, and 2 mL of the $CHCl_3$-isoamyl alcohol or bromochloropropane. The final mixture is mixed vigorously for 10 s and incubated on ice for 15 min. Centrifuge the suspension at $10^4 \times g$ for 20 min at 4°C and transfer the aqueous (upper) RNA-containing phase to a new tube. Precipitate the RNA by the addition of 1 volume of 100% isopropanol. Incubate for 30 min at –20°C and then centrifuge at $10^4 \times g$ for 20 min at 4°C. Discard the supernatant. Redissolve the RNA pellet in 0.3 mL of the denaturing solution and transfer to a microcentrifuge tube. Reprecipitate the RNA with 1 volume of 100% isopropanol for 30 min at –20°C. Centrifuge for 10 min at $10^3 \times g$ and discard the supernatant. Resuspend this RNA pellet in 75% C_2H_5OH (v/v) and collect the pellet as before. Dry the RNA pellet under vacuum for 5 min. Redissolve the RNA pellet in 100–200 µL of DEPC-treated H_2O and incubate 10–15 min at 55°C–60°C. Store the final RNA at –70°C. The total RNA concentration may be estimated by measuring the absorbance at 260 nm (A_{260} = 1.0 for a solution of 40 µg mL^{-1}, with a 1 cm pathlength).

Reagents for mRNA Preparation:

1. Oligo(dT)-cellulose is available from a number of supplies.
2. Binding buffer: 10 mM Tris–HCl (pH 7.5) containing 0.5 M NaCl, 1 mM EDTA, and 0.5% SDS (v/v). Prepare a 2× binding buffer as well.
3. Wash buffer: 10 mM Tris–HCl (pH 7.5) containing 0.1 M NaCl and 1 mM EDTA.
4. Elution buffer: 10 mM Tris–HCl (pH 7.5) containing 1 mM EDTA.
5. 3 M sodium acetate.
6. Microfuge spin columns ultrafree-MC 0.45 µm filter units (Waters, Bedford, MA).
7. 100% C_2H_5OH.
8. As described in the previous section, all reagents and glassware must be meticulously treated and subsequently handled to avoid contamination with RNases.

The basic procedure can be varied depending upon the scale.[333] Oligo(dT)-cellulose (0.1 g [mg total RNA]$^{-1}$) is suspended in 1–5 mL of binding buffer and equilibrated for 60 min at room temperature with gentle agitation. The slurry is then pelleted and resuspended in fresh binding buffer, rewashed, and finally resuspended in binding buffer (50 mg mL^{-1}). The RNA is suspended at 1 mg mL^{-1} in elution buffer and heated at 65°C for 5 min. Chill on ice and dilute the sample with an equal volume of 2× binding buffer. The RNA sample can be added to equilibrated oligo(dT)-cellulose (from which excess binding buffer has been removed by a brief spin) immediately prior to loading. RNA is incubated with the oligo(dT)-cellulose for 15 min at 23°C with gentle rocking. The sample can then be loaded into a DEPC-treated microfuge spin column. The flow-through (void) fraction should be collected by a brief spin and reapplied to the column, repeat. The column is washed with 5–10 volumes of binding buffer followed by 5 volumes of wash buffer. The bound RNA is eluted with 2–3 column volumes of elution buffer adjusted to 0.5 M NaCl with 2× binding buffer; the entire procedure is repeated (i.e., binding, washing, elution). RNA in the final sample is recovered via ethanol precipitation by adding 0.1 volumes of ethanol and centrifuging. The reuse of the oligo(dT) resin is not recommended.

Northern and Southern Blotting

Specific DNA and RNA sequences can be detected by blotting and hybridization, referred to as Southern and *Northern* blotting.[334] Northern blotting differs from Southern blotting primarily in the initial gel fractionation step (*Northern* and *Western* are slang based on the first use of a method developed by Southern for DNA).[335] RNA molecules are single stranded and thus can form secondary structures. They must be electrophoresed under denaturing conditions for good separations to occur. Denaturation is achieved by the addition of formaldehyde to the gel and buffers or by treating the RNA with glyoxal and dimethyl sulfoxide (DMSO). Previous precautions mentioned for dealing with RNA apply here. All materials must be handled meticulously and all glassware should be DEPC treated and baked. A gel tank should be set aside for RNA work. You should not utilize a DNA tank for RNA work.

Reagents for Electrophoresis and Blotting[336,337]:

1. 5× MOPS [3-(*N*-morpholino)propanesulfonic acid] running buffer and 1×: 0.2 M MOPS buffer pH 7.0 with 50 mM sodium acetate and 5.0 mM EDTA.
2. 37% formaldehyde (12.3 M), pH > 4.
3. Deionized formamide: if formamide has a yellowish color, it can be deionized by adding 5 g of mixed-bed ion-exchange resin (e.g., Bio-Rad AG 501-X8) per 100 mL, stir 1 h at room temperature, and filter through Whatman #1 filter paper. Formamide is a teratogen, so handle with care.[335]
4. Loading buffer: 1 mM EDTA, pH 8.0, 0.25% (w/v) bromophenol blue, 0.25% (w/v) xylene cyanol, and 50% (v/v) glycerol. This can be stored up to 3 months at room temperature.
5. 1× SSC buffer: 15 mM sodium citrate (pH 7.0) containing 150 mM NaCl. Prepare 20×, 10×, and 0.25× as well.
6. Ethidium bromide, 5 mg mL^{-1}.
7. Prehybridization buffer: mix 60 mL formamide, 3 mL of sonicated solution of 10 mg mL^{-1} salmon

sperm DNA, 12 mL of 100× Denhardt's solution (2.0% Ficoll [w/v], 2.0% polyvinylpyrrolidone [w/v], and 2.0% bovine serum albumin [w/v]), 6 mL of a solution of 1 mg/mL polyA, 1.2 mL of 10% SDS (w/v), 30 mL of 20× SSC buffer (*vide supra*), and 7–8 mL DEPC-treated H_2O.

8. SDS, 10% (w/v).

To pour a 20 × 20 cm gel, boil 3 g of agarose in 186 mL of DEPC-treated H_2O until dissolved and then cool to 60°C. Add 60 mL of 5× MOPS buffer and 54 mL of 37% formaldehyde. Pour the gel into the gel box with the comb such that the slots are 1 mm above the horizontal surface. Once the gel has set, remove the comb and add enough 1× MOPS buffer to completely cover the gel.

Each sample should contain 2 µL of 5× MOPS buffer, 3.5 µL of 37% formaldehyde, and ≤20 µg RNA in 5 µL. Mix using a vortex device, centrifuge in a microfuge for 5–10 s, and incubate for 15 min at 55°C or 5 min at 65°C. Add 2 µL of loading buffer to every sample and spin again for 5–10 s in a microfuge. Load samples onto the gel and run at a constant voltage of 5 V cm^{-1} until the bromophenol blue band has migrated halfway to two-thirds down the gel. It can be advantageous to run duplicate sets of gels, in that one gel may be stained with ethidium bromide and the other used for transfer. For staining, place the gel in pan, cover with 20× MOPS, and add a few drops of the stock ethidium bromide solution. Incubate for 40 min, then examine the gel on a UV transilluminator to visualize bands, and photograph. Two sharp bands, the 18S and 28S rRNA, should appear if total RNA was used in the electrophoresis.

The gel to be transferred should be rinsed several times with H_2O. It is necessary to remove the formaldehyde as it can hinder retention of RNA to nitrocellulose and nylon membranes.[335] Replace the H_2O with 500 mL of 20× SSC. A piece of nitrocellulose is cut 3 mm smaller on each side than the gel. Wet this for 1 min in H_2O followed by 5–10 min in 20× SSC buffer. Cut five sheets of Whatman 3MM paper 3 mm smaller on each side than the nitrocellulose. In order to prepare a wick, cut a piece of chromatography paper 2 cm larger than the gel with four tabs extending out 10 cm on each side. A glass plate, slightly larger than the gel, is placed on top of a large buffer reservoir. One wick is place on every side of the glass plate hanging down into the 20× SSC buffer reservoir. Remove any air bubbles trapped between the wick and the glass plate with a glass rod. At this point, the gel is carefully placed on top of the wicks, taking care to remove any air bubbles. Cover the four edges of the gel with either plastic wrap or parafilm to prevent wicking at the edges as the gel contracts. The nitrocellulose sheet is placed on top of the gel. This is in turn covered with the Whatman papers one at a time, taking care to remove air bubbles after the addition of each new sheet. Cover the stack with 5 cm of paper towels cut to the same size followed by another glass plate. Add a weight to hold everything in place. Transfer will occur overnight.

Remove all the materials to expose the nitrocellulose sheet. Mark the wells and front to back. It is best to use pencil, as ink will wash off in subsequent washes. If nitrocellulose was used, place it between two sheets of Whatman paper and bake for 2 h at 80°C. Nylon membranes may be baked as described or wrap the dry membrane in UV-transparent plastic wrap, such as Saran wrap, and place the RNA side down on a UV transilluminator (254 nm) and irradiate for the appropriate length of time. For hybridization, the blot is placed in a sealable bag with 1 mL of formamide prehybridization solution per 10 cm^2 of membrane. The bag is rotated and incubated at 37°C–42°C for 2 h to overnight. An appropriate probe might be either (1) nick translation of a cDNA fragment, (2) random labeling, (3) PCR, or (4) oligonucleotide synthesis followed by ^{32}P-end labeling. For additional information, consult current literature in the field. Longer probes with higher levels of incorporation are more sensitive, while shorter probes can be more specific when optimized for differences. The probe is mixed with hybridization solution and heated at 95°C for 10 min. Hybridization will occur overnight at the same temperature used for prehybridization. On the next day, the bag or box is opened and the filter is removed. The filter is washed twice, 1–2 min each, with 2× SSC buffer at room temperature. Two similar washes follow 45 min each with 1× SSC containing 0.10% SDS (w/v). The hybridization can be changed by varying the temperature of the hybridization or the wash and the salt concentration of the wash buffer, in order to increase the *stringency* of the wash and the specificity of hybridization.[338] The filter is exposed to film. Time needed for an appropriate exposure varies with the specific activity of the probe, stringency of the hybridization, and the concentration of the RNA and DNA. Most work has been done with ^{32}P-labeled probes. Alternative procedures utilize ^{33}P, avidin/biotin, immunochemical, and luminescence procedures (consult commercial vendors). These procedures may increase in use due to decreased cost and increased restrictions on the disposal of radioactive waste.

Reagents for Southern Gels:

1. 0.25 M HCl
2. Denaturation solution: 1.5 M NaCl plus 0.5 M NaOH
3. Neutralization solution: 1.5 M NaCl plus 0.5 M NaOH (pH 7.0)
4. 20× and 2× SSC

Once the DNA samples have been digested with the restriction enzymes of choice, run an agarose gel with the appropriate markers and stain with ethidium bromide. Photograph the gel with a ruler alongside so that band positions may be compared to the membrane after hybridization. Rinse the gel in distilled water and place it in a dish containing 10 gel volumes of 0.25 M HCl. Shake slowly for 30 min at room temperature. Remove the HCl and rinse with distilled H_2O. Add 10 gel volumes of denaturation solution and shake for 20 min at room temperature. Repeat this step one time. After the second incubation, rinse the gel and incubate 2 times, 20 min shaking with 10 gel volumes of neutralization solution.[339] The setup for a Southern transfer is exactly

the same as for the Northern transfer. Refer to the Northern section (*vide supra*) on how to assemble the gel and membrane for transfer. After the DNA has been transferred to the membrane, it must be immobilized. The remainder of the protocol is the same as for a Northern blot. Place the nitrocellulose membrane between two sheets of Whatman 3MM paper and bake for 2 h at 80°C. The nylon membrane may be UV irradiated. Hybridization of probes can proceed as described under Northern blot.

Plasmid DNA Isolation (Minipreps)

Alkaline lysis is the most common procedure used for minipreps.[340,341] This procedure is simple and multiple samples can be run at the same time. Many commercial vendors offer kits based on this procedure. Plasmid DNA is isolated from small amounts of plasmid-containing bacteria. The bacteria are lysed using SDS and NaOH. The SDS denatures the bacterial proteins and the NaOH denatures the chromosomal and plasmid DNA. This solution is neutralized with potassium acetate. The covalently closed plasmid DNA reanneals rapidly. The chromosomal DNA and proteins precipitate and are removed by centrifuging the sample. The plasmid DNA is recovered from the supernatant by ethanol precipitation.[342]

Reagents for DNA Isolation:

1. Luria–Bertani (LB) media with an appropriate antibiotic (i.e., selective for your plasmid).
2. Cell resuspension buffer: 25 mM Tris–Cl (pH 8.0) buffer containing 10 mM EDTA and 50 mM glucose. Sterilize and store at 4°C.
3. Cell lysis buffer: 0.2 M NaOH, 1% (w/v) SDS (prepare immediately prior to use).
4. Cell neutralization buffer: 5 M potassium acetate (pH 4.8): start with 29.5 mL glacial CH_3CO_2H and add KOH pellets to pH 4.8. Add H_2O to 100 mL. Do not autoclave. Store at room temperature.
5. 95% and 70% C_2H_5OH (v/v).

Inoculate a single colony in 5 mL of LB^+ antibiotic medium and grow overnight. Spin down 1.5 mL of the cells in a microcentrifuge for 20 s at maximum speed. Remove the supernatant and add 100 µL of the cell resuspension buffer. Incubate for 5 min. (It is important that the cells are completely resuspended.) Add 200 µL of the cell lysis buffer and mix by tapping the tubes (by finger). Place tubes on ice for 5 min. Next, add 150 µL of cell neutralization buffer and mix. Incubate on ice for 5 min. Precipitate the chromosomal DNA and cellular debris by spinning in microfuge for 3 min. Transfer the supernatant to a new tube and add 0.8 mL of 95% C_2H_5OH (v/v). Incubate for 2 min at room temperature. The DNA is precipitated by microcentrifuging for 1 min. Carefully remove the supernatant and add 1 mL of 70% C_2H_5OH to wash the pellet. Dry the pellet under vacuum. The DNA pellet may be resuspended in 30 µL of sterile H_2O and stored at –20°C or –70°C. Some procedures call for storing the DNA in TE buffer (10 mM Tris–HCl [pH 8.0] containing 1.0 mM EDTA); however, TE can interfere with sequencing reactions. The DNA concentration can be determined by measuring A_{260}: a solution with an A_{260} of 1.0 contains 50 µg mL^{-1} of DNA (1 cm pathlength).[343] Plasmids can be maintained for a short amount of time (2–4 weeks) on selective media plates by storing them at 4°C. Permanent storage should involve storage of the isolated plasmid in addition to storage of the bacterial strain. Bacterial strains can be stored be growing the cells to saturation in the presence of the selective antibiotic. An equal volume of bacteria is added to sterile 100% glycerol and quick frozen in liquid nitrogen (*glycerol stocks*). Cells may then be stored at –70°C. For recovery, simply streak out a sample on selective media and grow.

Polymerase Chain Reaction

The basic principles of the method were developed in 1986 and are relatively straightforward.[344] The process provides the opportunity for considerable innovation in the application to a wide variety of research problems. The reader is advised to consult the current literature, in that only the basic points are mentioned here. The double-stranded DNA is heat denatured, and the two primers complementary to the ends of the target segment are annealed at a temperature close to the temperature of the oligomers and then extended at a temperature optimal for the polymerase used. One set of these three consecutive steps is referred to as a cycle. Thus, the amount of the original sequence of interest is expanded in a geometric progression. The process is greatly facilitated by the use of heat-stable polymerase isolated from a thermophilic bacterium; such polymerases function most effectively at high temperatures, for example, 72°C–78°C. Many cycles can be carried out with the same enzyme. The cycle times are relatively short and commercial instruments can be programmed to cycle through steps automatically. DNA segments can be amplified 10^5- to 10^9-fold. Heat-stable polymerases of very high fidelity are available and reduce errors.

A typical PCR would be performed on a 100 µL scale in 0.5 mL sterile thin-walled microcentrifuge tubes. There is considerable potential to generate false positives and it is imperative to minimize laboratory errors. Reagent purity is important, and avoiding contamination at every step is crucial. Carryover of amplified sequences contributes to the majority of false positives; thus, appropriate precautions include physical separation of pre- and post-PCR and aliquoting reagents to minimize the number of repeated samplings. Positive placement pipettes are the best choice for PCR work. Some other general precautions include changing gloves frequently, careful uncapping of samples to prevent aerosol formation, addition of nonsample components (buffer, nucleotides, primers) to the reaction mixture prior to DNA addition, and (absolutely) the use of new pipette tips for every addition.

The PCR sample may be single- or double-stranded DNA or RNA. If the starting sample is RNA, reverse transcriptase is used to first prepare cDNA prior to conventional PCR, that is, RT-PCR. PCR primers are 20–30 base long oligonucleotides that are complementary to sequences defining the 3′ ends of the complementary template strands. Several computer

programs can assist in primer design. Bear in mind that computer design is not foolproof. Utilizing these programs will aid in detecting primer pairs with intra- or intermolecular complementarities (primer dimers). Ideally, 40%–60% G+C content is recommended, without long stretches of either base. Many computer programs will analyze the primer secondary structures and calculate the T_m values. The T_m values for both primers should be well matched. Internal secondary structure (e.g., hairpin loops) should be avoided in primers. Nontemplate-complementary 5′ extensions may be added to primers to allow a variety of useful operations on the PCR product, for example, the addition of restriction enzyme sites, without significant perturbation to the amplification.

Optimal annealing temperature must be determined empirically. A good annealing temperature from which to begin optimizing is 5°C–10°C below the T_m of the primers. Another critical parameter for PCR is $MgCl_2$ concentration needed in the reaction to generate maximum product. Titration of the Mg^{2+} concentration over a range of 1.5–4 mM is recommended to find the concentration producing the highest yield of product (the fidelity of *Taq* polymerase decreases in the presence of high Mg^{2+}). *Pfu* polymerase has a higher fidelity rate compared to *Taq* (Stratagene). This multifunctional, thermostable enzyme possesses both 5′–3′ DNA polymerase activity and 3′–5′ exonuclease activity. This latter activity results in a 12-fold increase in fidelity over *Taq* polymerase. A typical PCR (performed in 100 µL) would contain dATP, dCTP, dGTP, dTTP (200 µM each), primer (0.25 µM), template (0.1–500 ng), and 10 µL of a stock buffer containing 0.20 M Tris–HCl (pH 8.75), 0.10 M KCl, 0.10 M $(NH_4)_2SO_4$, 20 mM $MgCl_2$, 1.0% Triton-X 100 (w/v), and 1.0 mg nuclease-free bovine serum albumin mL^{-1} (w/v). The tubes are mixed gently and centrifuged briefly. It is important to note that some protocols call for the addition of mineral oil. If the thermocycler being utilized has a heated lid, then mineral oil is not needed in the reaction; add 50 µL of mineral oil if the thermocycler does not have a heated lid. Heat samples to 95°C for 5 min and then cool to the desired annealing temperature to allow the primers to anneal to the template DNA. *Pfu* polymerase (2.5 units) is added. Primer extension proceeds at 75°C. Cycles are then repeated to achieve adequate amplification. PCR products are checked by electrophoresis, with detection by ethidium bromide staining or hybridization to labeled probes as appropriate. An alternative to ethidium bromide staining is SYBR Gold nucleic acid gel stain from Molecular Probes/Life Technologies (Grand Island, NY), which is 25–100 times more sensitive than ethidium bromide, is easier to use, and permits optimization of 10- to 100-fold lower starting template copy number.[345]

Site-Directed Mutagenesis

Site-directed mutagenesis has been defined as "any of various techniques by which defined mutations can be made in vitro in a cloned DNA."[346] The Kunkel method of site-directed mutagenesis is a classic method for introducing mutations into a DNA sequence. This method of site-directed mutagenesis by deoxyuridine incorporation depends on the host strain to degrade template DNA that contains uracil in place of thymidine.[347,348] A number of dUTPs are incorporated into the template strand in place of dTTP in a host that lacks dUTPase (i.e., it is *dut*$^-$) and uracil *N*-glycosylase (i.e., *ung*$^-$) activities. Uracil itself is not mutagenic and base pairs with adenine. Under normal cellular conditions, dUTPase degrades deoxyuridine and uracil *N*-glycosylase removes any incorporated uracil. Postmutation replication in a *dut*$^+$*ung*$^+$ *E. coli* strain is used to then degrade the nontarget strand DNA. This approach requires single-stranded DNA be utilized so that only one strand contains the uracils that are susceptible to degradation.

A more convenient method for site-directed mutagenesis is based on PCR using the selection method of DAM methylation. This is commonly sold in a commercial kit available from Stratagene known as QuickChange™. However, the procedure can be accomplished without the purchase of a kit, and everything needed is available individually. There is no need to isolate single-stranded DNA. The entire process is PCR based, utilizing *Pfu* polymerase. After the PCR has finished, the products are digested with the restriction enzyme *Dpn*I. This restriction enzyme is specific for DAM-methylated $G^{Me6}ATC$ sequences.[349] The wild-type template will be digested by *Dpn*I and the PCR-generated mutant DNA will not be cleaved by this enzyme. Therefore, the reaction is enriched for the mutant DNA population. Multiple mutations can be introduced using the *Dpn*I method. A selection feature one can incorporate through the primer design is the addition of other unique restriction enzyme sites (e.g., unique to the DNA sequence of interest). This method works well with plasmids of moderate size (<8 kb) and eliminates the need for subcloning.

Another type of mutagenesis is cassette mutagenesis. In the basic form of cassette mutagenesis, a small section of DNA is removed from the wild-type gene and is replaced with a synthetic segment that carries one or more desired mutations.[350]

Cassette mutagenesis can also be utilized to produce multiple mutations within a target zone. One efficient way to generate the pool of oligonucleotides is to synthesize one strand of the cassette with equal mixtures of all four nucleotides in the first two positions and an equal mixture of G and C in the third.[351] This composition will result in all 20 amino acids.[352] The second strand for the cassette is synthesized with inosine at each target position. Inosine will base pair with all four bases.[353] The two strands are annealed and the population of cassettes is ligated into a vector.

GENOTOXICITY ASSAYS LINKED TO METABOLISM

One use of bacterial P450 systems is the development of convenient genotoxicity assays. This area has been reviewed elsewhere, including the expression of enzymes in *S. typhimurium*.[193,202] More recently, *E. coli* systems have

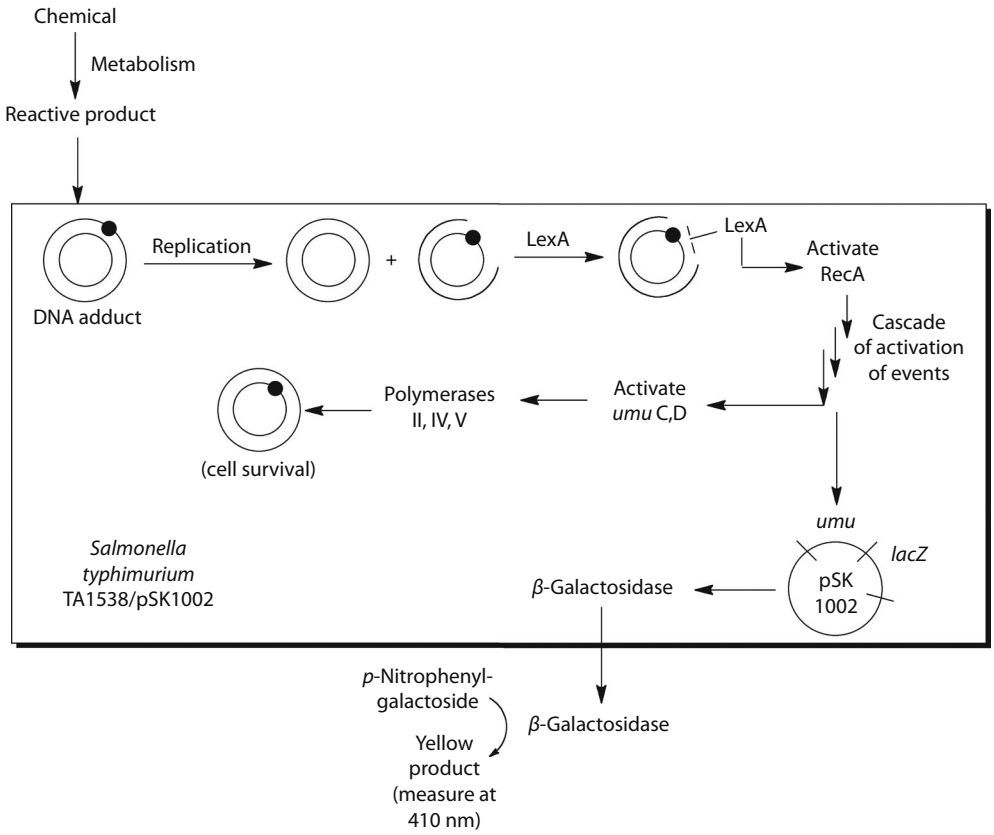

FIGURE 40.33 Use of bacterial SOS response to identify genotoxins with the *umu* response. A chemical is incubated with a metabolic system capable of converting it to a reactive product, in the presence of *S. typhimurium* cells containing the plasmid pSK1002. Formation of DNA adducts blocks replication of the modified strand and leaves regions of single-stranded DNA, to which the protein LexA binds. The protease LexA is then activated and cleaves RecA, leading to more events in a cascade and activating >30 genes. One of these is *umuC*, which codes for a translesion polymerase that the bacteria use to bypass DNA adducts and replicate. A reporter plasmid in the cell (pSK1002) contains the regulatory region of the *umu* gene attached to *lac*Z. Thus, generation of DNA adducts has the overall effect of activating this *umu*-based plasmid and producing the products β-galactosidase. The production of β-galactosidase can be quantified by lysing cells and using a colorimetric assay.

been developed where the endpoint is *lac* protrophy instead of the usual *his* in the Ames test. A bacterial *N*-acetyltransferase can be concurrently expressed to increased sensitivity to aryl and heterocyclic amines. Such systems have been shown to respond to concentrations of some aryl amines as low as the classical *S. typhimurium* systems.[176] These systems offer several advantages. In other work, it has been possible to express rat and human GSH transferases along with *N*-acetyltransferase in *S. typhimurium* for use in genotoxicity assays.[201,354,355] More recently, several human P450s have been coexpressed with NADPH–P450 reductase in *S. typhimurium*.[356] These systems have considerable potential, in that bacterial systems will continue to be the mainstay of high-throughput, first-check genotoxicity screens. In these systems, reactive products are generated with the cells and more closely approximate the normal cellular situation.

Some examples are the *S. typhimurium umu* test (or the similar *E. coli* chromotest) in which the reporter gene is linked to a promoter that responds to a cascade emanating from damage to bacterial DNA.[175,357] These systems often have faster readout than colony-counting systems (e.g., conventional Ames test) with their colorimetric endpoints, which are often seen within a few hours. The Ames test relies on the reversion of a variety of different *S. typhimurium* mutants with histidine dependent growth requirements to prototrophy by a chemical carcinogen. All of the strains contain two additional mutations that disrupt excision repair and cause loss of the lipopolysaccharide barrier.[358] In the *S. typhimurium umu* test, DNA damage as a result of chemical carcinogenesis invokes the SOS response (Figure 40.33). The SOS response initiates proteolytic cleavage of the LexA protein by the activated RecA protease and ultimately results in β-galactosidase activity that can be colorimetrically quantified.[175] Briefly, a chemical is incubated with a metabolic system capable of converting it to a reactive product, in the presence of *S. typhimurium* cells containing the plasmid pSK1002. This can be liver microsomes or a recombinant P450 system expressed within the cells. Formation of DNA adducts blocks replication of the modified strand and leaves regions of single-stranded DNA, to which the protein LexA binds. The protease LexA is then activated and cleaves RecA, leading to more events in a cascade and activating >30 genes. One of these is *umu*C, which codes for a translesion polymerase that the bacteria use to bypass DNA adducts and replicate. A reporter plasmid

in the cell (pSK1002) contains the regulatory region of the *umu* gene attached to *lac*Z. Thus, generation of DNA adducts has the overall effect of activating this *umu*-based plasmid and producing the products β-galactosidase. Production of β-galactosidase can be quantified by lysing cells and using a colorimetric assay (Figure 40.33). The assay can be done in microtiter plates.

The *E. coli* chromotest is very similar although unlike the previous examples, this system utilizes only one strain and also relies on the cell SOS response system. In this case, cell division is tied into the assay; thus, survival of the host is not important.[359] The *E. coli* strain has the same mutation that renders the strain lipopolysaccharide deficient, allowing for better diffusion of chemicals through the outer membrane.[360] Several steps occur between the reaction of a carcinogen with DNA and a resulting mutation.

In this laboratory, we have recently utilized two different systems to study DNA repair. One system is the human p53-driven *Ade* reporter system in the yeast *S. cerevisiae*. Cells with the wild-type p53 human tumor suppressor gene express *Can1* and these cells are able to take up canavanine, which is cytotoxic and limits growth on selective media. Cells with mutant p53 are unable to express *Ade2* accumulate an adenine metabolite intermediate and the colonies are red in color.[361]

The second system utilizes resistance to the antibiotic rifampicin in *E. coli* through mutations in the *rpoB* gene as a result of carcinogen exposure.[362,363] Utilization of this system enabled the identification of the direct inactivation of O^6-alkyguanine DNA alkyltransferase (AGT) and formation of AGT-Cys^{145}-CH_2-DNA adducts by which methylene dibromide (dibromomethane) can cause genotoxic damage.[363] Additional work resulted in identification of another ethylene dibromide DNA adduct, guanine N^7-alkylation, and a potential second site that was not identified.[362]

CONCLUSIONS

Enzymes have important roles in the metabolism and toxicology of many chemicals. Important examples are known with drugs and with *environmental* chemicals, and the principles are the same. Some background has been presented here, along with some detailed procedures for working with these systems. Obviously, the examples are not comprehensive, and they can be modified to make them more useful for particular needs. The need for better understanding of the biochemical and molecular events involved in toxicology (Figure 40.4) will continue for some time, and we hope that this information will facilitate some of the studies in the area.

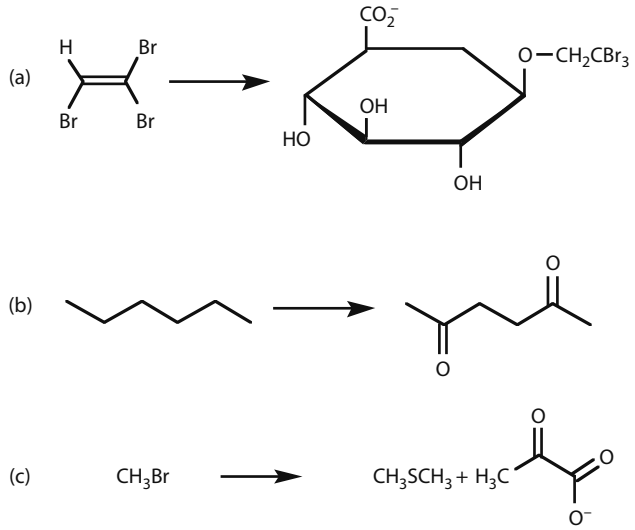
QUESTIONS

40.1 Most assays for competitive inhibition of cytochrome P450 enzymes involve direct studies with assays of substrate oxidation. How could you develop a high-throughput screening strategy for identifying high-affinity inhibitors of a particular cytochrome P450 (e.g., 2D6) without the need to do assays of catalytic activity?

40.2 A new chemical of interest induces total hepatic cytochrome P450 (as measured spectrally) and is hepatotoxic (in rats). Are the two phenomena necessarily related? How would you establish the relationship?

40.3 An investigator tells you that he has found that a particular recombinant human cytochrome P450 enzyme catalyzes a reaction of interest to you. What other pieces of evidence are needed to put this information into the perspective of how much this enzyme contributes to the process in human liver?

40.4 The pathways shown in the following have been extended to demonstrate an example of situations often encountered in practical situations. Provide reasonable stepwise pathways to the products indicated. The number of steps is not specified. For each step, provide the necessary cosubstrate(s) and name of enzyme (if enzymatic, only group name, no need for individual form).



40.5 You have encountered an interesting enzyme in your research and wish to further study its function. This enzyme requires glycosylation for activity. How does this influence your choice of expression systems?

ACKNOWLEDGMENTS

41 Modern Instrumental Methods for Studying Mechanisms of Toxicology

Peter A. Crooks, Howard P. Hendrickson, David R. Worthen, Gary D. Byrd, J. Donald deBethizy, and William S. Caldwell

CONTENTS

INTRODUCTION

The mechanisms underlying an organism's response to a toxic insult are usually complex, involving the toxicant itself, metabolites derived from it, and numerous tissue-derived endogenous compounds. The ability to monitor the chemical changes that result from intoxication is critical to understanding these mechanisms. Our ability to monitor chemical changes associated with intoxication has often limited our mechanistic understanding of toxicity. The development of gas chromatography (GC) in the 1950s and 1960s extended the lower range for detecting chemical changes in organisms and in the environment. The realization that exposure to chemicals such as DDT was widespread and that these chemicals could concentrate in the food chain fueled the development of modern toxicology. This early breakthrough in instrumental analysis led to the development of a host of powerful instruments and techniques that have profoundly increased our ability to define mechanisms of toxicity. Because each instrumental method has both strengths and limitations, it is important for toxicologists to be aware of available analytical methods and to understand the types of studies for which each is suited.

This chapter is not intended to be a comprehensive survey of modern instrumental methods; rather, it focuses on those techniques that are likely to be most useful to toxicologists. Some of these techniques, such as mass spectrometry (MS) and nuclear magnetic resonance (NMR) spectroscopy, are widely used in toxicology. Others, such as near-infrared (IR) spectroscopy, are not as commonly used but have proven extremely useful for toxicological studies. Recent advances in the important areas of in vivo toxicology and metabolomics further underscore the importance of these analytical methods in toxicological research. Emphasis has been placed on practical applications, not in-depth theoretical discussion. This chapter serves as a starting point for further study. The interested reader is encouraged to consult the cited references to gain a more in-depth understanding of modern instrumental methods.

MASS SPECTROMETRY

MS is an analytical technique that determines the mass-to-charge (m/z) ratio of ionized molecules and their fragments and adducts. It is perhaps the most generally applicable tool in chemical analysis and the method of choice for many specific analytical procedures. In addition to its application as a universal detector in qualitative analysis, MS can be fine-tuned to quantify trace amounts of specific components in complex mixtures. Mass spectrometers are often part of a hyphenated analytical system where chromatography (usually gas or liquid) precedes mass spectrometric detection. MS has impacted biomedical, environmental, and toxicological research, including the study of toxic substances and their fate in the body. Considerable progress has been made in toxicology using MS as an analytical tool. This section looks at the basic principles of MS, new trends in the field, and some examples where MS has been applied to toxicology studies such as elucidation of detoxification mechanisms and exposure assessment. This is not a comprehensive review of recent breakthroughs in the area as much as it is a starting point for the curious student of the art. A good text covering routine techniques in MS with consideration of biochemical applications has been written by Boyd et al. [21], and Richardson has recently reviewed applications of MS specifically related to environmental toxicology [163].

Mass Spectrometers and Mass Spectra

There are many different types of mass spectrometers [49], but certain features are common to them all. Ions, unlike neutral compounds, can be manipulated by electromagnetic forces such that a separation by m/z ratio is possible. A mass spectrometer is a device that creates ions from sample molecules, separates them by m/z ratio, and determines the number of ions at each particular ratio. The mass spectrum is a plot of m/z ratio on the x-axis vs. relative ion abundances (RA) on the y-axis. The mass spectrum can give molecular weight and structural information about the compound that was ionized. Ions are normally produced with single charges ($z = 1$), so the m/z ratio gives the mass in daltons (Da) of intact molecules and fragments directly. A simple model of a molecule AB undergoing electron ionization (EI) is shown in the following:

$$AB \rightarrow \text{Ionization process} \rightarrow AB^{+\bullet} + A^{+} + B^{+}$$

The ionization process in this case produces a molecular ion $AB^{+\bullet}$ (usually designated as $M^{+\bullet}$) that is the sample molecule with an electron removed. Often, enough energy is imparted in the process so that a portion of the molecular ions decompose to form various stable fragment ions as shown by A^{+} and B^{+} earlier. The spectrum is highly characteristic of a particular compound and has been likened to a fingerprint that can be

used for identification purposes. Mass spectra of compounds with known structures are continuously reported and compiled, so patterns of fragmentation are established following EI. This knowledge is useful in interpreting spectra of unknown compounds. In addition, computerized searches of mass spectral databases can facilitate compound identification. The sensitivity of conventional mass spectrometers permits good spectra to be obtained on less than 10 ng of material, so, although the ionization process destroys the sample, the mass spectrometer requires very small amounts of material for analysis.

Instrument Design

Basic Configuration

The many different types of mass spectrometers vary in size and complexity from small benchtop units to large multiple-sector analyzers. Nevertheless, mass spectrometers can all be broken down into a few basic components and their functions: sample introduction, ion production, mass analysis, and ion detection. The ion source configuration is dependent on the physical state of the sample matrix entering the mass spectrometer. Ionization sources have been developed for gas, liquid, or supercritical fluid inlets. Electron ionization (EI) sources have been used for gas and liquid inlets and must be under vacuum. Atmospheric pressure ionization (API) techniques are available for liquid and supercritical fluid inlets. These components are shown schematically in Figure 41.1.

Inlet Systems

Samples are introduced into the mass spectrometer housing via some type of inlet. The inlet selected depends on the sample, the nature of the sample matrix, and the type of ionization desired. Many mass spectrometers are designed with multiple inlets to accommodate a wide variety of samples with minimal time required for instrument reconfiguration. For solid materials, the simplest means of introduction is to place the sample onto a probe or surface that is inserted directly into the ion source or atmospheric pressure source such as electrospray. For samples that are thermally stable, a probe containing the sample can be placed directly into the EI source. Analytes that occur in mixtures may require some separation before direct probe analysis. Although some separation of components in time is achieved by heating the probe slowly, it is a crude means of separation and works best on reasonably pure samples. Headspace sampling is often used as a means of introducing volatile analytes onto a GC column and offers the advantage of leaving nonvolatile components behind. This technique also allows for portable sampling and analysis in the field or in the laboratory [78,226]. Probes are also used in conjunction with other ionization techniques where they serve merely to place the sample in a position to be ionized. Examples of this would be *laser desorption* (LD), desorption electrospray ionization (DESI), and direct analysis in real time (DART), which are described later in this chapter.

Chromatographic separation techniques coupled to the source add another dimension of analysis, and most mass spectrometer systems used in biological sciences are configured in this manner. GC-MS has worked very well in this regard, making GC-MS perhaps the most common hyphenated method for performing organic analysis [22]. Although applications with packed GC columns are still reported with various types of interfaces, most GC-MS is performed with fused silica capillary columns. These columns use gas flows of 1–2 mL/min, and the ends can be placed directly into the ionization source. High-resolution chromatography of reasonably volatile and thermally stable samples is possible with these columns.

Many compounds will not pass through a gas chromatograph, and *liquid chromatography–MS* (LC-MS) has been

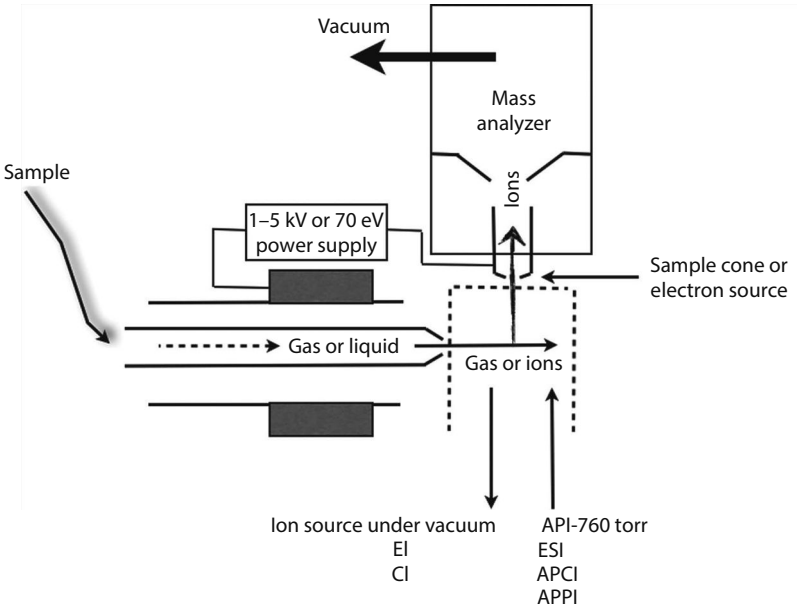

FIGURE 41.1 Schematic of a basic mass spectrometer system interfaced to an inlet. API and EI are both represented here.

developed as an alternative method for introducing analytes dissolved in solution into the mass spectrometer. In fact, because biological samples are usually aqueous based and include thermally labile and polar substances, LC-MS now rivals GC-MS in popularity. This is due to the development and refinement of many reliable interfaces in the last two decades. *High-performance liquid chromatography* (HPLC) methods using a variety of columns and flow rates have used MS as a detector. General procedures are well documented for LC-MS techniques [217].

Another chromatographic technique used with MS is *capillary electrophoresis* (CE) [196]. A high electric field in a small-diameter capillary tube filled with aqueous solution is used to separate charged compounds. CE offers the advantages of high resolution, low sample consumption, and short analysis times. It is well suited to the analysis of ions in solution. Interfacing to the mass spectrometer is often accomplished through electrospray ionization (ESI) or continuous-flow fast atom bombardment, which are described in the succeeding text. Due to the high salt concentration required for effective CE, coupling CE to MS remains a challenge and these two techniques are rarely used together.

Supercritical fluid chromatography has been coupled to MS and proven to be a powerful technique for resolution of closely related isomers, including enantiomers [32,188].

Ionization Sources for Volatile Compounds

This discussion of ionization sources is divided into two parts based on the volatility of the compound of interest. It might well be divided into the same parts based on the two popular chromatography methods interfaced to mass spectrometers: GC and LC. Because MS was originally limited to volatile samples, these types of ionization sources are considered conventional. Volatile samples are introduced directly into the ion source using a leak valve for gases, a heated direct insertion probe described earlier for solids, or a GC. This section describes methods used in these types of applications.

The most established means of ionization for volatile samples is EI, in which a sample is volatilized into the gas phase and passes through a beam of energetic (70 eV) electrons boiled from a filament. The process may be written as

$$M + e^- \rightarrow M^{+\bullet} + 2e^-$$

The high-energy electron displaces an electron from molecule M, which may remain intact as the molecular ion $M^{+\bullet}$ and thus provide direct molecular weight information. The energetics of the process can also cause fragmentation of the molecule. Fragmentation patterns are related to the structure of the molecule and thus can be interpreted as representative of that compound. As an example, Figure 41.2 shows the EI mass spectrum of nicotine identified in an extract of urine from a smoker. The highest mass ion in the spectrum is *m/z* 162, which is the molecular ion. The most abundant peak in the spectrum (referred to as the base peak) is *m/z* 84 and

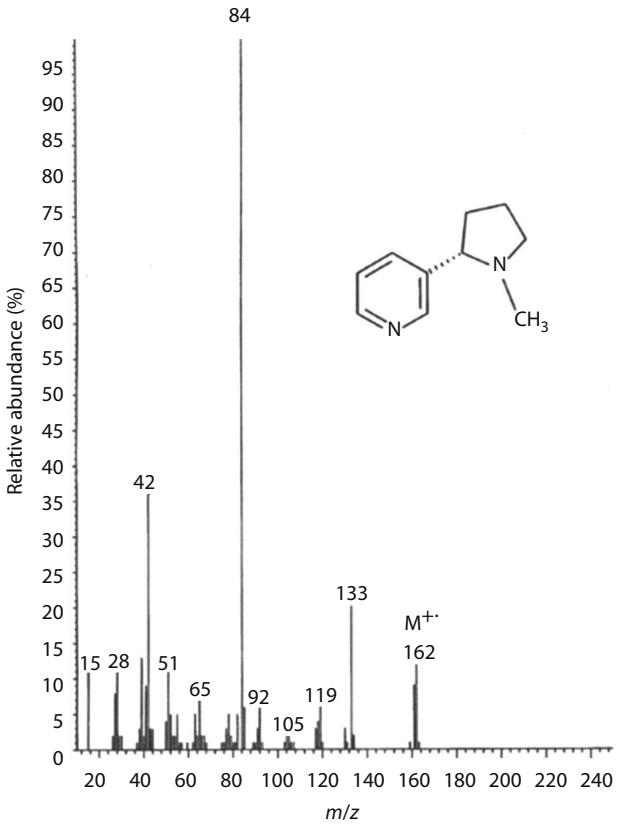

FIGURE 41.2 EI mass spectrum of nicotine. Data acquired on a quadrupole GC-MS system.

results from cleavage of the bond between the two rings with the charge remaining with the pyrrolidine ring.

EI has several advantages. Both fragment and molecular ions are produced in most EI spectra. The mass spectra are fairly reproducible from one instrument to the next, which makes it possible to match sample spectra to reference EI mass spectra with some certainty. Several large mass spectral databases of compounds are available that can be readily searched against an EI spectrum produced on most types of mass spectrometers. Some disadvantages of EI include the occasional lack of a molecular ion for some compounds, the difficulty of distinguishing between mass spectra of isomers, and limited application to samples with sufficient gas-phase volatility and thermal stability.

An alternative ionization method called *chemical ionization* (CI) can be used in cases where the molecular ion is weak or not present in the EI mass spectrum. The process derives its name from the use of gas-phase chemical reactions to produce ions from the sample. The two types of CI are *positive-ion chemical ionization* (PICI or PCI) and *negative-ion chemical ionization* (NICI or NCI). In both cases, the ionization is softer than EI, resulting in less fragmentation. PICI is most often accomplished through a gas-phase proton transfer reaction. The ion source is flooded with a reagent gas, usually methane, at a relatively high pressure (1 torr). During electron bombardment under these conditions, a series of gas-phase reactions occur

as depicted in the following for reagent gas methane and sample molecule M:

$$CH_4 \rightarrow CH_4^+$$

$$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$$

$$CH_5^+ + M \rightarrow CH_4 + (M+H)^+$$

Methane molecular ions formed in the high-pressure source collide with neutral reagent molecules (CH_4) and produce protonated methane. CH_5^+ acts as a strong Brönsted acid and transfers a proton to the sample molecule to produce the protonated molecular adduct $(M + H)^+$. PICI works best for samples with a relatively high proton affinity such as those containing a heteroatom. Fewer fragment ions and more abundant molecular ions characterize PICI mass spectra. In addition, sensitivity is enhanced relative to EI. The higher source pressure used, however, contaminates the instrument more rapidly and results in more frequent maintenance. Also, some modifications to the source are usually required when switching from EI to CI operation:

$$M + CH_4 + e^{-\bullet} \rightarrow M^{-\bullet} + CH_4$$

This process is rather selective, as not every molecule will readily form a stable $M^{-\bullet}$. Another process is adduct formation where a background anion such as Cl^- will attach to a molecule to form $(M + Cl)^-$. Numerous ion–molecule reactions are possible, and some can be rather complex. Proton abstraction is common and works well for samples with an acidic proton. Negative-ion formation can be enhanced using derivatization to form an analog with a high electron affinity. The sensitivity and selectivity of such assays can be very high; for example, one group reports conversion of nicotine using heptafluorobutyric anhydride to a stable electron scavenger derivative that can be detected at the femtogram (10^{-15} g) level on column [37].

Ionization Sources for Nonvolatile Compounds

This section describes ionization sources for compounds that cannot be volatilized sufficiently for EI, particularly those that decompose upon heating. These include very polar or very large molecules such as those encountered in biological samples. For these types of samples, LC is preferred over GC for chromatographic separation. A number of interfaces deal with samples in solution such as those that emerge from an LC column. Before introduction into the high vacuum of the mass spectrometer, most of the solvent molecules must be removed and the sample molecules ionized. Heat, nebulization with gas, and differential pumping are techniques used to remove the solvent. Ionization of the sample molecules can occur by a variety of different methods as described in this section. Some methods, such as particle beam, have distinct ionization steps, while others, such as electrospray, have ion formation inherent in the process. With the exception of particle beam, LC-MS ionization methods are soft like CI and produce mostly molecular adduct ions with gain or loss of a proton being the most common means of ionization.

Early development of these LC-MS interfaces was designed for low flow rates (i.e., 0.05–10 μL/min) because vacuum system was not capable of efficiently removing solvent when higher flow rates were employed. The early interfaces included thermospray [18], particle beam [12,13], and continuous-flow fast atom bombardment [224]. These earlier techniques required frequent maintenance and suffered from poor sensitivity. These techniques are only mentioned briefly here to provide the reader with a historical perspective. The exponential growth in MS as a routine detection methodology was made possible by the development and commercialization of API techniques: ESI, atmospheric pressure chemical ionization (APCI), and atmospheric pressure photoionization (APPI). A discussion of these ionization interfaces follows.

A widely used method of API, ESI, is simply an existing ion from solution into the gas phase by using a high electric field [213]. For Figure 41.1, the ESI interface is under high vacuum starting at the sample cone. The LC effluent passes through a capillary needle that is maintained at a high voltage (1–5 kV). At low flows (1–10 μL/min), the high electric field at the tip produces a mist of charged droplets at atmospheric pressure. For higher flow rates (i.e., 50–1000 μL/min), a nebulizing gas delivered coaxially to the needle assists production of the mist. As evaporation decreases droplet size, ions are ejected as depicted for sample molecules M and solvent molecules S in Figure 41.3. Of course, the analyte must already

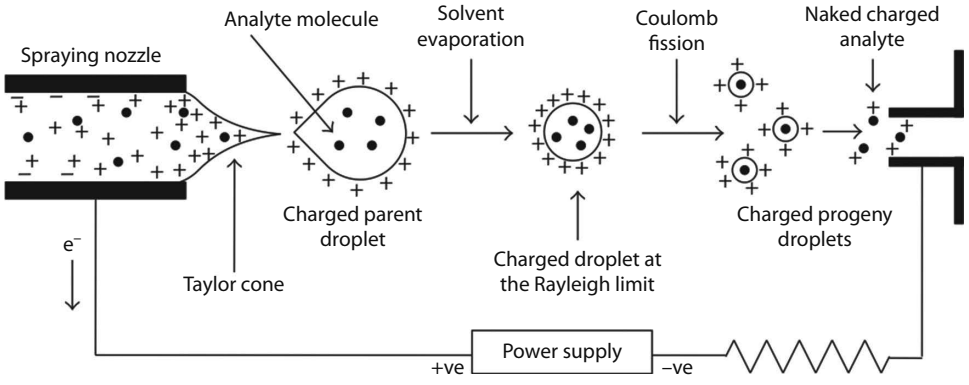

FIGURE 41.3 The ESI process.

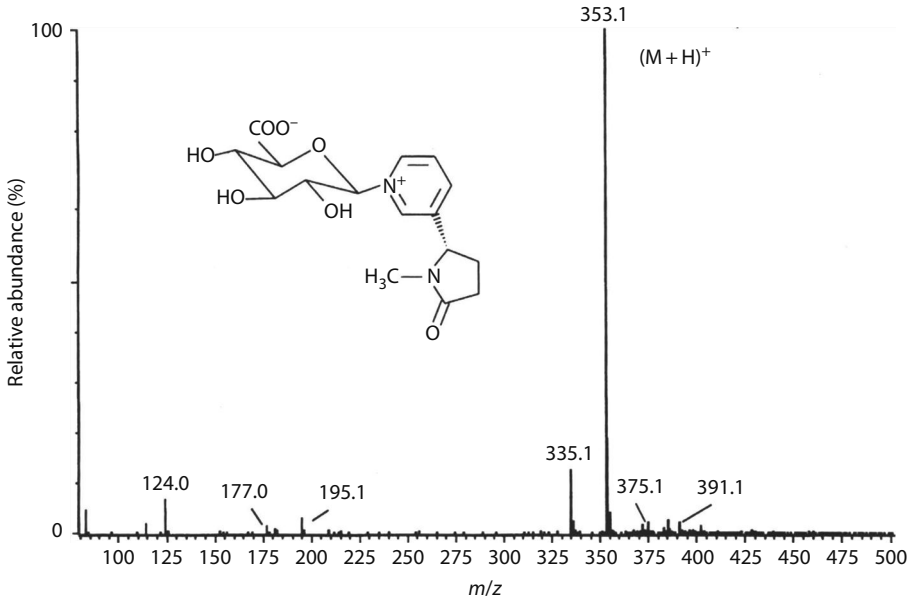

FIGURE 41.4 ES mass spectrum of cotinine-*N*-glucuronide taken with a quadrupole mass analyzer.

exist as an ion in solution, but this is easily accomplished by adjusting the pH. Positive ions are shown in the figure, but the process works equally well for negative ions. The ions are swept through a sampling cone and passed through a differential pumping system to remove solvent and nebulizing gas molecules before the ions enter the mass analyzer through a tiny aperture. ESI is a very gentle ionization method that can be used with either small or large molecules. Figure 41.4 shows an ESI spectrum of the glucuronide conjugate of cotinine, a phase II metabolite of nicotine. This thermally labile compound produces $(M + H)^+$ as the base peak at *m/z* 353. An interesting feature of ESI is the ability to produce ions with multiple charges. Because mass spectra are plotted with *m/z*, this permits the available mass range of the analyzer to extend to thousands of daltons; for example, a compound with $(M + H)^+$ at *m/z* 5000 would have $(M + 5H)^{+5}$ at nominal *m/z* 1001. This feature is less useful for small molecules such as common pharmaceuticals and their metabolites but is very useful for macromolecules such as proteins. ESI works well with aqueous mobile phases and some organic solvents.

APCI shares the same atmospheric pressure interface as ESI but uses a different probe for producing ions [81]. Instead of the capillary needle shown in Figure 41.3, APCI introduces the LC effluent to a heated tube (400°C–550°C), where the solvent and samples are volatilized at atmospheric pressure. A nebulizing gas (nitrogen) is used to assist with volatilization. A discharge needle after the heated tube creates plasma where reagent ions and electrons are produced. CI occurs in the gas phase to produce protonated solvent ions and this proton is transferred to the analyte. Therefore, analyte ionization is preferred when the solvent is a stronger acid than the analyte. APCI is rugged, reliable, and very sensitive due to efficient ionization, especially for molecules with heteroatoms. The rapid heating does produce some thermal degradation of labile species. APCI can accommodate analytes that are less polar than those suited for ESI and HPLC flows of 2 mL/min and works well with most types of solvents.

Direct APPI or dopant-assisted APPI has gained popularity due in large part to favorable ionization of less polar analytes, when compared with that typically achieved with ESI or APCI. It was first described by Jorgenson and coworkers with an interface to open tubular LC [46] and later adapted for use with traditional LC by Robb et al. [164]. A proposed mechanism for ionization with APPI is illustrated as follows:

$$\text{Dopant} + \text{hv} \rightarrow \text{Dopant}^{+\bullet} + e^-$$

$$\text{Dopant}^{+\bullet} + n[\text{solvent}] \rightarrow [\text{dopant} - \text{H}] + [(\text{solvent})_n + \text{H}]^+$$

$$[(\text{solvent})_n + \text{H}]^+ + \text{M} \rightarrow n[\text{solvent}] + [\text{M} + \text{H}]^+$$

The dopant is a compound with an ionization energy (I_1) less than $h\nu$ (10.6 eV), while the solvent or mobile phase has ionization energy greater than $h\nu$. Toluene (I_1 = 8.8 eV) is typically used as the dopant due to its relative safety and compatibility with material components of the MS system. Methanol and acetonitrile have favorable proton affinities and have been found to work well with APPI interfaces as well as begin versatile organic modifiers for reversed-phase LC [93].

DESI is an exciting ionization technique that eliminates the need for a bulk solvent but uses a traditional ESI probe [36,112]. The DESI experiment is performed by spraying a stream of charged solvent particles across an analyte surface while collecting the deflected droplets in a portable, charged wand, which serves as an atmospheric pressure ion transfer inlet into the MS. In this way, analytes may be collected from the surface of an object, such as a briefcase, a floor tile, or an article of clothing, which is suspected of being contaminated

with toxins, drugs, or other materials of interest. The portability and ease of sample handling make DESI a particularly promising technique for remote environmental testing, field forensics, and counterterrorism. Growing interest in these toxicological disciplines continues to foster the development of portable field MS units for remote sensing.

For all of these interfaces, an important consideration in coupling an HPLC method to a mass spectrometer is mobile-phase compatibility. Popular LC-MS mobile-phase solvents are water, methanol, and acetonitrile. They are good solvents for a wide range of samples, and their low molecular weights reduce background ions in the mass spectrometer. Organic modifiers such as triethylamine, which are often used to improve chromatography, should be avoided as they can suppress ionization of sample molecules. Although many of the interface/ionization sources listed here work best with a buffer at low concentrations (<20 mM), it must be a volatile organic buffer such as ammonium formate or ammonium acetate, or simply formic acid, which will not leave deposits that block the apertures leading to the mass analyzer. When a basic mobile is warranted, ammonium bicarbonate (5–10 mM) is very effective.

Other Ionization Sources

The bombardment of solid or liquid surfaces with intense light from a laser offers a soft means of ionizing nonvolatile, thermally labile compounds. This technique is called LD. In *matrix-assisted laser desorption ionization* (MALDI), the sample is suspended in a matrix material that absorbs light near the wavelength of the laser. Absorption of the energy desorbs and ionizes the analytes in the matrix, resulting in molecular adducts such as $(M + H)^+$ or $(M + Na)^+$ with little fragmentation. MALDI is used with isolated samples rather than online chromatography and has been used to successfully distinguish various bacteria when combined with high-resolution MS [97].

In addition to organic and bioanalytical analyses, MS used for inorganic analysis figures prominently in toxicology [8]. Unlike organic MS, inorganic MS is mostly concerned with atomic ions instead of molecular ions; thus, methods have been developed for producing atomic ions of various elements from samples. A common ionization method used in inorganic MS is *thermal ionization* that takes place when an atom or molecule interacts with a heated surface. Samples are deposited directly on a filament and heated. Another method is the use of *inductively coupled plasma* (ICP), where the sample is volatilized, atomized, and ionized in a few milliseconds at plasma temperatures of 7000–8000 K.

An interesting field of expanding applications is *accelerator mass spectrometry* (AMS). Unlike the ion sources described previously, AMS is a high-energy (MeV) nuclear physics technique that uses a Van de Graaff accelerator to measure very small amounts of rare and long-lived isotopes [175]. For ^{14}C analysis, the sample is converted to graphite powder by oxidation followed by reduction. A cesium ion gun bombards the sample, and the negative carbon ions produced are selected from the source and accelerated at 3–10 MeV. They pass through a thin foil or gas where electrons are stripped from C^- to create positive ions. These ions are then accelerated to several MeV, selected by a mass analyzer (quadrupole or magnet), and detected. AMS was first applied to geochemical and archaeological samples but has seen growing biomedical applications, particularly in the monitoring of ^{14}C-labeled drugs. The high sensitivity of this method (10^{-18} mol) permits low doses of labeled materials to be monitored in humans. Given its high sensitivity and specificity, AMS has been particularly useful for in vivo studies involving microdosing of xenobiotics [106]. Because the sample is prepared in a manner that is unique to any other MS-based analysis and the LC is offline from the mass spectrometer, a unique validation procedure has been developed [74].

Mass Analyzers

Mass analysis is the process by which a mixture of ions is separated according to their *m/z* ratios. Several types of mass analyzers are commonly used, and these form the primary differences between various mass spectrometer systems. Each analyzer uses electric or magnetic fields or both for separating ions. Although many experimental combinations and variations are available, this section briefly describes the popular commercial models and the basis of their operation.

The basic modes of analysis for mass spectrometers are *repetitive scanning* and *selected ion monitoring* (SIM). In repetitive scanning, a mass range is covered in a fixed interval and constantly repeated; for example, a GC-MS system might be set to scan repetitively *m/z* 40–400 in 1 s. This would detect any compound producing ions in this mass range every second, which is necessary for a high-resolution separation technique such as capillary GC. The resulting plot of all responses vs. time is a *total ion chromatogram* (TIC). Wide-range repetitive scanning is very useful for screening samples such as body fluid extracts for all types of compounds present. The mass range may be adjusted to detect only signals of interest or to exclude interferences such as low-molecular-weight solvents. This procedure offers less sensitivity than SIM but provides much more information. In addition, ion chromatograms can be produced from the stored data file. Ion chromatograms are reconstructed responses for a particular ion and are useful in quantitation to exclude interferences in complex chromatograms. For quantifying specific analytes, it is useful to restrict the ions detected to those of interest. Operating in the SIM mode, where the analyzer scans discontinuously, rapidly switching between only a few ions does this. Because more dwell time is spent on these ions, sensitivity is increased on the order of 10–100 times. This technique ignores ions from background materials and is useful in quantifying analytes in fairly complex matrices. Multiple-stage analyzers are capable of several more modes of scanning, and these are described later in a separate section.

The most popular analyzer system used today is the quadrupole mass analyzer. These compact systems are relatively inexpensive and durable and can scan very rapidly. The quadrupole assembly consists of four parallel rods arranged

equidistant around a central axis. Direct-current (dc) and radio-frequency (RF) voltages are applied to opposite pairs of rods to form a fluctuating electric field. Ions formed in the source are directed and focused into this field by electrostatic lenses or a series of parallel plates that generate a square wave. Only ions with a particular *m/z* ratio as determined by the dc and RF field strength can pass through to the detector; thus, the analyzer scans for particular ions by ramping these parameters. Typically, a full mass spectrum of *m/z* 40–400 can be taken in less than 1 s with good sensitivity. After ions are converted to electrons, a detector is located at the end of the quadrupole assembly.

By using quadrupole analyzers in series (*multiple-stage quadrupoles*), tandem MS is possible. Although sector instruments with magnetic and electrostatic fields can be used as stages, quadrupoles are more often used for tandem MS. These systems operate by selecting a particular ion from the first-stage analyzer and sending it into a second stage where the ion collides with an inert gas (such as argon) to produce further fragmentation. A third stage analyzes the resulting fragments, thus producing a mass spectrum from an ion in a mass spectrum. This technique is referred to as *MS/MS* or *collision-induced dissociation* (CID) and is often used with soft ionization such as CI, ESI, APCI, or APPI to produce fragments from molecular adducts. An example is given in the following for a molecular adduct produced by ESI:

Source	Analyzer 1	Collision Cell	Analyzer 2
$[M + H]^+ \rightarrow$	$(M + H)^+ \rightarrow$	Argon (eV)$\rightarrow$	A^+, B^+, C
	(Precursor)		(Products)

The selected ion is usually referred to as the *precursor* or *parent*, and its fragments as *products* or *daughters*. Precursors and products can be linked to establish fragmentation pathways, thereby producing additional structural information. MS/MS (MS^2) systems can also be set to monitor specific fragmentation pathways, a process known as *multiple reaction monitoring* (MRM). Setting the mass analyzer for a specific transition creates a very specific detector that can monitor an analyte in very complex samples. In this regard, it is analogous to SIM. Although the cost of an MS/MS system is more than for a single-stage mass spectrometer system, the increased structural information and selectivity of these instruments are very attractive. They have become workhorse systems for characterizing and quantitating metabolites or pharmacokinetic samples, particularly when interfaced to HPLC. Further structural information about an analyte can be gained by MS/MS/MS and can be accomplished using triple quadrupole instruments, if one applies sufficient energy for fragmentation to occur in the source.

Mass analyzers that are also found in analytical laboratories are the *ion trap* [196,217]. These mass analyzers are a type of 3D quadrupole composed of a doughnut-shaped ring and two end caps. Ions are contained in the circular electromagnet by an RF field until swept into a detector by an applied RF voltage–amplitude ramp. Ions are ejected according to their resonance energy, which is related to their mass, and a spectrum is thus produced. A time sequence of events produces ions in the trap and then ramps the RF field to detect specific masses. Both GC-MS and LC-MS ion trap systems are commercially available. When coupled directly to a GC, ions are formed by EI just as for a quadrupole system, and switching between EI and CI modes is simple. For LC-MS, ions are usually injected into the trap from an external source such as ESI. Ion traps are similar to quadrupoles in sensitivity, size, and cost, but they are also capable of MS/MS analysis. MS/MS in the ion trap is performed in a timed series of events by colliding the ions while trapped either with themselves or a collision gas. The product ions are then detected. In addition, MS/MS on the product ions may be performed such that MS/MS/MS/… (MS^n) is possible but not practical unless the sample concentration is sufficiently high. Ions are ejected from the ion trap each time an MS experiment is sampled. This limits the usefulness of ion traps to roughly three (e.g., MS/MS/MS) transitions. For LC-MS interfaces that produce molecular adducts, the ion trap is a less expensive option over the triple-stage systems described previously to perform CID analyses.

Somewhat related to the ion trap but longer in use is Fourier transform MS (FTMS) [90]. Ions are produced by EI in a cubic cell consisting of opposing pairs of trapping plates, transmitting plates, and receiving plates. Ions may also be injected into the source from an external ionization source such as ESI. A high constant magnetic field and electrostatic trapping plates trap the ions formed. Each ion undergoes cyclotron motion at a frequency determined by its *m/z* ratio. All the ions are excited (resulting in increased radius of motion) simultaneously by applying a burst of RF energy over a range of frequencies corresponding to the cyclotron frequencies of the ions. The ions are detected simultaneously by measuring the image current induced on the detection plates of the cell. The frequencies form a beat pattern, and by Fourier transformation, the individual cyclotron frequencies of the ions are determined and the *m/z* values produced. Many operational aspects of FTMS are similar to FT-NMR. High mass resolution (discussed in the following text) is possible with these systems, as is MS^n described for the ion trap previously.

Time-of-flight (TOF) analyzers work on the simple principle that ion velocity is mass dependent [220]. A high voltage sent down a tube accelerates ionized sample ions, and the different *m/z* ratios are separated in time. The arrival time at the detector is based on *m/z*, and a mass spectrum is produced. Naturally, scanning speed is very fast and mass range is large. Coupled with MALDI ionization sources described earlier, they have been applied to a variety of studies in biomedical research that require the mass analysis of very large molecules. TOF mass spectrometer systems have shown a growing popularity recently due to techniques that have improved their performance, including mass resolution. TOF has been interfaced with LC and GC systems, and these systems are often complement each other [72,124,143,151].

High-resolution mass analyzers can measure masses to within a thousandth of a mass unit (0.001 Da) or better.

The utility of this feature is based on the fact that atomic masses, although close to integral values, are not truly integral. Although ^{12}C is assigned 12.000000 Da, ^{16}O is actually 15.994915 Da, ^{1}H is 1.007825 Da, ^{14}N is 14.003074 Da, and so on. Thus, high-resolution mass measurements can lead to the determination of elemental composition; for example, the exact mass of citrulline + H ($C_6H_{13}N_3O_3$) is 176.1030. Using a high-resolution mass spectrometer, its molecular ion would be distinguishable from that of another compound with a nominal *m/z* 176 but different molecular formula such as *3,3-dinitroazetidine-1-carbaldehyde* ($C_4H_6N_3O_5$ = 176.0308). The slightly higher mass for citrulline is due to fewer number of oxygen atoms relative to the latter compound. As detectors, high-resolution mass spectrometers offer more selectivity than low-resolution mass analyzers by monitoring very narrow mass ranges and thus eliminating potential interferences. Quadrupole analyzers are not capable of resolving power much in excess of 0.1 mass units and cannot produce high-resolution spectra. The most commonly used high-resolution system is a double-focusing instrument with an electrostatic sector to first select ions of a specific kinetic energy before analysis by magnetic sector. As mentioned earlier, FTMS and most TOF systems are capable of high-resolution mass spectra.

Ion Monitoring

Conventional mass spectrometer systems (quadrupoles and magnetic sector instruments) focus the resolved beams of ions from the mass analyzer onto a detector. The most common detector is an electron multiplier, which is a series of electrodes. When an ion impinges on the first electrode, it releases a shower of electrons that impact a second electrode and so on. The cascading effect produces gains on the order of 10^6. Such high gain produces sensitivity, so a complete mass spectrum can be produced from a few nanograms or less of material.

Interpretation of Mass Spectra

Interpretation of mass spectra involves correlating the plots of ion abundance vs. *m/z* ratio with structure. For unknowns, it is best performed with all auxiliary information possible regarding a compound such as its origin and preparation, chromatographic behavior, and spectra from ultraviolet (UV), IR, NMR, etc., to assign structure with confidence. In this section, basic interpretation of EI mass spectra is reviewed followed by a discussion of mass spectra produced by softer ionization techniques.

EI Mass Spectra

Fragmentation in EI MS can be complex but rich in information if correctly interpreted. It remains difficult to interpret all features in a mass spectrum, but a few simple rules can be used to glean useful information and there have been recent descriptions of automatic algorithms for interpreting data [174]. The most significant datum in identifying an unknown compound is its molecular weight; thus, assignment of the molecular ion in the spectrum is the most important step in its interpretation. The molecular ion must be the highest mass ion in the spectrum and fragment ions must be logical neutral losses from this ion. Keep in mind that not all compounds will give a molecular ion. Fragmentation peaks in the spectrum result from one or more cleavages that may or may not involve rearrangements. The particular fragments produced are related to the strength and chemical nature of the bonds that held the fragment to the rest of the molecule; thus, an understanding of organic chemistry is useful in assigning fragment ion structures and the associated neutral species lost. EI mass spectra are very reproducible on different instruments, and assistance is available in the form of libraries of mass spectra that are searchable by computer. These are included with most data systems and are very straightforward to use. The data system suggests the best matches for your compound and provides some number indicating its confidence in the assignment. These libraries are useful for quickly identifying known compounds and suggesting identities for others. The ability to create your own library is an option in most data packages.

Soft Ionization Mass Spectra

These mass spectra are those produced by less energetic ionization methods such as CI, MALDI, and LC-MS interfaces such as ESI, APCI, and APPI. They are all marked by the appearance of molecular adducts such as $(M + H)^+$. Other common adducts depend on the sample matrix and may include $(M + Na)^+$ and $(M + K)^+$. When using ammonium buffers in LC-MS, $(M + NH_4)^+$ is common along with adducts formed with solvent molecules such as $(M + H_2O + H)^+$ or $(M + CH_3CN + H)^+$. Also, clusters such as $(2M + H)^+$ may occur, especially when higher concentrations of analyte are present. These spectra serve primarily to verify the molecular weight of the compound.

CID Mass Spectra

Mass spectra produced by MS/MS are greatly influenced by different parameters such as collision energy and collision cell pressure [141]. These conditions can vary from one compound to the next and also from one instrument to the next for the same compound; thus, CID spectra are less quantitatively reproducible than EI mass spectra, yet CID spectra remain extremely useful for qualitative structure elucidation. Common neutral losses such as H_2O for hydroxyl groups $[M + H - 18]^+$, loss of glucuronic acid from a glucuronide conjugate $[M + H - 176]^+$, or loss of sulfur trioxide from a sulfate conjugate $[M + H - 80]^+$ are very informative and complement the soft ionization techniques. Fragmentation mechanisms for CID involve the movement of $2e^-$, which is different from what occurs with EI where $1e^-$ movements cause bond breakage. A recent review by Holčapek et al. offers the toxicologist excellent background material and examples of interpretation of these CID spectra [75].

Experimental Design

With such a variety of instruments and methods available, some thought must be given to designing a mass

spectrometric analysis. This section provides some basic guidance for acquiring qualitative and quantitative information for a sample.

Method Selection

The nature of the sample determines the best approach; for example, if the sample is a large protein, it is unlikely to ionize by EI or pass through a GC. Another consideration is the complexity of the sample. Purified samples may not require chromatography but mixtures do. GC-MS and LC-MS are established techniques that perform separation and mass analysis and can rapidly identify unknowns and assess the relative composition of a sample. Samples that are thermally labile or nonvolatile must be ionized with a soft ionization method such as ESI or APCI. MS/MS techniques are useful for providing structural information and a dramatic improvement in signal to noise ratio (S/N). If high mass resolution is required, the mass analyzer must be a double-focusing sector instrument, an FTMS, or a TOF system.

Qualitative Analysis

Qualitative analysis refers to correctly identifying an unknown substance. Although interpretation of mass spectra has already been discussed, other considerations must be mentioned. Many compounds have similar mass spectra, and a single mass spectrum cannot give certain identification in every case. For example, at least three polycyclic aromatic hydrocarbons have a molecular weight of 252 (benzo(*a*) pyrene, benzo(*e*)pyrene, and perylene), and all have similar EI mass spectra. In these situations, using a separation technique such as GC or LC prior to mass analysis can assist identification. When an unknown gives a matching spectrum and coelutes with an authentic standard, then confidence in its identification is high. When no authentic standard is available, the use of multiple chromatographic techniques and ionization methods can enhance confidence in the identity of an unknown. It should be emphasized that, even though MS is a powerful tool in determining the identity of an unknown, auxiliary techniques outside of MS should be used whenever possible to provide increased confidence in the identification of a compound.

Quantitative Analysis

The number of ions detected in the mass spectrometer is proportional to the amount of material introduced to the source, making quantitative analysis possible. Using standard analytical calibration principles, mass spectrometers are capable of very precise, accurate, and sensitive determinations of analytes. The response of the mass spectrometer is calibrated using a series of standards that contain known amounts of the analyte or analytes of interest. External standard calibration plots are possible but are prone to errors due to instrument response variation through the course of analyzing several standards and samples.

A preferred calibration system is the use of internal standards where a known amount of a reference compound is added to the samples and also to the standards. A response ratio of the analyte to an internal standard is produced, which can partially offset variations in sample preparation and instrument sensitivity. The internal standard should be added to the sample prior to any mixing, extraction, derivatization, enzyme treatment, or chromatography to account for any sample losses during these processes. The instrument is usually calibrated with a series of standards that contain a fixed amount of the internal standard and varying amounts of the analyte of interest. The range of analyte concentrations in the standards must cover the values expected for the samples. A calibration plot can be produced from the response ratio vs. analyte concentration. Analyte concentration can be obtained from this plot by interpolation. Most analysts prefer linear curves because the data are easier to process; however, many analytical software packages are available that will fit curves to nonlinear plots. Good texts are available that provide rigorous coverage of calibration plots, calculation of concentration, and limits of detection and quantitation [21,199].

A special case in quantitative MS is the use of a labeled analog of the analyte as an internal standard in a procedure known as *isotope dilution*. Isotope dilution provides a more accurate and precise means of calibration than either external standards or conventional internal standard methods. The isotopically labeled analog has physical, chromatographic, and mass spectral properties that are nearly identical to those of the analyte and thus compensates in like manner for any losses due to sample preparation or instrument variability [34,56]. Stable isotopes (such as ^{2}H, ^{15}N, and ^{13}C) are preferred to radioactive isotopes because of reduced hazards of handling the samples.

Sample Preparation

Investigations in toxicology involve the analysis of biological samples from in vivo and in vitro sources. Such samples include urine, blood, saliva, tissue extracts, and cell suspensions. The use of specific detection methods such as SIM or MRM coupled with chromatography permits these very complex samples to be analyzed directly with LC-MS; sample preparation is minimal (e.g., filter and inject). As trace analysis becomes important, however, many samples require a preconcentration step prior to analysis so adequate limits of detection can be obtained. Isolation and purification techniques commonly employed are solid- or liquid-phase extraction, preparatory HPLC, thin-layer chromatography (TLC), or a combination of these. GC-MS analyses require the sample to be volatile and thermally stable. If the analyte of interest does not meet these requirements, derivatization of an analyte can assist in its analysis. Derivatization can enhance sensitivity, selectivity, and chromatographic performance in some cases. Thus, it should be considered as an alternative when difficulties with an analyte are discovered. Ideally, the mass spectrum of the derivative will provide an intense molecular ion or unique fragment ion. A common derivatization choice is trimethylsilylation of hydroxyl or amine groups to increase volatility and thermal stability.

Several commercial trimethylsilylating reagents are available such as bis-trimethylsilylacetamide (BSA).

Applications

MS analysis is extensively employed in general toxicological disciplines, such as clinical toxicology, forensics, and metabolomics. This versatile technique is also highly specific, as it has been used for the study of specific toxins, including heavy metals, aromatic amines, natural products, and DNA adduct formers. In the emergency clinical setting, the presentation of a highly intoxicated patient requires prompt blood and body fluid analysis, as one or a number of common intoxicating agents may be involved. Van Hee et al. [200] developed a method for rapidly screening body fluids for a series of intoxicating agents and their characteristic metabolites. A 20 μL sample of blood, plasma, or urine is derivatized with a trimethylsilyl agent, mixed with a 1,3-propylene glycol internal standard, and analyzed by GC/EI MS. γ-Hydroxybutyric acid, a common "date-rape" drug, and several other potential intoxicants and metabolites were readily separated and quantified using this method. These compounds were detectable at body fluid concentrations of less than 1 mg/L, and the entire process, from derivatization to analysis, took less than 30 min.

Metabolomics is the exciting discipline of studying changes in the production and relative concentration of low-molecular-weight endogenous biochemicals and metabolites in living organisms before and after exposure to xenobiotics or pathological processes [4,5,92]. Metabolomic fingerprinting enables the toxicologist to identify likely xenobiotic exposure, monitor environmental stressors, and predict chemical toxicity. Dynamic metabolomic profiles consist of complex mixtures of very similar compounds that are constantly changing in terms of composition and relative amount. Accordingly, the precision and extreme sensitivity of MS are very useful in metabolomic studies, and examples of this application are numerous. Using a targeted metabolomics approach, Wang and coworkers demonstrated a positive correlation between the development of future diabetes and five branched-chain and aromatic amino acids [207]. Targeted metabolomics begins with some knowledge of the disease process so that authentic standards and appropriate stable isotope standards can be used. Analytical methodologies, even LC-MS, lack the selectivity necessary for an untargeted approach. Identification of metabolites with authentic standards should always be used to validate a metabolomic study.

Determination of Toxic Metals Using Stable Isotope Dilution

Cadmium is another toxic heavy metal derived from a variety of industrial and environmental sources. Aggarwal et al. [1] have developed a stable isotope dilution GC-MS method for determining cadmium exposure. Their method determined cadmium in urine by using the chelating agent lithium bis(trifluoroethyl)dithiocarbamate (Li[FDEDTC]), to form the chelate $Cd(FDEDTC)_2$, which was analyzed by GC-MS with EI. $M^{+\bullet}$ was monitored for quantitation. The internal standard used was ^{106}CdO. Cd determination in urine was possible with this method at the 10 μg/L level with good precision and accuracy. The researchers note that the isotope dilution technique provides freedom from matrix effects so that precision and accuracy are not affected by incomplete recovery.

Determination of Aromatic Amines in Human Milk Using GC-MS

Aromatic amines come from several environmental pollution sources and have been associated with breast cancer in humans. The presence of these compounds in human breast milk was demonstrated in a straightforward manner by DeBruin et al. [44] using GC-MS. The method used *solid-phase microextraction* (SPME) to sample the headspace over a heated milk sample. The SPME fiber was then inserted into the injector port of a GC-MS and desorbed onto the column. Aromatic amines identified were aniline, *o*-toluidine, and *N*-methylaniline. Two internal standards, aniline-d_5 and *o*-toluidine-d_9, were added to the milk samples prior to preparation. For quantitation, a quadrupole mass spectrometer was operated in the SIM mode with a base ion for each analyte selected. A qualifying ion was also used to confirm the identity. Using a calibration curve constructed from standards made in bovine milk, the authors quantified the three analytes in milk samples at the sub-ppb level.

Serum Cotinine by LC-MS/MS Using APCI

Serum cotinine is often used as a biomarker of exposure to nicotine. If methods have sufficient limits of detection, exposure to extremely low amounts of nicotine as in environmental tobacco smoke can be assessed. The analysis of low concentrations of analytes in complex matrices may be approached in different ways. One approach seeks to perform extensive sample cleanup to present a relatively clean sample to the instrument. Although this is labor intensive and requires meticulous attention to handling of the sample, it permits the analytical system to operate longer and more reproducibly between servicing. A good example of this approach is the determination of cotinine in serum by the method of Jain and Bernert [86]. They desired to measure exposure to nicotine for large numbers of samples from both smokers and nonsmokers. A rapid, sensitive LC-MS/MS method with APCI was developed for serum cotinine that utilized sample extraction and concentration. Although sample preparation has many steps, the results of this method are impressive. The HPLC method had a retention time of less than 1 min for the analyte and internal standard, which permitted samples to be injected every 2 min. Under routine operation, 100 samples a day were analyzed. A detection limit of 0.05 ng/mL was achieved that was sufficient to monitor serum cotinine in nonsmokers exposed to environmental tobacco smoke.

Sample preparation began with the addition of the internal standard, methyl-D_3-cotinine, to 1 mL serum. The sample was acidified and centrifuged to remove protein. The supernatant was basified and extracted with methylene chloride,

dried, reconstituted for transferal to a microvial, evaporated to dryness again, and finally reconstituted in 20 µL of toluene. For LC-MS/MS analysis, 10 µL was injected onto a 4.6 mm × 3 cm C_{18} column for an isocratic separation with a flow rate of 1 mL/min of 80% methanol and 20% 2 mM ammonium acetate. The effluent was introduced to an APCI source on a triple-stage quadrupole mass spectrometer set to operate in the MRM mode. Ions monitored were *m/z* 177 → *m/z* 80 for cotinine and *m/z* 180 → *m/z* 80 for the internal standard. For a confirming transition for cotinine, *m/z* 177 → *m/z* 98 was also monitored.

The key features of this method were sample extraction and concentration followed by very specific detection. Recoveries were 60%–70%, and most background materials were removed. Reducing the final volume to 0.02 mL resulted in a >10-fold concentration of the sample. Highly specific MRM analysis and focusing on only one analyte reduced chromatography requirements so retention time could be minimal, and a simple isocratic method that did not require equilibration could be used. Thousands of serum samples were analyzed by this method but only for cotinine. The mass spectral parameters of this method could be modified to include nicotine as it could be extracted by this same procedure. Extension to other more polar metabolites of nicotine such as *trans*-3′-hydroxycotinine would be problematic as the method now exists, because they are more difficult than cotinine to efficiently extract into an organic phase.

Determination of DNA Adducts

LC with tandem MS (LC-ESI-MS/MS) is a powerful tool in the analysis of DNA adducts [82,83]. Modified bases can be determined in tissue with excellent sensitivity. The use of stable isotope-labeled standards is necessary to compensate for the loss of analyte during sample preparation and is a critical step in eliminating the matrix effects on the analysis of modified bases by ESI-MS. Ishii et al. have recently described methodology for the determination of lucidin-3-*O*-primeveroside (LuP) adducts of guanosine and adenosine in rats. The animals were fed a diet containing LuP. The adducts were detected in the liver and kidney of the exposed animals [82].

RATIONALE FOR CHOOSING MS FOR AN ANALYSIS

Contemporary MS combines specificity and sensitivity and gives highly reliable analytical results. Femtomolar determinations are commonplace. The unique fingerprint identification provided by mass spectra gives a great deal of confidence that an analysis has been performed correctly. Improvements in inlet systems, ionization sources such as ES and APCI, and mass analyzers such as multiple-stage quadrupoles for tandem MS have greatly expanded the applicability and portability of MS. LC-MS is the workhorse in modern bioanalytical laboratories. It is the method of choice for toxicokinetic and pharmacokinetic studies and is commonly used for metabolite characterization, quantification, and metabolomic profiling. Its high sensitivity makes it ideal for quantifying exposure to environmental toxins. Nevertheless, the analyst must keep in mind that MS is a technique that destroys the sample. This is particularly important in cases where sample sizes are very small and result from time-consuming and labor-intensive isolation and purification methods. Despite these limitations, MS is critical to studying mechanisms of toxicity.

NMR Spectroscopy

In 1946, Purcell, Torrey, and Pound of Harvard University and Bloch, Hansen, and Packard of Stanford University independently detected NMR effects of the hydrogen nucleus in paraffin wax (Purcell) and water (Bloch). These first observations of NMR won the Nobel Prize in Physics for Bloch and Purcell in 1952. In 1951, Packard reported that the NMR spectrum of ethanol consisted of three distinct resonances and that these resonances arose from the three different chemical environments for the hydrogen nuclei in the molecule (CH_3, CH_2, and OH). This discovery quickly caught the attention of organic chemists who realized that NMR spectroscopy could be used as a tool for determining chemical structure [94,154]. NMR spectroscopy has since emerged as the most powerful technique for structural characterization of organic compounds. NMR is the method of choice for determining the identity of xenobiotic metabolites if they can be isolated in microgram to milligram quantities. In this regard, it is often used in conjunction with chromatographic and mass spectral methods. It can also be used to probe the structures of xenobiotic adducts to biological macromolecules such as DNA and proteins. NMR is used to quantify xenobiotic exposure and changes in endogenous compounds in response to such exposure, and it is widely employed in metabolomic studies.

Due to its selectivity and the wealth of information that is available from NMR spectroscopy, it has found increasing application in pharmacology, toxicology, and biomedical research. Recent advances in NMR technology have enabled researchers and clinicians to study chemical and physiological changes within cell suspensions, isolated organs, and living organisms in a noninvasive manner. In vivo spectroscopic techniques have been used to measure cellular metabolism, intracellular pH, cytosolic sodium, magnesium, and calcium levels, organ damage in response to toxicants, and a host of other toxicologically relevant phenomena.

NMR spectroscopy is a very powerful tool for studying mechanisms of toxicology. Toxicologists should be familiar with the strengths and limitations of NMR spectroscopy and the types of studies for which it is suited. The following sections include an overview of the theory of NMR and numerous examples of its application in toxicology and related disciplines. Although a detailed mathematical treatment of magnetic resonance is beyond the scope of this chapter, mathematical formulae will be used to describe and clarify the phenomena. It is assumed that the reader has encountered traditional proton and carbon NMR spectroscopy in an introductory organic chemistry course, and very little discussion of the interpretation of NMR spectra appears. A number of

extremely good texts on the theory, application, and interpretation of NMR are available. The interested reader might refer to them for more detail [45,47,154,159,166].

Basic Theory of NMR Spectroscopy

Nuclear Spin

An understanding of the NMR phenomenon begins with a look at the atomic nucleus. Nuclei are composed of protons and (except for ^{1}H) neutrons; therefore, all atomic nuclei carry a positive charge. Many nuclei also rotate about the nuclear axis, and the angular momentum of this spinning charge is described in terms of the spin quantum number, *I*. Spin numbers have values of 0, 1/2, 1, 3/2, and so forth. For our purposes, the most important spin-active nuclei are ^{1}H, ^{13}C, ^{31}P, and ^{19}F, all of which have $I = 1/2$.

Behavior of Nuclei in an External Magnetic Field

Because a spinning nucleus ($I > 0$) is a charge in motion, it generates a magnetic field and behaves like a small bar magnet with a magnetic moment (μ). Just as a bar magnet will align itself with an external magnetic field, so too will any nucleus with $I > 0$. For $I = 1/2$, the nuclei can adopt one of two orientations relative to the external magnetic field. They may be aligned with the field (low-energy state) or against the field (high-energy state).

A nucleus with $I > 0$ exhibits another important property when placed in an external magnetic field. That property is precessional motion. We have all observed the behavior of a spinning top. As it spins, the axis of the top slowly revolves around the vertical. The top is said to be precessing around the vertical axis, and this type of behavior is called *precessional motion*. A nucleus spinning in an external magnetic field also exhibits precessional motion, with the magnetic moment (μ) precessing around the axis of the applied magnetic field B_o (Figure 41.5). The frequency at which the magnetic moment precesses about B_o is called the precessional frequency, ν. While the spinning frequency of any given nucleus is constant, ν varies directly with the strength of the external magnetic field B_o:

$$\nu \propto \mathbf{B}_o$$

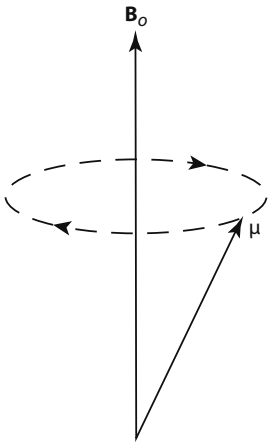

FIGURE 41.5 Magnetic moment, μ, of a spinning nucleus precessing about the applied magnetic field, $\mathbf{B}_o$, with precessional frequency ν.

This proportionality is the most fundamental relationship of NMR spectroscopy and leads to the fundamental NMR equation:

$$\nu = \frac{\gamma \mathbf{B}_o}{2\pi} \tag{41.2}$$

The proportionality constant (γ) is the magnetogyric ratio and is a fundamental nuclear constant. It is related to the nuclear magnetic moment (μ) and the spin quantum number (*I*):

$$\gamma = \frac{2\pi\mu}{hI} \tag{41.3}$$

where *h* is Planck's constant.

A proton (hydrogen nucleus) has a magnetogyric ratio of 2.6752×10^8 rad/s/T; therefore, in a magnetic field of 7.1 T, its precessional frequency is approximately 300 MHz. A proton in a magnetic field of 14.1 T will have $\nu \approx 600$ MHz. The magnetogyric ratio of ^{13}C is 6.727×10^7 rad/s/T, so in a field of 7.1 T, $\nu \approx 75$ MHz. Table 41.1 lists the precessional frequencies at selected field strengths for several common magnetic nuclei. NMR spectrometers are most frequently

TABLE 41.1
Precessional Frequencies of Several Common Nuclei at Selected Field Strengths

	Precessional Frequency (MHz) at Field Strength (T)									
Nucleus	**1.4**	**2.3**	**4.7**	**7.1**	**9.4**	**11.7**	**14.1**	**17.6**	**18.8**	**21.1**
^{1}H	60.0	100.0	200.0	300.0	400.0	500.0	600.00	750.0	800.0	900.0
^{2}H	9.2	15.4	30.7	46.1	61.4	76.8	92.1	115.1	122.8	138.2
^{13}C	15.1	25.1	50.3	75.4	100.6	125.7	150.9	188.6	201.2	226.3

^{19}F	42.4	94.1	188.2	282.2	376.3	470.4	564.5	705.6	752.6	846.7
^{23}Na	15.9	26.5	52.9	79.4	105.8	132.3	158.7	198.4	211.6	238.1
^{31}P	24.3	40.5	81.0	121.4	161.9	202.4	242.9	303.6	323.8	364.4

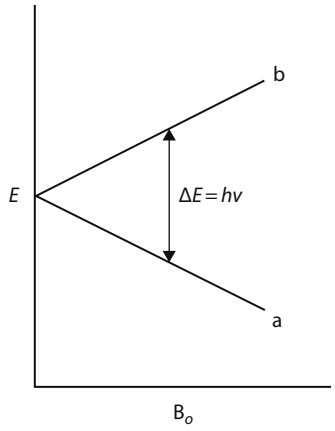

FIGURE 41.6 Energy level diagram for a spin 1/2 nucleus in a magnetic field $\mathbf{B}_o$.

classified by the precessional frequency of the ^{1}H nucleus at the field strength of the magnet; for example, a spectrometer with a field strength of 7.1 T is commonly referred to as a 300 MHz NMR.

A spin 1/2 nucleus in a magnetic field will have a precessional frequency (ν) and will be able to adopt one of two orientations, or spin states, relative to B_o. It will be aligned with (parallel) or against (antiparallel) the external field. The parallel orientation (α) is a low-energy state for the system, and the antiparallel orientation (β) is a high-energy state (Figure 41.6). A nucleus precessing in the parallel orientation can absorb energy (electromagnetic radiation) and be excited to the high-energy, antiparallel orientation. The precessing nucleus will only absorb electromagnetic radiation with a frequency equal to ν. Because precessional frequencies are on the order of MHz, the electromagnetic radiation that will excite a precessing nucleus is in the RF range. When the applied RF equals ν, the precessing nucleus and the RF are said to be in resonance, hence the name NMR. The frequency at which resonance occurs for a given nucleus is called its *resonance frequency.*

Relaxation Times

When a nucleus has absorbed energy and is excited to the high-energy spin state, it will tend to lose energy and return to the low-energy state. In addition to direct reemission of RF, there are two radiationless processes by which nuclei can exchange energy with their environment. These relaxation processes are a direct result of interaction of the nucleus with some electromagnetic vector in the local environment. The nucleus is surrounded by solvent molecules, and energy can be transferred to the solvent or other nearby atoms in a process called *spin-lattice* relaxation. The spin-lattice relaxation time (T_1) depends on such factors as temperature and solvent viscosity, with higher temperature and lower solvent viscosity slowing T_1 relaxation.

The nucleus can also transfer energy to nearby nuclei in a process called *spin–spin* relaxation. In spin–spin relaxation, one nucleus loses energy and the other one gains energy so there is no net change in the populations of the two spin states. The spin–spin relaxation time (T_2) depends on molecular mobility, and nuclei in large molecules that have highly constrained molecular motions have very efficient spin–spin relaxation (short T_2). The magnitude of T_1 and T_2 determines the line widths of NMR spectral lines; short relaxation times lead to broad lines, and long relaxation times lead to sharp lines. This means that NMR spectra obtained in viscous solvents (short T_1) will have broader lines than those obtained in nonviscous solvents. Also, NMR spectra of biological matrices such as plasma or cell suspensions will show many very broad resonances from proteins, nucleic acids, and other macromolecules that have very short T_2 relaxation times. These broad resonances can obscure the signals of small molecules of interest such as xenobiotic metabolites. A variety of NMR techniques have been developed that enable the observation of low-molecular-weight compounds in the presence of macromolecules [160].

Chemical Shifts

In the simplest NMR experiment, *continuous-wave NMR* (CW-NMR), a sample is placed in a strong, uniform magnetic field and the nuclei in the sample precess with their characteristic frequency ν. The sample is irradiated with radiowaves of increasing frequency, and when the RF equals ν, the nuclei are excited to the high-energy state and RF is absorbed. This absorption is recorded as the NMR spectrum. If all nuclei of a given type (e.g., ^{1}H) precessed with exactly the same frequency, an NMR spectrum would convey very little structural information. It would consist of a single line. Fortunately, the exact value of ν for a given nucleus depends on the chemical environment of that nucleus.

So far, we have discussed the magnetic properties of spinning nuclei, but atoms and molecules also contain electrons. Under the influence of an external magnetic field, electrons will circulate and generate their own magnetic field that will tend to oppose $\mathbf{B}_o$. This results in a magnetic shielding of nearby nuclei, which slightly shifts their precessional frequencies. The density of the circulating electron cloud depends greatly on its chemical environment, so different nuclei in a molecule will experience different degrees of shielding and hence will have different values of ν. The shift in ν depends on the chemical environment of the nucleus, and for this reason, it was given the name *chemical shift.*

Relative to the resonance frequency, chemical shifts are quite small. For protons in a field of 7.1 T ($\nu \approx 300$ MHz), the chemical shifts cover a range of about 4000 Hz. The absolute value of chemical shifts in frequency units depends on the strength of the applied magnetic field. The greater the value of B_o, the greater the chemical shift range. This explains, in part, the desire to move to higher and higher field strengths for NMR spectroscopy. The higher the field, the greater the resolution of chemical shifts.

Chemical shifts are rarely (if ever) expressed in absolute frequency units; instead, they are measured relative to a standard reference compound. For ^{1}H and ^{13}C NMR, the universally accepted reference is tetramethylsilane (TMS). It is commonly added to samples as an internal standard

at concentrations <1%. TMS has several important properties that make it a near ideal reference standard. It contains 12 magnetically equivalent protons and 4 magnetically equivalent carbons, so it gives a single intense peak in the ^{1}H and ^{13}C NMR spectra. It is chemically inert, soluble in most organic solvents, and volatile (b.p. = 27°C), so it can be removed easily from the sample after analysis. The protons and carbons of TMS absorb at a lower frequency (are more shielded) than those of almost all other organic compounds, so their chemical shifts can be arbitrarily set to 0 Hz, and most other chemical shifts measured relative to them will be positive. TMS is not soluble in water, so for aqueous solutions, a suitable water-soluble internal standard must be chosen. The most widely used internal standard for aqueous samples is the sodium salt of 3-(trimethylsilyl)-propanoic acid (TSP).

Because chemical shifts vary with the strength of the applied magnetic field, their values (in Hz) vary from one NMR spectrometer to the next. Protons that absorb at 300 Hz relative to TMS in a field of 7.1 T (300 MHz instrument) will absorb at 100 Hz on a 2.3 T (100 MHz) instrument. To avoid confusion and enable comparisons of chemical shifts from instrument to instrument, chemical shifts are expressed in dimensionless units designated δ. The chemical shift in δ units is defined according to the following relationship:

$$\delta = \frac{\vartheta_s - \vartheta_{\text{std}}}{\text{Operating frequency}} \times 10^6 \text{ ppm} \qquad (41.4)$$

where ϑ_s and ϑ_{std} are the resonance frequencies of the sample and standard, respectively.

Spin–Spin Coupling

Whereas a great deal of structural information may be obtained from the chemical shifts of nuclei in a molecule, even more information is available from an NMR spectrum. Nuclei that are closely connected through bonding electrons are influenced by the spin state of their neighbors. Consider two closely connected protons, H_a and H_b:

$$\begin{array}{ccc} H_a & & H_b \\ | & & | \\ C & - & C \end{array}$$

The bonding electrons in the H_a–C bond tend to align their spins with the spin of H_a, the C–C bonding electrons tend to align with the spin of the H_a–C bonding electrons, and the H_b–C bonding electrons tend to align with the spin of the C–C bonding electrons. Finally, H_b tends to align its spin with the spin of the H_b–C bonding electrons. In this way, the spin state of H_a directly influences the spin state of H_b. Because H_a can have two spin states, parallel or antiparallel, the resonance line of H_b is split into two closely spaced lines, a so-called *doublet*. H_b influences the spin state of H_a in exactly the same way, so H_a also appears as a doublet. The spacing between the lines in the H_a doublet is the same as that in the H_b doublet. Figure 41.7 illustrates the appearance of the H_a and H_b NMR signals. This phenomenon, called *spin–spin coupling* (or simply *coupling*), results in characteristic splitting of NMR signals, which is dependent on the number of neighboring spin-active nuclei, their geometrical arrangement, and the number of bonds between them. Coupling is usually not important beyond four bonds, and magnetically equivalent nuclei do not show coupling. Unlike chemical shifts, coupling is independent of $\mathbf{B}_o$.

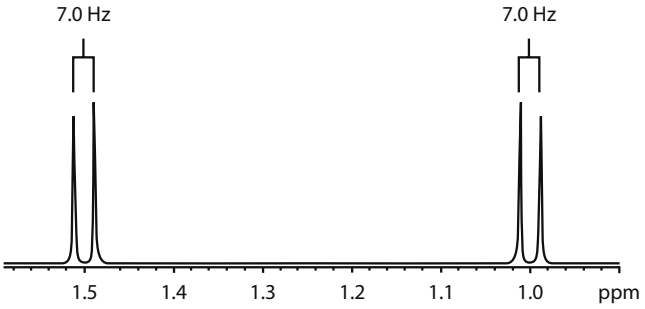

FIGURE 41.7 Proton NMR spectrum of the H_a/H_b spin system. Note the coupling constant, *J*, is 7.0 Hz.

The number of lines into which an NMR signal is split depends on the number of adjacent nuclei. The general rule is that *n* adjacent spin-active nuclei will split a signal into $2nI + 1$ lines. For spin 1/2 nuclei such as ^{1}H, two adjacent nuclei will split a signal into three lines (a triplet), three adjacent nuclei will split the signal into four lines (a quartet), and so forth. The relative line intensities within a multiplet are determined by the coefficients in the binomial expansion. A triplet will have intensities of 1:2:1, a quartet will have intensities of 1:3:3:1, and so on. The separation between spectral lines due to coupling is the coupling constant (*J*) (Figure 41.7). The magnitude of a coupling constant depends on the number of intervening bonds and the bond geometry. The coupling constants for protons that are *trans* to one another in a rigid molecule are greater than those for protons that are *cis*. Spin–spin coupling is most important in proton NMR spectroscopy, as most organic molecules have adjacent protons and show extensive coupling. In ^{13}C NMR spectroscopy, proton coupling to the carbons is often undesirable because it leads to very complex spectra and reduced S/N ratio. For these reasons, it is usually suppressed by irradiating over the entire proton resonance frequency range to saturate the proton transitions. This so-called decoupling produces carbon spectra made up of only singlets.

Integral Areas

The area under a peak in an NMR spectrum is proportional to the total number of nuclei giving rise to that signal; in other words, the area of a peak can be used to gain information about the concentrations of the spin-active nuclei. All modern NMR spectrometers are capable of integrating peak areas, and the resulting integrals can be plotted on the spectrum. In the case of a multiplet, the total area of the signal is integrated. By comparing integrals within a proton spectrum, it is possible to determine which signals are due to

methyl (3 H), methylene (2 H), or methine (1 H) groups. This is a powerful aid in interpretation of proton NMR spectra.

Because peak areas are proportional to the concentrations of the spin-active nuclei, NMR can be used for quantitative analysis of molecules in solution. This is particularly useful for quantification of xenobiotic metabolites in biological matrices. If the analytes are present in high enough concentration (see succeeding text for a discussion of NMR sensitivity) and signals due to the presence of the analytes of interest can be distinguished in the spectrum, then very little sample preparation is required. For quantitative analysis, analyte integrals are compared to integrals of an internal standard that is added to the sample at a known concentration. Quantitative analysis by NMR requires very careful calibration and attention to spectral acquisition parameters, so it should be carried out cautiously. Excellent discussions of quantitative analysis by NMR are available [154,197].

For heteronuclear NMR (such as carbon) where broadband proton decoupling is used, the peak areas do not always give an accurate estimate of the concentration of spin-active nuclei. Decoupling gives rise to nuclear Overhauser effects that complicate the interpretation of integral areas. For this reason, carbon spectra are rarely integrated; however, spectral acquisition parameters can be adjusted to correct for these effects if accurate integrals are required from a carbon (or other heteronuclear) NMR spectrum.

Sensitivity

For nuclei in an external magnetic field, the energy difference between spin states is quite small. This means that the two spin states are almost equally populated at room temperature, with the population of the low-energy state exceeding that of the high-energy state by only about 0.001%. The intensity of absorption (and hence the sensitivity of NMR) is proportional to the number of nuclei absorbing RF energy. As the population difference between spin states increases, there will be more nuclei to absorb RF energy, and the sensitivity will increase. From Equation 41.3, we see that the energy difference between spin states ($\Delta E = h\nu$) is proportional to the magnetogyric ratio (γ). This means that the sensitivity of NMR depends on the magnitude of γ. Detection of nuclei with relatively large magnetogyric ratios (such as ^{1}H and ^{19}F) will be fairly sensitive. The sensitivity of NMR also depends on the natural abundance of the spin-active nucleus under observation. Nuclei with a high natural abundance will be detected with greater sensitivity. Table 41.2 lists natural abundance, spin quantum number, magnetogyric ratio, and sensitivity for some selected nuclei.

The energy difference between spin states ($\Delta E = h\nu$) is also proportional to the magnetic field strength B_o. One way to increase the sensitivity of NMR is to increase the field strength. This approach has been somewhat successful; however, even at a field strength of 14.1 T, the energy difference between spin states is only on the order of 10^{-4} kJ/mol. NMR is (and is likely to remain) less sensitive than optical techniques such as electronic absorption spectroscopy, where ΔE is considerably larger. Even with the most sensitive high-field instruments, tens to thousands of micrograms of sample are required.

FT-NMR

Because the energy difference between spin states is small, NMR signals are invariably weak. In fact, they are often only slightly more intense than the background noise caused by the electronics of the NMR spectrometer. To improve the S/N ratio, several spectra can be obtained and the resulting collection of data averaged. The NMR signals in these spectra would always occur at the same frequencies; however, the random noise would not. The desired signals would build up over time relative to the noise and the S/N would increase. It can be shown that, for n repetitions, the signal increases by a factor of n and the noise increases by a factor of $\sqrt{2}$. As a result, signal averaging increases the S/N by a factor of $\sqrt{2}$.

If signal averaging were applied to the CW-NMR experiment described previously, the spectrum would be scanned repetitively over the frequency range of interest and the resulting spectra averaged. This would result in an increase in S/N, but the time required for the experiment would be quite long. Consider a proton spectrum covering 10 ppm at a field strength of 2.3 T. The sweep width (frequency range) of this spectrum is 1000 Hz. A sweep rate of 1 Hz/s is required to achieve a spectral resolution of 1 Hz, so it would take 1000 s

TABLE 41.2
Selected NMR Properties of Several Common Nuclei

Nucleus	Natural Abundance (%)	Spin Quantum Number *I*	Magnetogyric Ratio ($\times 10^{-7}$ rad/s/T)	Relative Sensitivity at Constant Field
^{1}H	99.985	1/2	26.752	1.000
^{2}H	0.015	1	4.107	9.65×10^{-3}
^{13}C	1.108	1/2	6.727	0.016
^{14}N	99.635	1	1.933	1.01×10^{-3}
^{15}N	0.365	1/2	2.711	1.04×10^{-3}
^{17}O	0.037	5/2	3.627	0.029
^{19}F	100	1/2	25.167	0.834
^{23}Na	100	3/2	7.076	0.093
^{31}P	100	1/2	10.829	0.067

to acquire one spectrum. Increasing the S/N by a factor of 4 requires 16 repetitions ($\sqrt{2}$), so this experiment would take almost 4.5 h. You can see that signal averaging in CW-NMR is not very practical. How, then, do we achieve a significant increase in the S/N in a reasonable amount of time?

The solution to this problem is found in a technique called *pulse NMR*. In pulse NMR, the sample is irradiated with a pulse of RF energy containing all the frequencies required to excite the nuclei of interest. This pulse is applied for a very short period of time (on the order of μs), and the nuclei are allowed to relax to their equilibrium state with the emission of all the frequencies previously absorbed by the nuclei. This signal decays over time and is called *free induction decay* (FID). The FID contains all the spectral information including chemical shifts, coupling constants, and intensity. To convert this information from the time domain to the frequency domain, which is the normal mode for an NMR spectrum, the FID is subjected to a mathematical operation called *Fourier transformation*. To achieve signal averaging, a series of FIDs are acquired and averaged prior to Fourier transformation. The resulting FT-NMR spectrum is equivalent to a CW spectrum and is obtained in considerably less time. Figure 41.8 shows the FID and resulting proton FT-NMR spectrum of a 0.1% solution of ethylbenzene. For this spectrum, 64 repetitions, or transients, were acquired, requiring a total time of 4.7 min. Note the large TMS peak at 0 ppm and the presence of an impurity peak at about 1.55 ppm. Figure 41.9 shows the effect on the S/N of increasing the number of transients. These proton spectra were obtained on the same ethylbenzene sample used to generate Figure 41.8, and only the quartet is plotted.

All modern NMR spectrometers are of the FT type. FT-NMR has allowed insensitive nuclei such as ^{13}C to be studied routinely and sensitive nuclei such as ^{1}H and ^{19}F to be studied at much lower concentrations than previously possible. It has also opened up a multitude of powerful new multipulse and 2D NMR experiments, some of which will be discussed in a later section.

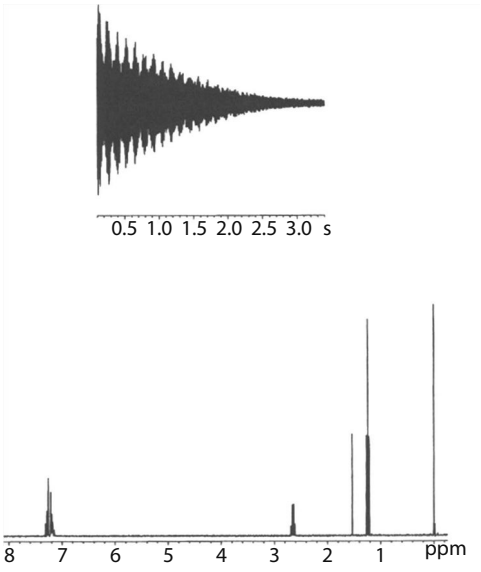

FIGURE 41.8 FID and proton NMR spectrum of a 0.1% solution of ethylbenzene in $CDCl_3$. The data were collected at a frequency of 300 MHz and a field strength of 7.1 T.

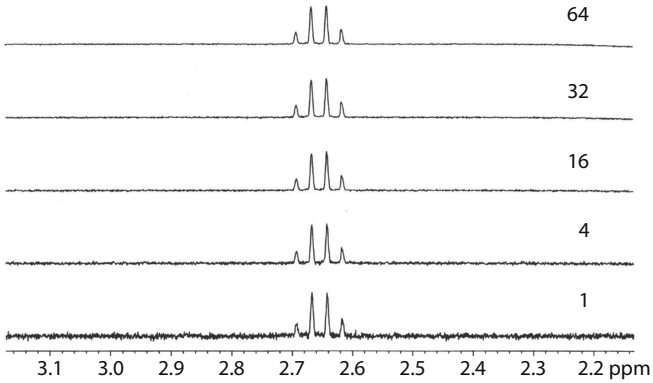

FIGURE 41.9 The effect of increasing the number of transients on the *S/N* ratio of the proton NMR spectrum of ethylbenzene.

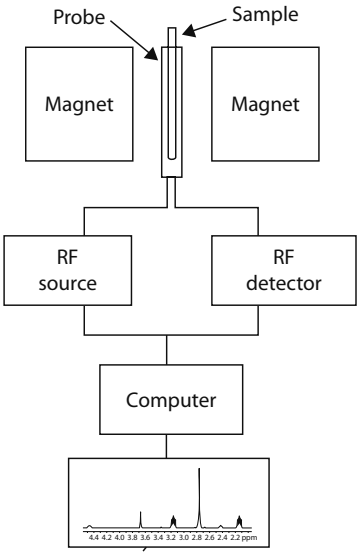

FIGURE 41.10 Schematic representation of an NMR spectrometer.

Instrument Design

Although NMR spectrometer design and construction vary from one manufacturer to the next, all spectrometers share the same basic components. Figure 41.10 shows a schematic representation of the basic features of a high-field NMR spectrometer. The heart of the spectrometer is the NMR probe that sits inside the superconducting magnet. The probe contains coils that transmit the RF pulses to the sample and receive the NMR signals that are emitted. Specialized probes for a variety of NMR experiments are available, and selection of the proper probe for the particular experiment is crucial to its success. They are exchangeable, and most NMR laboratories have more than one type. For in vivo spectroscopy, the probe may be surface coils placed in close proximity to the organ under study. The spectrometer contains an RF source for generating RF pulses and an RF detector for receiving

and amplifying the NMR signal. A computer that is also used for storing, processing, and displaying data controls the RF source and detector.

Experimental Design

The proper design of toxicological NMR studies depends on a number of factors. The first consideration when designing an NMR study is the nature of the sample. If the sample is a solution or cell suspension or can be dissolved in a suitable solvent, then a host of liquid-state NMR experiments is possible. If the sample is alive (perfused organs, laboratory animals, or humans), then in vivo spectroscopy using surface coils or imaging techniques is required. The choice of nuclei, type of NMR experiment, probe, solvent (if liquid-state analysis is required), and method of sample preparation will affect the outcome of the study. This section provides some guidance to the researcher in designing NMR studies. Particular emphasis is placed on liquid-state methods, as spectrometers for liquid-state analyses are more readily available than those for in vivo spectroscopy, and liquid-state methods are by far the most commonly used for toxicology research.

Choice of Nucleus

The most useful NMR-active nuclei for toxicology studies are ^{1}H, ^{13}C, ^{31}P, and ^{19}F. When the effects of heavy metal exposure are of interest, nuclei such as ^{199}Hg or ^{113}Cd can sometimes be used. Biologically derived samples are often complex mixtures, and NMR signals from the matrix can cause significant interference. This is particularly troublesome for ^{1}H and ^{13}C, as these nuclei are ubiquitous. With proper sample cleanup and utilization of appropriate NMR techniques, these matrix effects can be overcome. ^{1}H is the most sensitive NMR-active nucleus (in absolute terms) and is present in almost all organic compounds. If care is taken to minimize signal overlap from the matrix, it can provide qualitative and quantitative information on the metabolism and biochemical effects of xenobiotics. ^{1}H spectra can be obtained for compounds present in concentrations greater than about 50–100 μM in a reasonable amount of time. For these reasons, ^{1}H is the most commonly used NMR-active nucleus for studying mechanisms of toxicology. A number of studies of crude urine or urine extracts have been reported; however, biological fluids are usually concentrated and fractionated by HPLC prior to ^{1}H NMR analysis. In some cases, 2D NMR experiments such as correlation spectroscopy (COSY; discussed in the following text) can adequately resolve signals of interest with little or no sample cleanup.

^{13}C is of very low natural abundance (about 1%), and its magnetogyric ratio is four times lower than ^{1}H. As a result, its absolute sensitivity is over 5000 times less than ^{1}H. Despite this low sensitivity, ^{13}C NMR spectra can be obtained for compounds present at concentrations >10 mM in a reasonable amount of time. As in ^{1}H NMR studies, samples are most often concentrated and purified by HPLC prior to analysis. In some cases, isotopic enrichment with ^{13}C has been used to increase sensitivity. Enrichment to 90 atom-% ^{13}C results in a 90-fold increase in sensitivity, rendering direct analysis of crude urine for low-molecular-weight metabolites feasible. Combined with 2D NMR experiments such as INADEQUATE, isotopic enrichment with ^{13}C is a powerful tool for metabolite characterization. Noninvasive in vivo ^{13}C NMR spectroscopy has been used to study the pharmacokinetics of ^{13}C-enriched xenobiotics in the rat [134]. The high cost and limited availability of ^{13}C-enriched materials are the main disadvantages to isotopic enrichment.

^{31}P is a sensitive nucleus with a 100% natural abundance. As such, it is an attractive candidate for NMR studies. ^{31}P is one of the most commonly used nuclei for in vivo NMR spectroscopy and has been used extensively to determine the effects of xenobiotics on in vivo energy metabolism and intracellular pH [121]. It is much less useful for studies of xenobiotic metabolism, as very few xenobiotic metabolites contain phosphorous.

^{19}F is almost as sensitive as ^{1}H, and because it is not normally found in biological samples, ^{19}F NMR signals from the matrix are not a problem. If the xenobiotic of interest contains fluorine, useful information such as quantitative determination of fluorinated metabolites and excretion rates can be obtained from ^{19}F NMR. Most fluorinated compounds contain only a few fluorine atoms (one to three), so structural characterization of metabolites by ^{19}F NMR is rare. ^{19}F is a very good tracer for in vitro and in vivo spectral determination of organ perfusion and has been used to determine cerebral, hepatic, and muscular blood flows [135]. Using fluorophenols as model toxins, the microbial degradation of environmental pollutants has been examined in a detailed metabolomic study using ^{19}F NMR [19]. In practice, NMR studies often utilize more than one type of NMR-active nucleus. Characterization of metabolites is best accomplished with more than one type of NMR experiment. Typically, both 1D ^{1}H and ^{13}C spectra and a variety of 2D experiments are used.

Choice of NMR Experiments

Although a detailed discussion of modern NMR experiments is far beyond the scope of this chapter, several excellent books on the subject are available [45,47,127,166]. A brief description of those experiments that are likely to be most useful for studying mechanisms of toxicology is appropriate. NMR experiments can be divided into two main categories: 1D and multidimensional. One-dimensional NMR experiments are of the type discussed in the earlier section on basic theory. The output of a 1D experiment is a spectrum of intensity vs. frequency (or chemical shift in δ units). The ^{1}H spectrum of Figure 41.8 is a very good example. In principle, 1D spectra can be obtained for any spin-active nucleus. One-dimensional spectra are the type used most often for quantitative analysis.

For structural characterization of organic compounds, 1D proton and carbon spectra are almost always used. These spectra contain information about the chemical environments of the hydrogen and carbon atoms in the molecule. The proton spectrum, with its coupling information, also helps in assigning connectivities, as coupling constants and peak multiplicity can assist the spectroscopist in determining which hydrogens are coupled. Coupling constants also

help in assigning geometry in rigid systems (e.g., *cis* or *trans* isomers). Although a great deal of structural information can be obtained from these 1D spectra, it is often useful to obtain 2D spectra as well.

For 2D experiments, two or more RF pulses with variable delay times between them are used to excite the nuclei. The variable delay times introduce a second time domain, and after 2D Fourier transformation, a spectrum with two frequency domains is obtained. No attempt to explain the details of 2D NMR is made here; the interested reader should refer to other texts for such detail [127]. The 2D experiments, which are likely to be the most useful in toxicology research, are used to investigate spin–spin coupling by COSY. COSY spectra reveal ^{1}H–^{1}H spin–spin correlations and generate all connectivities between coupled protons. HETCOR (or HMQC and HMBC) spectra reveal proton–heteroatom correlations (usually ^{1}H–^{13}C correlations) and generate connectivities between protons and heteroatoms, such as carbon. INADEQUATE spectra (which are used much less frequently and most often for ^{13}C-enriched compounds) are used to generate connectivities between carbons. Two-dimensional experiments are very useful for resolving signals of interest from overlapping matrix signals in biological samples, and examples of their application in metabolism studies are presented in a later section.

Instrument Considerations

Ideally, the instrument with the highest available field strength (frequency) should be used to obtain maximum resolution and sensitivity. Commercial instruments with a field strength of 900 MHz are available. NMR but advances in magnet design should make even higher-field instruments possible. Price must be considered when purchasing an instrument. Fortunately, most academic NMR laboratories make instrument time available free or for a reasonable hourly rate.

In toxicology research, sample size is often limited. It may take many hours (or weeks) to isolate a few hundred micrograms of a xenobiotic metabolite, so sensitivity is a major concern. For a given field strength, the component that has the greatest influence on sensitivity is the probe. The most common probes are designed for 5 mm sample tubes and in many cases will give adequate sensitivity. Where sample size is limited, the smallest possible probe should be used. Microprobes designed for 3 mm sample tubes are available, and a 1.7 mm probe has been developed [126].

Probes are tuned to the resonance frequency of the nucleus under observation. Selectively tuned probes are designed to work over a very narrow frequency range. They are selected based on the frequency of the nucleus under observation. Selectively tuned probes for proton may be tuned slightly lower to observe fluorine but can never be tuned low enough to observe carbon. Broadband probes can be tuned over a very broad frequency range (a factor of 10 from lowest to highest), so one broadband probe can be used to observe most NMR-active nuclei. Although this sounds very attractive, there is a trade-off when using such a probe. Broadband probes are inherently less sensitive than selectively tuned probes. The S/N with a broadband probe will be at least a factor of two less than with a selectively tuned probe. For maximum sensitivity, it is best to use selectively tuned probes.

A powerful method for heteronuclear correlation experiments, called *indirect* or *reverse detection* [39,126], considerably increases the sensitivity of heteronuclear correlation experiments. It takes advantage of the sensitivity of proton NMR and the selectivity of heteronuclear NMR. It requires irradiation at the heteroatom frequency and observation at the proton frequency. Probes specifically designed for indirect detection are available in 5, 3, and 1.7 mm sizes. Using a 1.7 mm indirect detection probe reduces the sample size required for heteronuclear correlation experiments from ~50 μmol for a 5 mm probe to <0.05 μmol [126].

Sample Preparation

Interference from the sample matrix and the dilute nature of many biological samples often require a purification or preconcentration step prior to NMR analysis. HPLC, solid- or liquid-phase extraction, and TLC have all been used to purify xenobiotic metabolites. The method of choice will depend on the nature of the matrix, the chemical properties of the metabolites, and the sample size. If organic solvents are used for the purification, it is very important to remove as much of the solvent as possible by evaporation prior to NMR analysis. Residual solvents can add very large signals to proton and carbon spectra. These large signals often obscure significant portions of the spectra and, if large enough, can make detection of small signals difficult or impossible due to the limited dynamic range of most spectrometers.

Liquid-state NMR requires the sample to be dissolved in a suitable solvent. Solvents used for most NMR analyses are deuterated; that is, they contain deuterium (^{2}H) instead of protium (^{1}H). Deuterium is required for the spectrometer frequency lock, which corrects for field drift during spectral acquisition. For proton NMR, deuterated solvents are also desirable as they cut down on the intense solvent resonance that would appear in the presence of protiated solvents. Common NMR solvents, commercially available in >99 atom-% deuterium, are $CDCl_3$, CD_2Cl_2, d_4-methanol, d_6-DMSO, d_6-acetone, and D_2O. If samples in H_2O are to be analyzed, a small amount of D_2O (10%–20%) should be added for frequency locking, and a suitable solvent suppression method (discussed later) should be used.

When the sample has dissolved in a suitable solvent, it should be filtered to remove particulate matter. Even small particles can result in a loss of resolution, so filtration is particularly important when closely spaced signals or very small couplings are to be observed.

Solvent Suppression

Many biological samples are aqueous solutions. Acquisition of ^{1}H NMR spectra of such samples is complicated by the fact that the solvent water protons are present at a concentration of 110 M and the analytes of interest are often present in submillimolar concentrations. As a result, weak solute signals are often obscured or undetectable in the presence of

the very large solvent signal. It is essential to attenuate the water signal to observe weak signals in the ^{1}H NMR spectra of biological samples. A variety of so-called solvent suppression methods have been developed to reduce or eliminate the water peak in ^{1}H NMR spectra [80].

The simplest solvent suppression method is the removal of H_2O by lyophilization. The sample is lyophilized to dryness and reconstituted in D_2O. Typically, this is repeated several times to remove the last traces of H_2O prior to spectral acquisition. In practice, it is extremely difficult to eliminate the water peak completely because lyophilized biological samples such as urine are often quite hygroscopic and the sample invariably picks up moisture from the air. This method does, however, provide adequate reduction in the size of the water peak for most purposes. An additional advantage to this approach is that dilute samples can be concentrated to increase overall sensitivity.

Several instrumental methods are available for solvent suppression. Perhaps the simplest of these involves irradiation at the solvent resonance frequency to saturate the solvent signal. This irradiation may be continuous or it may be gated off during the pulse and acquisition. Suppression ratios of 1000 are possible for water. Unfortunately, peaks close to it are often attenuated or distorted. To suppress the water peak with less distortion of other resonances, selective relaxation methods based on T_1 relaxation differences between solvent and solute, such as the *water elimination Fourier transform* (WEFT) method, have been used. Although adequate water suppression is often achieved with WEFT, if signals from the molecule of interest have slow relaxation times, their intensities may be attenuated. If accurate integration is required for signals with a range of relaxation times, other solvent suppression methods should be used.

A powerful method for water suppression takes advantage of rapid proton exchange between water and an added chemical agent such as ammonium chloride. Rapid proton exchange greatly reduces T_2 for the water signal, which is suppressed using a special pulse sequence called *spin echo.* This pulse sequence allows the water signal to relax but still permits detection of the desired solute resonances that have longer T_2 relaxation times. This method, *water attenuation by T_2 relaxation* (WATR), can reduce the intensity of the water signal by factors of $>10^4$. WATR was employed in the determination of benzene and *N*-nitrosodimethylamine in aqueous solution by 500 MHz proton NMR with limits of detection of 35 and 510 ng/mL, respectively [57].

Recent advances in the theory and technology of NMR have led to the development of a host of pulse sequences designed specifically for solvent suppression. Fortunately, modern NMR computer control systems contain software for all common solvent suppression pulse sequences, and they are now routinely used with a minimum of operator involvement. A very powerful method, based on the 2D experiment NOESY, is called NOESYPRESAT. This method results in attenuation of the water signal by a factor of 10^5 or more. Using NOESYPRESAT (for 1D spectra), a series of 2D experiments, and a 750 MHz spectrometer, Nicholson et al. [141] were able to assign over 150 resonances in the ^{1}H spectrum of human blood plasma diluted with 10% D_2O.

Applications

Identification of Metabolites

NMR is often critical for elucidating the structure of unknown organic compounds. Both 1D and 2D NMR spectra were used to fully characterize *S*-(−)-cotinine-*N*-glucuronide, a previously unidentified metabolite of nicotine. The structure of this glucuronide was determined using 1D proton and carbon and 2D COSY and HETCOR spectra. The 1D spectra (Figure 41.11) were consistent with the proposed structure. The COSY spectrum shown in Figure 41.12A was used to establish connectivities of the coupled protons enabling the complete assignment of the proton resonances in the 1D spectrum. In COSY spectra, the contours that fall on the diagonal correspond to the 1D spectrum except they are seen as if the observer were looking down from above the spectrum. Contours that fall off the diagonal result from spin–spin coupling, so they reveal correlations between coupled protons. COSY spectra are usually presented with the 1D spectrum plotted on the top to facilitate interpretation. The HETCOR spectrum shown in Figure 41.12B was used to establish proton–carbon connectivities and enabled the complete assignment of the carbon resonances in the 1D carbon spectrum. HETCOR spectra may be thought of as a carbon spectrum plotted against a proton spectrum. Contours that appear in the HETCOR result from ^{1}H–^{13}C coupling and reveal proton–carbon connectivities—that is, which protons are bound to which carbons. This HETCOR spectrum is presented with the carbon spectrum (projection) plotted on the vertical axis and the proton spectrum plotted on the horizontal axis.

Perhaps the most common applications of NMR in toxicology research involve characterization of xenobiotic metabolites. Usually, NMR spectra of the purified metabolites are used in conjunction with mass spectral characterization and are included as final confirmation of the proposed structure. Such applications of NMR have contributed to the understanding of xenobiotic detoxification mechanisms. NMR analysis of crude or partially purified biological samples, although not frequently used, can be useful for metabolic studies. Typically, 1D proton NMR spectra of crude biological samples are very complex, with many overlapping signals. Nicholson and Wilson [139] have demonstrated the utility of 2D COSY NMR spectroscopy of crude urine for the simplification of such complex spectra. They collected urine from a human volunteer before and 3 h after ingestion of 1 g paracetamol. The urine was lyophilized, reconstituted in D_2O, and examined directly by 1D proton and COSY NMR. The 1D spectrum revealed considerable signal overlap in the aromatic region; however, in the COSY spectrum, well-resolved cross peaks for five paracetamol metabolites were immediately evident. They pointed out that 2D techniques are costly in terms of instrument time but can be used quite successfully when a

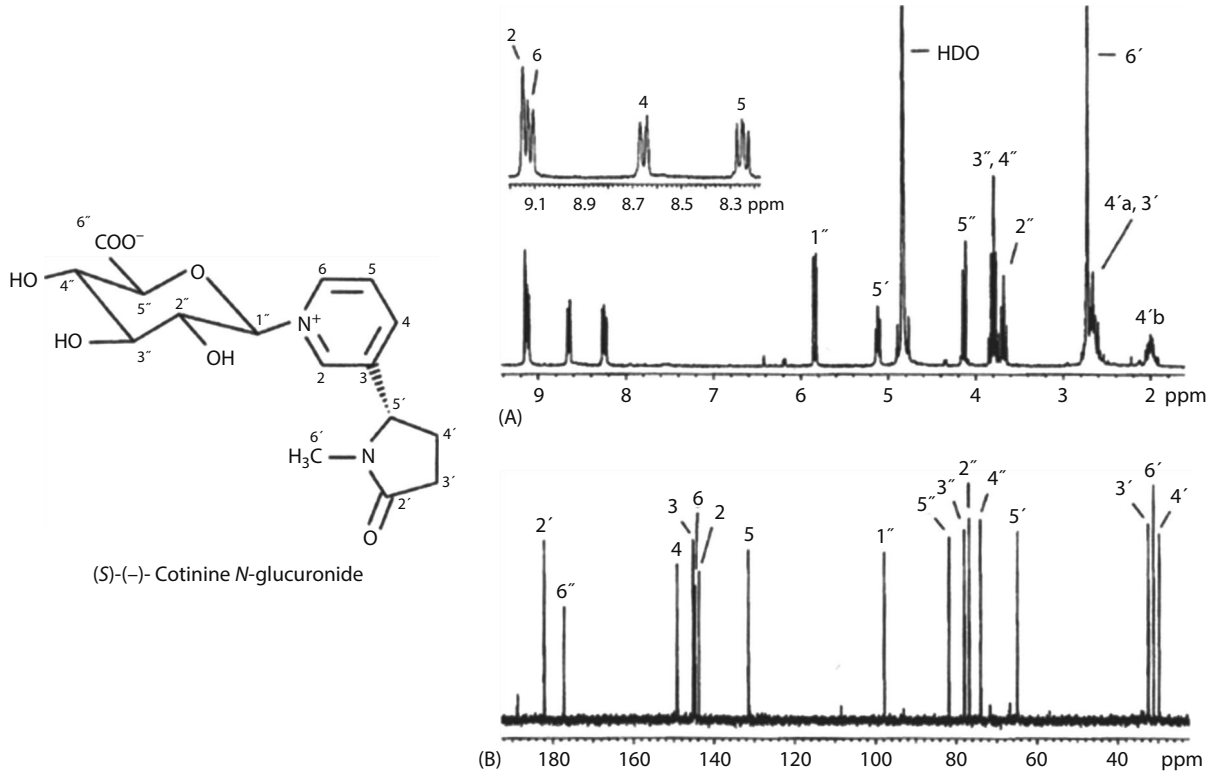

FIGURE 41.11 One-dimensional proton (A) and carbon (B) NMR spectra of (S)-(–)-cotinine-*N*-glucuronide.

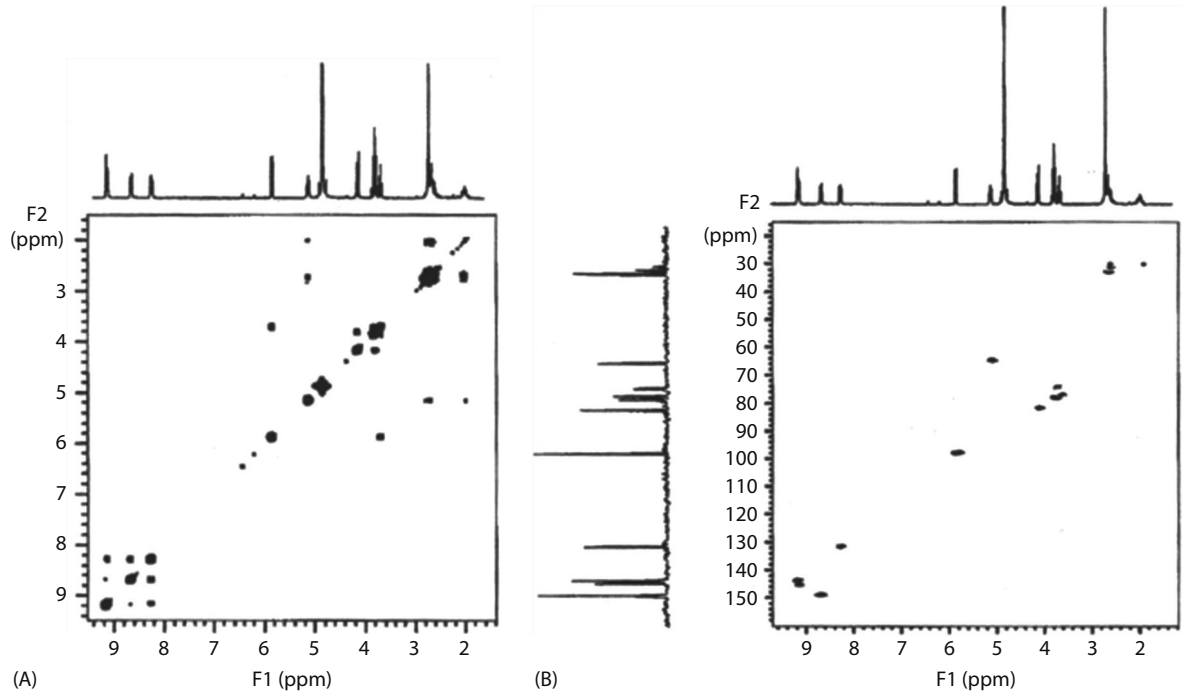

FIGURE 41.12 COSY spectrum (A) and HETCOR spectrum (B) of (S)-(–)-cotinine-*N*-glucuronide.

great deal of metabolic information is required from a few samples or spectral assignments are difficult from the 1D spectra alone.

When NMR spectroscopy is coupled with partial purification, structural characterization is often possible from 1D spectra alone. Solid-phase extraction (SPE) is a good method for the partial purification of biological samples on a moderately large scale and has been applied successfully to the characterization of ibuprofen metabolites by 1D proton and carbon NMR [139]. For this study, a normal, healthy male

volunteer was administered 400 mg ibuprofen and urine was collected predose, at 0–2 h, and at 2–4 h. The urine was lyophilized and reconstituted in D_2O, and 1D proton spectra were acquired. The samples were next applied to a C18 SPE column and eluted with a stepwise gradient of increasing methanol concentration. Fractions were collected, the solvent was evaporated, and the residue was reconstituted in D_2O. Spectra of each fraction were acquired to follow the progress of metabolite elution. Using this method, three ibuprofen metabolites, including the glucuronide, were recovered essentially free of impurities.

Mechanistic Studies of Xenobiotic Metabolism

To elucidate the mechanism of xenobiotic metabolism, detailed structural characterization of metabolites is required. Often, such detail is only available from NMR spectroscopic analysis. Because many metabolites are present in very small quantities, extremely sensitive NMR methods are required. A type of indirect detection called *proton-detected heteronuclear multiple quantum* coherence (HMQC) NMR provides detailed structural information (proton–carbon connectivities) with very good sensitivity. Using a novel 1D application of HMQC, Hackett et al. [66,67] have studied the microsomal hydroxylation of the herbicide triallate. They determined that cytochrome P450–catalyzed oxidation of triallate leads to the formation of an intermediate *allylic radical* (AR) that undergoes rearrangement leading to hydroxylation at two different positions (Figure 41.13). The structural characterization that led to such detailed mechanistic understanding was carried out on 20–45 μg of material isolated and purified by HPLC after microsomal incubation of ^{13}C-labeled triallate. Hackett et al. [66,67] used a 500 MHz NMR equipped with a 5 mm indirect detection probe. Even greater sensitivity could be realized with a higher-field NMR or a 1.7 mm probe. Their work has demonstrated the utility of 1D HMQC for mechanistic studies when sample size is quite limited and no other suitable analytical method is available.

Biochemical Changes Associated with Xenobiotic Toxicity

Exposure to toxins invariably leads to certain biochemical changes. These include changes in the urinary excretion of endogenous compounds such as carbohydrates, amino acids, and carboxylic acids. Mercury is known to accumulate in the kidneys of experimental animals after injection, causing damage to the proximal tubular epithelium and severe kidney failure. Mercury-induced nephrotoxicity is characterized by increased urinary excretion of amino acids, glucose, calcium, phosphate, bicarbonate, and low-molecular-weight proteins. Nicholson et al. [138] have studied changes in urinary and plasma levels of a large number of low-molecular-weight compounds in rats exposed to mercuric chloride by proton NMR and correlated these changes with histopathology and enzyme excretion. They quantified metabolites in untreated urine and plasma and observed dose-dependent decreases in urinary excretion of creatinine and citrate and increases in glucose, glycine, alanine, α-ketoglutarate, succinate, and acetate. They observed increases in plasma levels of lactate and creatinine. The observed changes were consistent with Hg^{2+} inhibition of certain citric acid cycle enzymes and intracellular, tubular acidosis. Their NMR data provided not only a sensitive measure of Hg^{2+}-induced nephrotoxicity but mechanistic insight as well. Similar quantitative NMR techniques may also prove useful for studying the mechanism of action of other toxins.

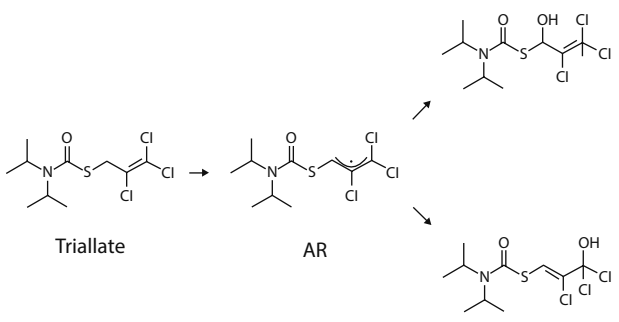

FIGURE 41.13 Cytochrome P450–catalyzed oxidation of triallate showing the AR intermediate.

Metabolomics

The systematic evaluation of biochemical responses to intoxication is the foundation of metabolomics. NMR spectroscopy of biological fluids and tissues, coupled with pattern recognition and chemometric analysis, is often essential to metabolomic studies [96]. Principal component NMR analysis of urine from rats treated with the phosphodiesterase inhibitor CI-1018 allowed researchers to differentiate between both vascular lesions and an independent inflammatory response secondary to CI-1018 treatment [181]. Indeed, for over a decade, NMR analysis of urine from humans and animals has been used to identify the metabolic perturbations associated with drug toxicity, such as the nephrotoxicity associated with ifosfamide treatment [54]. Metabolomic studies are certainly not limited to the study of toxic pharmaceuticals. The powerful combination of NMR and principal component analysis was employed in the development of a rapid throughput analysis of urine from rats treated with common hepato- and nephrotoxins [165]. Metabolomic analysis of urine components readily and reliably detected both the onset and reversal of toxicity associated with carbon tetrachloride, 4-aminophenol, and other compounds.

Hydrazine, a model hepatotoxin, is an excellent example of a compound that may be systematically studied using NMR-based metabolomics. The onset and recovery from hydrazine-induced liver toxicity in rats were easily monitored in a time- and dose-dependent manner using NMR analysis of urine, coupled with pattern recognition and pattern classification algorithms [187]. Similar analysis of urinary biomarkers, including lactate, acetate, taurine, and β-alanine, allowed researchers to distinguish between different rat strains and their biochemical response to treatment with hydrazine [77]. Predictive models for classifying the type of intoxication and the strain of intoxicated rat were highly accurate and reproducible. Interspecies variations in the biochemical responses to hydrazine intoxication are also readily discernible using

NMR-based metabolomics. Urinary metabolomic analysis of hydrazine metabolites and biochemical markers, including citrulline and trimethylamine-*N*-oxide, was very effective for detecting and differentiating between hydrazine toxicity in rats and mice [20].

Lipids are a particularly useful group of metabolomic markers for toxicological studies. Often, changes in lipid profiles in biological matrices are both pronounced and readily detectable by NMR after intoxication. Metabolomic studies of urinary dicarboxylic aciduria, which combined NMR with multivariate statistical analysis, were very useful for detecting and characterizing the mechanism of liver toxicity attributed to MrkA, an experimental therapeutic [132]. The effect of rosiglitazone, an antidiabetic compound, on several metabolic pathways was characterized by NMR metabolomics. Changes in liver–plasma lipid exchange, de novo fatty acid synthesis, lipid levels in the peroxisome, cardiac lipid metabolism, and lipid metabolism in adipose tissue were all detected using this method, which served as a phenotypic model for assessing clinical response to the drug [209]. Metabolomic analysis of urine from rats treated with chloroquine, amiodarone, or DMP-777, an elastase inhibitor, showed distinct differences in phospholipidosis and phenylacetylglycine levels, depending on which drug was administered [50]. This allowed the authors to correctly determine drug exposure, as well as differentiate between tissue-specific toxicity, based on the unique metabolomic profile of each compound.

Metabolomic studies employing NMR may also be very useful for the environmental toxicologist. Both acute and chronic environmental stresses, including toxin exposure, may be detected by metabolomic analysis of field samples. Principal component analysis of extracts from abalone foot muscle, digestive gland, and hemolymph allowed toxicologists to distinguish between the biochemical profiles of healthy, stunted, and diseased abalone, an important commercial shellfish [203]. In addition to providing a means of assessing the presence of toxins and other environmental stressors, this metabolomic approach also allowed the researchers to diagnose withering syndrome, a common disease in abalone. High-resolution NMR was employed in a metabolomic study of earthworms treated with 3-fluoro-4-nitrophenol, a model toxin. Changes in the relative concentrations of organic acids (in particular, acetate and malonate) served as a reliable marker of toxin exposure [23].

As discussed, the intensity and resolution of NMR spectra may be compromised by a number of factors, including pH, solvent effects, and overlapping peaks. These may limit the reliability and robustness of NMR-based metabolomics. Accordingly, several specialized systems and mathematical approaches have been developed to overcome these limitations. Variations in peak position might be overcome by employing orthogonal projection, back-scale plots, and weighted variable peak position data in NMR plot analysis [113]. Two-dimensional J-resolved spectra, combined with precision spectral preprocessing and logarithmic transformation, afford proton-decoupled projected 1D spectra with reduced peak congestion and more accurate integration of metabolomic peaks [202]. Magic-angle spinning NMR is a more sophisticated technique that has been successfully employed for identifying and correlating metabolomic analytes with histopathological changes in thioacetamide toxicity [208]. Advances in NMR technology for metabolomic applications have been reviewed by Griffin and Bollard [63]. Advances in the mathematical approaches used to interpret metabolomic NMR spectra include advanced pattern recognition algorithms, hierarchical cluster analysis, and nearest neighbor classification systems [11,62].

In Vivo Spectroscopy and Imaging

Advances in NMR theory and hardware have enabled the study of morphological and metabolic changes in isolated organs and whole animals and humans based on NMR principles. Magnetic resonance imaging (MRI), widely used in clinical medicine, relies mainly on the detection of hydrogen nuclei in water and fat to construct high-resolution images. The contrast in these images results from different T_1 and T_2 relaxation times for hydrogen nuclei in different tissue environments. In vivo magnetic resonance spectroscopy (MRS) is used to obtain spectral information (such as chemical shift and intensity) on chemical compounds within living tissues and can be used to monitor metabolic changes resulting from disease or xenobiotic exposure. MRI and MRS are based on the same principles as liquid-state NMR—that is, the behavior of nuclei in a magnetic field under the influence of RF pulses—but the hardware, pulse sequences, and data processing are somewhat different. Several good reviews describe these differences in detail [9,131,193].

In vivo ^{31}P MRS has been used to monitor energy metabolism in tumors in laboratory animals during growth [190] and following hyperthermia [201], treatment with interleukin-1α [35], and endocrine therapy [189]. In many cases, the changes seen in phosphorous metabolites (ATP, ADP, PCr, P_i, β-nucleoside triphosphate, phospholipids) correlate well with tumor growth. These results demonstrate the potential for noninvasive monitoring of tumor development by in vivo NMR spectroscopy.

Both MRI and MRS have been used to study liver damage induced by hepatotoxic halocarbons. Locke and Brauer [116] monitored the response of rat liver in situ to bromobenzene by proton MRI and ^{31}P MRS. They found that a sublethal dose of bromobenzene-induced acute hepatic edema and decreased energy metabolism. Both effects had an onset of 15–20 h and were maximal at 25–60 h. These effects were blocked by Trolox C, a potent inhibitor of lipid peroxidation.

In vivo NMR spectroscopy has tremendous potential as a tool for studying mechanisms of toxicology. MRI and MRS techniques provide detailed information on the response of specific organs to toxicants and can also be used to monitor xenobiotic metabolism in vivo. In addition, they could greatly reduce the number of animals required for toxicology studies, as a single animal could be followed over an extended period of time to monitor internal changes. As spectrometers for in vivo NMR become more readily available to the practicing

toxicologist, in vivo NMR spectroscopy will almost certainly become the method of choice for many toxicology studies.

LC-NMR

Hyphenated techniques coupling MS and various separation methods such as GC, LC, and CE are standard analytical tools widely used in toxicology research. Advances in the design of NMR probes and in methods for adequate solvent suppression together with the availability of high-field NMR spectrometers have enabled the coupling of NMR with LC. This hyphenated method takes advantage of HPLC separations and the wealth of structural information provided by 1D and 2D NMR spectra. This section provides a brief overview of LC-NMR instrumentation, methods, and applications in toxicology research. For more detailed information, the interested reader is referred to several very good reviews of the topic [113–115,137].

The complex nature of most biological samples makes direct analysis by NMR spectroscopy difficult. Spectra of crude biological samples typically contain many overlapping resonances, which greatly complicate their interpretation. One approach to the simplification of such samples is the removal of endogenous components and the separation of the compounds of interest. The use of SPE followed by 1D NMR analysis (SPE-NMR) for the isolation and characterization of ibuprofen metabolites from human urine has already been mentioned [139]. Although SPE-NMR can be quite effective, it suffers from several limitations. SPE is a relatively low-resolution separation method. It is inadequate for very complex mixtures or mixtures of very similar compounds. SPE-NMR is a tedious and time-consuming technique involving the collection of samples, solvent removal, and reconstitution of samples in an appropriate NMR solvent. It also requires a relatively large amount of sample. Although this is usually not a problem for the analysis of human urine, it can be limiting in some circumstances. These limitations are largely removed by hyphenation of NMR with HPLC.

Although reports of successful LC-NMR experiments date back to the late 1970s, the limited sensitivity of NMR and the technical hurdles associated with suppression of signals from the protonated solvents commonly used for LC greatly limited the utility of LC-NMR. With the advent of micro NMR probes, the greater availability of high-field NMR spectrometers (>300 MHz) with increased dynamic range, and the development of truly effective solvent suppression methods, LC-NMR has come into its own as a widely used analytical technique. Hardware and software making LC-NMR a relatively routine method are now commercially available from major vendors.

Although the configurations of LC-NMR systems vary from vendor to vendor and laboratory to laboratory, all systems share the same basic components. The design of a typical LC-NMR system is shown schematically in Figure 41.14. The LC pumps, injector, column, and detector are all standard equipment. From the detector, the flow enters the LC-NMR interface, which contains components for flow control and peak sampling. The LC-NMR interface can send the flow directly to the NMR probe, divert the flow to waste, or store peaks detected by the in-line detector for subsequent NMR analysis. The NMR probe contains a flow cell that replaces the standard glass NMR tube and typically has a volume between about 50 and 250 μL. The probe can be of the selectively tuned type for direct detection of ^{1}H, ^{19}F, ^{31}P, etc., or it can be of the indirect detection type. Broadband probes are inherently less sensitive than selectively tuned or indirect probes and therefore are rarely, if ever, used for LC-NMR. The most commonly used LC-NMR probe is the dual $^{1}H/^{13}C$ indirect probe. Instruments configured as shown in Figure 41.14 can be used in the continuous-flow mode if peaks eluted from the LC column pass through the LC-NMR interface to the flow cell for detection in real time. This so-called online LC-NMR works well for fairly concentrated samples (mass detection limits >10 μg in the flow cell), but because the residence time in the flow cell is limited, it is difficult to obtain

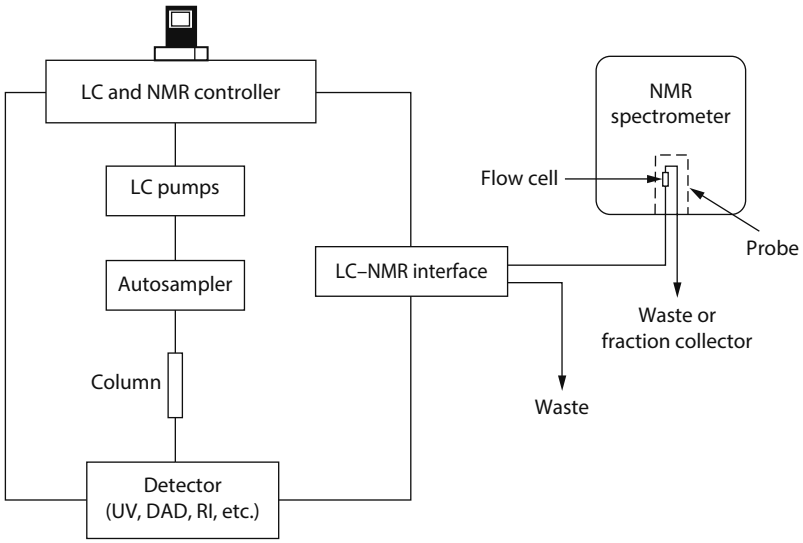

FIGURE 41.14 Schematic representation of an LC-NMR system.

more than 32–64 transients, and 2D experiments are not possible. When higher resolution or sensitivity is required, the LC-NMR interface can be programmed to stop the flow once a peak of interest enters the probe. Such stop-flow or static LC-NMR offers the opportunity to acquire as many transients as necessary for adequate S/N in 1D experiments and is compatible with 2D experiments as well. Using stop flow, samples of ~1 μg or less can be analyzed. A variation of the stop-flow technique involves programming the LC-NMR interface to store peaks of interest in sample loops and then pass them one at a time to the probe. Once a peak enters the probe, the flow is stopped and the peak is scanned.

A major development in the evolution of routine LC-NMR was in the area of solvent suppression. Because most LC separations of biological samples depend on reversed-phase columns, they utilize solvent mixtures containing water and protonated organic solvents such as methanol or acetonitrile. The most common LC-NMR solvent mixtures are D_2O/acetonitrile or D_2O/methanol. The use of D_2O reduces the effective concentration of solvent protons and provides a source of deuterium for the instrument lock. Because D_2O is relatively inexpensive, it is a very good alternative to H_2O. As discussed previously, the use of protonated solvents (such as acetonitrile) requires attenuation of the solvent signals to observe the weak signals from solute molecules. Fortunately, LC-NMR control systems contain computer software for solvent suppression pulse sequences such as NOESYPRESAT. The suppression of signals from mixed solvents is now a routine operation requiring minimal operator involvement.

Major NMR vendors offer systems for fully automated LC-NMR. Naturally, such systems are capable of automated online LC-NMR, but they are also capable of automated stop-flow LC-NMR. A typical system can

- Autodetect an LC peak
- Transfer the peak to the flow cell
- Stop the flow
- Shim the NMR magnet
- Optimize solvent suppression
- Acquire the spectrum
- Restart the LC pump
- Send the peak to waste or a fraction collector
- Repeat the procedure for any desired peaks in the chromatogram

Such a system can also automatically store peaks of interest in the LC-NMR interface for subsequent analysis.

The most common applications of LC-NMR involve the characterization of xenobiotic metabolites. An early example, reported by Spraul et al. [186], was the characterization of ibuprofen metabolites in human urine. For this study, a normal, healthy male volunteer was administered 400 mg ibuprofen and urine was collected for the period from 0 to 4 h after dosing. The urine was lyophilized and reconstituted in a D_2O–d_3-acetonitrile mixture prior to LC-NMR analysis. Gradient-elution LC was accomplished with (1) potassium dihydrogen phosphate in D_2O and (2) acetonitrile. A linear gradient from 2% to 45% acetonitrile at a flow rate of 1 mL/min was used for stop-flow analysis. For online analysis, a flow rate of 0.5 mL/min was used. The 500 MHz NMR was equipped with a commercial selectively tuned ^1H flow probe with a 60 μL flow cell, and solvent suppression was accomplished using the NOESYPRESAT pulse sequence. For online analysis, 16 transients were collected for each peak, giving a time resolution of 12 s. For stop-flow analysis, both 1D (256 or 512 transients) and 2D TOCSY experiments were performed. Using online analysis, Spraul et al. [186] were able to identify five metabolites, including three glucuronide conjugates. The stop-flow analyses provided high-resolution 1D ^1H spectra and 2D TOCSY spectra that permitted unambiguous characterization of the five metabolites. On-column detection limits were 10 μg for the online analyses and 1 μg for the stop flow. Using LC-NMR, the authors were able to identify one metabolite, the dicarboxylic acid metabolite of ibuprofen, which was not observed using SPE-NMR.

Glucuronic acid conjugates of carboxylic acids can undergo an isomerization reaction known as *acyl migration*, where the carboxylic acid moiety migrates from the 1 position of the glucuronic acid to the 2, 3, or 4 position. Such isomerizations can occur in vivo and in vitro at physiological pH and under mildly alkaline conditions. The resulting acyl-migrated positional isomers can exist as either β- or α-anomers. Lenz et al. [111] used LC-NMR to characterize the glucuronic acid conjugates of the nonsteroidal anti-inflammatory drug 6,11-dihydro-11-oxodibenz(*b*,*e*)oxepin-2-acetic acid in human urine and study the pH dependence of the acyl migration reaction in that matrix. They used a 400 MHz NMR with a 120 μL flow cell in the stop-flow mode to obtain ^1H spectra of the α- and β-anomers of all possible acyl migration products. For one metabolite, they used a 600 MHz NMR to obtain higher-resolution spectra that aided in full characterization. This work is noteworthy in that the α- and β-anomers were not separated by the LC and yet using NMR as a detector allowed the unambiguous characterization of the metabolite anomers. The high-resolution and rich information content of NMR spectra can often be used to characterize closely related metabolites that coelute in the liquid chromatogram.

The use of very high-field NMR spectrometers (800 MHz) greatly increases spectral resolution and can aid tremendously in metabolite characterization by LC-NMR. Sidelmann et al. [179] used SPE-NMR at 400 MHz and stop-flow LC-NMR at 800 MHz to identify the major phase II metabolites of tolfenamic acid in human urine. They identified glucuronide conjugates of the parent compound and five metabolites, the first report of the direct identification of these phase II metabolites in biofluids. The 800 MHz NMR was particularly useful in determining the exact position of hydroxylation of the aromatic ring of tolfenamic acid. The increase in spectral dispersion obtained at ultrahigh field provided very high-resolution 1D ^1H spectra, thus permitting unambiguous assignments.

LC-NMR has also been applied to studies of in vitro microsomal metabolism. Corcoran et al. [38] identified the metabolites of two phenoxypyridines obtained from incubation with

rat microsomes using stop-flow LC-NMR at 750 MHz. They were able to characterize one metabolite that was 6% of the total and another that was only 0.6%. The unequivocal identification of these metabolites without the use of radiolabeled substrates or synthetic metabolite standards demonstrated that LC-NMR can be used for metabolite characterization in in vitro systems and could be used in a high-throughput mode for lead optimization in drug discovery.

In an effort to further reduce the sample size required for hyphenated separation NMR techniques, some laboratories have explored microbore or capillary LC as well as other separation methods such as CE and capillary electrochromatography (CEC) coupled to NMR. Wu et al. [222] developed a theoretical model for predicting the S/N ratio as the NMR flow-cell volume is scaled down. Their model predicted only a twofold reduction in S/N for a 400-fold reduction in flow-cell volume. They constructed a 50 nL flow cell by wrapping narrow-gauge copper wire around a fused silica capillary column. Using this microflow cell and a 300 MHz spectrometer, they realized a mass limit of detection of ~1 μg on-column in an online microbore LC-NMR analysis. The most serious limitation to their approach was the relatively broad line widths in the online NMR spectra. When the analysis was performed in the stop-flow mode, they were able to optimize the NMR shims and other instrument parameters and reduce the line widths to <1 Hz. As a result, 2D experiments such as COSY and NOESY were possible.

Pusecker et al. [158] constructed a 240 nL capillary flow cell coupled to a packed fused silica microbore column. This column could be used for CE, CEC, or capillary HPLC separations. Using a 600 MHz NMR, they realized a mass limit of detection of ~300 ng in the stop-flow mode. They also reported that in the online mode, the limit of detection was adequate for all three microseparation techniques. A major advantage to this system is the ease of changing from one separation method to another. When this microflow cell was used in an online CE analysis of paracetamol metabolites in an extract of human urine (at 600 MHz), the mass limit of detection was ~10 ng [171]. Online CEC analysis afforded a similar mass limit of detection. Identification of metabolites by NMR could be accomplished with nanoliter sample volumes. Improvements in flow cell and probe design are likely to reduce limits of detection even further, and microseparation methods coupled to online NMR detection will almost certainly become routine tools for metabolite identification. Metabolomic studies are routinely performed using NMR-LC systems; for example, a high-throughput metabolomic profiling system that used a short monolithic column, a rapid gradient, and a high flow rate to analyze large numbers of urine samples was recently reported [148].

LC-NMR-MS

The hyphenated techniques of LC-MS and LC-NMR are both very powerful tools for characterization of xenobiotic metabolites, but they both suffer from unavoidable limitations. Neither technique can, by itself, provide the unequivocal assignment of chemical structure in all cases. MS often cannot distinguish between positional isomers, but NMR is very good for this application. Certain functional groups do not contain NMR-active nuclei and are invisible in NMR spectra. An example of an NMR-invisible functional group is the sulfate group of sulfate conjugates. In such cases, MS can be used to characterize the sample. Because MS and NMR are complementary techniques and both have been successfully hyphenated with LC, it was inevitable that these techniques would be merged to form LC-NMR-MS. The first report of successful LC-NMR-MS appeared in 1995 [156] and was soon followed by reports of its application for characterization and quantification of xenobiotic metabolites [24,42,79,167–169,178,215]. The advantages of LC-NMR-MS are obvious in these reports. By capitalizing on the strengths of NMR and MS in one method, it affords rapid identification of unknown compounds in complex mixtures such as urine in a single chromatographic run. With the increasing availability of LC-NMR instruments that can be coupled to mass spectrometers, more reports of LC-NMR-MS in toxicology research are sure to appear.

Limitations

Although NMR spectroscopy is a very powerful tool for studying mechanisms of toxicology, it is subject to a number of significant limitations. Perhaps the greatest limitation of NMR is its sensitivity. As discussed earlier, even the most sensitive spectrometers require nanograms of sample for NMR analysis. Advances in magnet, flow cell, and probe design have greatly reduced the amount of sample required for NMR, but it would be unrealistic to assume that NMR will be as sensitive an analytical technique as MS in the foreseeable future. Another limitation of NMR is cost and, hence, availability. NMR spectrometers are quite expensive, and their price goes up dramatically with field strength. High-field spectrometers are not common laboratory instruments, so instrument time must be purchased from a local (or regional) NMR laboratory or acquired through collaboration. NMR spectroscopy is a specialized discipline requiring a significant amount of expertise. Operation of NMR spectrometers and interpretation of spectra are not straightforward and require a great deal of training and experience. A toxicologist lacking this training and experience would do well to establish an active collaboration with an NMR spectroscopist to carry out sophisticated NMR studies.

EPR Spectroscopy

A free radical is a chemical species that contains an unpaired electron. Extremely reactive, free radicals play a role in the mechanisms of tissue injury and toxicity of many chemicals [7,68,133]. Free radicals are often formed during xenobiotic metabolism by enzymes such as the cytochromes P450 and peroxidases. In the Haber–Weiss reaction, superoxide forms the extremely reactive hydroxide radical (HO·) in the presence of ferrous ion. The toxic effects of iron overload have been attributed to the hydroxyl radical. Free radicals are also involved in lipid peroxidation, leading to LDL oxidation and

atherosclerosis. Because free radicals are so reactive, they have short lifetimes and are present at very low concentrations in biological systems; consequently, they are usually difficult to detect. Although indirect methods such as product analysis, inhibition by antioxidants, and other radical scavengers and photolysis have been used to detect free radicals in biological systems, these methods provide little information on the nature of the radical. *Electron paramagnetic resonance* (EPR) spectroscopy, also known as *electron spin resonance* (ESR) spectroscopy, is the most versatile and information-rich method for free-radical analysis. The following sections provide a concise discussion of the theory of EPR spectroscopy, as well as several examples of its application in toxicology research. The basic phenomenon of magnetic resonance is common to both EPR and NMR; thus, the reader should be familiar with the preceding theoretical discussion of NMR spectroscopy. More detailed descriptions of the theory and instrumentation of EPR are available [3,6,153].

Basic Theory of EPR Spectroscopy

Like a proton, an electron rotates about its axis and has a magnetic moment (μ). In an applied magnetic field, B_o, this magnetic moment will precess around the axis of B_o with a characteristic precessional frequency (υ). Because the spin quantum number (*S*) of an electron is 1/2, it exists in two energy states in a magnetic field. The energy difference (*E*) between these two spin states is given by

$$E = h\nu = gB_o \frac{eh}{4\pi m_e c} \tag{41.5}$$

where

m_e is the electron mass
e is the electronic charge
c is the speed of light
h is Planck's constant

The proportionality constant (*g*), the spectroscopic splitting factor, is the ratio of the magnetic moment to the angular momentum and has a value of 2.0022319 for an unbound electron.

The exact precessional frequency of an electron in a radical and the position of its resonance signal depend on its chemical environment. In NMR spectroscopy, the position of the resonance signal is denoted by the chemical shift (δ). In EPR, resonance positions are expressed as *g* values. Tables of the *g* values of common radicals are available [59]. Because the magnetic moment of an electron is approximately 700 times greater than that of a proton, the energy difference between spin states is correspondingly higher in EPR than in NMR. Accordingly, EPR is more sensitive than NMR, and EPR spectra can be obtained from radicals present in low micromolar concentrations. The larger energy difference between radical spin states also means that EPR requires more energy than NMR spectroscopy. The frequencies used for EPR are in the microwave region of the electromagnetic spectrum. In a typical EPR spectrometer operating at a field strength of 0.34 T, the precessional frequency of an electron is approximately 9.5 GHz.

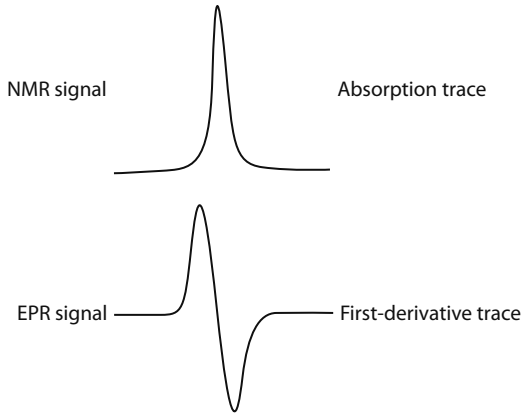

FIGURE 41.15 NMR spectrum plotted as an absorption trace and an EPR spectrum plotted as a first-derivative trace.

EPR signals are typically much broader than NMR signals. Assignment of EPR resonance positions (*g* values) is facilitated by plotting first-derivative traces. Although NMR spectra are plotted as absorption vs. frequency, EPR spectra are plotted as the rate of change of absorption vs. frequency. These two types of spectral traces are shown in Figure 41.15. Because radicals have only one unpaired electron, the EPR spectrum of a single radical species will generate only one signal. If a sample contains more than one radical species, multiple signals will appear. The total area under a peak in an EPR spectrum is proportional to the number of unpaired electrons in a sample associated with that peak. For quantification of unknown radical concentrations in a sample, direct comparison to a radical standard of known concentration is made. Common radical standards include diphenylpicrylhydrazyl (DPPH), which contains 1.53×10^{21} unpaired electrons/g.

In a radical, the unpaired electron is not associated with only one atom. The electron spin is distributed over several atoms in the radical and may interact with any spin-active nuclei with which it is associated. The interaction of electron and nuclear spins leads to spin–spin coupling called *hyperfine splitting*, similar to the coupling seen in NMR. An EPR signal will be split into $2nI + 1$ peaks, where *n* is the number of equivalent nuclei of spin *I*. The hyperfine splitting constant is denoted a_i, where *i* is the atomic symbol of the nucleus to which the electron is coupled. Hyperfine EPR splitting constants are typically measured in gauss (G) or in hertz (Hz). Figure 41.16 shows a computer-simulated spectrum of the methyl radical. The unpaired electron is coupled to three equivalent protons, so the signal appears as a quartet. The magnitude of the hyperfine splitting constant is directly proportional to the electron spin density at the coupled nucleus. It is thus related to the probability of finding the unpaired electron associated with the coupled nucleus. Hyperfine splitting constants are often applied in the interpretation EPR spectra. Tables of a_i values are available for reference [59].

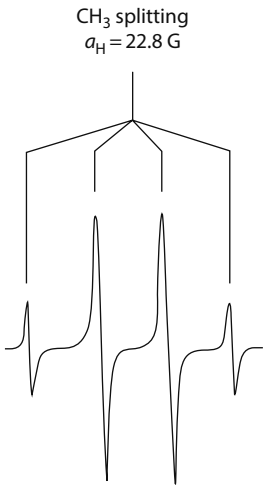

FIGURE 41.16 Computer-simulated EPR spectrum of the methyl radical showing the 22.8 G hyperfine splitting caused by coupling of the unpaired electron to the three spin 1/2 protons.

Instrument Design

EPR spectrometers contain the same basic components as NMR spectrometers: a probe, a magnet, a source of electromagnetic microwave radiation, a transmitter and receiver with amplifiers, and a data collection system. In conventional EPR, the microwave frequency is typically held constant, and the magnetic field is varied during spectral acquisition. Most conventional EPR spectrometers operate with a field strength of 0.34 T with field swept over a several hundred G range. The microwave frequency for a field strength of 0.34 T is about 9.5 GHz. FT methods and frequency pulse techniques are also employed in EPR. Multipulse 1D experiments and sophisticated 2D experiments may be performed.

Spin Trapping

Some free radicals are stable enough in solution to be directly detected by EPR; however, most free radicals of interest to the toxicologist are quite unstable, so an indirect detection method is often required. Spin trapping is the most commonly used method for indirect free-radical detection. Spin trapping entails adding a spin trap (typically a nitrone or nitroso compound) to the sample prior to radical generation. When the radical is generated, it rapidly reacts with the spin trap to produce a secondary radical or spin adduct, more stable than the parent free radical and detectable by EPR. Although the detectable species is not the parent radical, the nature of the parent radical may often be determined by comparison with model reactions between known radicals and the spin trap. Detailed descriptions of in vitro and in vivo EPR experiments are available [25,26].

Applications

Model Studies

The EPR study of appropriate model systems in aqueous solutions may yield important insights into related in vivo radical reactions and pathways. Such model systems are often used to study free-radical processes thought to play a role in radical toxicity. Compounds containing cobalt or other transition metals have been linked to free-radical generation by reaction of the metal ions with lipid hydroperoxides. An examination of the in vitro reaction of Co(II) with H_2O_2 and lipid hydroperoxides in the presence of various biological ligands and the spin trap DMPO revealed that, in the presence of sulfhydryl-containing molecules, Co(II) can react with H_2O_2 and lipid hydroperoxides to generate free radicals [176]. This observation may be important for understanding Co(II)-mediated toxicity and carcinogenicity. High-field EPR and site-directed spin labels have been used to study the structure and conformational dynamics of toxic proteins, thereby providing detailed information on transient intermediates and their relationship to biological action [130]. D-Mannitol has neuroprotectant properties and reduces sensory neurological disturbances associated with ciguatera intoxication. In vitro EPR analysis of rat neurons exposed to the toxin and several potential neuroprotectants and antioxidants revealed that toxin-induced changes in neuronal excitability could not be attributed to toxin-mediated hydroxyl radical generation alone. The authors suggest that the neuroprotectant effects of D-mannitol are more complex than simple osmotic reduction in neuronal swelling and may be due to reduced toxin association with ion channels [16].

Spin Trapping

Direct evidence for in vivo free-radical generation in response to xenobiotic exposure may be obtained with EPR spin-trapping techniques. Ozone exposure is believed to cause pulmonary damage as a result of lipid peroxidation in lung tissue. Kennedy et al. [95] employed a spin trap with EPR in ozone-exposed rats and detected a spin adduct in lipid extracts of lung tissue obtained from exposed animals. The concentration of the radical spin adduct in lung extracts correlated well with ozone exposure, suggesting both free-radical production and toxicity in ozone-exposed lungs.

Nitric oxide is an important endogenous metabolite, vasoactive substance, and neurotransmitter in many organisms. At higher concentrations, nitric oxide may have toxic effects, and its production may be induced by exposure to xenobiotics. Nitric oxide contains an unpaired electron and is a relatively stable free radical. Nitric oxide binds to Fe(II)-containing molecules such as hemoglobin and endogenous iron–sulfur proteins, thereby forming stable complexes readily detectable by EPR. EPR is useful for studying nitric oxide–Fe(II) complexes in iron-containing biomolecules generated in response to environmental toxins and disease. The administration of an endogenous spin trap has also been extensively employed for EPR studies. Kubrina et al. [98] used an Fe(II)–diethyldithiocarbamate (Fe-DETC) complex, which forms a characteristic radical spectrum with nitric oxide, to clearly demonstrate that nitric oxide originates from the guanidine nitrogens of L-arginine in vivo. ^{15}N-labeled L-arginine (L-guanidineimino-^{15}N-arginine) was administered to rats along with the Fe-DETC complex and lipopolysaccharide.

EPR analysis of the livers from sacrificed animals revealed a very characteristic doublet hyperfine splitting associated with ^{15}NO complexed with the iron. This study clearly demonstrated the application of both spin trapping and stable isotope labeling in EPR while providing the first direct evidence that L-arginine is the ultimate precursor of endogenous nitric oxide.

EPR Imaging

Sensitive and specific, EPR is readily adaptable to in vitro and in vivo imaging of free radicals in biological samples [185]. Measurements of in vivo blood oxygenation in rats [101] and in vivo imaging of kidneys [100] and tumor heterogeneity and oxygenation in mice [102] are some examples. A murine model of septic shock has been developed using EPR for in vivo monitoring of real-time nitric oxide generation secondary to intoxication with bacterial lipopolysaccharide [84]. The authors employed both surgically implanted in situ radical probes and a soluble systemic probe with EPR to monitor and localize both oxygen and nitric oxide. In vivo EPR techniques are also extensively employed in the pharmaceutical industry. Pharmacokinetic and pharmacodynamic interactions, as well as the metabolism of nitroxides and metals, have been measured noninvasively in vivo with EPR [120]. An in vivo evaluation of adriamycin nephropathy in rats [145] employed EPR with a nitroxide radical to monitor the reducing ability of renal tissues in adriamycin-exposed rats. The decay rate of the EPR signal intensity correlated with renal reducing activity and the extent of drug-induced nephropathy.

Limitations

EPR analysis in toxicology is limited by the very nature of the species under study, the free radical. Unstable free radicals are generally detected indirectly by spin-trapping techniques. The spin trap itself may have toxic effects independent of the toxic mechanisms under study. Because spin adducts are secondary radicals, it is not always possible to determine the structure of the parent radical by EPR analysis of the spin adduct. EPR is nonetheless a very important tool for studying free-radical mechanisms of toxicity and may be combined with other analytical techniques, such as stable isotope labeling. EPR remains the method of choice for detecting and monitoring free radicals both in vitro and in vivo.

UV-VIS Spectrophotometry

Principles

UV and visible (VIS) absorption spectrophotometry has been the principal methods of chemical analysis for many years. It involves the measurement of light absorption by substances in the wavelength region from 190 to 380 nm for UV absorption and from 380 to 900 nm for VIS light absorption [41,48,173,184]. Light absorption in these regions arises from electronic transitions within the molecule. The frequency of absorption depends on the energy difference between the normal or ground state of an electron and that of the excited

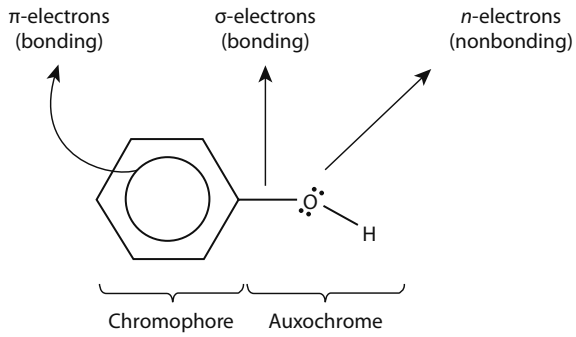

FIGURE 41.17 Some basic terminologies in UV spectrophotometry.

state (higher energy level). Absorption of UV or VIS light is also accompanied by vibrational and rotational transitions that result in relatively broad band characteristic of UV-VIS spectra.

A molecule containing electrons in σ, π, and *n* orbitals (see Figure 41.17) may absorb light energy and be promoted from the ground state to higher energy states. Antibonding orbitals (σ* and π*) exist in the excited state for the bonding electrons, and *n* electrons may be associated in the ground state with heteroatoms that do not participate in bonding yet can absorb energy and be promoted to either σ* or π* orbitals. From a practical consideration, the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions are of most utility because these transitions occur in the useful range (200–750 nm) of the UV-VIS spectrum; $\sigma \rightarrow \sigma^*$ transitions require more energy and usually occur at wavelengths of less than 200 nm. Compounds that contain nonbonding electrons on oxygen, nitrogen, sulfur, or halogen atoms can undergo $n \rightarrow \sigma^*$ transitions; however, these are of lower energy than $\sigma \rightarrow \sigma^*$ transitions. The absorption due to $n \rightarrow \sigma^*$ transitions is of limited utility because it is very weak and in most cases occurs at wavelengths too short to be easily measured on conventional instruments—for example, trimethylamine (λ, 277 nm; ε, 227) and methanol (λ, 183 nm; ε, 150). Molecules that contain oxygen, nitrogen, sulfur, or halogen atoms usually show an intense absorption, known as *end absorption*, around 200 nm due to $n \rightarrow \sigma^*$ transitions.

The energy required for the $\sigma \rightarrow \sigma^*$ transition is very high; consequently, compounds in which all valence shell electrons are involved in single-bond formation, such as saturated hydrocarbons, do not show absorption in the ordinary UV region. An exception is cyclopropane, which shows a wavelength of maximum absorption (λ_{max}) of about 190 nm (propane shows λ_{max} about 135 nm). Transitions to antibonding π* orbitals are associated with unsaturated centers in the molecule such as alkenyl, carbonyl, imino, and azo groups. These transitions are of relatively lower energy requirements and occur in the useful part of the UV spectrum—for example, C=O: ~285 nm (low intensity, $n \rightarrow \pi^*$) and 185 nm (high intensity, $\pi \rightarrow \pi^*$). The $\pi \rightarrow \pi^*$ transitions lie between $n \rightarrow \sigma^*$ and $n \rightarrow \pi^*$ transitions in terms of energy content. Figure 41.18 illustrates in a nonempirical manner the relative electronic excitation energies for the previously mentioned electronic transitions.

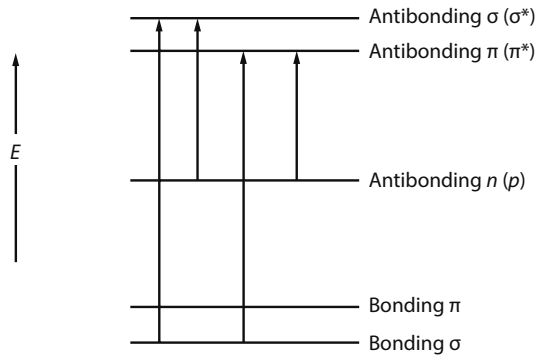

FIGURE 41.18 Summary of electronic energy transitions.

Quantitative Aspects of UV-VIS Spectrophotometry and the Beer–Lambert Law

When UV light traverses a cell containing an absorbing solute dissolved in a suitable solvent, the light intensity is diminished by reflection at the inner and outer surfaces of the cell, by light scattering by any particles in the solution, or by absorption of light by the molecules of the solute. The intensity of the light absorbed can be expressed as

$$I = I_{\text{absorbed}} - I_0 - I_T \tag{41.6}$$

where

I_0 is the original intensity incident on the cell
I_T is the reduced intensity transmitted from the cell

The transmittance (T) is the ratio I_T/I_0 and the percent transmittance ($\%T$) is given by

$$\%T = \frac{100 I_T}{I_0} \tag{41.7}$$

The *absorbance* (A) is the common logarithm of the reciprocal of T:

$$A = \log \frac{I_0}{I_T} \tag{41.8}$$

It can be shown that the intensity of a beam of parallel monochromatic radiation decreases exponentially as it passes through a medium of homogeneous thickness. Or, alternatively, the absorbance is proportional to the path length (b) of the solution. This is the basis of Lambert's law.

Beer's law states that the intensity of a beam of parallel monochromatic radiation decreases exponentially with the number of absorbing molecules, or more simply the absorbance is proportional to the concentration (c). A combination of the two laws yields the Beer–Lambert law:

$$A = \log \frac{I_0}{I_T} = abc \tag{41.9}$$

The proportionality constant (a) is the absorptivity. The name and value of a depend on the units of concentration. When c is in mol/L, the constant is called *molar absorptivity* or the *molar extinction coefficient* (ε). Thus,

$$A = \varepsilon bc \tag{41.10}$$

The molar absorptivity at a specified wavelength of a compound in solution is the absorbance at that wavelength of a 1 mol/L solution in a 1 cm cell. The units of ε are therefore L/mol/cm. Expressing the absorptivity in terms of a 1 mol/L solution facilitates the comparison of the light-absorbing abilities of compounds with widely differing molecular weights. Substances that have ε values less than 100 are weakly absorbing; those with ε values above 10,000 are intensely absorbing. Many absorbing xenobiotics and drugs have ε values at their wavelengths of maximum absorption of $10^{3.5}$–$10^{4.5}$.

Another form of the Beer–Lambert proportionality constant is the *specific absorbance*, which is the absorbance of a specified concentration in a cell of specified path length. The most common form is the A (1%, 1 cm) value, which is the absorbance of a 1 g/100 mL (1% w/v) solution in a 1 cm cell. The Beer–Lambert equation therefore takes the following form:

$$A = A_{1\text{ cm}}^{1\%} bc \tag{41.11}$$

where

c is in g/100 mL
b is in cm

Whenever an analyte is involved in an equilibrium, such as protonation or deprotonation, tautomerism, dimerization, or complex formation, the material added to the solution will be distributed among several forms, and the apparent concentration (amount of material dissolved/volume) will not be proportional to the actual concentration of the parent substance. A deviation for Beer's law will be observed under these circumstances unless the absorptivity is identical for all the species present or the equilibrium is controlled in some manner. If only two species are present and their spectra are not too different, useful measurements following Beer's law can be made by measuring at the isosbestic point rather than at λ_{max}. The isosbestic point is the wavelength at which the UV spectra of the two species cross when measured at equal molarities or, equivalently, the wavelength at which their molar absorptivities are equal. Deviations arising from acid–base equilibria can be avoided by carefully buffering the solutions because the ratio of protonated to deprotonated analyte will be constant at constant pH. A variety of other equilibria can be controlled in a similar manner.

Absorption spectra of compounds with conjugated chromophores or aromatic moieties in their structure show maxima shifts to longer wavelengths (bathochromic shifts) when compared to the wavelength of individual chromophores. This is due to increased stability of the π-electron system, which requires less energy for the $\pi \rightarrow \pi^*$ transition. This bathochromic shift is usually accompanied by an increase in intensity of the absorption (a hyperchromic shift).

Instrument Design

Single-Beam Spectrophotometers

The arrangement of the components in a commercially available, single-beam, UV-VIS spectrophotometer is shown in Figure 41.19. The essential characteristic is that the light travels in a single continuous optical path between the light source and the detector. Single-beam instruments are relatively inexpensive and are satisfactory when many samples are being assayed by a simple measurement of absorbance at the same wavelength. A major disadvantage is the need to reset the 100% transmission value at each wavelength to compensate for the large variation of intensity of light from the lamp at each wavelength.

Double-Beam Spectrophotometers

In this type of instrument (Figure 41.20), the monochromatic light is split by a rapidly rotating beam chopper into two beams that are alternately directed in rapid succession through a cell containing the sample and one containing only solvent. If there is greater absorption of light in the sample cell than in the reference cell, the recombination of the beams at the detector produces a pulsating current that is converted

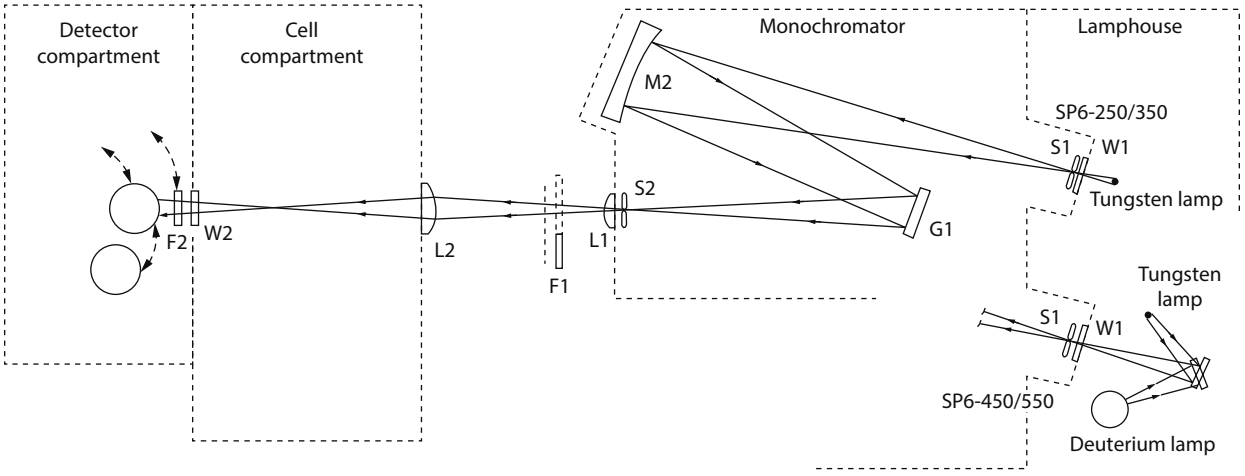

FIGURE 41.19 Optical diagram of a single-beam UV spectrophotometer; abbreviations: F = filter, G = grating, L = lens, M = mirror, S = slit, and W = window. (Courtesy of Pye Unicam, Ltd.)

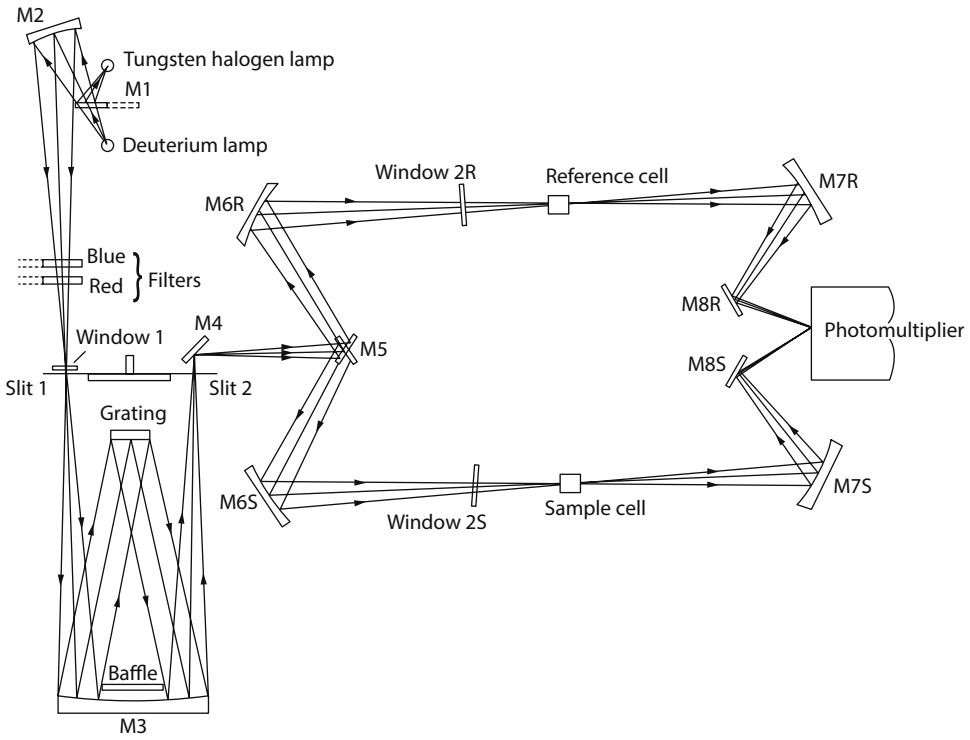

FIGURE 41.20 Optical diagram of a double-beam UV-VIS spectrophotometer. (Courtesy of Pye Unicam, Ltd.)

into two dc voltages proportional to the light intensities I_0 and I_T transmitted by the reference solution and the sample solution, respectively. The ratio of voltages is recorded as a transmission. Double-beam optics, therefore, automatically compensate for variation of I_0 with wavelength. Recording spectrophotometers are double-beam instruments equipped with a wavelength scanning device that enables rapid automatic scanning of spectra.

Solvents and Sample Conditions

Solvents

The solvent of choice in UV-VIS spectrophotometry is determined by several factors, including the solubility of the analyte and the absorption of the solvent at the wavelength employed for analysis. The solvent should be available in a purity grade suitable for carrying out spectrophotometric work, devoid of contaminants that are either fluorescent or absorb at the analytical wavelength. Moisture-sensitive compounds require nonhygroscopic solvents that are easily dried. Recovery of the analyte after analysis requires the use of more volatile solvents.

It is important to note that the analyte may be sensitive to pH changes; for example, acid–base equilibria, tautomerism, complex formation, and other equilibria are often pH dependent. In such systems, then, a strongly acidic or basic solvent may be indicated to ensure that the analyte is present in solution as a single species. Nonabsorbing buffers may also be used in UV analysis for this purpose.

The exact wavelength of a particular electronic transition depends not only on the chromophore but also on the solvent, on substituents present on the chromophore, and on chromophore geometry. The solvent effect arises because solvation alters the electronic energy levels of a chromophore, and the degree of solvation is frequently different for the ground and excited states. If the ground state is solvated more strongly than the excited state, the energy difference between the levels is increased. The increase in energy difference is reflected in a shift of the absorbance to shorter wavelengths (hypsochromic or blue shift) than those observed in the gas phase where there is no solvation. If the excited state is solvated more strongly, the energy difference decreases and absorbance is shifted to a longer wavelength (bathochromic or red shift). Absorption due to $n \rightarrow \sigma^*$ and $n \rightarrow \pi^*$ transitions is usually shifted to shorter wavelengths in more polar solvents.

If a group is more polar in the ground state than in the excited state, the nonbonding electrons in the ground state are stabilized (relative to the excited state) by hydrogen bonding and other electrostatic interactions with a polar solvent. The absorption is shifted to shorter wavelengths (higher energy) with increasing solvent polarity. Conversely, if the group is more polar in the excited state, the nonbonding electrons of the excited state are stabilized (relative to the ground state) by interaction with a polar solvent, and the absorption is shifted to longer wavelengths (lower energy) with increasing solvent polarity. Thus, polar solvents generally shift the $n \rightarrow \pi^*$ and $n \rightarrow \sigma^*$ bands to shorter wavelength and the $\pi \rightarrow \pi^*$ band to longer wavelength.

Cells

UV-VIS cells (also called *cuvettes*) may be made of glass (for use down to about 360 nm) or silica. Disposable plastic cells are also available. They usually have a transmission cutoff at about 320 nm and may not be suitable for high-precision work. Modern cells are fused and may be square, rectangular, or (rarely) cylindrical in section. Silica is substantially transparent between about 190 and 1000 nm, and special grades extend this range downward to below 180 nm and upward to about 2000 nm. For precision work and operation near the wavelength limits, the use of these purer silicas is recommended.

Path Length and Concentration

Optimum accuracy and precision in UV spectrophotometric analyses are obtained when the absorbance is about 0.9; however, in practice, absorbencies in the range of 0.3–1.5 are sufficiently reliable, and the combination of cell path length and concentration of analyte should be adjusted to give an absorbance within this range.

Correlation of Molecular Structure to UV-VIS Absorption

An isolated functional group not in conjugation with any other group is said to be a *chromophore* if it exhibits absorption of a characteristic nature in the UV or VIS region. If a series of compounds has the same functional group and no complicating factors are present, all of the compounds will generally absorb at nearly the same wavelength and will have nearly the same molar extinction coefficient. Thus, the spectrum of a compound, when compared to published spectra for known compounds, can be a valuable aid in determining the functional groups present in the molecule.

Auxochromes are groups that do not in themselves show selective absorption above 200 nm but that, when attached to a given chromophoric system, usually cause a shift in the absorption to longer wavelength and an increased intensity of the absorption peak. Common auxochromic groups are hydroxyl, amino, sulfhydryl (and their derivatives), and some of the halogens. These groups all contain nonbonding electrons; transitions involving these *n* electrons are responsible for these effects; for example, the absorption band at the longest wavelength of *trans*-pethoxyazobenzene is shifted 65 nm to longer wavelengths and is about twice as intense as that of the corresponding band of *trans*-azobenzene. Benzene shows λ_{max} 255 nm and ε 230, and aniline shows λ_{max} 280 nm and ε 1430. (Interestingly, the anilinium ion, which has no nonbonding electrons, shows λ_{max} 254 nm and ε 160.) Some functional groups that do not contain nonbonding electrons, such as alkyl groups, can also be considered as auxochromes due to weak inductive or hyperconjugative effects.

If two or more chromophoric groups are present in a molecule and they are separated by two or more single bonds, the effect on the spectrum is usually additive, as there is little electronic interaction between isolated chromophoric groups. However, if two chromophoric groups are separated by only one single bond (a conjugated system), a large effect on the

spectrum results because the π-electron system is spread over at least four atomic centers. When two chromophoric groups are conjugated, the high-intensity ($\pi \rightarrow \pi^*$ transitions) absorption band is generally shifted 15–45 nm to a longer wavelength as compared to the unconjugated chromophore.

Many colorimetric analyses developed for UV-absorbing drugs, xenobiotics, and metabolites have been based on the formation of an analyte-specific, multiple conjugated chromophoric system that readily absorbs in the visible range of the spectrum. This helps to avoid interfering UV absorption from impurities in the sample observed when the underivatized analyte is analyzed.

Compounds containing an extensively conjugated chromophore will appear colored to the eye if they absorb above 400 nm. As UV absorption peaks are frequently broad, the absorption of a peak with a λ_{max} of approximately 350 nm will generally extend into the VIS region. Usually, if a compound appears to be colored, it will contain not less than four and usually five or more conjugated chromophoric and auxochromic groups.

Substitution of aromatic chromophores with auxochromic groups is worthy of mention. When benzene is substituted by halogen or alkyl groups, only a slight shift with a small increase in extinction coefficient is seen; however, substitution by groups carrying nonbonding electrons or π-electrons (e.g., –OH, $–NH_2$, –CHO) causes a pronounced wavelength shift and a greatly intensified absorption relative to benzene.

In aromatic and conjugated structures where an auxochromic group may function as an acid or base, the effect of pH on the absorption spectrum of the conjugated system can be qualitatively useful; for example, the conversion of phenol (PhOH) to the phenolate ion (PhO^-) by addition of base results in an additional electron pair and a formal negative charge being located on the auxochromic group. The interaction of these electrons with the conjugated system results in a bathochromic–hyperchromic shift when compared to the neutral phenol spectrum. Adjusting the pH of the solution reverses this process, such that the phenol is regenerated. The conversion of aniline ($PhNH_2$) to the anilinium ion ($PhNH_3^+$) by lowering the pH of the medium results in a hypsochromic–hypochromic shift that is reversible by increasing the pH of the medium.

In polyaromatic compounds, as the number of fused rings increases, the absorption band is shifted to longer wavelengths. Extensively conjugated polyaromatics, such as naphthacene (λ_{max}, 480 nm; ε, 11,000—yellow) and pentacene (λ_{max}, 580 nm; ε, 12,000—blue), absorb in the VIS region of the spectrum. The spectra of simple heterocyclic aromatic compounds such as pyridine, pyrrole, indole, furan, thiophene, and their derivatives generally resemble the spectra of analogous benzenoid or naphthalenoid structures.

UV Spectrophotometry: Direct and Indirect Methods

When carrying out a quantitative spectrophotometric assay, the analyte is dissolved in a solvent that is transparent in the wavelength region to be examined. The wavelength normally selected is that at which the analyte exhibits maximum absorption (λ_{max}). The usual procedure is to obtain the absorbance value of the solution under nonscanning conditions (i.e., with the monochromator set at the analytical wavelength). Alternatively, if a recording double-beam spectrophotometer is used, the absorbance may be read from a recording of the spectrum. This latter procedure is generally utilized for qualitative purposes and in assays in which absorbances at more than one wavelength are required.

The measurement of absorbance is generally carried out using one of three methods:

1. Comparison with a standard absorptivity value
2. Use of a calibration curve
3. Single- or double-point standardization

Use of a standard absorptivity value is generally restricted to compounds that exhibit broad absorption bands and are not significantly affected by variation in instrumental parameters. An available value obviates the need to prepare a standard solution for absorptivity determination if the reference analyte is difficult to obtain.

The use of a calibration curve is a common procedure for carrying out quantitative spectrophotometric assays. The absorption of four or more standard solutions of the reference compound at concentrations above and below the expected concentration of the analyte is determined. A concentration vs. absorbance graph is then constructed. The concentration of the analyte in the sample solution is then read from the graph as the concentration corresponding to the absorbance of the solution. Calibration data are essential if the absorbance has a nonlinear relationship with concentration, if it is necessary to confirm the proportionality of absorbance as a function of concentration, or if the absorbance or linearity is dependent on the assay conditions. In certain VIS spectrophotometric assays of colorless substances, performed by converting the analyte to a colored derivative by heating it with one or more reagents, slight variation of assay conditions, such as pH, temperature, and time of heating, may cause a significant variation in absorbance. Here, experimentally derived calibration data are required for each set of samples.

Single- or double-point standardization is often used in place of a calibration curve. In the single-point procedure, the absorbance of a solution of the sample and that of a standard solution of the reference substance (the concentration should be close to that of the sample solution) are determined. The concentration of the test compound is calculated as follows:

$$C_{test} = \frac{A_{test} \times C_{std}}{A_{std}} \tag{41.12}$$

where

C_{test} and C_{std} are concentrations in the sample and standard solutions, respectively

A_{test} and A_{std} are the absorbances of the sample and standard solutions, respectively

This method is best suited for those compounds that obey Beer's law and for which a reference standard of acceptable purity is readily available.

Occasionally, a linear but nonproportional relationship between concentration and absorbance occurs, which is indicated by a significant positive or negative intercept in a Beer's law plot. A two-point bracketing standardization is therefore required to determine the concentration of the sample solutions. The concentration of one of the standard solutions is greater than that of the sample, while the other standard solution has a lower concentration than the sample. The concentration of the substance in the sample solution is given by the following equation:

$$C_{\text{test}} = \frac{(A_{\text{test}} \quad A_{\text{std}_1})(C_{\text{std}_1} \quad C_{\text{std}_2}) + C_{\text{std}_1}(A_{\text{std}_1} \quad A_{\text{std}_2})}{A_{\text{std}_1} \quad A_{\text{std}_2}} \qquad (41.13)$$

where std_1 and std_2 refer to the more concentrated standard and the less concentrated standard, respectively.

Direct spectrophotometric analysis of a xenobiotic or metabolite may not be possible for several reasons. The natural absorption of the analyte may occur at too low a wavelength to be useful, the molar absorptivity may be too small to give the required sensitivity, or other materials contaminating the analyte may absorb at the same wavelength. These problems can be overcome in many cases by chemical modification of the analyte to change its absorption characteristics. Some examples of useful derivatization procedures for spectrophotometric utility include (1) diazotization and coupling of primary aromatic amines, (2) condensation reactions (e.g., between amines or hydrazines and carbonyl compounds), (3) reduction of tetrazolium salts in the presence of an α-ketol group (–CHOH–C=O), (4) ion pairing of amines with ionized acidic dyes, (5) oxidation of the side chains of weakly absorbing compounds containing an aromatic ring, and (6) metal–ligand complexation. It is also possible to measure a substance by the change in absorbance when a chromophore is destroyed.

Difference Spectrophotometry

This method of spectrophotometric analysis is useful for obtaining selective and accurate analytical data on solutions of analytes containing absorbing interferants. Basically, the technique measures a difference absorbance (ΔA) between two equimolar solutions of the analyte in different chemical forms that exhibit different spectral characteristics. The method is valid provided that *reproducible* changes are induced in the spectrum of the analyte by the addition of one or more reagents and that the absorbance of the interfering substance is not altered by the reagents.

The simplest and most commonly employed technique for altering the spectral properties of the analyte is the adjustment of the pH by means of aqueous solutions of acid, alkali, or buffers. The UV-VIS absorption spectra of many substances containing ionizable functional groups, including phenols, aromatic carboxylic acids, and amines, are dependent on the state of ionization of the functional groups and consequently on the pH of the solution.

The pHs chosen must quantitatively form single species with at least 99% spectral purity. This can be achieved with monofunctional analytes (e.g., aromatic amines or aromatic carboxylic acids and phenols) by simply working at a pH at least 2 pK_a units above the pK_a of the analyte. The difference spectrum is obtained by placing one form of the analyte in the sample cell of the spectrophotometer and the other form in the reference cell and plotting the observed absorbance against wavelength. The value of difference spectrophotometry is that it provides a reference solution that contains both analyte and interfering substances in the same concentrations but at a pH different from that of the analyte solution in the sample cell. Interferants present in the sample should not be affected by the pH changes, and their contribution to the total absorbance is therefore cancelled.

The absorption spectra of the drug benzthiazide are shown in Figure 41.21 in both acidic and basic media [54]. The difference absorption spectrum is plotted as the difference in absorbance between the basic solution and the acidic solution against pH. The spectrum may be generated automatically using a double-beam recording spectrophotometer with the basic solution in the sample cell and the acidic solution in the reference cell. At 255 and 287 nm, both solutions have identical absorbance and consequently exhibit zero difference absorbance. Such wavelengths of equal absorptivity are the isosbestic or isoabsorptive points. Above 287 nm, the basic solution absorbs more intensely than the acidic solution and the ΔA is positive. Between 255 and 287 nm, ΔA has a negative value. A maximum in the difference spectrum occurs at

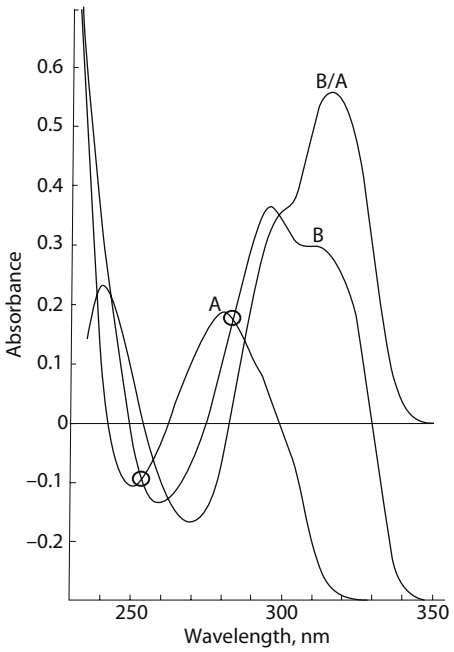

FIGURE 41.21 Conventional and difference spectra of benzthiazide (15 g/mL) in acidic solution (A) and basic solution (B) and the difference spectrum of basic vs. acidic solutions (B/A). (Courtesy of American Pharmaceutical Association.)

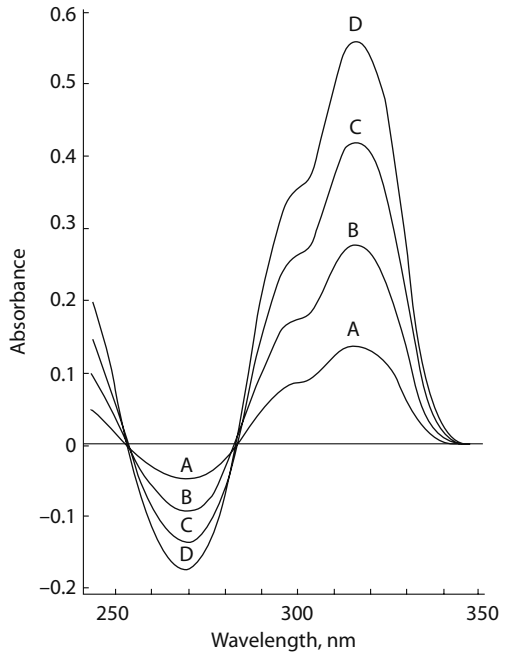

FIGURE 41.22 Difference spectra used to verify Beer's law for benzthiazide. Plots are basic vs. acid difference spectra for concentrations of 5 (A), 10 (B), 15 (C), and 20 g/mL (D). (Courtesy of American Pharmaceutical Association.)

313 nm and a minimum at 271 nm. The absorbance difference at these two wavelengths is termed the *amplitude*. A plot of absorbance differences vs. drug concentration will obey Beer's law and can be used for quantitative determinations. The isosbestic points are useful indicators of whether the absorbance of interferants in the sample is affecting the measurement of the absorbance of the drug. Figure 41.22 shows the isosbestic points for benzthiazide generated from several concentrations of the analyte. Any sample containing the drug or any standard curve concentration should show zero absorbance at the isosbestic wavelengths unless an interfering compound is present. If this is not observed, an alternative assay procedure or removal of the interferant is indicated.

Difference spectrophotometry is useful in the analysis of macromolecules such as proteins, peptides, and nucleic acids, as conformational effects are likely to be accompanied by changes in the environment of aromatic residues, which will in turn lead to small wavelength shifts as well as other perturbations. A difference spectrum in a protein may be generated by unfolding or by proteolytic degradation, as well as by more localized changes engendered by conformational adjustments or subunit association or dissociation, or, in favorable cases, the binding of a ligand, as well as a change in bulk solvent. The latter effect can be achieved simply by adding a benign perturbant, such as glycerol, sucrose, or D_2O, or by a change of temperature below the region of denaturation. Such a change in solvent character will in general affect only those aromatic residues in contact with solvent and therefore provides a means of determining, at least in a semiquantitative way, what proportion of aromatic residues are so exposed and following any change in this degree of exposure.

Special Considerations in the Spectrophotometric Determination of Xenobiotics and their Metabolites in Biological Matrices

The determination of xenobiotics and their metabolites in biological matrices, such as blood, tissues, or urine, is a more challenging procedure than the simple quantitation of aqueous solutions of analytes. Often, only a very small quantity of the xenobiotic or metabolite is present in a large volume of blood, urine, or tissue. Accordingly, solvent extraction of the analyte may be required. This nonspecific extraction may produce an extract that contains, in addition to the xenobiotic, endogenous compounds such as pigments and proteins that may render optical methods of analysis subject to additional error. Care should be taken in developing the analytical methodology, including choice of solvent, the pH of extraction, and the purification procedure. Solvent extractions for the quantitative recovery of the analyte may be further complicated by emulsification induced by surface-active components, as well as managing large volumes of solvent for evaporation. These problems may be ameliorated by utilizing a large solvent-to-sample ratio and by carrying out control analyses with biological matrices spiked with the analyte. Extraction procedures must account for xenobiotics that may be present both free and as polar, water-soluble conjugates such as glucuronide or sulfate. Another complicating factor for many drug molecules is protein binding. This can lead to poor recoveries of the drug, thereby necessitating the inclusion of a protein denaturation step in the overall extraction procedure.

Direct spectrophotometric procedures, even after purification of the sample by solvent extraction or chromatographic cleanup, often lack the sensitivity and selectivity required for the assay of low concentrations of drugs that are found in body fluids after the administration of therapeutic doses. Modified spectrophotometric techniques, however, such as those involving chemical derivatization or difference spectrophotometry, are sufficiently discriminating and sensitive for the assay of many drugs and other xenobiotics.

Flow-Through UV Detection

Many of these difficulties associated with the spectrophotometric determination of xenobiotics and metabolites in biological matrices can be overcome by using a tandem separation method with flow-through UV detection. CE, affinity columns, size-exclusion chromatography, and HPLC are routinely employed in flow-through UV detection systems. Indeed, because many xenobiotics exhibit characteristic UV spectra, the most common HPLC detector for toxicological applications is a UV spectrophotometer. UV detectors may be fixed-wavelength spectrophotometers operating at a single predetermined wavelength, variable-wavelength spectrophotometers that can be tuned to the λ_{max} of the analyte of interest, or scanning spectrophotometers that can collect spectra over the entire UV-VIS range. In all cases, the eluent from an HPLC column passes through a small flow cell placed between the light source and the photodetector. Flow-cell volume is typically on the order of 1–10 μL, so chromatographic resolution is not lost due to a large dead space. The

output of a UV detector is a chromatogram that plots change in absorbance vs. time. Perhaps the most significant development in the design of flow-through UV detectors is the rapid scanning multiwavelength photodiode array detector. This detector permits collection of spectra over the entire UV-VIS range during a chromatographic run. The data may be plotted as typical chromatograms at a wavelength of choice; absorption spectra of eluted peaks; or as 3D projects of absorbance, wavelength, and time. The use of HPLC with photodiode array detection has greatly facilitated the identification of xenobiotics and metabolites in biological samples.

Applications

Changes in the production of glycolytic metabolites may be useful biomarkers for monitoring pathophysiology, toxic injury, and clinical therapeutics. A metabolomic analysis of glycolysis cycle metabolites in human erythrocytes was developed using a tandem CE-UV analytical method [123]. The nine components of the glycolytic metabolome of 22 volunteers were readily and reproducibly assayed in micromolar quantities with minimal error. Temporal changes in the microbial metabolome may also be monitored using tandem UV methods. Over 400 fungal metabolites, including important mycotoxins, have been analyzed and identified in culture using chromatographic UV-MS systems [140].

Martin et al. [125] developed an in vivo VIS spectrophotometric assay to simultaneously monitor the nitric oxide, hemoglobin, and deoxyhemoglobin contents in discrete areas of the rat brain. The overlapping absorption of spectra of these oxidized hemoglobin chromophores has complicated their analytical resolution in biological matrices. Here, the combination of VIS spectroscopy with least-squares mathematical analysis allowed the researchers to study the interaction of the important biomolecule and potential toxin, nitric oxide, with hemoglobin status in brain tissue.

Tandem HPLC-phased diode array analysis has simplified the rapid detection and identification of drugs, toxins, and their metabolites in a variety of systems. This may be particularly useful for the clinical toxicologist [155]. When integrated with a database of known retention parameters and UV spectra, tandem HPLC-phased diode array analysis may be one of the most effective techniques for the rapid, systematic toxicological analysis of biological samples.

UV spectroscopy is often combined with other detection methods for specialized toxicological analyses. Domoic acid is a potent neurotoxin that causes amnesic shellfish poisoning in humans who have ingested contaminated shellfish. The presence of domoic acid in bivalve mollusks was determined for the first time in commercial shellfish harvested in Ireland using an LC-photodiode array UV-MS system [87]. Another application of tandem UV analysis in the area of food toxicology was conducted using size-exclusion chromatography with UV-MS detection for the determination of toxic metals in edible mushrooms [223]. The association of silver, arsenic, cadmium, mercury, lead, and tin with the high- and low-molecular-weight fractions of edible mushroom components was strongly influenced by mushroom species and growth medium composition.

IR Spectroscopy

Basic Technique

IR spectroscopy [146] deals with the absorption of electromagnetic radiation in the wavelength range from 0.8 μm (800 nm) to 1000 μm (1 mm). This range can be subdivided into the near-IR region (0.8–2 μm), the middle or fundamental IR region (2–15 μm), and the far-IR region (15–1000 μm). The fundamental IR region is the one that provides the greatest amount of information for the elucidation of molecular structure. Most IR spectrophotometers are designed to carry out measurements in this wavelength range.

When a molecule absorbs IR radiation, changes in the vibrational energy in the ground state of the molecule occur. All but the simplest of molecules have a large number of accessible vibrational and rotational energy levels with a correspondingly large number of allowed transitions. The energies of these transitions are strongly influenced by molecular structure; thus, IR spectra are highly structured, with unique features that are ideally suited for the identification of xenobiotics, drugs, and other organic substances. A typical IR spectrum of the antibacterial drug sulfacetamide is illustrated in Figure 41.23.

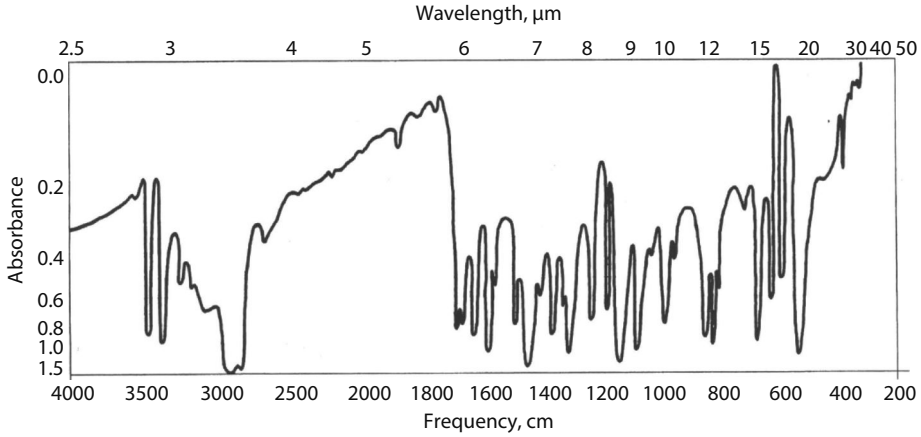

FIGURE 41.23 IR spectrum of sulfacetamide.

For energy to be transferred from the IR source to the molecule, the frequency of vibration of both must coincide, and energy transfer must be accompanied by a change in the dipole moment of the molecule. Molecules that contain certain symmetry elements will display more simplified spectra; for example, the C=C stretching vibration of ethylene and the symmetrical C–H stretching of the four C–H bonds of methane do not produce an absorption band in the IR region. For nonlinear polyatomic molecules, the number of fundamental modes of vibration is $3n - 6$ ($3n - 5$ for linear molecules), where n is the number of atoms. Certain groups within a molecule, such as –OH, –C=O, $–NH_2$, –CN, and –CC–, have characteristic absorption frequencies known as *group frequencies*. These frequencies are generally independent of the structure of the rest of the molecule and can therefore be used diagnostically to confirm the presence of the functionality in a molecule of unknown structure.

In practice, it is usually not possible to observe the calculated number of peaks in the spectrum of a known compound. This may be due to the superimposition or coalescing of absorptions that are too close to be resolved. A fundamental band may be too weak to be observed. Alternatively, additional (nonfundamental) bands may be observed that are either overtones and harmonics that occur with greatly reduced intensity or combination and difference bands.

Molecules have two types of fundamental vibrations. Stretching occurs when the distance between two atoms increases or decreases but the atoms remain in the same bond axis. Polyatomic molecules may produce in-phase (symmetric) or out-of-phase (asymmetric) stretching vibrations (see Figure 41.24). Bending (or deformation) occurs when the position of the atom changes relative to the original bond axis.

The stretching frequency (ν) of a bond is related to the masses of the two atoms involved (M_a and M_b, in g), the velocity of light (c), and the force constant of the bond (k, in dynes/cm). An approximate value for the stretching frequency can be calculated from the following equation:

$$\nu\,(\text{in cm}^{-1}) = \frac{1}{2\pi c}\sqrt{\frac{k}{M_a M_b/(M_a + M_b)}} \qquad (41.14)$$

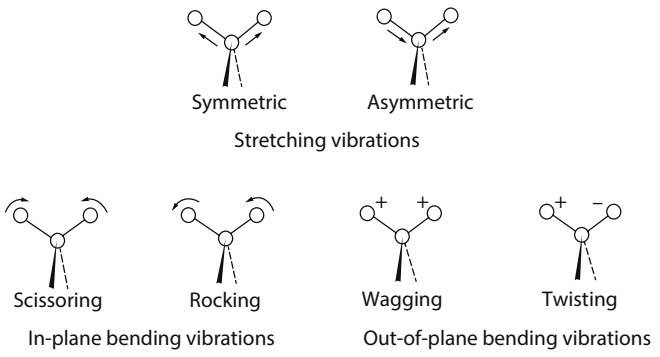

FIGURE 41.24 IR vibration modes of groups of atoms (+ and – refer to vibrations above and below the plane of the paper, respectively).

Note that the force constants for sp^3, sp^2, and sp bonds have values of 5, 10, and 15 $\times 10^5$ dynes/cm, respectively.

IR spectra are usually recorded as plots of sample absorbance (or percent transmittance) vs. wavelength or frequency in reciprocal cm (wave numbers). The relationship between wavelength and wave number is

$$\text{Wavenumber}\,(\text{cm}^{-1}) = \frac{1\times 10^4}{\lambda\,(\mu\text{m})} \qquad (41.15)$$

Unlike UV-VIS spectra, IR spectra are by convention plotted with zero absorbance (or 100% transmittance) at the top of the spectrum—that is, in an inverted mode relative to UV-VIS spectra.

Qualitative Uses and Interpretation of Spectra

The complexity in the IR spectra of organic molecules is a valuable tool that can be used for the unambiguous identification of unknown compounds if an authentic standard is available. If all the bands in the IR spectrum of the unknown structure are identical in all respects (i.e., in their wave number value and their relative intensity) when compared with an IR spectrum of an authentic standard, then the two compounds are identical. The region 1430 to 910 cm^{-1} contains many absorptions caused by bending vibrations as well as absorptions caused by C–C, C–O, and C–N stretching vibrations. As a molecule has many more bending vibrations than stretching vibrations, this region of the IR spectrum is particularly rich in absorption bands and shoulders and has been termed the *fingerprint region*. Although similar molecules may show very similar spectra in the region 4000 to 1430 cm^{-1}, there will nearly always be discernible differences in the fingerprint region. Spectral comparisons are best carried out in the solution state. Compounds can often be prepared in different polymorphic forms, both crystalline and amorphous, depending on the conditions of crystallization. Polymorphic forms of the same compound may show significant differences in the fingerprint region of the spectrum; therefore, if spectral comparisons are to be made in the solid state, then both the unknown and an authentic standard should be recrystallized from a specific solvent in the same manner.

A second important use of qualitative IR spectroscopy is that it gives structural information about an unknown molecule. The previously mentioned group frequencies, together with frequencies of other characteristic bands, can be utilized in the form of comprehensive frequency correlation charts that have been compiled for easy reference [59]. This type of compilation is invaluable as a means of confirming the presence or absence of a particular functionality in an unknown structure. In this respect, the region between 4000 and 1500 cm^{-1} is probably easier to interpret than that between 1500 and 650 cm^{-1}, as the latter includes many skeletal vibrations, typical of molecules as a whole, which are not diagnostic.

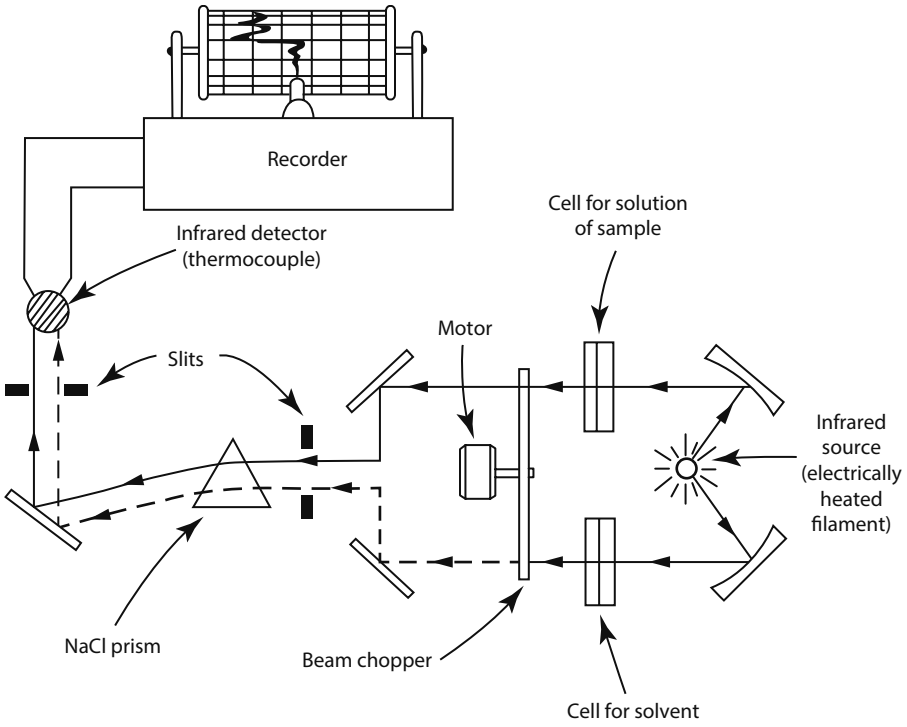

FIGURE 41.25 Schematic representation of a double-beam recording IR spectrophotometer.

Instrument Considerations

Dispersive IR Spectrophotometers

The arrangement of a typical double-beam recording IR spectrophotometer is shown in Figure 41.25. The beam chopper, which is a rotating mirror, permits radiation passing alternately through sample cell and solvent cell to reach the IR detector. The difference in absorption by solute and solvent is measured as an alternating electric current from the thermocouple. The system operates on the optical null principle with the recorder pen linked mechanically to a "comb" (not shown), which is placed across the solvent cell beam and moved by a servomechanism to reduce or increase the solvent cell-beam intensity. The servomechanism is actuated by the amplified thermocouple output to make the solvent beam intensity equal to the solution beam intensity, which reduces the detector output to zero or the null point. The spectrum can be scanned through the various wavelengths by rotation of the prism in synchronization with the motion of the recorder drum or chart. Most modern instruments now utilize a diffraction grating in place of the prism. Sodium chloride prisms can be used for the entire region from 4000 to 650 cm^{-1} but suffer from the disadvantage of low resolution at 4000 to 2500 cm^{-1}. The use of a grating monochromator provides a better overall resolution throughout the range 4000 to 625 cm^{-1}.

Fourier Transform IR Spectrometers

FTIR spectrometers are widely used in chemical analysis [2,64]. The FTIR spectrometer is built around an interferometer rather than a monochromator (see Figure 41.26). The beam from the light source passes through the chopper and is collimated and directed to the beam splitter via mirror C. The beam splitter is a half-silvered mirror that reflects 50% of the incident light onto movable mirror F and allows 50% to pass through fixed mirror E. The beams reflected from

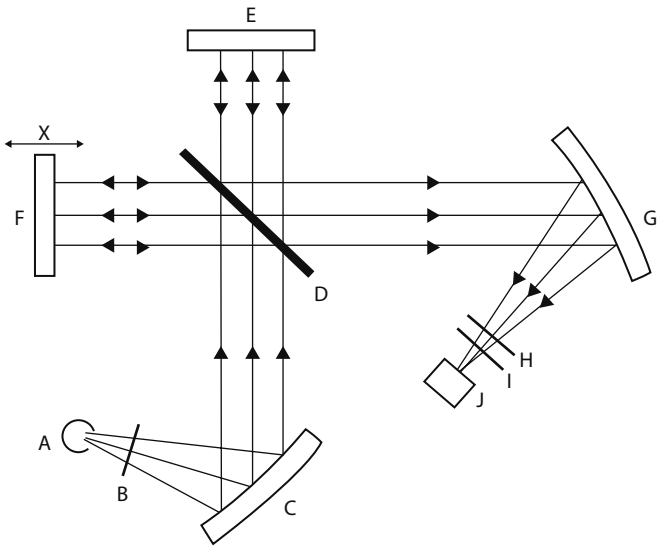

FIGURE 41.26 Layout of the optics of an FTIR spectrometer.

mirrors F and E are then combined at the beam splitter, so an interference pattern results, and this is focused by mirror G onto detector J. The sample to be analyzed is located in the combined beams between spectral filter H and the detector.

The interferogram of the source is obtained by driving the moveable mirror over a fixed distance and determining the interference pattern as a function of path length difference traveled by the light beams in the two arms of the interferometer. Each frequency of light that passes through the interferometer produces its own interference pattern. Because all of the frequencies generated are observed all at once by the detector, the spectrum is said to be multiplexed, and no grating is required to disperse the radiation. The increased energy reaching the detector allows the relatively rapid accumulation of data, so repetitive scans can be carried out.

Extensive data analysis must be undertaken to extract the frequency information from the interferogram. The principle computation required is Fourier transformation of the interferogram. Because data that have been transformed to the frequency domain are available in digital form, manipulations such as substitution of solvent background and smoothing are simplified.

FTIR analysis offers considerable advantages over conventional prism or grating instruments. The S/N under the conditions of the FT experiment is increased from the conventional apparatus by $N^{1/2}$, where N is the number of resolution elements in the spectrum; thus, for a 1000 cm^{-1} scan with 2 cm^{-1} resolution, the S/N advantage is $(1000/2)^{1/2}$ or about 22. These high S/N values permit the accurate subtraction of backgrounds due to liquid H_2O. Accordingly, one principle application of FTIR spectrometry is in the acquisition of protein spectra in aqueous media. In terms of sample preparation and analysis time, FTIR is considered to be a truly high-throughput analytical technique.

Quantification of IR Bands

Quantitative analysis of compounds by IR spectrophotometry utilizes the same basic principles involved in UV-VIS spectrophotometry; however, the complexity of the spectra obtained allows the selection of several bands for quantitative work. Generally, the selection of a fairly strong band for each component in a mixture is made, so no interference occurs between components. The areas of absorption bands are typically integrated; however, with sharp IR bands, peak heights may also be used for quantitative calculations. A calibration curve of absorbance vs. concentration can then be constructed. If Beer's law is obeyed, a direct comparison of the sample absorbance with that of a standard can be made.

In IR studies, very short path lengths (0.025–0.1 mm) are used, and solution concentrations of analytes are often in the 10% region. All solvents absorb in some part of the IR spectrum. Given this high concentration of solute, the accurate cancellation of solvent absorption is difficult to achieve. For this reason, the baseline technique is usually applied (see Figure 41.27). This technique assumes that absorption due to solvent (or a second component) is constant or varies linearly with wavelength over the region of the absorption band. The determination of small amounts of impurities or low amounts of solutes in a preparation can also be improved by introducing the major component, or the solvent, into the reference beam of the spectrophotometer, thereby compensating for the absorption of this component.

Due to the higher concentrations of samples required for IR analysis, deviations from Beer's law are encountered much more frequently in IR spectrophotometry than in UV-VIS spectrophotometry; thus, significant intermolecular hydrogen-bonding effects may be observed that increase as the concentration of the solute increases. Notably, the absorbance at the λ_{max} of a free OH group actually decreases with increasing concentration of the analyte.

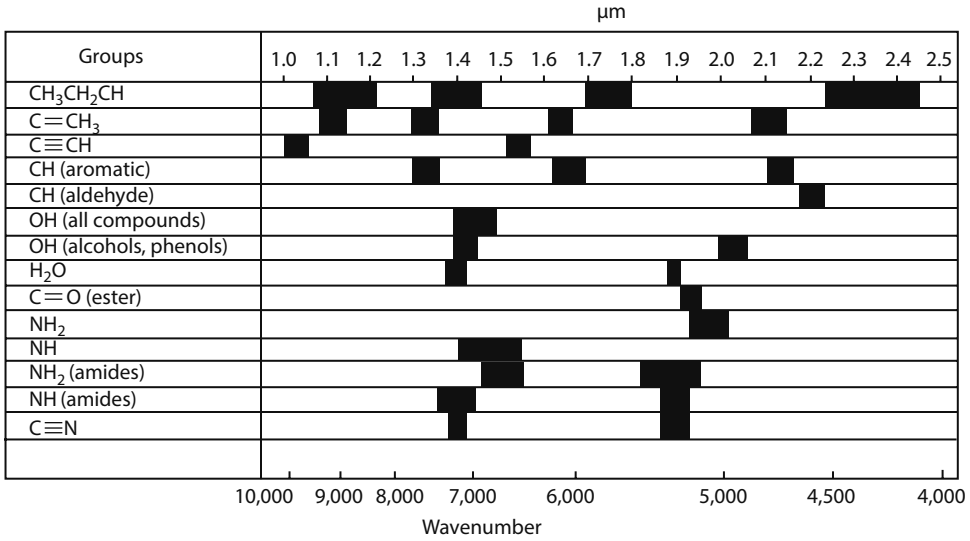

FIGURE 41.27 Characteristic group frequencies in the near-IR spectrum.

Sample Preparation and Sample Cells

Although IR spectra have been obtained on materials in every physical state from solids to gases, most analyses are carried out on the neat liquid analyte, solutions of the analyte in organic solvents, suspensions, Nujol suspensions, and KBr disks. Solution spectra are preferred for quantitative analysis, as errors arising from nonhomogeneous samples and path lengths are minimized. KBr disks are often used for qualitative analysis because subtle structural differences such as polymorphism can often be observed in this medium.

Cells for quantitative IR analysis of solutions consist of a pair of sodium chloride plates with a thin metal spacer between them. This unit is housed in a metal frame along with protective washers. The plate spacing is ~10^{-2} cm. Considerable care in handling and storing the IR cells should be exercised, because the windows are easily fogged by traces of moisture and are easily scratched. When not in use, cells should be stored in a desiccator.

Neat liquids and Nujol suspensions or mulls for qualitative analysis are usually placed as a drop on an unmounted circular sodium chloride plate, and a second plate is pressed on top until the liquid is spread into a thin film with a thickness on the order of 1×10^{-4} to 50×10^{-4} cm. The plates are held in a frame, while the spectrum is scanned. Nujol mulls are prepared by grinding the solid analyte in a small mortar with mineral oil until a milky emulsion is obtained. Other suspending agents such a perfluorokerosene, hexachlorobutadiene, or other heavy liquids can also be used. The spectrum obtained with mulls will consist of bands from the analyte superimposed upon bands from the mulling agent. The C–H regions of the spectrum will be obscured when mineral oil mulls are used, and the C–F or C–Cl regions will be obscured when the halogenated mulls are used.

Qualitative analysis of solid analytes is typically performed using KBr disks. Here, the analyte (0.3–9 mg) is ground with 300 mg of spectral-quality KBr (~400 mesh). Between 100 and 300 mg of the grind is then pressed into pellets or disks at between 20,000 and 100,000 psig using a stainless steel die and a vacuum pump. The finished pellet is transparent and produces excellent spectra. Unlike mulling agents, KBr does not contribute extraneous bands in the IR spectrum; however, KBr is slightly hygroscopic and may pick up moisture during the disk preparation. This will lead to characteristic water bands at 3300 and 1640 cm^{-1}.

Applications

High S/N spectra and sophisticated data-reduction techniques have made FTIR a versatile, high-throughput analytical technique. Advances in the acquisition of FTIR spectra from preparations such as monolayers, tissues, and samples in situ include fiber-optic waveguides for beam handling and remote field sensing. Metabolic fingerprinting, a process where crude metabolite mixtures are rapidly screened and analyzed by multivariate mathematical models, is central to metabolomic studies. FTIR is critical to these studies, wherein mixed sample profiles are correlated to biological origin, metabolic status, and exposure to chemical or environmental stimuli.

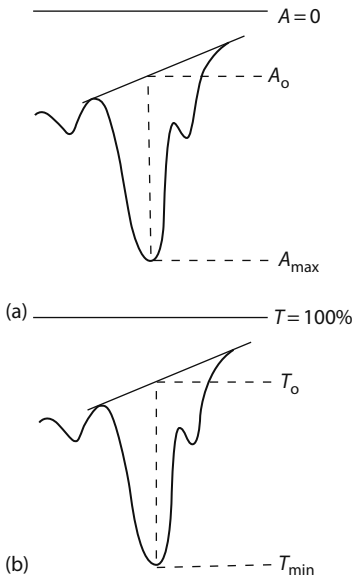

FIGURE 41.28 Measurement of IR band intensities using the baseline technique. (a) When the scale is linear in absorbance, peak absorbance = $A_{max} - A_o$. (b) When the scale is linear in transmittance, peak absorbance = $-\log (T_{min}/T_o)$.

Near-IR spectroscopy is particularly useful as a noninvasive in vivo analytical tool. Virtually every organic compound has a near-IR spectrum that can be measured. Near-IR spectra consist of overtones and combinations of fundamental mid-IR bands. These IR spectra are characterized by good penetration of light into tissues and a high capacity to identify organic compounds. Figure 41.28 illustrates some of the structural moieties that can be determined by near-IR and their absorption characteristics.

The application of in vivo FTIR microspectroscopy in the diagnosis of disease has been reviewed [91,108]. FTIR spectroscopy is used for studying human arteries, cancers and tumors, and brain tissues from stroke and Alzheimer's patients [109,110,122]. Wetzel et al. [211] utilized FTIR microspectroscopy for deuteration studies investigating the metabolic activity in various layers of the cerebellum. Some specific examples of the use of FTIR spectroscopy in disease diagnosis and toxicological research follow.

Analysis of Solid Human Tumor Cells by FTIR Microspectroscopy

Early detection of human tumors often allows for a higher survival rate. Cells from normal and neoplastic human lung tissues have been analyzed by means of FTIR microspectroscopy [14]. Reliable spectra that can differentiate between normal and neoplastic cells may be obtained. Neoplastic cells show an increase in the intensity of the bands corresponding mainly to the PO_2 symmetrical and asymmetrical vibrations (1080–1540 cm^{-1}) of DNA compared to normal cells. This analytical method may be useful for recognizing early neoplastic transformation that is usually not possible with traditional procedures. Similar results have been observed in the FTIR spectra of sections of normal and malignant human colon tissues and in other malignant tissues such as stomach,

esophagus, skin, liver, cervix, and vagina [219]. The results suggest that, in cancerous tissues, most PO_2 groups become hydrogen bonded and the intermolecular packing among PO_2 groups becomes closer. Nucleic acids may be the molecules primarily responsible for the observed changes in the $\nu_s(PO_2^-)$ and $\nu_{as}(PO_2^-)$ bands.

Analysis of Stroke-Induced Changes by Near-IR Spectroscopy

Historically, near-IR spectroscopy has been used to monitor fat and protein in agricultural products. Near-IR spectroscopy is also well suited for animal work because tissue penetration by near-IR light is good, excellent S/N values can be obtained in near-IR measurements, and discrimination between various types of tissue constituents is possible because the near-IR signals arise from combinations and overtones of the fundamental IR bands of these constituents. The gerbil brain is an established animal model of stroke. The gerbil skull is relatively thin, making near-IR spectroscopy of the brain readily achievable in vivo with common spectrometers of moderate light intensity. In addition, the gerbil brain is enriched in polyunsaturated fatty acids. Dramatic changes occur in fatty acid metabolism during the ischemia and reperfusion stages. Near-IR techniques have been used to examine stroke-induced changes in the lipids and proteins of whole gerbil brains [28]. The changes parallel the hypothesized series of free-radical and altered enzymatic events that occur during transient ischemia and reperfusion in the human brain.

To understand the early changes in lipid and protein metabolism following stroke and trauma, animal models have been developed to recreate these changes. The examination of whole brains has been made possible by a combination of hardware modifications and mathematical techniques designed to make the sample presentation to the spectrometer quite reproducible. A refrigerated sample compartment with dry nitrogen purge can be constructed for analysis of whole frozen brains. The cooled compartment enables repeated scans of frozen brains to be collected over time without thawing. The spectrophotometer itself can be purged with dry nitrogen gas, eliminating spectral artifacts associated with lipid/protein oxidation and atmospheric water vapor or other gases. A geometric noise filter removes spectral variations arising from positional variation of the brain. The BEST and extended BEST algorithms, which scale spectral vectors in multidimensional hyperspace with a directional probability, can be used with a supercomputer to analyze the spectra collected.

In addition to changes observed in stroke, age-related changes occur in the polyunsaturated fatty acid pool and in the state of protein oxidation within the central nervous system. Near-IR spectral analysis has many applications to aging and stroke research, including

- Determination of age from brain spectra
- Prediction of short-term memory deficit from the spectra of injured brains
- Simultaneous multicomponent analysis of lipids and proteins
- Quantification of edema
- Transcranial scanning of the brain in vivo

Near-IR scanning of brains in vivo simplifies the testing of antiepileptic drug candidates by reducing the number of subjects required, by allowing each subject to be used as its own control, and by eliminating variance due to outlier subjects, such as those that have had a stroke before the experiment.

Near-IR Fiber Optics as Arterial Probes for Studying Cardiovascular Disease

Another tool for studying mechanisms of toxicology couples near-IR with fiber-optic arterial probes. Fiber-optic catheters have been used to locate atherosclerotic lesions, but the techniques merely distinguish lesions from healthy arterial tissue. Near-IR fiber optics may be used to spatially map lesions and their chemical constituents [30]. Chemical analysis of lesions in vivo permits the kinetic study of atherogenesis and contributes to the understanding of lesion formation and growth. The chemical imaging power of this technique permits the testing of hypothetical mechanisms of lesion formation, growth, and regression, including those involving toxic injury and antioxidant protection.

Toxicological Studies

IR spectroscopy is extensively employed in toxicological research. The toxic effects of selenium exposure on the external cell membranes of living bacteria may be efficiently analyzed by FTIR directly in the biomass [53]. FTIR spectroscopy was employed to assess the hepatotoxic effects of a single dose of carbon tetrachloride in rat liver [40]. Dynamic chemical changes in liver samples were monitored over time by analyzing the IR spectra in the lipid (1800 to 1000 cm^{-1}) and C–H stretching (3000 to 2400 cm^{-1}) regions and comparing them to untreated controls. Changes in band shape and intensity were correlated with toxicity. To develop a high-throughput metabolomic toxicology assay, researchers hypothesized that FTIR could be used to detect differences between urine collected from rats treated with lipopolysaccharide, a potent inflammatory agent, and urine obtained from untreated controls [69]. In addition, cotreatment with ranitidine, a drug often associated with idiosyncratic hepatotoxicity, was performed to determine whether or not the FTIR method would be useful for predicting this idiosyncratic toxicity. The results of this pilot study suggest that similar methods might be applied for the rapid metabolomic screening of drug toxicity. In the occupational and environmental toxicology settings, FTIR analysis may be useful for the continuous monitoring of the presence of airborne toxins. Over a 2-year period, 39 selected air toxins were measured at 11 different petrochemical sites using open-path FTIR [31]. The data enabled the researchers to calculate the hazard indices for both acute and chronic health effects attributable to these toxins over time and by location, thereby estimating potential health risks to workers.

Specialized Instrumentation

Several modified approaches for performing IR spectroscopic imaging microscopy have been developed. One instrument integrates an acousto-optic tunable filter (AOTF) and charge-coupled device (CCD) detector with an infinity-corrected microscope for operation in the near-IR spectral regions [198]. Images at moderate spectral resolution (2 nm) and high spatial resolution (1 μm) can be rapidly collected. Data can be presented with 128 × 128 pixels. The CDD is a true imaging detector, with wavelength selection provided by the AOTF and quartz tungsten halogen lamp to create a tunable source. The instrument can be utilized for both absorption and reflectance spectroscopies.

Synchrotron FTIR (SFTIR) microscopy, which does not require sample mounting or specialized preparation, has been used to probe the molecular responses to toxic injuries in intact, living cells [76]. SFTIR allows the observation of several types of molecular responses and lesion development induced by stressors such as radiation and toxic compounds in the same cell over time. Real-time changes in nucleic acids and proteins in live human cells treated with dioxin were studied using this technique.

Portable FTIR units are available and broadly deployed for field use. Potential applications include the rapid detection of toxins and suspected bioterror agents at remote locations. To evaluate the utility of these portable systems for the field-based characterization of biological threats, a series of peptide and nonpeptide toxins were analyzed and compared to libraries of known spectra [172]. In the case of pure compounds, this spectral searching technique allowed the researchers to discriminate between aflatoxin, mycotoxin, and strychnine at a 99% confidence level. Nonpeptide toxins were readily identified in chemical mixtures, and peptides such as ricin were correctly identified in mixtures at a 95% confidence level. FTIR analysis is being rapidly developed as a versatile tool for on-site identification of chemicals, toxins, and biological threats.

Raman Spectroscopy

Raman spectroscopy is closely related to IR spectroscopy, in that the information about molecular vibrational frequencies provided by the latter technique is of the same kind as that provided by the Raman vibrational spectrum [27,146]. In molecules with a center of symmetry, however, vibrational transitions that are allowed in the IR spectrum are forbidden in the Raman effect, and vice versa, providing useful information about molecular symmetry. Structurally symmetrical diatomic molecules such as H_2 and O_2 are also electrically symmetrical and do not give IR absorption spectra. These molecules do afford Raman spectra due to excitation of symmetrical vibrations. In a molecule such as tetrachloroethylene (CCl_2=CCl_2), the double-bond stretching frequency is symmetrical and the molecule does not show a double-bond stretching frequency in the IR spectrum; however, this vibration appears strongly in the Raman spectrum of tetrachloroethylene and provides evidence of a symmetrical structure (see Figure 41.29). Thus, the two techniques are complementary to each other.

The Raman effect is a scattering process in which the interaction between photon and the molecule occurs in a very short period of time, and the Raman peaks obtained correspond to photons that have bounced inelastically off the molecule. The Raman spectrum arises as a result of the light photons being captured momentarily by molecules in the sample and giving up (or gaining) small increments of energy through changes in the molecular vibrational and rotational energies before being emitted as scattered light. These changes in vibrational and rotational energies result in changes in wavelength of the incident light. The convention in Raman spectra is to quote the positions of vibrational peaks as the difference between the absolute wave numbers of the exciting line and the absolute wave numbers of the resulting scattered photons. The Raman effect is extremely weak, and only a minute portion of the incident photons are useful emergent photons; thus, relatively high-power lasers must be used to create a high photon flux. Sophisticated optical and electronic equipment is also required to detect the scattered photons.

One of the major advantages of Raman spectroscopy is that spectra may be obtained for molecules in aqueous solutions, as water has a weak Raman spectrum that interferes only minimally with the spectrum of the solute. Analyte concentrations in the range of 0.1 to 0.01 M in water are normally used. In resonance Raman spectroscopy, concentrations of chromophoric molecules in the range 10^{-4} to 10^{-6} M can be used, making this technique particularly useful for biochemical studies.

Basic Optics of the Raman Experiment

In a standard Raman experiment, intense monochromatic radiation provided by a CW laser is focused onto or into the sample. Some of the resultant scattered light is collected by optics and directed to a dispersing system that is usually a monochromator. The monochromator separates the scattered light on the basis of frequency, and these frequencies are then detected and recorded either by single-channel (scanning) or multichannel detection. Figure 41.30 illustrates the optics involved in a conventional Raman experiment.

Sampling Techniques and Problems

Samples for Raman spectroscopy may be examined in any physical state. Liquid samples are usually measured in a quartz (1 cm) cuvette similar to the type used in fluorescence spectroscopy; however, because the incident laser beam travels longitudinally down the length of the liquid column, the cell bottom must be transparent. Capillary cells are often used for biological samples, especially when material is limited in availability. Single crystals and fibers can be analyzed by mounting on a goniometer head. Solid crystalline or polycrystalline materials can be pressed into pellets, prepared as KBr disks, or packed into capillary microprobes. Samples in the form of thin films can also be examined. Potential problems include the breakdown of photolabile analytes during laser irradiation. This can be reduced or eliminated for liquid samples by utilizing a spinning cell, a cell in which the liquid sample is continually moved through the laser beam, or a

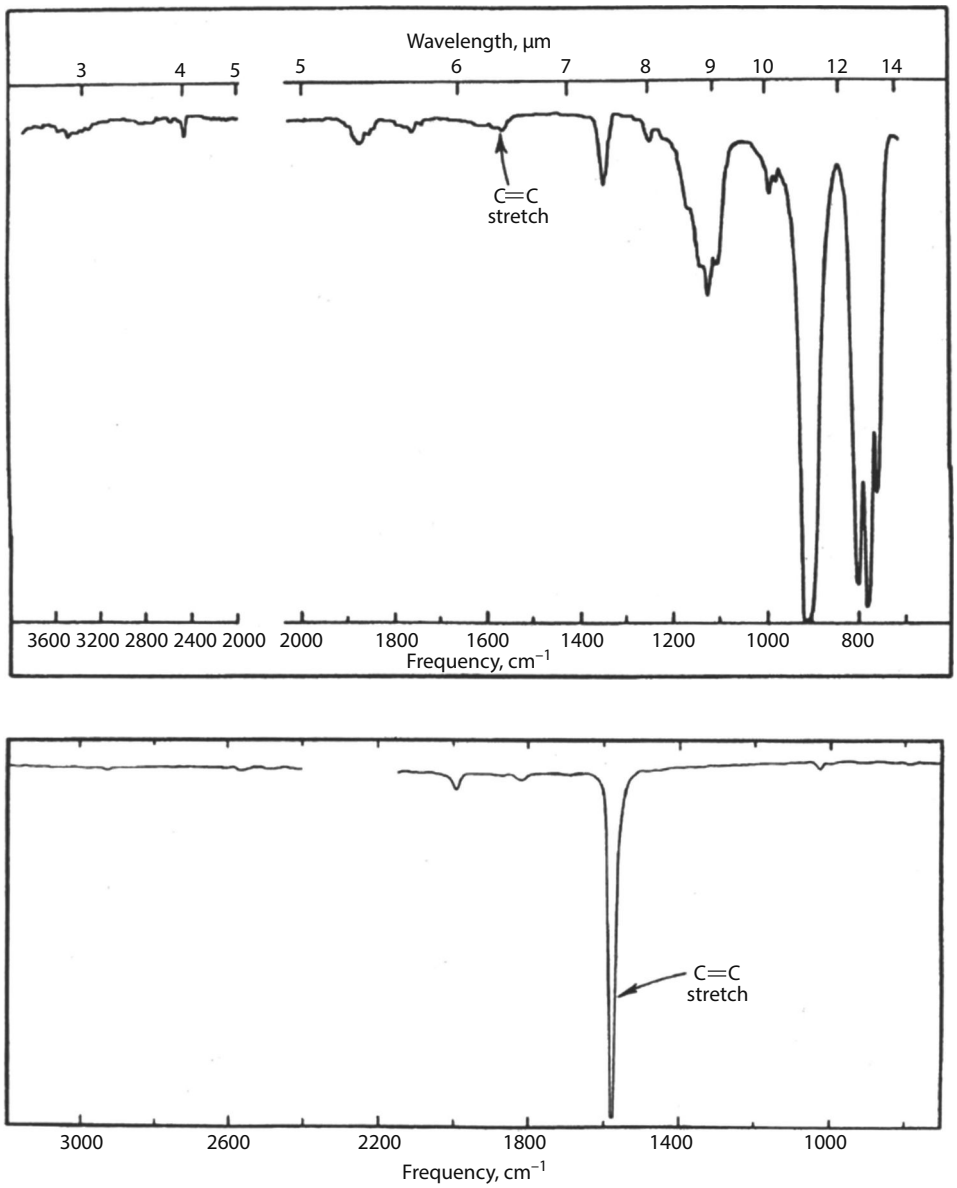

FIGURE 41.29 IR (top) and Raman (bottom) spectra of tetrachloroethylene.

cell in which the liquid is continually stirred with a magnetic stirrer. These procedures reduce the buildup of degradation products usually observed with static sample analysis.

In Raman spectroscopy, it is important for the analytes to be optically homogeneous, especially in the case of biological samples. Particulate matter in solutions should be removed either by centrifugation or filtration; otherwise, hot spots may occur in the sample on irradiation, leading to possible degradation. Luminescence, which may often obliterate the Raman effect, may occur if the sample or an impurity in the sample has a chromophore. Luminescence can often be reduced or eliminated by changing the wavelength of excitation or adding a quenching agent such as KI.

Protein Conformation Determination

Protein molecules are classical examples of the application of Raman spectroscopy to biomolecules. This technique can probe structural details such as average peptide backbone conformation, as well as the side chains of some amino acids, such as tyrosine and tryptophan. Protein spectra are usually obtained in the 450–650 nm region. UV-excited resonance Raman spectra of proteins containing aromatic amino acids of interest are often conducted with excitation below 300 nm. The normal Raman spectrum of proteins contains diagnostic amide I (C=O stretch) and amide III (N–H in-plane bending) bands that can be utilized to characterize the secondary structure of the protein or peptide backbone. Table 41.3 gives approximate positions for the amide I and amide III bands in both the IR and Raman spectra of various polypeptide conformations. Characterization of the secondary structure of a protein depends on the determination of characteristic amide I and III frequencies in the Raman spectrum for α-helical, β-sheet, and random protein conformations. This is often achieved by using polypeptide models and proteins

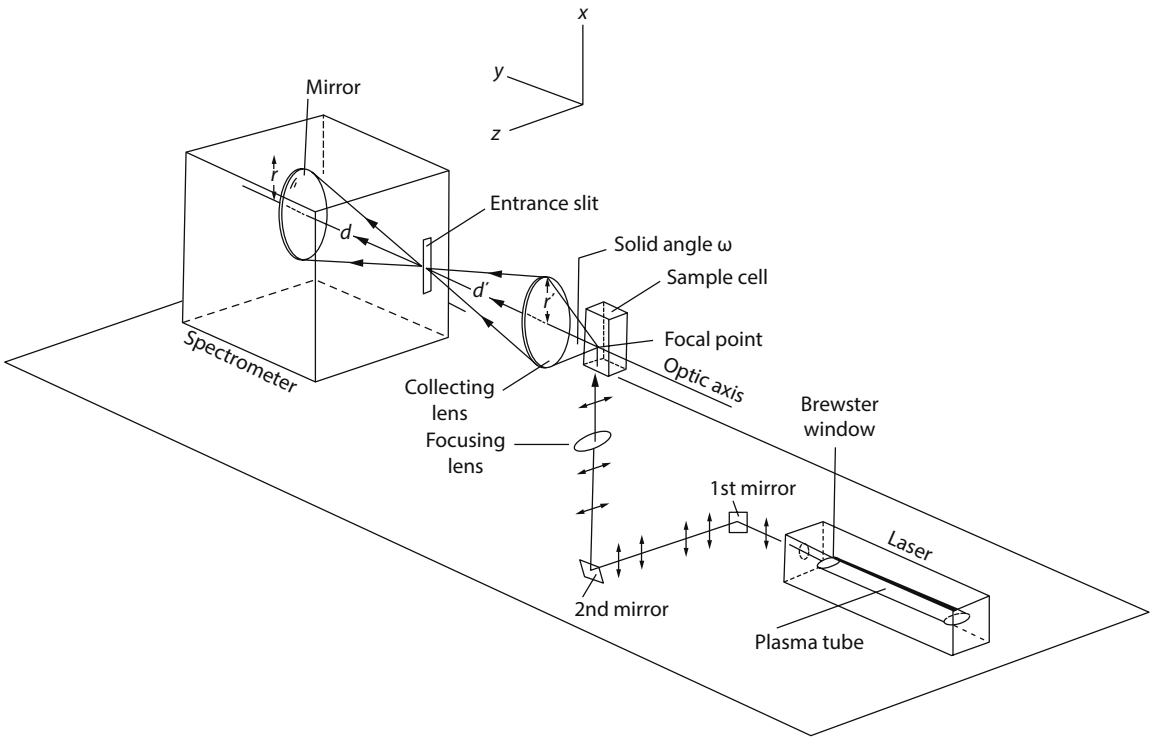

FIGURE 41.30 The optics of a conventional Raman spectrometer.

TABLE 41.3
Approximate Positions (cm^{-1}) of the Most Intense Amide I and Amide III Bands in Raman Spectra and the Amide I Band in IR Spectra for Various Polypeptide Conformations

	Amide I		Amide III
Conformation	**Raman**	**IR**	**Raman**
α-Helix	1645–1660	1650.00	1265–1300
β-Sheet	1665–1680	1632.00	1230–1240
Unordered	1660–1670	1658.00	1240–1260

of known conformation. Figure 41.31 illustrates the Raman spectra, run in water, of native and denatured ribonuclease A and shows the change in the amide III band in the disordered protein [33].

Resonance Raman Labels

Resonance Raman labels are chromophores that have been carefully designed to mimic natural biochemical components and that are themselves biologically active molecules. They provide detailed vibrational and electronic spectral data when in the vicinity of a biologically important site. Extrinsic protein-bound chromophores, such as methyl orange bound to bovine serum albumin, have been studied in detail. Other systems that have been studied include protein–ligand interactions, such as drug–enzyme and hapten–antibody complexes where the drug or hapten is the chromophoric resonance Raman label. This method is useful for studying enzyme–substrate complexes and can provide vibrational spectra of the substrate during enzyme catalysis.

RNA and DNA Structural Analysis

Analysis of polynucleotides by Raman spectroscopy affords bands (~30) primarily attributable to purine or pyrimidine ring modes. In addition, the phosphate group shows interesting features in the spectrum. The sugar moieties in DNA and RNA molecules and the related polynucleotides are poor Raman scatterers. From the Raman spectrum, it is possible to obtain a semiquantitative estimate of the relative population of bases in the polynucleotide molecule. Base protonation in DNA has been studied using Raman spectroscopy. Metal–nucleotide binding has also been investigated. The mode of binding of ions such as Ca^{2+}, Mg^{2+}, Co^{2+}, Cu^{2+}, and Mg^{2+} to adenosine triphosphate over a wide pH range has also been studied. Raman spectroscopy can detect the disruption of base-pairing and base-stacking interactions [105]. In Figure 41.32, raising the temperature of poly(rA) · poly(rU) from 32°C to 82°C results in thermal disruption of the helix. Important features in the difference spectra are the radical changes in the carbonyl region (1650–1700 cm^{-1}) due to the disruption of H bonding in the Watson–Crick model. Phosphate backbone conformation in nucleic acids has also been studied by monitoring the –O–P–O– symmetrical stretching vibration (800 cm^{-1}) and the $–PO^{2–}$ symmetrical stretch motion (1100 cm^{-1}). The interaction of nucleic acids with proteins is an area of active study; for example, the stabilizing effect of the viral capsids on the secondary structure of the viral RNA has been investigated. Also, Raman data on DNA–histone interactions have indicated that the

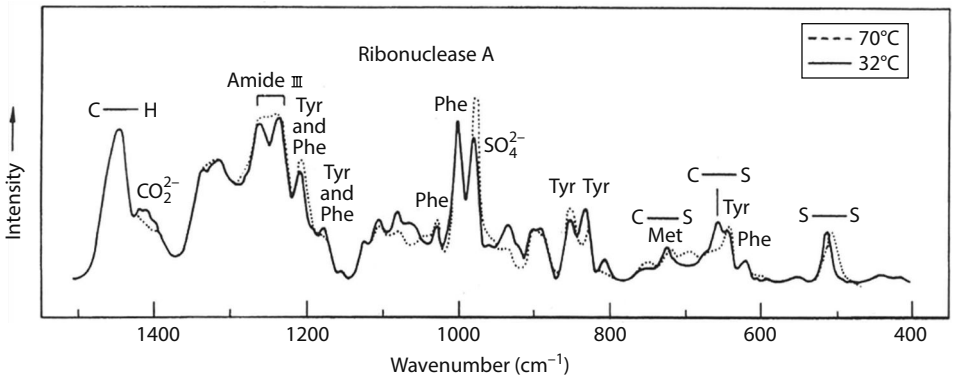

FIGURE 41.31 Raman spectra of native and denatured ribonuclease A, at 32° and 70°, respectively, after correction for the water background and being normalized to the intensity of the methylene deformation mode at 1447 cm^{-1}. Protein concentrations of about 10% were used with typical spectral conditions of 488 nm excitation, 200 mW power, and 7 cm^{-1} spectral slit. (From American Chemical Society. With permission.)

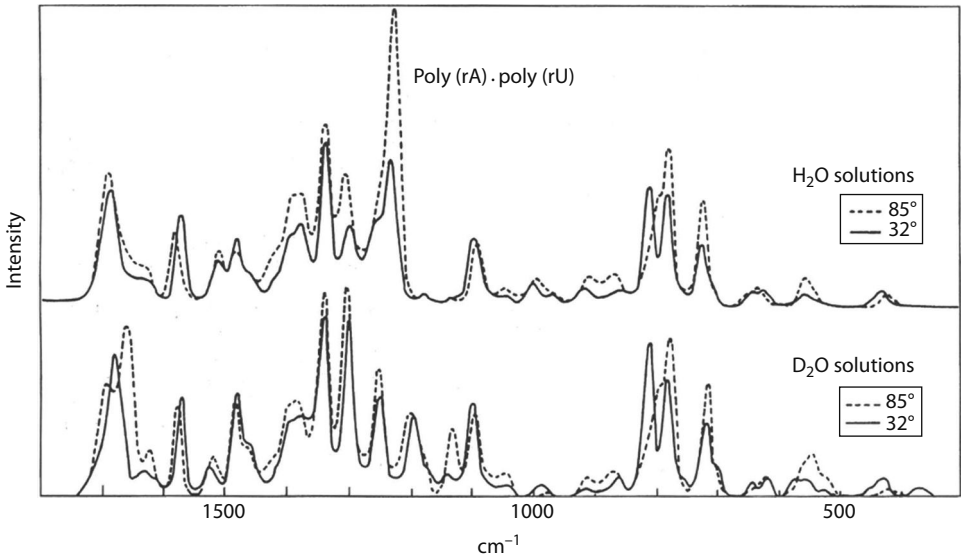

FIGURE 41.32 Raman spectra of H_2O and D_2O solutions of poly(rA)poly(rU) at 32°C and 85°C, respectively. The background of Raman scattering by the solvent has been subtracted from each spectrum. (From Lafleur, L. et al., *Biopolymers*, 11, 2423, 1972 [77]. With permission.)

sites of DNA–protein interactions are probably located in the grooves running along DNA.

Lipids and Membranes

Raman spectroscopy is ideally suited for the study of lipids and membranes and has some advantages over other techniques. The analysis time frame of fractions of a picosecond provides instant snapshots, thereby eliminating the line broadening commonly seen in magnetic resonance spectra. No probe molecule is required, and both gel and liquid-crystal hydrocarbon regions can be monitored. The most useful regions are 1000–1150 cm^{-1} (C–C accordion stretch) and the 2800–3000 cm^{-1} (C–H stretching mode). Transitions from gel to liquid crystal in membranes are indicated by marked changes in the bands assigned to the C–C stretch mode, and the C–H stretch region is extremely sensitive to conformational change within the individual fatty acid chains.

Applications

Raman spectroscopy has become the tool of choice for many chemical and biological applications [6]. Extremely sensitive to minute structural changes, Raman techniques require minimal sample preparation and are extensively employed in noninvasive studies. Raman microspectroscopy also offers high spatial resolution for analyzing discrete regions of biological matrices. These characteristics make Raman spectroscopy particularly useful for exploring biological processes in living tissues and in individual living cells and organelles [157]. Continuous Raman spectroscopy monitoring of living A549 human lung cells was employed to evaluate the effects of nonionic surfactant exposure on biochemical processes and the sequence of events in cell death. The molecular mechanisms of cell death were strongly associated with specific decreases in Raman peaks associated with nucleic acids and proteins [143]. Western blotting analysis supported

the conclusions derived from the Raman spectroscopy data. Raman spectroscopy analysis of specific, time-dependent biochemical changes might be applied to tissue engineering and high-throughput toxicity screening.

Evans et al. [51] combined coherent anti-Stokes Raman scattering (CARS) with video-rate microscopy for real-time monitoring of dynamic processes in lipid-rich tissues of living mice. CARS imaging of the methylene stretching vibrational band afforded exceptional subcellular resolution in tissues such as adipocytes, corneocytes, and the sebaceous glands. Important processes such as in vivo cellular transport, xenobiotic diffusion, and transcorneal absorption might be monitored using the CARS method.

Several reports on the biomedical applications of in vivo Raman spectroscopy (IV-RS) have been published [91,107,177]. These include the in vivo diagnosis of certain diseases in their very early stages [177]. In vivo Raman scattering has been explored as a means of measuring levels of the antioxidant molecules lutein and zeaxanthin in the retinas of young and older adults [58]. The results indicated that the concentration of these protective pigments decreased with increasing age, even in normal eyes. The authors suggest a role for Raman screening of retinal carotenoid levels in populations at risk for macular degeneration, a leading cause of blindness. The potential use of IV-RS for diagnosing arterial disease and cancer in gynecological tissues, soft tissues, breast, colon, bladder, and brain has been discussed by Manoharan et al. [122]. Lawson et al. [107] reviewed the application of Raman spectroscopy to the study of human arteries, tumors, gallstones, hair, and nails. Brain tissues have also been investigated using FT-Raman spectroscopy, and spectra from the cerebral cortex, cerebral white matter, caudate–putamen, thalamus, synaptosomal fraction, and myelin fractions have been recorded [128,129]. Brain tumors have also been studied using FT-Raman spectroscopy [128].

Ong et al. [144] studied the substantia nigra of the rostral midbrain in monkeys using Raman microspectroscopy to determine differences between white and gray matter. As compared to the laser spot size of 20 μm in IR microspectroscopy, the 1 μm laser spot size in Raman microspectroscopy afforded much greater spatial resolution in sample analysis. The white and gray matter could be clearly distinguished and their relative proportions evaluated from Raman frequencies in the 3000 cm^{-1} region.

Singer et al. [180] evaluated Raman confocal microscopy as a means of assessing environmental pollutant bioavailability and toxicity in a cell culture system. Phenanthrene, dodecane, 3-chlorobiphenyl, and pentachlorophenol (four common environmental pollutants) were detected and quantified using this potential pollution bioassay.

Along with IR spectrometers, portable Raman spectrometers have also been developed for remote field use. Raman analysis with portable instrumentation was used in a blind field test to analyze a matrix of 58 unknowns for comparison with a standard hazardous materials response library of known spectra [70]. Despite the inclusion of multiple solvents and compounds with uncataloged spectra, over 97% of the samples were correctly identified with no false positives. Freebase crack cocaine and its hydrochloride salt were readily identified and distinguished from common street adulterants using fiber-optic Raman spectroscopy [29].

Raman spectroscopy systems have been developed for the detection of toxins associated with bioterror, including chemical and microbial weapons. The capacity of a human lung cell–based Raman spectroscopy system to detect and differentiate between sulfur mustard and ricin exposure was assessed noninvasively over time [142]. Differences in cellular Raman spectra correlated with characteristic changes in cellular biochemistry and structure. Damaged cells were detected with high sensitivity and specificity, and toxic agent identification was reasonably accurate for ricin (71.4%) and sulfur mustard (88.6%).

Isotopic Labeling

The use of isotopes to study the fate of xenobiotics in vitro and in vivo developed initially with the use of radioisotopes. The development of methods for detecting and quantifying energy emitted from radioisotopes led to synthetic xenobiotics containing radioactive isotopes that could be tracked or traced in organisms. The development of sophisticated NMR and mass spectral methods has made the use of stable isotopes for studying the fate of xenobiotics fairly common. Stable isotopes are popular because they often yield a great deal of structural information about xenobiotic metabolites without the hazards to the organism (often humans) inherent in radioisotopes. The following sections provide an introduction and overview of isotope methods. More comprehensive information is available [89,99,212,218].

Radioisotopes

Most elements exist as several isotopes that vary in atomic weight. Some of these isotopes are radioactive, spontaneously decaying to form an atom of another element. This decay is accompanied by the emission of radiation. The radiation emitted is of three distinct types: alpha (α), beta (β), and gamma (γ). Alpha particles are actually helium nuclei (^{4}He), β-particles are electrons, and γ-rays are high-energy electromagnetic radiation. Isotopes that emit β-particles, so-called β-emitters, are less hazardous to laboratory workers than γ-emitters because β-particles do not possess sufficient energy to penetrate the skin. Beta emitters are only hazardous if ingested or where they otherwise come in contact with cells. In contrast, γ-emitters are more hazardous to laboratory workers because γ-rays are highly energetic and can easily penetrate the skin. Special precautions such as lead shielding are often required when working with γ-emitters.

Radionuclides are quantified in terms of their *specific activity*, which is the radioactivity per unit mass of material. Specific activity can be given in curies per mole (Ci/mol) or becquerels per mole (Bq/mol). A becquerel is defined as 1 disintegration per second (dps) and 1 curie = 3.7×10^{10} dps; thus, 1 Ci = 3.7×10^{10} Bq. The most commonly used radionuclides are ^{3}H and ^{14}C. Both of these isotopes are weak β-emitters that emit fast-moving electrons that can penetrate up to 50 cm in air and up to 0.5 cm in aluminum. Both ^{3}H- and ^{14}C-labeled

compounds can be handled easily and safely with the use of glass containers, protective gloves, and safety glasses. ^{14}C β-particles carry significantly more energy (β^- = 155 keV) than ^{3}H β-particles (β^- = 18.6 keV). This difference enables mixtures of radionuclides (e.g., double-labeled $^{3}H/^{14}C$-containing compounds) to be measured simultaneously (see later discussion). Although ^{14}C is a more energetic nuclide and therefore a more easily detected tracer atom than ^{3}H, its maximum specific activity when incorporated into a drug molecule is only 62.4 mCi/milliatom of carbon, compared to a maximum specific activity for ^{3}H of 29.1 Ci/milliatom of hydrogen.

The energy emitted when radioactive isotopes decay is easily traced, as the radionuclide itself is not metabolically altered by the biological system under study. The radioisotopes most commonly used in biological systems are shown in Table 41.4.

Xenobiotic Disposition Studies Using Radiolabeled Tracers

The most common use of radiolabeled xenobiotics in toxicology is the study of the fate of a chemical in animal models. These studies are often referred to as absorption, distribution, metabolism, and excretion (ADME). The successful ADME study requires

- A radiolabeled xenobiotic with the most appropriate isotope and position of the label
- An analytical method for separating the parent compound and its hypothesized metabolites
- Methods for quantifying the amount of radioactivity

Choice and Location of Label

The radioisotope of choice for xenobiotic ADME studies is carbon-14 (^{14}C) because it is a radioactive form of the element that forms the backbone of most xenobiotics. In addition, ^{14}C has a very long half-life (over 5000 years), and as a weak β-emitter, it poses fewer health risks to laboratory workers. The position of the label must be carefully selected to ensure that the label is not lost upon metabolism. Researchers using ^{14}C will often uniformly label one of the aromatic rings of a xenobiotic if it is thought not to undergo ring opening during metabolism. These positions are preferable to ^{14}C labeling in a methyl group attached to an oxygen or a nitrogen, because both of these carbons will undergo demethylation reactions catalyzed by either cytochrome P450 or flavin-containing monooxygenase. Sometimes there are limitations for placing the label, based on synthetic concerns. Every effort should be made to locate the label in a chemically and metabolically stable position.

Tritium (^{3}H), the radioactive form of hydrogen, is often used as a tracer because of the high specific activity that can be obtained with this isotope. High specific activity increases the researcher's ability to detect smaller amounts of the xenobiotic. Receptor binding assays typically use tritiated ligands for this reason; however, the use of tritium has some shortcomings, including a relatively short half-life (12.33 years) that requires adjustment of the specific activity over time. In addition, because tritium is an isotope of hydrogen, it undergoes exchange with nonradioactive protium (^{1}H) in solvents. This so-called *solvent exchange* must be taken into account when positioning a label on the xenobiotic. Positions that readily undergo solvent exchange are not good candidates for labeling. These positions are referred to as *labile positions* (e.g., protons attached to oxygen, nitrogen, or sulfur atoms are labile). Tritium may also be lost due to metabolism of the xenobiotic, and an experienced investigator will usually avoid inserting labels at positions in the molecule where they may be lost during biotransformation; for example, ^{3}H labeling at a carbon adjacent to a heteroatom or at a hydroxylation site on a phenyl ring or a ^{3}H-labeled *N*-methyl group, which may often be lost by oxidation, should generally be avoided.

Radiochemical Purity

The purity of labeled compounds is usually critical to the success of an experiment. When following (tracing) a radiolabeled compound, there is no specificity to the radioactivity emitted by the radioactive isotope. Chemical impurities containing the radioisotope will be indistinguishable from the xenobiotic of

TABLE 41.4
Radioactive Isotopes Commonly Used to Study the Fate of Xenobiotics

Atomic No.	Element	Atomic Weight	Half-Life	Radiation (MeV)
1	Hydrogen	3	12.33 years	β^- (0.019)
6	Carbon	11	20.4 min	β^+ (0.96)
		14	5730 years	β^- (0.156)
15	Phosphorus	32	14.28 days	β^- (1.71)
		33	25.3 days	β^- (0.25)
16	Sulfur	35	87.5 days	β^- (0.167)
17	Chlorine	36	3×10^5 years	β^- (0.71)
37	Rubidium	87	4.8×10^{10} years	β^- (0.272)
53	Iodine	125	60.14 days	γ (0.035)
		131	8.040 days	β^- (0.607, 0.336) γ (0.080, 0.284, 0.364, 0.637, 0.723)

interest; therefore, the original material administered to the organism should be of the highest purity possible to ensure that the radioactivity detected is derived from the parent compound. Radiochemical purity should be confirmed by a suitable method, such as radiochromatography (discussed later), prior to using a radiolabeled compound for an ADME study.

In addition to radiochemical purity, enantiomeric purity may also be important. Many biological processes are stereoselective, with either the S or R enantiomer of a biologically active compound having significant activity. That is, only one of the stereoisomers of a compound is active in the system under study; for example, the (S)-(–) enantiomer of nicotine is responsible for most of its pharmacological activity. The affinity of the (R)-(+) enantiomer for high-affinity nicotinic acetylcholine receptors is 60-fold less than the (S)-(–) enantiomer. With the recognition that many toxic responses are receptor mediated, the enantiomeric purity of radiochemicals has become more important.

The solvent selected for storage of a radiolabeled compound is an important consideration; for example, radiolabeled peptides and proteins that have been stored in water may undergo extensive degradation. Solvent exchange can also be a problem for tritiated compounds, as described earlier. The selection of a solvent is usually a compromise between adequate solubility and a minimum of inherent reactivity with the radiolabeled compound.

Route of Administration

A primary consideration when conducting an ADME study with radiolabeled xenobiotics is the route of administration. The xenobiotic is usually administered to the animal model by a route appropriate to either the anticipated major route of exposure to the species of interest (usually humans) or by a route of administration that is consistent with the goals of the research; for example, if the xenobiotic of interest is a component of a consumer product applied to the skin, then the appropriate route of delivery may be dermal administration. If, however, the objective of the ADME experiment is to determine the pharmacokinetics of the xenobiotic in blood and tissues, then the intravenous route of administration would be chosen over the dermal route. The solubility of the compound in an appropriate delivery vehicle must also be considered when deciding on a route because many vehicles are not compatible with intravenous administration.

Liquid Scintillation Spectrometry

Total xenobiotic-derived radioactivity can be determined in all excreta including urine, feces, and expired air to quantify the routes of excretion for a xenobiotic and its metabolites. Total radioactivity in aqueous samples is relatively easy to quantify using liquid scintillation spectrometry. This method for quantifying radioactivity involves mixing an aliquot of the sample with a *liquid scintillation mixture* (LSM) that uses an organic compound or mixture of compounds that are scintillators, compounds that give off light when they absorb radioactive energy. Traditionally, these scintillators were dissolved in toluene-based mixtures that enabled counting both organic and aqueous samples. For aqueous samples, a typical mixture of two-part sample to eight-part LSM formed a gel that was counted. These LSMs could disperse no more than about 20% water. Newer LSMs that are less hazardous, can disperse more water, and can be discarded down the sanitary sewer have replaced toluene-based LSMs for most applications. The mixture of the radioactive sample and the liquid scintillation mixture is placed in special vials that are highly efficient at passing light without absorbing radioactive energy. The vials are counted by placing them in a liquid scintillation counter uses two opposed photomultiplier tubes to detect light-emitting events triggered by the radioactive decay of the isotope. Coincidence circuitry is used to separate random events from radioactive isotope–driven events. The counting region is lined with lead to shield the vial from extraneous environmental radiation. The sample is compared to a blank or background vial that contains everything but the radioisotope-containing sample. The radioactive counts from the background vial must be subtracted from the sample to obtain net radioactivity.

The liquid scintillation counter expresses data in counts per minute (CPMs) that must be corrected to disintegrations per minute (DPMs) to account for inefficiencies in capturing all of the radioactive energy emitted. The method employed in most liquid scintillation counters today involves the use of external standard calibration. Here, a radioactive source housed in the instrument is placed automatically near the vial containing the sample, and the photomultiplier tubes detect the resulting light emitted from the scintillator within the sample vial. The CPMs detected by the instrument are then automatically compared to the known DPMs of the external standard source, and a counting efficiency is determined. The counting efficiencies for ^{14}C are usually much higher than for the less energetic β-emitter tritium.

In addition to the inefficiencies in transferring the energy of radioactive decay into light energy, there is also *quenching* of the light emitted from the scintillator. Many solvents and biological molecules can quench the light emitted by the scintillator, so the researcher must correct for the amount of quenching within the sample by comparing the expected DPMs to a quench curve and determining the actual DPMs present in the quenched sample. This is usually accomplished automatically by the liquid scintillation counter by first running a set of vials containing a known amount of radioactivity with increasing amounts of a quenching agent added to each vial. The resulting quench curve is stored in the counter memory and used to determine the DPMs of the sample.

Radioactive samples containing scintillant are often sensitive to external light, especially sunlight, which results in excitation and abnormally high CPMs on analysis. This phenomenon, called *chemiluminescence*, is usually more of a problem with ^{3}H-containing rather than ^{14}C-containing radiolabeled samples and can usually be minimized or eliminated by storing scintillation fluids and samples containing scintillant in the dark for 30–60 min before analysis.

Combustion Techniques

Many samples are not amenable to liquid scintillation counting because they are either solids or otherwise incompatible

with LSMs. Total radioactivity in tissue samples and fecal samples can be determined by combustion of the sample to carbon dioxide and water. ^{14}C in the original sample is converted to $^{14}CO_2$ and tritium is converted to tritiated water. Combustion instruments automatically combust samples on a platinum electrode covered with a glass chimney. The products of combustion are swept away by an airstream and trapped in appropriate solvents. Liquid scintillation mixture is added and sample radioactivity is measured in a liquid scintillation counter.

Autoradiography

Autoradiography is the production of an image by the emission of radioactive decay energy from a radionuclide. It provides a qualitative visual image of the tissue distribution of a xenobiotic and has been used to provide quantitative distribution data, as well. ^{14}C is probably the most often used radionuclide for autoradiography because of its long half-life and relatively high energy. Tritium is used when greater resolution is required because it is a weaker emitter. Radioisotopes of nitrogen and oxygen do not have sufficiently long half-lives to permit development of an image. Iodine, sulfur, chlorine, and phosphorous are also used for autoradiography.

Whole-body autoradiography is an excellent technique for visualizing the distribution of xenobiotic-derived radioactivity in an animal model. This technique involves administration of the xenobiotic to the animal; following anesthesia, the animal is quick frozen by immersion in hexane or acetone with dry ice. The time interval between administration and freezing must be selected based on some knowledge of the rate of elimination of the compound. After complete freezing, the animal is placed in a block of carboxymethylcellulose ice on the stage of a microtome, an instrument that uses a sharp blade to shave thin sections off one side of the block. Sections varying in thickness from 5 to approximately 80 μm are captured from the microtome blade using an adhesive matrix. The section is then placed on x-ray film and stored in a freezer, while the radiation emitted by the isotope exposes the film. The resulting pictures (autoradiograms) illustrate where in the body the xenobiotic-derived radioactivity has distributed. Highly perfused organs such as the kidney, liver, and heart are the first to light up with the compound [206]. Over time, it becomes obvious which tissues sequester the compound.

Digital imaging techniques have enabled quantitative analysis of whole-body autoradiograms providing absolute concentrations of xenobiotic-derived radioactivity in tissues. Zane et al. [225] have shown that autoradiography with quantitative digital image analysis compared extremely well with the more traditional combustion method. For this comparison, they treated rats with ^{14}C-labeled CGS 18102A and sectioned the animals as described earlier. They also took 16 tissue samples from each animal for combustion analysis. The sections were placed on x-ray film along with a series of calibration standards of known radioactivity. After 3 weeks of film exposure, the autoradiograms were analyzed with a digital imaging system. The concentrations obtained from digital analysis of the autoradiograms compared very well to those obtained by combustion analysis. Jacob et al. [85] used quantitative whole-body autoradiography (QWBA) with digital image analysis to study the transplacental uptake and covalent binding of [^{14}C]-chloroacetonitrile (CAN) to various tissues in normal and glutathione-depleted pregnant mice. Their finding that covalent binding of CAN to maternal and fetal tissue was elevated in glutathione-depleted mice suggested a modulatory role of glutathione in CAN distribution and transplacental toxicity and demonstrated the utility of QWBA in mechanistic studies.

Although x-ray film provides excellent resolution and has been used successfully for QWBA, it is not necessarily the medium of choice. Exposure times for x-ray film are typically weeks to months. Also, x-ray film often does not provide a linear calibration over the wide range of radioactivity (optical densities) common in QWBA. To avoid these limitations, storage phosphor screens are commonly employed for QWBA instead of x-ray film. Storage phosphor screens trap the energy released by radioactive samples. The energy is stored by the phosphor screen and is only released when the screen is scanned with a laser beam. The released energy appears in the form of blue light, which is detected by a photomultiplier tube and converted to a digital signal that is stored in a computer file. To quantify the levels of radioactivity in the whole-body sections, a series of standards are analyzed and the response of each is determined. A regression equation, derived for the standard responses, is used to determine the absolute concentration of radioactivity in the whole-body sections.

The autoradiograms can also be visualized by converting the digital data to a graphics file and printing the results. Commercially available hardware and software are available for QWBA using storage phosphor screens. Storage phosphor screens overcome the major limitations of x-ray film. They have a linear response over a 5 log-unit range and can be developed in hours to days. It has been estimated [214] that a 2-week exposure to x-ray film is equivalent to a 24 h exposure to a storage phosphor screen. For a more comprehensive introduction to storage phosphors for QWBA, the reader is referred to the work of Wilson and Kraus [214] and Herman and Chay [71].

An interesting application of storage phosphor QWBA is illustrated in Figure 41.33. For this study, Sprague Dawley albino rats received [^{14}C]-RJR-2403 at a dose of 15 mg/kg by gastric gavage. Animals were euthanized at specific time points and sectioned (30 μm) as described earlier. Sections were exposed to storage phosphor screens for 7 days, and data were collected using a PhosporImager SF (Molecular Dynamics). Figure 41.33A shows an autoradiogram obtained at 30 min, and Figure 41.33B shows an autoradiogram obtained at 4 h after dosing. Table 41.5 lists the tissue concentrations by tissue for each time point. Note that radioactivity was extensively absorbed and distributed throughout the tissues of the rat at 30 min after the dose. Tissue concentrations were highest in the kidney and liver. High levels were also detected in the stomach, heart, lung, and spleen. By 4 h postdose, tissue concentrations decreased considerably, with

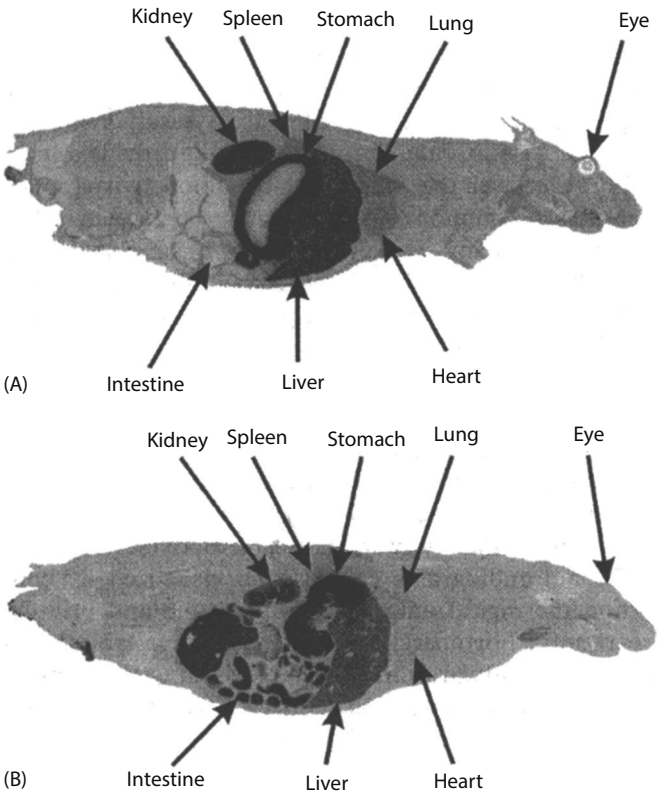

FIGURE 41.33 Quantitative whole-body autoradiograms of male albino rats after administration of [^{14}C]-RJR-2403 at a dose of 15 mg/kg by gastric gavage. (A) 30 min after dosing and (B) 4 h after dosing.

TABLE 41.5
Tissue Concentrations of Total Radioactivity after Single Oral Administrations of [^{14}C]-RJR-2403 to Male Albino Rats

Tissue	30 min	4 h
Eye	1.01	0.67
Heart	5.39	2.46
Kidney	39.17	39.15
Large intestine wall	3.28	Not measured
Liver	26.12	17.53
Lung	6.49	3.52
Spleen	5.18	4.96
Stomach wall	15.38	7.53

Note: Target dose is 15 mg/kg; results are expressed as μg equivalents/g.

high levels seen in tissues associated with metabolism and excretion such as the liver and kidney.

Analytical Methods for Determining Chemical Form

Total radioactivity data are of limited value because of their lack of specificity. When major routes of excretion have been determined, it is important to characterize the chemical form of the excreted radioactivity. As an example, expired CO_2 can be selectively trapped in base such as sodium hydroxide or ethanolamine, thereby providing insight into how extensively a xenobiotic is metabolized. Acrylic acid and ethyl acrylate, two monomers used extensively in the plastics industry, are rapidly metabolized, and 70% of the compounds are eliminated from the body as CO_2 via normal catabolic biochemical pathways that degrade the carbon skeleton of the molecule [43]. On the other hand, many xenobiotics are metabolized to polar compounds by selective metabolism of functional groups on the molecule without catabolic degradation of the carbon skeleton. HPLC is useful for quantifying metabolites in biological matrices because metabolites that are relatively hydrophilic and nonvolatile can be chromatographed easily. Other methods for separating metabolites from the parent compound include LC-MS, LC-NMR, TLC, capillary zone electrophoresis, chemical reaction interface MS, and GC-LC.

The simplest approach to characterizing the radioactivity in excreta is to inject urine directly onto an HPLC. Usually the urine is filtered first by passing it through a centrifugal ultrafilter with a small pore size (0.2–0.45 μm). HPLC guard columns are used to protect the analytical column from the high concentration of other organics such as creatinine and salts that are found in urine. The metabolites of the parent compound are detected after adequate separation of the radioactivity in excreta on the HPLC column. Radioactive peaks eluting from the HPLC column can be collected in scintillation vials as a series of fractions and the radioactivity counted in a liquid scintillation counter. A histogram of radioactivity in the fractions should reveal distinct peaks of radioactivity. The radioactive peaks can be coeluted with synthetic standards of putative metabolites by injecting the standards along with the sample onto the HPLC column. Radioactive effluent from the HPLC column can also be detected using commercially available flow-through radioactivity detectors [147], which have replaced the more labor-intensive fraction collection method in many laboratories. Radioactive flow detectors use two types of flow cells. Solid scintillator cells use glass beads, calcium fluoride, or yttrium silicate and permit the recovery of unadulterated effluent. Using this type of detector, peaks containing radioactivity can be collected and analyzed by some other method such as MS to determine the identity of the radiolabeled metabolite. Liquid scintillator cells mix liquid scintillation mixture with the column effluent prior to passing in front of the photomultiplier tubes where the radioactivity is detected. The mixture of effluent and LSM must be discarded as radioactive waste. The choice of the type and volume of the flow cell depends on the isotope and specific activity of the label. Optimization of these parameters permits rapid and accurate determinations.

Double-Label Techniques

The use of doubly labeled compounds in metabolic experiments is often necessary to obtain in-depth information on metabolic pathways and biotransformation mechanisms; thus, one part of a xenobiotic molecule may be labeled with ^{14}C, and another group in the molecule may contain a ^{3}H label. Because ^{3}H and ^{14}C have different maximal β-energies

(see earlier discussion), this allows the quantitative measurement of both ^{3}H and ^{14}C within the same sample. Similarly, other β-emitting nuclides, such as ^{35}S, can also be measured in the presence of ^{3}H or ^{14}C. The determination depends on the fact that there will be a region in the energy spectrum of the mixture where the β-particles from only one of the nuclides will be present. By measuring this region and comparing it with a nuclide standard, the appropriate isotope content in the mixture can be obtained. Some very elegant experiments have been conducted using doubly labeled xenobiotics. Pool and Crooks [152] used ^{3}H and ^{14}C to determine the in vivo stability of (R)-(+)-[^{3}H–N′–CH_3; ^{14}C–N–CH_3]-*N*-methylnicotinium ion, a primary nicotine metabolite in the guinea pig.

Positron Emission Tomography

Positron emission tomography (PET) was introduced in the early 1970s as a noninvasive diagnostic technique to study in vivo physiological processes in both animals and humans [161,194]. The process is an imaging technique that provides quantitative, regional measurements and kinetics of specific biochemical and physiological processes in living animals or human subjects. PET is similar to x-ray computerized axial tomography and MRI in that images of cross-sectional slices of the body are produced. The technique involves the use of a substance with the desired biological activity containing a positron-emitting radioactive isotope. Positron-emitting nuclides are neutron deficient compared to their stable isotopes and decay by spontaneous conversion of a proton to a neutron. This conversion is accompanied by release of a positron, which travels a small distance before encountering an electron, resulting in antimatter–matter annihilation. This annihilation event releases energy in the form of two 511 keV tissue-penetrating γ-ray photons radiating at approximately 180° from one another. A circular array of scanners consisting of scintillation crystals arranged so that opposing crystals are grouped in coincidence circuits are placed around the subject to detect the paired γ-rays as they simultaneously arrive on opposite sides (see Figure 41.34) [60]. The PET scanner's coincidence circuits enable the localization of the source of each annihilation. A computer then uses this information to reconstruct an image of radionuclide distribution within the body. Several million coincidences may be assimilated during a 1–15 min scan interval. In this way, a tomographic image can be obtained, illustrating the spatial distribution of the radionuclide. When images are recorded at appropriate intervals after the administration of the radionuclide, quantitative measurements reflecting the dynamic process under study can be obtained. Images can also be color coded to show differences in the levels of activity from one time point to the next.

Positron-Emitting Isotopes

The radionuclides most commonly used in PET are carbon-11, nitrogen-13, oxygen-15, and fluorine-18. All of these isotopes decay exclusively by positron emission, producing readily detectable tissue-penetrating γ-ray photons, but have relatively short half-lives (see Table 41.6). Their brief existence means that they must be manufactured close to the detection site, and more importantly, fast chemical reaction techniques and isolation procedures must be developed to ensure the production of a useful radionuclide. In addition, the use of such labeled compounds is limited to biochemical processes with rapid rates of turnover.

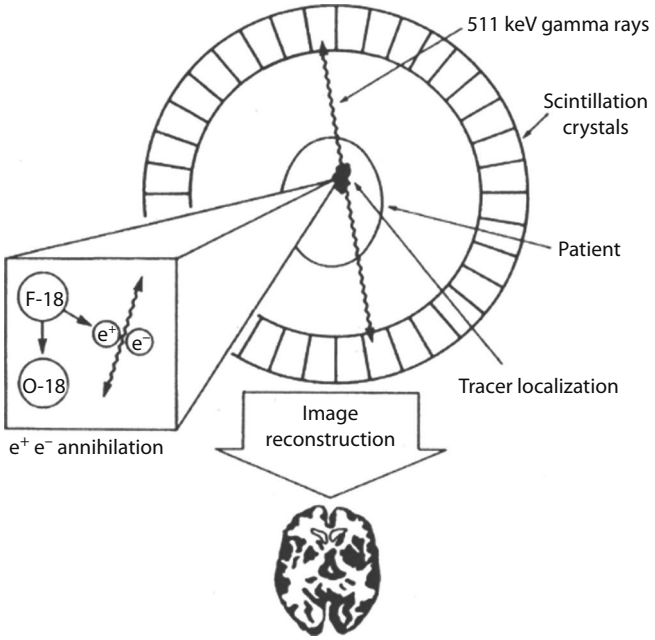

FIGURE 41.34 Key features of a PET scan: radiopharmaceutical localization, radioisotope decay by positron emission and immediate positron–electron annihilation; detection of body-penetrating 511 keV annihilation radiation by an external circular assay of scintillation crystals; and reconstructed image of radioactivity distribution. (From Derome, A.E., *Modern NMR Techniques for Chemistry Research*, Pergamon Press, Oxford, U.K., 1987. With permission.)

TABLE 41.6
Positron-Emitting Isotopes Commonly Used in PET

Nuclide	Half-Life (min)	Carrier-Free Specific Activity (Ci/mol)
^{11}C	20.40	9.22×10^3
^{13}N	9.96	1.89×10^4
^{15}O	2.07	9.10×10^4
^{18}F	109.70	1.7×10^3

The production of positron-emitting isotopes is normally carried out using on-site medical cyclotrons immediately prior to use, via the transmutation of stable isotopes; for example, ^{11}C is usually prepared by irradiating nitrogen or boron with accelerated protons, ^{15}O by irradiating nitrogen with deuterons, and ^{13}N by irradiating nitrogen with deuterons or irradiating carbon with deuterons. In the case of the longer-lived ^{18}F, stocks may be obtained from a regional distribution center. At sites remote from an available cyclotron, a radioactive generator system may be used to derive short-lived isotopes from longer-lived radioactive nuclides as they decay.

Although in some cases the positron-emitting isotope can be used directly in its elemental form (e.g., ^{15}O can be

directly used in metabolic studies, and ^{13}N is routinely used for studying lung ventilation), its incorporation into an unlabeled precursor molecule represents a formidable challenge for the imaginative synthetic chemist. In addition to the usual risk of working with body-penetrating radiation, the chemist must design suitable synthetic procedures that will proceed rapidly and in high radiochemical yield, avoid unintentional dilution of the radionuclide by stable carrier, and avoid difficult and time-consuming separation procedures. The number of steps in the synthetic process should be minimal to avoid working with large quantities of radioactivity and to ensure compatibility with the half-life of the isotope.

A description of the successful synthesis of L-[^{13}N]-tyrosine serves to illustrate the previous points [60]. A mixture of [^{13}N]-nitrate and [^{13}N]-nitrite obtained from an on-site cyclotron is converted to [^{13}N]-NH_3 by reduction with Devarda's alloy/NaOH reagent. The product is collected by distillation and immediately reacted with α-ketoglutarate and NADH. The reaction mixture is then passed through a column containing glutamate dehydrogenase immobilized on a solid support to give [^{13}N]-glutamate. Passage of this product down a second column containing immobilized glutamate oxaloacetate transaminase transfers the [^{13}N]-NH_2 group from glutamate to *p*-hydroxyphenylpyruvate to give L-[^{13}N]-tyrosine in radiochemically pure form and 28% overall radiochemical yield. The total synthesis time is 25 min.

Instrument Design

A functional PET unit consists of a data-acquisition system and a data-processing computer. The acquisition system incorporates the radiation detectors, their associated circuitry, and in some designs a mechanical system that imparts a small motion to the detectors to obtain better sampling. Data from the acquisition system are assimilated in a computer, and a display system for immediate viewing and recording of the image is available, with interactive capabilities for image analysis.

Specific Applications

PET is an extremely versatile method for probing fundamental biochemical processes in living systems. Important applications include metabolism, drug disposition and pharmacokinetics, and physiological and neurochemical mechanisms. In the brain, PET has been used to measure regional blood flow [170], glucose utilization, blood volume, oxygen utilization, the oxygen extraction ratio, the permeability–surface area product for water, acid–base chemistry, protein synthesis, and the characterization of dopamine D_2, benzodiazepine, and opiate receptors. PET measurement of regional rates of cerebral glucose metabolism utilizes [^{18}F]-2-fluoro-2-deoxyglucose (FdG) as the tracer component [61,149]. This procedure can quantitatively determine glucose utilization, because FdG, unlike dG, cannot be biotransformed further after its initial conversion to FdG-6-phosphate (FdG-6P) by hexokinase, due to the absence of an hydroxyl group at C2; thus, FdG-6P (and dG-6P) is metabolically trapped within the cell. Regional accumulation of FdG radioactivity is therefore proportional to blood glucose and is a sensitive index of brain function.

Regional blood flow and glucose utilization are established markers of local neuronal activity, and PET measurement of these parameters has been used to identify regions of the brain that are activated during visual, auditory, and somatic sensations; limb and eye movements; speech; semantic associations; and pathologic and normal forms of anxiety. Such parameters are also being used to identify regional brain abnormalities in patients with schizophrenia, panic disorders, epilepsy, Parkinson's and Huntington's diseases, obsessive–compulsive disorder, and clinical depression. An FdG-PET study in patients with acquired immune deficiency syndrome (AIDS) has focused on improving the diagnosis of the AIDS dementia complex (ADC), the major neurological outcome of AIDS that results in behavioral, cognitive, and motor disturbances [60]. In this study, progressive development of ADC correlated well with regional rates of cerebral glucose metabolism, particularly in the basal ganglia and thalamus. PET studies have also indicated that patients with Alzheimer's disease exhibit characteristic patterns of cerebral blood flow and glucose utilization; glucose metabolism in such patients is significantly reduced in the posterior parietal temporal region of the brain, compared to control patients [88]. PET images of cerebral glucose utilization have also been used to localize the epileptogenic foci in patients with intractable partial epilepsy.

The use of PET with radiolabeled synthetic drugs or radiolabeled analogues of naturally occurring neurotransmitters may lead to more reliable diagnoses of neurological disorders, perhaps even presymptomatic diagnosis. *N*-Methyl-[^{18}F]-spiroperidol (NMSP), a neuroleptic drug with high affinity for dopamine-D_2 receptors, has been used to visualize brain receptors in vivo in both normal and schizophrenic patients. The effectiveness of the antiparkinson drug, L-deprenyl, as a monoamine oxidase inhibitor in the brain has been verified from PET studies with ^{11}C-labeled L-deprenyl [150]. Ricaurte et al. [162] employed PET imaging of a ^{11}C-labeled serotonin transporter ligand to assess the long-term neurotoxicity of the recreational drug MDMA (Ecstasy) in humans. Here, reduced serotonergic receptor binding positively correlated with the extent of previous MDMA use.

Other studies [115,116] have shown that [^{18}F]-4′-fluoroclebopride ([^{18}F]-FCP) is a most promising candidate ligand for studying D_2 receptors with PET, and [^{18}F]-(+)-fluorobenzyltrozamicol ([^{18}F]-(+)-FBT) is a suitable ligand for studying cholinergic terminal density with PET via the vesicular acetylcholine transporter [117]. [^{18}F]-FCP has been used in PET studies designed to measure synaptic dopamine levels and D_2 receptor numbers in rhesus monkeys after treatment with psychostimulants such as (–)-cocaine, D-amphetamine, methylphenidate, and D-methamphetamine [115]. In these studies, psychostimulants caused an increase in the rate of washout of [^{18}F]-FCP from the basal ganglia. D-Methamphetamine and D-amphetamine had the greatest effect on washout kinetics of [^{18}F]-FCP relative to (–)-cocaine and methylphenidate, which was consistent with their ability to elevate synaptic dopamine levels. Thus, challenge studies with [^{18}F]-FCP may be a useful technique for

studying the dynamics of interaction between psychostimulant-induced increases in synaptic dopamine and postsynaptic D_2 receptors.

PET and [^{18}F]-FCP analyses have been utilized in chronic stress studies. Chronic stress results in heightened synaptic dopaminergic levels and a concomitant downregulation of D_2 receptors, analogous to the downregulation of dopaminergic receptors found following chronic cocaine exposure. Experiments with [^{18}F]FCP in dominant and subordinate cynomolgus monkeys showed a clearly greater uptake of the ligand in the basal ganglia by the dominant monkeys [60]. The data provide strong evidence that stimuli controlling behavior/physiological consequences (stress) have a neurochemical correlate that can be imaged with PET techniques and suggest that chronic stress results in heightened synaptic dopaminergic levels and a concomitant downregulation of D_2 receptors. Previous PET studies have found downregulation in dopaminergic receptors in human cocaine addicts [204,205] and alcoholics [73]. PET may also be a powerful tool in addressing the etiology of complex behavioral disorders associated with stress.

[^{18}F]-(+)-FBT has high affinity for the vascular acetylcholine transporter and low affinity for σ_1 and σ_2 receptors [119]. Its high uptake in the basal ganglia and reversible binding kinetics in vivo indicate that this tracer can provide quantitative measurements of vesicular acetylcholine transporter function in vivo with PET imaging. The vesicular acetylcholine transporter is a marker for cholinergic nerve terminals and may be directly related to cholinergic neuronal density. An important goal in PET studies is relating cholinergic neuronal density to cognitive performance. Such studies may be able to correlate an individual's change in behavioral performance (i.e., cognition) with a change in (reduction in) cholinergic function.

PET scanning of the torso is routinely employed in the diagnostic evaluation of patients with certain disorders of the heart. Modeling metabolic processes in the heart is more complex than in the brain, because the heart draws energy from several substrate pools, such as fatty acids, carbohydrates, and lactate. FdG-PET studies and blood flow [^{13}N]-ammonia-PET measurements have been used to diagnose coronary artery disease with better than 95% accuracy. Other studies have utilized [^{11}C]-palmitate, which is accumulated homogeneously by the heart muscle, to diagnose cardiovascular abnormalities [52]. Whole-body copper flux following transgastric injection was assessed in Long–Evans Cinnamon (LEC) rats with a defective copper transporter using ^{64}Cu and PET imaging [17]. The authors concluded that increased biliary secretion may not provide sufficient protection against high doses of orally administered copper, whereas the trapping of copper in the upper gastrointestinal tract may be critical to reducing toxicity.

PET images of glucose utilization and amino acid uptake are particularly useful for examining patients with a variety of tumors throughout the body. PET images of labeled estradiol uptake are used to examine patients with primary and metastatic breast tumors.

An established technique in diagnostic medicine, PET is now widely used for neuroscientific, pharmacological, and toxicological studies in vivo. Two major obstacles to more general use of this technique are its cost effectiveness and the availability of appropriate radiotracers. The synthesis of novel positron-emitting drug molecules remains a challenge for the radiochemist. Nevertheless, PET has advantages over other functional imaging techniques such as single-photon emission computed tomography (SPECT). Unlike MRI, it has the potential to measure characteristics of biological compounds, such as neurotransmitters and neuroreceptors, that exist in minute concentrations. Improvements in the methodology for determining anatomical localization, data analysis, and the performance of PET systems are ongoing. This important analytical tool continues to offer unique opportunities for researchers in the study of physiology, biochemistry, pharmacology, and toxicology.

Stable Isotopes

Most elements exist as several isotopes that vary in atomic weight. Some of the heavy isotopes are stable and do not decay with the emission of radiation. These so-called *stable isotopes* typically have a low natural abundance and chemical and physical properties that are nearly identical to those of their more abundant counterparts. Carbon exists naturally as a mixture of isotopes, ^{12}C, ^{13}C, and ^{14}C. ^{12}C is the most abundant isotope of carbon (98.89%); ^{13}C, the stable isotope of carbon, is much less abundant (1.11%); and ^{14}C is a radioisotope of carbon with a natural abundance so low as to be insignificant (except for its special application for carbon dating). Hydrogen also exists as a mixture of isotopes, ^{1}H, ^{2}H, and ^{3}H. ^{1}H (protium) is the most abundant isotope of hydrogen (99.985%); ^{2}H (deuterium), the stable isotope of hydrogen, is much less abundant (0.015%); and ^{3}H (tritium) is a radioactive isotope of hydrogen with insignificant natural abundance. Other stable isotopes that are useful for toxicology research include ^{15}N (0.37%), ^{17}O (0.037%), and ^{18}O (0.204%). A wide variety of chemicals specifically labeled with ^{2}H, ^{13}C, ^{15}N, ^{17}O, and ^{18}O at high atom-% enrichments are commercially available.

Stable isotopes with low natural abundance make ideal tracers for studying mechanism of toxicology. Because they are stable, they pose no significant health risk to the researcher or the experimental subject. No special license is required for the acquisition and use of stable isotopes, and no special precautions are necessary for their safe handling (other than the normal precautions used for handling the unlabeled compound). Because their chemical and physical properties are very similar to those of the more abundant isotope, their behavior in vivo is also quite similar. Compounds enriched in a stable isotope can be studied in the presence of natural abundance compounds with minimal background interference. Finally, a wealth of mechanistic information is available from stable isotope studies through the application of modern magnetic resonance and mass spectral techniques.

Choice and Location of Label

The stable isotope of choice for a toxicology study depends on the nature of the study (ADME, exposure assessment, mechanism of toxicity) and the instrumental method that will be used for analysis. The most common stable isotopes for toxicology research are ^{13}C, ^{2}H, ^{15}N, and ^{18}O. Stable isotopes of heavy metals such as ^{199}Hg and ^{206}Pb have been used to study mechanisms of toxicity and clearance. If NMR is used for analysis, it is best to use a spin 1/2 isotope for maximum sensitivity. For ^{13}C NMR analysis, uniform labeling offers distinct advantages in terms of metabolite characterization as will be discussed further in the following. For mass spectral analyses, the stable isotope that will give the greatest mass difference between natural abundance and labeled analytes is appropriate. Multiple sites of labeling are quite common and provide greater mass discrimination. If GC-MS is used, the optimum mass difference is 2–4 amu. A greater mass difference can lead to altered retention times and introduce uncertainty in quantitative analysis. Unlike radioisotopes where enrichments are quite low, stable isotopic enrichments are typically high, at least 90 atom-%. In general, the factors that govern the position of a radioisotopic label (stability and exchangeability) also govern the position of a stable isotopic label.

Applications: Pharmacokinetics and Metabolism of Isotopically Labeled Nicotine

Due to the widespread use of tobacco products, the pharmacokinetics of nicotine and its metabolites have been the subject of much study. Early studies focused on nicotine and its major metabolites cotinine and nicotine-1′-oxide. Kyerematen et al. [104] reported a pharmacokinetic study of nicotine and 12 of its metabolites in the rat. They administered ^{14}C-labeled nicotine in serial intra-arterial doses and collected blood for up to 30 h and urine up to 120 h. Nicotine and 12 of its metabolites were quantified by HPLC with radiometric detection. One previously unidentified metabolite, collected from the HPLC and analyzed by EI MS, was identified as allohydroxy-demethylcotinine. Plasma nicotine half-life, total body clearance, and apparent volume of distribution and half-lives of urinary excretion of cotinine, cotinine-*N*-oxide, and allohydroxy-demethylcotinine were all determined. Radiolabeled nicotine afforded convenient determination of nicotine and 12 of its metabolites with high sensitivity, demonstrating the power of this method for the study of nicotine pharmacokinetics.

Kyerematen et al. [103] also determined the disposition of radiolabeled nicotine and eight of its metabolites in humans. The use of radiolabeled nicotine enabled detection of plasma and urinary nicotine and metabolites from a very low dose (190 μg/subject), so a comparison of smokers and nonsmokers was possible. Two new urinary metabolites, 3′-hydroxycotinine glucuronide and demethylcotinine $\Delta^{2',3'}$-enamine, were identified by mass spectral analyses.

The ability to distinguish labeled from unlabeled nicotine by GC-MS enabled the study of nicotine pharmacokinetics and bioavailability in humans [15]. After smoking a cigarette, smokers received nicotine labeled with deuterium in both 3′ positions (previously shown to be stable to metabolism). Plasma levels of both labeled and unlabeled nicotine were monitored by GC-MS with SIM. The sensitivity of the analytical method and the specificity of the labeled nicotine that eliminated background interference from unlabeled nicotine gave high-quality pharmacokinetic data.

Metabolomic analysis is also facilitated using these techniques. At the microbial scale, a mixture of uniformly labeled ^{13}C-labeled metabolites was extracted from yeast grown on ^{13}C-labeled substrates [221]. The labeled metabolites were then used as internal standards for the LC-MS analysis of the glycolytic and TCA cycle metabolites produced in yeast grown under varied conditions. The precision and efficiency of cellular extraction, sample processing, and quantification of metabolite recovery for each metabolite were significantly improved when using labeled metabolites as internal standards.

Characterization of Urinary Metabolites

Detection of ^{13}C resonances of natural abundance xenobiotic metabolites in a complex matrix such as urine is often difficult due to interference from endogenous compounds. Appropriate use of ^{13}C-enriched xenobiotics can facilitate the characterization of metabolites in whole urine by ^{13}C NMR spectroscopy with little or no sample cleanup. In higher organisms, the characterization and quantification of dynamic renal xenobiotic metabolism have been extensively explored using ^{13}C-labeled compounds coupled with NMR and other analytical methods [10].

Isotopically labeled ^{13}C-benzene was employed to distinguish benzene metabolites produced from known benzene exposure from background levels typically present in the urine [210]. Human volunteers were exposed to an environmentally relevant dose of benzene, 40 ± 10 ppb, for 2 h. Benzene metabolites, readily discernible from unlabeled background metabolites, were then quantified using GC-MS. The percentage of muconic acid metabolites excreted was higher than that reported after exposure to occupational levels. The authors suggest that such stable isotope studies may be useful for validating toxicokinetic models and occupational exposure risk extrapolation.

Sumner et al. [191] studied the metabolism of [1,2,3-^{13}C]-acrylamide in rats and mice using 1D and 2D ^{13}C NMR spectroscopic analyses of urine. The animals received the labeled xenobiotic orally. Urine was collected for 24 h and then centrifuged, and D_2O was added to a final concentration of 15%. INADEQUATE spectra were used to correlate all carbon signals. HET2DJ spectra revealed the number of protons attached to each carbon for all metabolites. These spectral data, along with calculated chemical shifts of proposed metabolites and spectra of synthetic standards, were used to identify five urinary metabolites of acrylamide. Quantification of the urinary output of acrylamide and the five metabolites was accomplished by integration of the carbons signals in 1D spectra relative to dioxane, an internal standard. Approximately 50% of the administered dose of acrylamide was recovered as the five metabolites, confirming

a previous study wherein 62% of the administered dose of ^{14}C-labeled acrylamide was recovered in urine within 24 h. Stable isotope labeling and ^{13}C NMR analysis enabled the characterization and quantification of xenobiotic metabolites in a complex matrix without the need for tedious sample cleanup or chromatographic separation.

Determination of Toxic Metals Using Stable Isotope Dilution MS

Stable isotopes are widely employed in elemental MS studies of toxic elements. Smith et al. [182,183] used stable lead isotopes to study the effectiveness of a chelating agent (DMSA) in removing lead from skeletal vs. soft tissue and the redistribution of lead in other tissues. Lead has four naturally occurring isotopes: ^{204}Pb (1.4%), ^{206}Pb (24.1%), ^{207}Pb (22.1%), and ^{208}Pb (52.4%). By enriching drinking water given to rats with ^{206}Pb, ingested lead was distinguishable from the endogenous lead already present in the animals. Here, the mass spectrometer used thermal emission to produce ions and measure the isotopic ratios, thereby quantifying the ^{206}Pb dose.

Cadmium is another highly toxic metal. Environmental and industrial cadmium exposure is of great concern. In contrast to the previous thermal emission mass spectrometric method for lead determination, a stable isotope dilution GC-MS method was employed for assessing cadmium exposure. Urinary cadmium was determined by using the chelating agent Li(FDEDTC) to form the chelate $Cd(FDEDTC)_2$. The chelate was then analyzed by GC-MS with EI, where $M^{+\bullet}$ was monitored for quantitation. Precise, accurate cadmium detection in urine at the 10 mg/L level was achieved. This isotope dilution technique eliminated matrix effects, so precision and accuracy were not affected by incomplete recovery.

INTEGRATION OF TECHNIQUES IN TOXICOLOGY

Mechanisms of xenobiotic toxicity are usually complex, involving not only the parent compound but also a broad array of metabolites and tissue-derived endogenous compounds. All of these materials are produced in a dynamic process as the intoxicated organism responds to the toxic insult and attempts to maintain homeostasis. Modern instrumental methods are powerful tools that have their greatest utility when they are used in conjunction with one another in a synergistic fashion to characterize materials in complex mixtures. Numerous examples are available in the literature of the use of multiple instrumental techniques to describe a variety of different chemical entities in complex mixtures.

The forensic toxicologist often conducts hair analysis to assess both acute and chronic exposure to drugs and toxins. Newborn hair analysis may be particularly suited for studying both fetal and maternal exposure to xenobiotics. Tagliaro et al. [192] assayed thyroxine concentration in newborn hair by first extracting the hair, fractioning it with HPLC, and then using a radioimmunoassay to quantify the analyte. The amphetamine and alkaloid drug content in hair samples was similarly assessed by derivatizing the amines in alkaline hair extracts to produce trichloroethyl carbamates, followed by combined GC-MS analysis of the derivatives [55]. Gustafson et al. [65] simultaneously determined plasma levels of THC and two of its metabolites, first by enzymatically cleaving their glucuronide conjugates, followed by SPE, separation, and finally, quantification by GC-MS. Given the large number of biomarkers and dynamic concentration ranges normally present in a metabolomic fingerprint, integrated separation and analytical techniques are commonly employed for mapping these complex mixtures. A method for multicomponent analysis has been developed wherein rat urinary metabolite profiles correlated with toxin exposure may be accurately determined by combining HPLC separation with simultaneous electrochemical redox array and MS analysis to identify intoxicated animals.

In one exemplary study, many of the techniques that have been described in this chapter were used to confirm the identity of many compounds. Wiltshire et al. [216] used diode array UV spectrophotometry, MS, NMR, radiolabeled tracers, open column chromatography, HPLC, and TLC to characterize the complex metabolic pathway of a calcium antagonist (Ro 40-5967) in the rat (Figure 41.35). A classic xenobiotic disposition study was conducted using Ro 40-5967 labeled with ^{14}C. Approximately 80% of the radiolabeled dose was recovered in all excreta including bile, urine, and feces; 37% of the dose was excreted in the bile, so chemical characterization of the biliary radioactivity was carried out. Bile was partially purified by passing it through an open column of Amberlite XAD-2 resin. The fractions collected from the open column were evaporated to dryness and partitioned between ethyl acetate and water. Two of the fractions contained an insoluble gum that was taken up in ethanol. All fractions (aqueous and organic) were taken to dryness and then dissolved

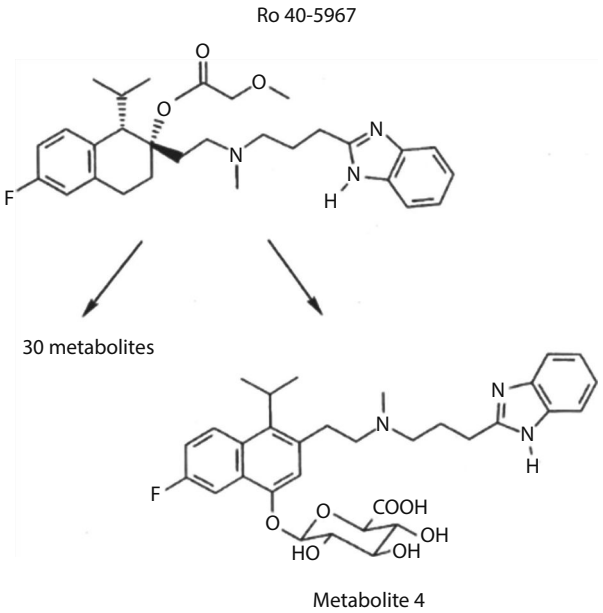

FIGURE 41.35 Metabolism of the calcium antagonist Ro 40-5967 in the rat. Characterization of metabolite 4 exemplifies the integration of modern instrumental techniques to study mechanisms of toxicology.

in aqueous methanol. These fractions were subjected to three sequential reversed-phase HPLC purification steps to obtain material that was suitable for further characterization. It was characteristic of major changes in the parent compound; for example, a λ_{max} at 280 nm is typical of oxygen substitution at the 5 position of the parent compound. It was obvious that approximately four of the metabolites fell in this class.

Further characterization of the metabolites required NMR and MS. Sufficient material from the HPLC purification was obtained from 11 of the XAD fractions. This represented approximately two-thirds of the radioactivity excreted in bile. The proton NMR spectrum of the parent compound possessed a number of characteristic features, and it was possible to see similar features in the spectra of the fractions. A number of the metabolite fractions contained resonances characteristic of glucuronic acid conjugation. Mass spectra were obtained from 45 subfractions of the original XAD fractions by thermospray LC-MS. As with the proton NMR spectra, features in the mass spectra were characteristic of the parent compound; for example, *m/z* 406 was characteristic of the loss of the side chain.

Rather than discussing the entire characterization that involved the description of 31 metabolites, it is instructive to describe the characterization of just one of the metabolites. Metabolite 4 was the major biliary metabolite and equivalent to about 25% of the total biliary radioactivity. It had a class 3 UV spectrum, indicating the presence of a substituted naphthyl group. Remember that the parent compound contains a tetrahydronaphthyl ring system where one of the rings of naphthylene is saturated. The very strong double peak at 240–250 nm is characteristic of a fully aromatic substituted naphthylene.

The proton NMR spectrum of this metabolite showed the presence of glucuronic acid as well as loss of the ester side chain. Evidence that the asymmetric center of the isopropyl side chain had been lost was obtained from a shift in the methyl resonances of the isopropyl group. Aromatization of the saturated ring was obvious by the addition of an aromatic singlet at 7.1 ppm. The metabolite structure was deduced to be an oxyglucuronide derivative of the parent compound in which the alicyclic ring had been aromatized. This was consistent with a mass spectrum containing a protonated molecular ion at *m/z* = 596, loss of the benzimidazole group (*m/z* = 438), and loss of glucuronic acid (*m/z* = 262).

This integrated application of instrumental techniques permitted a thorough characterization of metabolites that varied greatly in chemical structure and polarity. A total of 31 biliary metabolites, representing 67% of the excreted dose of Ro 40-5967, were characterized. Only through the integration of modern instrumental methods could this complex metabolic pathway be thoroughly elucidated.

QUESTIONS

41.1 Name four ways that MS has been used to assess exposure to xenobiotics.

Answer: MS has been used to determine metabolites of xenobiotics in biological fluids, to analyze the metabolomic profile of heavy metal exposure, to determine DNA adducts formed as a result of toxin exposure, and for the rapid identification of intoxicants.

41.2 An unknown compound in an organic extract of urine is sufficiently volatile to pass through a GC-MS system but fragments extensively under EI such that no $M^{+\bullet}$ is observed. Name at least two alternative approaches to determine the molecular weight of this compound using MS.

Answer: (a) A GC-MS system with PICI could be used to form $(M + H)^+$. (b) An HPLC method could be developed, and the material analyzed by LC-MS using a soft ionization method such as ES or APCI. (c) If the compound contained a hydroxyl or amine group, derivatization with a common trimethylsilation reagent could form a compound with a more stable molecular ion.

41.3 An LC-MS method with an ES ionization source runs a binary gradient with mobile phase 1 = 2 mM ammonium acetate and mobile phase 2 = 90% methanol:10% acetonitrile. There is a large background ion in the system at *m/z* 59. CID on this ion produces a fragment at *m/z* 42. What are likely assignments for these ions?

Answer: The *m/z* 42 is protonated acetonitrile. The mass difference of 17 Da (59 – 42) suggests ammonia (NH_3) as a neutral loss; thus, *m/z* 59 is likely an ammonium adduct of acetonitrile, $(CH_3CN)(NH_4)^+$, produced from background mobile-phase components.

41.4 EI mass spectrometers have several ions constantly present in the background mass spectrum at *m/z* 18, 28, 32, 40, and 44. Identify these components.

Answer: These are all components of air with moisture present: *m/z* 18 = H_2O; *m/z* 28 = N_2, *m/z* 32 = O_2, *m/z* 40 = Ar, and *m/z* 44 = CO_2.

41.5 Using positive ES, a large protein is ionized under acidic conditions that create an $(M+4H)^{4+}$ ion in the mass spectrum at *m/z* 712.2. What is the molecular weight of this compound?

Answer: Remember that four protons have been attached to this molecule, so *m/z* = 712.2 = (M + 4H)/4, → *M* = (712.2 × 4) – 4; *M* = 2844.8 Da.

41.6 $CDCl_3$ is a commonly used NMR solvent. Carbon NMR spectra of samples dissolved in $CDCl_3$ contain a residual solvent peak that is split due to ^{13}C–^{2}H coupling.

a. Into how many lines is this signal split?

Answer: ^{2}H has a spin quantum number (*I*) of 1. Applying the $2nI + 1$ rule, the number of lines is (2 × 1 × 1) + 1 = 3.

b. In most cases, carbon spectra are acquired with hydrogen decoupling. Why is not the ^{13}C–^{2}H multiplet reduced to a singlet under the conditions of this decoupling?

Answer: Decoupling is applied at the ^{1}H (protium) frequency. Deuterium (^{2}H) has a very different precessional frequency; therefore, it is not decoupled in the carbon NMR spectrum.

41.7 Why is ^{13}C–^{13}C coupling rarely seen in carbon NMR spectra?

Answer: Coupling is only seen for closely spaced nuclei (fewer than four to five bonds). To see ^{13}C–^{13}C coupling, two ^{13}C atoms would have to be in close proximity. The natural abundance of ^{13}C is only 1%, so the likelihood of two ^{13}C nuclei being in close proximity is very low. Carbon spectra of molecules composed of natural abundance carbon do not show ^{13}C–^{13}C coupling. ^{13}C–^{13}C coupling is only seen with isotopically enriched molecules.

41.8 Sensitivity in NMR depends on what factors?

Answer: (a) Magnetic field strength, (b) magnetogyric ratio, and (c) natural abundance of the spin-active nucleus.

41.9 Describe three approaches for increasing sensitivity for a given nucleus in NMR.

Answer: (a) Using a higher-field-strength instrument (magnet), (b) using a smaller NMR probe or a selectively tuned probe, and (c) signal averaging (FT-NMR).

41.10 Why are chemical shifts expressed in dimensionless units designated δ?

Answer: Chemical shifts vary with the strength of the applied magnetic field. To enable comparisons of chemical shifts from one instrument to the next, chemical shifts are expressed in δ units.

41.11 What factors limit time resolution in online LC-NMR?

Answer: (a) HPLC mobile-phase flow rate, (b) total time required to obtain one transient (scan), and (c) total number of transients acquired per LC peak.

41.12 Why is EPR inherently more sensitive than NMR?

Answer: The magnetic moment of an electron is 700 times greater than that of a proton. This means that the energy difference between spin states is greater for electrons than for protons. This greater energy difference leads to higher sensitivity. It also means that the energy required for an EPR transition is higher than that required for an NMR transition. NMR uses energy in the RF range; EPR uses energy in the microwave range.

41.13 The EPR spectrum of the Fe-DETC complex with ^{15}NO shows doublet hyperfine splitting.

a. Why?

Answer: ^{15}N has a spin quantum number (I) of 1/2. Applying the $2nI + 1$ rule ($n = 1, I = 1/2$), the number of lines is 2 (doublet).

b. How was this used to distinguish between NO produced from ^{15}N-labeled arginine and NO produced from endogenous arginine?

Answer: ^{14}N has a spin quantum number of 1; therefore, it splits electron signals into three lines (triplet hyperfine splitting). Endogenously formed NO is derived from natural abundance arginine. Natural abundance nitrogen is 99.6% ^{14}N, so it leads to triplet hyperfine splitting. Any doublet splitting results from NO produced from added ^{15}N-labeled arginine.

41.14 QWBA is becoming a very popular method for determining xenobiotic tissue distribution.

a. What is the major limitation of this technique?

Answer: QWBA is used to determine total radioactivity. It cannot distinguish between different chemical forms of radioactivity; in other words, it cannot distinguish between xenobiotic metabolites. It determines the sum of parent compound plus metabolites and, therefore, yields no information on xenobiotic metabolism.

b. In practice, how can this limitation be overcome?

Answer: To overcome this limitation, follow-up studies must be performed. QWBA is used to determine the distribution of a xenobiotic. QWBA data reveal the tissues containing xenobiotic-derived radioactivity. The follow-up studies involve administration of the xenobiotic (radiolabeled or natural abundance) and isolation of tissues containing the parent xenobiotic and its metabolites.

Extraction of these tissues provides solutions that can be analyzed for metabolites by suitable separation techniques such as LC-MS or LC-NMR.

41.15 What effect, if any, would you expect to observe in the UV absorbance spectrum of an ethanol solution of each of the following compounds: phenol, aniline, and *trans*-cinnamic acid, after the addition of a drop of 1 N aqueous sodium hydroxide solution to the UV cuvette containing the solution of each compound?

Answer: (a) Phenol—Addition of 1 N NaOH will convert phenol (PhOH) to the phenolate ion (PhO^-), leading to a formal negative charge on the auxochromic group attached to the phenyl ring chromophore. The interaction of these electrons with the conjugated phenyl ring produces a bathochromic–hyperchromic shift; that is, the absorption band of phenol shifts to a longer wavelength, and the extinction coefficient increases in value. (b) Aniline—Addition of 1 N NaOH will have no significant effect on the absorption spectrum of aniline, as the alkaline medium will not alter the structure of the molecule. (c) *trans*-Cinnamic acid—Addition of 1 N NaOH will generate the carboxylate ion of this organic acid ($R–COO^-$). As with phenol, this will result in a bathochromic–hyperchromic shift in the absorption band of *trans*-cinnamic acid.

41.16 Under what circumstances may the UV absorbance of organic molecules deviate from Beer's law?

Answer: The UV absorbance of organic molecules may not obey Beer's law if (a) protonation or deprotonation, (b) tautomerization, (c) dimerization, or (d) complex formation of the analyte occurs in solution.

41.17 Even relatively simple, low-molecular-weight compounds exhibit an abundance of absorption bands in their IR spectrum. What factors influence the number and value of the IR absorption bands in organic molecules?

Answer: The number of fundamental modes of vibrations (i.e., stretching and bending vibrations) is $(3n - 6)$ for nonlinear

polyatomic molecules and $(3n - 5)$ for linear molecules, where n is the number of atoms in the molecule. The factors that influence the value of IR absorption frequencies of chemical bonds in organic molecules are (a) the masses of the two atoms in the bond, (b) the velocity of light, and (c) the force constant of the bond.

41.18 Discuss the usefulness of group frequencies in the IR spectrum of unknown organic molecules.

Answer: Group frequencies are characteristic absorption frequencies of certain functionalities within an organic molecule, which can be used diagnostically to confirm the presence (or absence) of the functionality in an unknown molecular structure. Examples of such functionalities are C═O, C≡N, C≡C, −OH, and $-NH_2$. The frequencies of these structural moieties are usually independent of the structure of the rest of the molecule.

41.19 What is one of the major advantages of using Raman spectroscopy compared to IR spectroscopy for studying biochemical processes?

Answer: One of the major advantages of using Raman spectroscopy in biochemical studies is that spectra can be obtained for molecules in aqueous solution, as water exhibits a weak Raman spectrum that interferes only minimally with the spectrum of the analyte.

41.20 Which general class of nuclides is useful in PET scanning, and which isotopes are commonly utilized?

Answer: Positron-emitting radioactive nuclides, which are neutron deficient, are used in PET scanning. These isotopes are short lived and decay by spontaneous conversion of a proton to a neutron. This process is accompanied by release of a positron, which collides with an electron, resulting in annihilation and release of energy in the form of two tissue-penetrating γ-ray photons. Common positron-emitting isotopes used in PET scanning are ^{11}C, ^{13}N, ^{15}O, and ^{18}F. These nuclides have half-lives ranging from 2 to 110 min.

42 Methods in Environmental Toxicology

Anne Fairbrother, Mace G. Barron, and Mark S. Johnson

CONTENTS

Testing of chemicals for their toxic effects traditionally focused on safety and effects in humans using surrogate species. Beginning in the 1960s, the recognition that chemicals in the environment can have effects on nonhuman receptors has led to the emergence of the subdiscipline of ecotoxicology. Subsequently, testing protocols with a wide range of surrogate species have been established to address questions concerning thresholds of toxic effects and mode of action. By expanding the number of species tested in assessing the toxicology of a chemical, we are able to predict and diagnose possible adverse environmental effects and also gain considerable insight into a toxicant's mechanism of action, organ-specific toxicity, and acute and long-term effects. Field protocols emphasize methods and indicators for determining the consequences of chemical exposure on species and their populations. In this chapter, we provide principles and examples of laboratory and field protocols that have been developed to understand the effects of chemicals in the environment.

ENVIRONMENTAL BEHAVIOR OF CHEMICALS

When testing the toxicity of chemicals to organisms in the laboratory, the chemical is usually fed to or applied directly to the animal or incorporated into the medium in which the organism is living (i.e., soil, water, sediment). However, when a chemical is in the environment, it partitions among different media according to specific physical properties and chemical behaviors. This directly influences the amount and form of the chemical to which organisms are exposed. Therefore, to conduct toxicity tests with the relevant chemical form and concentrations, the environmental transport and fate of chemicals must be understood. While a detailed discussion of environmental chemicals is beyond the scope of this chapter, we provide a short review of the most salient topics. Practical methods for estimating environmentally important properties of organic chemicals can be found in Boethling and Mackay [1], while numerous textbooks describe the fundamental concept of chemical fate and transport (see, e.g., Manahan [2]).

Water Solubility and Lipophilicity

The most significant determinant of the transport and fate of a chemical in the environment is its water solubility. Highly soluble chemicals are transported through the hydrologic cycle and thus can be distributed over great distances from their points of introduction into the environment. Conversely, hydrophobic compounds tend to be more static and move little through the hydrologic cycle. Generally, the more water soluble the chemical, the less lipophilic it is, the less it is sorbed to soils and sediments, and the less it accumulates into biota. Water solubility is defined as the maximum amount of a chemical that can be freely dissolved in a given quantity of pure water at a particular temperature. It is important to note that even chemicals described in tables of physical constants as very insoluble may have sufficient water solubility to significantly influence their behavior in the environment. It is particularly important to note that metals and other inorganics with low water solubility may be converted to more water-soluble forms in the environment or introduced as soluble salts. A derivative property of the water solubility and lipophilicity of a chemical is its octanol/water partition coefficient (K_{OW} or P), frequently reported as log K_{OW}. K_{OW} is defined as the ratio of the concentrations of a chemical in the water phase and in the *n*-octanol phase after equilibrating between equal volumes of the two solvents. It is a key property of a chemical for environmental considerations, as it is a predictor of soil and sediment adsorption and subsequent bioaccumulation in organisms and potential biomagnification through trophic transfer up the food chain. In designing studies to assess the toxicity of a chemical in model ecosystems, such as microcosms [3] or mesocosms [4], the octanol/water partition coefficient must be known or experimentally determined, so the behavior of the chemical in the system can be predicted and the system designed appropriately.

Soil Adsorption

The extent of partitioning of a chemical between the solid and solution phases of a water-saturated soil or sediment is described by the soil sorption coefficient (K or K_d) [5,6]. It is determined experimentally using the Freundlich equation:

$$\frac{x}{m} = KC^{1/n}$$

where

x/m is the μg of chemical adsorbed per g of soil
C is the μg of chemical per mL of solution
K and n are constants for a particular soil type

The value of n must be determined experimentally but is frequently assumed to be 1. K_{OC}, the soil sorption constant, is determined from K by dividing by the percent organic carbon in the soil and multiplying the result by 100. This constant is observed to be relatively independent of the type of soil or sediment and is the value most frequently used to describe the adsorption of a chemical to soil or sediment. Consideration of the soil adsorption of a chemical is extremely important for the proper design of ecological test systems.

Atmospheric Particulate Matter

When pollutant-contaminated soils become airborne, chemicals sorbed to the resulting particulate matter must be considered in some testing protocols. Such sorbed chemicals may be bioavailable in biological systems. Soil-derived particulate matter is composed of a mineral fraction and an organic matter fraction. Affinity of organic chemicals for the mineral fraction is believed to be low, but hydrophobic organic chemicals may have a high affinity for the organic portion [1]. Once particulate matter is suspended in the atmosphere, gas/particle partitioning of adsorbed chemicals is a function of the vapor pressure of the chemical. Chemicals with a vapor pressure $<10^{-6}$ atm will be primarily in the particle phase, while those with a vapor pressure >1 atm will partition primarily to the gas phase [1]. Thus, under some testing conditions, the air quality of the test system must be controlled.

Vaporization

The vaporization of a chemical from a solid surface or a solution is an important mass-transfer process. Factors that control volatilization are diffusivity of the chemical, its water solubility, vapor pressure, the Henry's law constant, and temperature. Diffusivity is the rate of diffusion of a chemical through a medium and depends on the nature of the chemical itself and the nature of the medium through which it moves. Vapor pressure is the tendency of a liquid to change from the liquid to the gaseous state and is highly dependent on temperature.

The air/water interface is most important in environmental analyses, so the question of the ability of a chemical to diffuse across that interface is significant when evaluating its environmental behavior. The tendency of a chemical to escape from solution is described by the Henry's law constant. Henry's law states that the solubility of a gas in a liquid is directly proportional to the pressure of the gas above the liquid at equilibrium: $H = P/C$, where C is measured in mol/m^3 and P is in atm; that is, H is the ratio of the saturation vapor pressure and the water solubility of the chemical. Units of H are most often reported as atm-m^3/mol; however, if C is expressed in mol/L and P is expressed in mol/m^3, H is dimensionless. Under these circumstances, the Henry's law constant is sometimes referred to as the air/water partition coefficient.

Movement of chemicals in the environment occurs in the vapor state, as well as in solution or when adsorbed to particulate matter. The most important consideration in evaluating the extent of such movement is the Henry's law constant, because most chemicals will eventually be found in water solution, and their tendency to move into the air will have an impact on their potential for toxic effects in organisms that may be exposed. In the design of toxicology test methods, such considerations must be taken into account. Their importance is illustrated in Figure 42.1, in which the relation of the Henry's law constant of a chemical to its volatility characteristics is depicted.

Bioaccumulation

Certain chemicals accumulate in organisms that are exposed in their environments. Some chemicals biomagnify in the food chain, such that higher trophic-level organisms have higher concentrations of the substance in their tissues than do their prey. There are now many well-known cases of chemicals biomagnifying in food webs to the point that toxic effects are exhibited in organisms that may have had no direct exposure to the chemical itself at its point of application; polychlorinated biphenols (PCBs), organochlorine insecticides, and mercury are a few examples. The tendency of a chemical to be more concentrated in an organism than the concentration in its environment is described by its bioaccumulation factor (BAF) or bioconcentration factor (BCF). The BAF or BCF is calculated by dividing the concentration of the chemical in the organism by the concentration of the chemical in the soil, sediment, or water in which it lives. BAFs assume that exposure has occurred through all potential routes, including direct uptake from the environmental medium and ingestion of contaminated foods. BCFs refer to water exposures and are applied typically only to aquatic organisms; however, BCFs have been used considering pore-water transfer of chemicals to invertebrates in mesic soil environments. BCFs have units of water volume per unit tissue weight (e.g., mL/g) and can be viewed conceptually as the volume of water containing the amount of chemical in 1 g of tissue [7]. The BCF can be estimated from the water solubility of a chemical, K_{OW}, or K_{OC}. A number of empirical equations that are specifically useful for calculating BCFs for particular chemical groups can be found in Lyman et al. [5]. The estimates of BCF should be used in designing toxicity studies to understand the degree to which the test chemical will be taken up and stored in the organisms being used in tests; however, bioaccumulation and bioconcentration assume that the organism is at a steady state with the chemical in its environment and assumes net uptake and so does not account for the ability or rate at which an organism metabolizes the chemical. Therefore, the BCFs or BAFs are often species and site specific, and a lack of consideration of species-specific toxicokinetics may yield misleading conclusions.

Biodegradation

As organic chemicals move in the environment, they are subjected to breakdown, primarily by microorganisms, in a

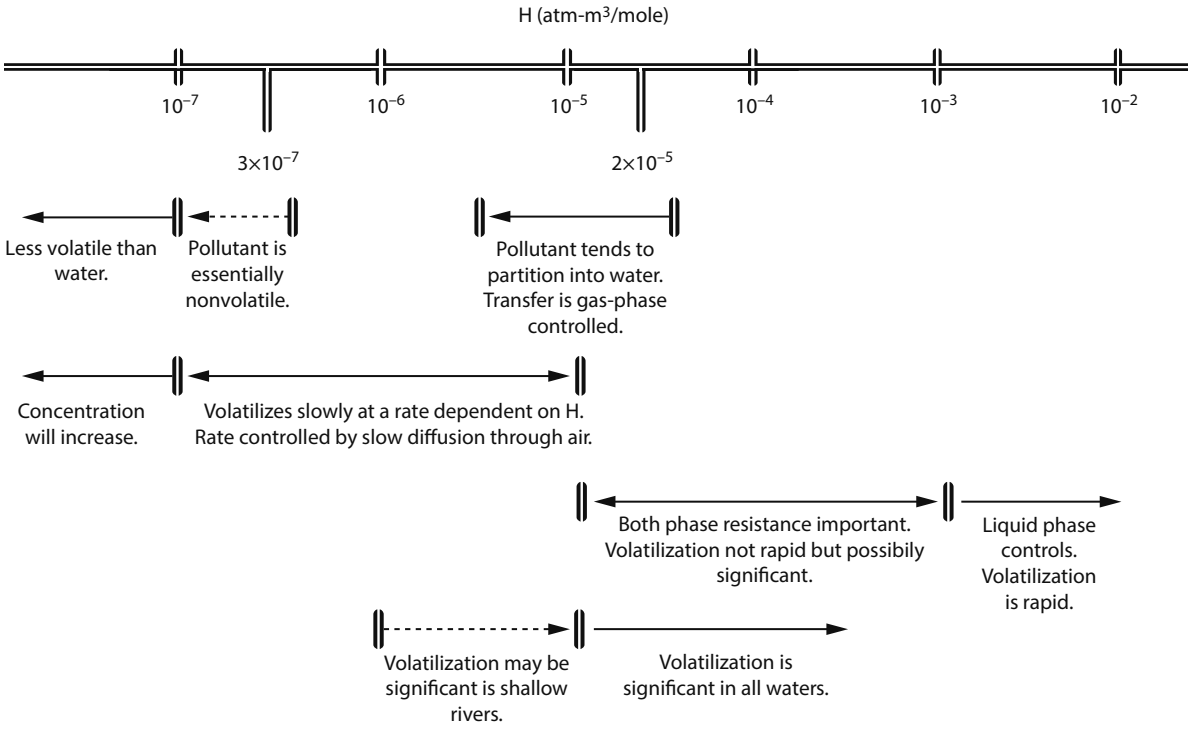

FIGURE 42.1 Volatility characteristics associated with various ranges of Henry's law constant. (From Smith, J.H. et al., *Environ. Sci. Technol*., 14, 1332, 1980; Reproduced in Lyman, W.J. et al., *Handbook of Chemical Property Estimation Methods*, McGraw-Hill, New York, 1982. With permission.)

process known as *biodegradation*. This process represents a significant loss mechanism in soil and sediments that can ultimately lead to mineralization of the compound—that is, degradation to carbon dioxide, water, and the inorganic forms of other elements the chemical may contain. Microorganisms are the primary converters of complex organic chemicals in to inorganic substances, although soil and sediment invertebrates also play a major role in the biodegradation process. In many instances, higher organisms are able to metabolize compounds, but they generally play a less significant role in environmental systems. Photochemical degradation and hydrolysis are other important abiotic degradation factors in the environment.

Almost all degradative reactions in the environment are oxidative, reductive, hydrolytic, or conjugative. Biodegradation can take place in virtually any environmental situation, aerobic or anaerobic; thus, in a test system designed to assess the toxicity of a chemical, the potential for biodegradation must always be considered regardless of the presence or absence of oxygen.

When testing chemicals in anything more complex than a single organism (i.e., the microcosms and mesocosms, discussed later in this chapter), the medium, whether water, sediment, soil, or a combination of these, plays an important role in the behavior of the system. Organic matter in the medium strongly influences its microbial density, and microorganisms may comprise as much as 80% of the biomass of soil. The microbial community in turn determines how stable a xenobiotic chemical will be in the system.

Organic compounds can be divided into four groups according to their biodegradability: (1) usable immediately by an exposed organism as a nutrient or energy source, (2) usable by microorganisms following an acclimation period, and (3) degraded slowly or not at all. In the fourth group, compounds are subject to co-metabolic degradation, wherein a compound that does not provide a nutrient or energy source for the degrading organism is broken down in conjunction with the degradation of other substances. Ideally, when evaluating the effect of xenobiotics on complex systems, one needs to consider all aspects of the biology and chemistry of all of the organisms and chemicals present. The best design of such test systems demands the most complete knowledge possible of all the potential interactions of chemicals and organisms in the system.

Other Considerations

Before presenting and discussing the specific test methods used in ecotoxicology, it is important to note that there are several significant differences between the practice of toxicology using laboratory animals and methods that use wild animals or plants, often located in their usual, or at least simulated, environmental conditions. Most importantly, the goal of ecotoxicology is considerably broader and more varied than that of human toxicological evaluations: while the assessment of a test chemical's impact on the health of an individual human is of primary importance in toxicology, an understanding of chemical ecosystem's impact, as well as its

component parts, is the paramount consideration in ecotoxicology. Furthermore, in ecotoxicology, the test organisms may be the actual targets for a chemical pollutant (such as pesticides), and the test method often investigates the endpoint subjects of concern, rather than a surrogate animal model. Finally, wild organisms live in a variable environment that is subject to a multiplicity of seasonal, physical, and chemical stressors that can alter the toxicity of the chemical [8]. Consequently, extrapolation of toxic responses from laboratory studies to field conditions is difficult and adds uncertainty. Methods for testing chemicals in situ have developed rapidly in recent years, and the methods presented in the following pages provide approaches on which to build the definitive and precise techniques for refining ecotoxicology in the future.

TESTING OF AQUATIC ORGANISMS

Aquatic systems, such as rivers, lakes, wetlands, and estuaries contain biota that may be represented by thousands of species. More complex environments with diverse habitats, such as that of the Gulf of Mexico, can contain tens of thousands of species (Table 42.1). The indigenous flora and fauna may be exposed to a variety of potentially toxic chemicals from human activities, resulting in adverse impacts. The study of these adverse effects of chemicals on freshwater and saltwater biota, and on the ecosystems that contain them, defines the subdiscipline of aquatic toxicology.

Aquatic toxicology differs from mammalian toxicology in several aspects. The primary goal of aquatic toxicology is to assess the effect of toxicants on the many diverse species, populations, and communities of plants and animals that inhabit saltwater and freshwater environments. The biota are usually cold blooded, and the naturally variable physical and chemical characteristics of the aquatic habitat have a considerable effect on their sensitivity to toxicants [8]. The aquatic test species of interest, unlike in studies of human health, can be tested directly. However, the internal dose is generally unknown, and the water or sediment concentration is used as an estimate of exposure. Mechanisms of toxic action may not be well understood, and not all test methods are well standardized.

Various species of aquatic organisms have been used in toxicity experiments for more than 130 years. One of the earliest reported studies was conducted with fish in 1863 [9], and the goldfish was proposed as the first standard test species in 1917 [10]. Toxicity tests have been conducted with increasing frequency since the 1960s due to the numerous environmental regulations that have been enacted in the past half-century. Consequently, the number of standardized test methods continues to increase, with the first couple of them being published in 1960 for animal test species and in 1970 for algae. Hunn [11] provides additional detail on the development of aquatic toxicology as a field of study.

Many toxicity test methods are available [12, Table 42.4]. They differ in their cost, precision, complexity, and the skill needed to conduct them; nevertheless, their objectives are similar. Toxicity tests are conducted to determine the relative potency among chemicals and the relative susceptibility among different species and life stages, as well as to identify environmental variables that influence the overall outcome of exposure. Toxicity tests are conducted frequently to meet regulatory guidelines for the use and discharge of commercial chemicals (including pesticides) and effluents [13–15]. In addition, toxicity results are used to assess water and sediment quality and to support cleanup goals for contaminated sites, as well as for the development of numerical, effects-based water quality standards and sediment quality benchmarks to protect aquatic life.

Aquatic toxicologists do not use all of the available toxicity tests to determine the effects for any single toxicant; instead, a tiered approach is used to provide a systematic and comprehensive process of deriving the toxicity data needed to assess the environmental hazard of a chemical. This approach consists of conducting short-term screening tests prior to using longer-term studies that are more costly and complex. This sequential evaluation provides a more efficient use of resources and reduces unnecessary testing. The criteria used to determine the appropriate level of testing are chosen based on the quality and quantity of data available and the specific regulatory requirements for the test substance of interest. For example, some regulatory programs, such as the U.S. Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), have extensive test data requirements, while other programs, such as the U.S. Toxic Substances Control Act (TSCA), rely heavily on quantitative structure–activity relationship (QSAR) models [16] to predict toxic effects based on chemical structure. The types of toxicity tests used in this tiered approach are discussed briefly in the following text.

TABLE 42.1
Estimated Number of Species of Fauna and Flora in the Gulf of Mexico

Taxa	No. of Species
Algae	30,000
Sea grasses	7
Sponges	800
Cnidarians	340
Crustaceans	2,600
Mollusks	2,500
Annelids	870
Echinoderms	5,200
Fishes	1,500
Reptiles	9
Birds	400
Mammals	30

Single-Species Toxicity Tests

Aquatic single-species toxicity tests can be categorized as either acute or chronic studies. Acute toxicity tests are short in duration and assess whole-organism responses to high concentrations of chemicals, with death or immobility as the typical response endpoints. In comparison, chronic tests require longer exposure times and lower concentrations to assess sublethal responses. A large historical database, dominated by acute tests, exists for many chemicals (Table 42.2), including detergent surfactants, trace metals, pesticides, and various other organic compounds [17–20].

Methods

Acute toxicity tests are used most often to quickly screen chemicals for toxicity or to determine the relative sensitivities of different species. Mortality is the effect endpoint measured during the usual test duration of 48 h (invertebrates) or 96 h (fish). In a typical acute toxicity test, 5–10 organisms are exposed under static conditions in glass test beakers to five test concentrations. A control without the test chemical or sample is included. A solvent control is included if a solvent is used to solubilize the test chemical. The test concentrations and control are usually conducted in triplicate. Daily observations are made on survival, and dead organisms are removed. At test termination, the concentration that kills 50% of the test organisms (LC_{50} value) is computed. Cumulative, chronic, and sublethal effects of a chemical are not evaluated in acute toxicity tests, although behavioral changes and lesions caused by a chemical can be reported.

Chronic toxicity tests are more complex and time consuming than acute studies and, for these reasons, are conducted less frequently (Table 42.2). The methods for these tests differ considerably from acute tests, because they are designed for the specific life histories of the various test species. Chronic toxicity tests may be for a full life cycle (egg–egg), partial life cycle (embryo–larvae), and partial life history (e.g., egg–juvenile or adult). Full life-cycle tests are uncommon with fish due to the long durations that are necessary (0.5–2 years), although standard methods are available [21]. Partial life-cycle tests with fish can be as long as 60 days. The early life stage of fish (embryo/larvae) is usually the most sensitive period; consequently, partial life-cycle tests are often used as surrogates for the full life-cycle studies. Chronic tests may be conducted for more than one complete life cycle if algal and invertebrate species are used because of relatively short life cycles compared to fishes. Lethal and sublethal effects monitored daily or weekly in chronic toxicity studies may include changes in growth, reproduction, behavior, and physiology, as well as mortality and histology. Calculated effects thresholds such as the LC_{50} value and the highest no-observable-adverse-effect concentration (NOAEC) and lowest (first)-observable-adverse-effect concentration (LOAEC) and EC_{20} values are determined based on the most sensitive effect parameter of interest. Although toxicity tests have similarities, as discussed in the following text, sensitivities, instrumentation, and methods differ among species and influence the outcomes and utility of the results.

Toxicity tests may be static, continuous flow, recirculating, or static renewal based on the toxicant dosing technique. Static and flow-through procedures are used more widely in toxicity tests conducted with pure chemicals. Chronic toxicity tests conducted with effluents are usually static renewal; those that test toxicity to algae are static (i.e., no renewal of test substance or water). Static tests with no renewal of exposure solution are the simplest and least expensive; however, the toxicant concentrations may decrease due to adsorption, uptake, volatilization, or biodegradation. In a static-renewal test, the test solutions and dilution water are renewed periodically, usually once daily. In a continuous-flow test, the dilution water and test substance are renewed continuously. Because the exposure concentrations remain fairly constant in static-renewal or continuous-flow tests, the dose–response relationship can be better defined.

Various aquatic toxicity test methods have been published for single species, and many have been standardized (Table 42.3). Some are required for approval to produce or release industrial chemicals, pesticides, new drugs, and wastewater (Table 42.4). Test-method development is an ongoing process, however, and test methods are continually being improved or modified to include additional measurement endpoints. For example, the U.S. Environmental Protection Agency (USEPA) currently is developing and validating in vitro and in vivo assays to determine the potential for chemicals to cause endocrine disruption (http://www.epa.gov/endo/pubs/assayvalidation/consider.htm). Endocrine tests will include assays for amphibian metamorphosis, fish screening for estrogenic and androgenic effects, amphibian

TABLE 42.3
Taxa of Aquatic Organisms Used and Toxicity Test Methods Available from Standards-Writing Organizations

Taxa	ASTM[a]	APHA et al.[b]
Phytoplankton	Algal growth potential	Bacterial bioluminescence
	Static tests with microalgae	Ciliated protozoans
	Bioluminescence dinoflagellates	Microalgae
Plants	Freshwater emergent macrophytes	Emergent vascular plants
	Duckweeds	Duckweed
	Seaweed	
Invertebrates	Rotifers	Rotifers
	Amphipods	Annelids
	Polychaete annelids	Mollusks, marine bivalves
	Bivalve mollusks	*Daphnia* spp.
	Daphnia magna	*Ceriodaphnia* spp.
	Ceriodaphnia dubia	Mysids
	Saltwater mysids	Decapods
	Echinoid embryos	Aquatic insects
	Macroinvertebrates	Polychaete
	Copepods	Oligochaetes

development and reproduction, and life-cycle tests with fish and mysid shrimp. Mutagenicity tests in bacterial and cell cultures, cytogenetic tests, and DNA tests for strand breaks and unscheduled synthesis in higher organisms have been used to screen the genotoxic effects of treated wastewaters, pesticides, sediment extracts, and dredged sediments [22,23]. The use of genomic endpoints is an emerging area and provides insight into the potential pathways of toxicity.

Experimental Conditions

In general terms, toxicity tests are conducted in a laboratory where the light cycle (photoperiod) and intensity, as well as air and water temperatures, are controlled. The test solutions containing the test species are typically monitored for pH, temperature, dissolved oxygen, ammonia, and hardness or salinity. The test organisms are exposed for a predetermined duration that varies depending on the type of test and test species.

Test Chambers

The type of test chambers used in toxicity tests depends on the test species. Various sizes of beakers, aquaria, jars, bowls, and petri dishes have been used. The test chambers are usually constructed of materials such as glass, Teflon®, and specific plastics that minimize leaching of potential toxicants such as plasticizers and adsorption of the test substance.

Test Concentrations

The chemical concentrations used in an acute toxicity test are based on results obtained from a pretest or range-finding test. Generally, 5–10 organisms are exposed to several test concentrations that are usually an order of magnitude apart. The dilution water and exposure conditions (i.e., water temperature, salinity, hardness, and pH) in range-finding tests are usually similar to those in the definitive test. The test concentration range for a chronic test is usually based on the results of an acute test conducted prior to the chronic test. The test compound is added to the dilution water, which may be well water, reconstituted water (e.g., deionized water with added salts), dechlorinated tap water, uncontaminated river water, or natural or artificial seawater.

An organic solvent is used to dissolve test compounds that have limited water solubility. Commonly used solvents include triethylene glycol, dimethyl sulfoxide, acetone, and dimethylformamide. The LC_{50} values for these solvents are between 9,000 and 92,500 mg/L [24], meaning they are essentially nontoxic. The concentration of the solvent in the test water should not exceed 0.5 mL/L or should not be greater than 1/1000 of the LC_{50} value of the solvent. A solvent control is included if a solvent is used in the study.

Reference toxicants often are used to determine the health and sensitivity of the test species, particularly in effluent testing. Although there is no universally used reference toxicant, typical ones include sodium dodecyl sulfate (anionic surfactant), sodium chloride, sodium pentachlorophenol, and cadmium chloride.

Toxicant delivery systems are used to deliver, on a once-through basis, the various test concentrations to the test chambers in continuous-flow toxicity tests. The serial proportional diluter (Figure 42.2) is the most common design used to mix the dilution water with the test substance to produce the desired test concentrations. The construction materials in toxicant delivery systems, as for the test chambers, should not be rubber or certain plastics, to prevent leaching of contaminating materials. The test concentrations are confirmed analytically prior to and during chronic toxicity tests. Analyses are performed at least weekly for each test concentration and control for tests of 7-days duration or longer. In tests of shorter duration, analyses are usually conducted on alternate days. Analytical verification of the test concentrations in range-finding and static acute toxicity tests is seldom performed, and the results from these tests are generally based on nominal concentrations of the test substance. However, this practice is being discouraged in favor of measuring all test solutions regardless of the duration of the toxicity tests.

Test Species

Historically, ecotoxicology has centered on determining the effects of anthropogenic chemicals on organisms inhabiting temperate zones. Tropical and polar species have

been tested less frequently, but there is a growing database on effects in these species and ecosystems [25,26]. Animal test species have been used more frequently than plant species, and freshwater species more frequently than marine species. This trend can be seen in Table 42.5, where the 10 most common species with test data are all freshwater organisms. Most toxicity tests are conducted with single cultured test species such as those listed in Table 42.6. The more commonly used freshwater species, particularly in tests used for regulatory compliance, are

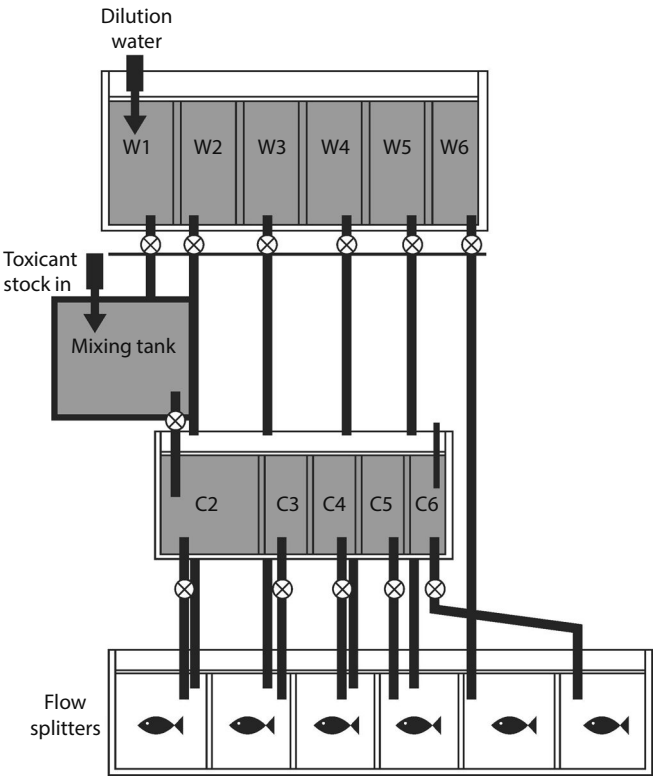

FIGURE 42.2 Diagram of a proportional diluter designed to ensure that five concentrations of a toxicant and a control treatment are delivered to the test species in a toxicity test. (Adapted from Landis, W.G. and Yu, M.H., *Introduction to Environmental Toxicology*, Lewis Publishers, Boca Raton, FL, 1995.)

fathead minnows (*Pimephales promelas*), daphnid species (*Daphnia magna*, *Ceriodaphnia dubia*), and a green alga (*Pseudokirchneriella subcapitata*). Freshwater sediment organisms include the midge (*Chironomus riparius*) and the amphipod (*Hyalella azteca*). Common marine species include sheepshead minnows (*Cyprinodon variegatus*), mysids (*Americamysis bahia*, formerly *Mysidopsis bahia*), and diatoms (*Skeletonema costatum*). The species in Table 42.6 were selected based on several criteria, primarily ease of culture, availability, and reproducible test methods. Sensitivity is also considered when choosing a test species, although the sensitivities of the species in Table 42.6 relative to one another, as well as to indigenous flora and fauna in the ecosystem, are a matter of scientific debate. No single animal or plant test species is consistently most sensitive to all toxicants or most reliable for extrapolation to all other organisms. Frequently, acute toxicity tests are conducted first with a variety of freshwater and marine test species, and the sensitive species are then used in subsequent chronic testing. However, it does not always follow that acutely sensitive species are the most sensitive in chronic studies.

A minimum of 10 animals are exposed to each test concentration and control. The test species are acclimated for a specific time prior to testing to eliminate diseased organisms and to acclimate the organisms to the test conditions. The recommended loading density for the test species is between 0.5 and 0.8 g/L in static tests and 1 and 10 g/L in continuous-flow tests.

TABLE 42.5
Most Commonly Reported Aquatic Test Species Based on Toxicity Records with Endpoint Data in the Ecotox Knowledgebase[a]

Species	Common Name	Percentage of Records[a]
Oncorhynchus mykiss	Rainbow trout	7.7
Daphnia magna	Water flea	6.2
Pimephales promelas	Fathead minnow	5.3
Lepomis macrochirus	Bluegill	2.8
Cyprinus carpio	Common carp	2.0
Danio rerio	Zebra danio	1.8
Oryzias latipes	Japanese medaka	1.4
Ceriodaphnia dubia	Water flea	1.3
Pseudokirchneriella subcapitata	Green algae	1.3
Ictalurus punctatus	Channel catfish	1.2

[a] 279,109 records with test endpoints (e.g., LC_{50}, EC_{50}; NOAEC, LOAEC); http://cfpub.epa.gov/ecotox/; [211] September 2012 download.

Calculations

The results of acute toxicity tests are reported as the LC_{50} value, with its corresponding 95% confidence interval. These calculations are determined using one of several statistical methods that are discussed by Stephan [27], such as probit analysis and moving-average interpolation. Probit analysis [28] is the most commonly used statistical method to determine LC_{50} values. Graphical interpolation can be used also to estimate the LC_{50} value where the proportion of deaths versus the test concentration is plotted for each observation time using probit or logit analysis or graphical interpolation. The NOAEC and LOAEC, as well as effect concentrations (e.g., EC_{20}), are the usual calculations reported from chronic toxicity tests. The NOAEC is the highest concentration in which the measured effect is not statistically different from that of the control. The LOAEC is the lowest concentration at which a statistically significant effect occurred. These concentrations are based on the most sensitive effect parameter, such as hatchability, growth, and reproduction. The statistical procedure for these calculations combines the use of analysis of variance (ANOVA) techniques and multiple comparison tests. In some cases, the maximum acceptable toxic concentration (MATC) is reported from chronic toxicity results. The MATC is a concentration (x) that is between the NOAEC and LOAEC ($NOEC < x < LOEC$) and is expressed as the geometric mean of the two. There is continuing debate in ecotoxicology on the value of NOAC/LOAEC values because of their dependence on experimental design, including number of replicates and data precision [29]. The use of alternative statistically derived effect concentrations based on describing the entire concentration–response relationship (e.g., EC_{20}) has been advocated

TABLE 42.6
Freshwater and Saltwater Test Species Used in Acute and Chronic Toxicity Tests Conducted with Commercial Chemicals and Wastewaters

for sublethal and chronic toxicity testing, but regulatory guidance still prescribes the use of NOAECs and LOAECs [29].

Variability/Precision

Laboratory toxicity tests conducted with freshwater and saltwater species are considered relatively precise and reliable based on current information from inter- and intralaboratory comparisons of toxicity results. Generally, the LC_{50} values from acute toxicity tests conducted under similar experimental conditions with the same toxicant vary less than threefold. This has been observed for metals, effluents, reference toxicants, and different organic compounds [15,20,30,31]. Statistical analyses of a large database of acute toxicity have shown the standard deviation of test variability to be about three [32]. Anderson and Norberg-King [33] reported the CV values for a variety of freshwater and marine species and found minimal variation. They concluded that biological tests can be conducted with a precision similar to that for chemical-specific measurements.

Multispecies Toxicity Tests

The results of the standard acute and chronic single-species toxicity tests conducted in the laboratory cannot be used alone to predict effects of chemicals on natural populations, communities, and ecosystems. First, the cultured species in laboratory tests are often different from those found inhabiting most ecosystems and conditions, and the size of the test species, its life stage, and nutritional state, among other factors, can have an effect on toxicity. Second, the laboratory tests conducted under controlled conditions cannot duplicate the complex interacting physical and chemical conditions of ecosystems, such as seasonal changes in water temperature, dissolved oxygen, salinity, and suspended solids. Third, aquatic species are usually exposed simultaneously to numerous potential toxicants (mixtures). Although the toxicities of binary and ternary mixtures have been evaluated for some chemicals in laboratory toxicity tests, the resultant information has predictive limitations.

Because of the deficiencies of single-species toxicity tests, multispecies toxicity tests have been developed to address ecosystem structure and functional processes [3,34,35]. As described in the following text, these tests include the use of laboratory microcosms and mesocosms such as outdoor ponds, experimental streams, and enclosures (Figure 42.3). Standardized procedures for these tests, with the exception of a freshwater microcosm [3], do not exist. They can be conducted indoors and outdoors, with plant and animal species obtained from laboratory cultures or collected from natural sources. The toxic effects, in addition to those determined in single-species tests, are determined for structural parameters such as community similarity, diversity, and density, and functional parameters such as community respiration and photosynthesis. Effects on these parameters are reported usually as the NOAEC and LOAEC. A brief description of the major types of multispecies toxicity tests follows, and

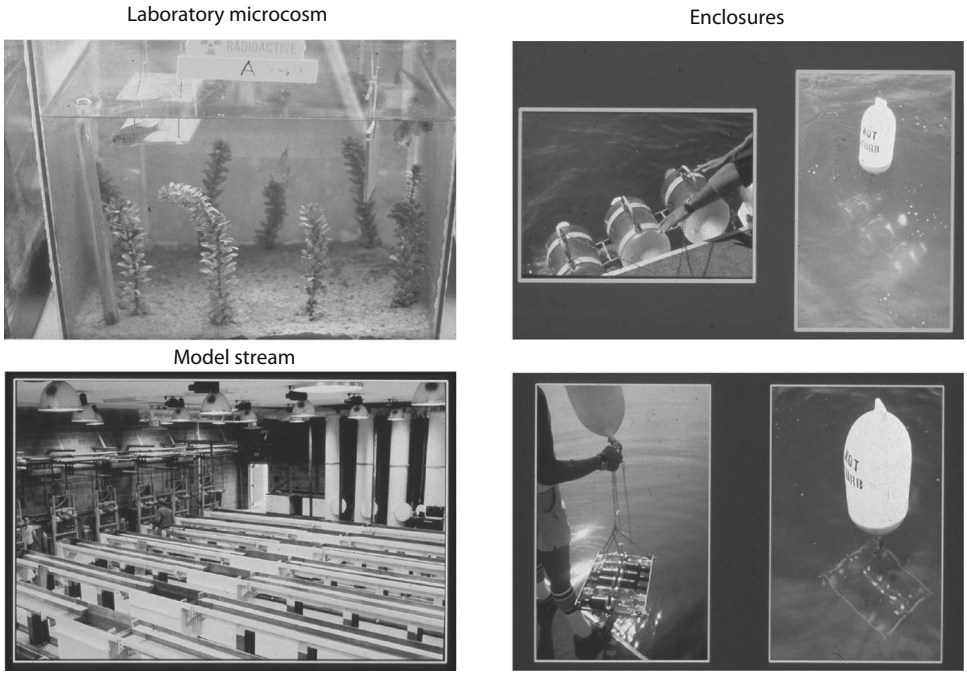

FIGURE 42.3 Examples of experimental systems used to expose either multiple test species simultaneously or natural biotic assemblages to toxicants. Test durations ranged from 3 h to 21 days.

TABLE 42.7
Advantages and Disadvantages of Single-Species and Multispecies Toxicity Tests

	Advantages	Disadvantages
Single species	Simple, rapid, reproducible	Responses of only individual determined
	Relatively low cost	Use nonindigenous species
	Standard protocols available	Ecological relevance uncertain
	Existing databases	Fate processes ignored
		Recovery rate not considered
		Cumulative effects not studied
		Ecological interactions not considered
Multispecies	Conducted under more realistic conditions	Costly
	Can simultaneously study different trophic levels	Standard protocols limited
	Can use indigenous species	Limited replication
	Can study the effect of environmental modification	Adaptation not considered
	Can be site specific	Stability of exposure concentration uncertain
	Can study species interactions	Data interpretation more difficult

their advantages and disadvantages relative to single-species studies are summarized in Table 42.7. More detail concerning specific test conditions, replicability, and regulatory usefulness is available from a number of reviews [34–37].

Laboratory Microcosms

A laboratory microcosm is a small model or component of an ecosystem contained in a test chamber. The use of microcosms provides an opportunity to study the effect of contaminants on a biotic community in a controlled environment. Microcosms are assumed to be functionally similar to the ecosystem they represent, but they may differ in origin and structure. The biotic component can be constructed from several cultured single species (artificial microcosms), or it may represent a sample of a natural ecosystem collected and placed in the test chambers. For example, a microcosm may contain sediment, water, and indigenous flora and fauna collected from a river, lake, or pond, or it may contain reconstituted water, artificial sediment, and a predetermined number of protozoa, plants, invertebrates, and fish obtained from laboratory cultures. The standardized aquatic microcosm (SAM) method has a set density of 15 species [3]. In this method, 24 3 L microcosms are used, and they can be aquaria. They contain a well-defined medium of trace metals and vitamins and 200 g of sand (sediment), to which chitin and cellulose are added. The tests are conducted in the laboratory at 22°C with a 12 h period of light at 80 $\mu E/m^2/s$. Ten species of freshwater algae and five species of freshwater invertebrates are added

to the microcosms, which are intended to represent a new pond ecosystem. The test species are exposed to three test concentrations of the contaminant for 63 days, during which observations are made on a variety of parameters, including algal biovolume, species diversity and density, and dissolved oxygen concentrations. The toxicant concentrations are renewed periodically during the study, and biological and chemical measurements are taken weekly or biweekly, depending on the parameter.

Outdoor Ponds

Outdoor ponds have been used primarily to investigate the fate and effects of pesticides on aquatic life [38]. There is no universally accepted test design, and various types of plant and animal life have been used in these systems. Ponds of various sizes and shapes have been used, with depths usually 1 m or less, and volumes ranging from 10 to 650 m^3.

Experimental Streams

Experimental streams have been used to assess the effects of thermal effluents, nutrients, metals, insecticides, and municipal and industrial effluents on natural biota in studies ranging in duration from several days to several years. Experimental streams may be flow through or circulating, and may be located indoors or outdoors. The streams range in length from 1 to 1000 m and have been constructed from Plexiglas®, concrete or aluminum troughs, or plastic-lined wood flumes. The depth of most streams is usually less than 1 m. The streams are colonized with organisms prior to use. Sources of organisms (periphyton, invertebrates, and fish) can be laboratory cultures or natural ecosystems. Time of colonization has varied from a month to over a year. See Kosinski [39] for additional detail.

Enclosures

Enclosures isolate a portion of an ecosystem that can be dosed with the toxicant in such a way that significant contamination beyond the limits of the enclosure will not occur. The size, shape, and volume of enclosures used have varied considerably. In freshwater experiments, the volumes have ranged from 8 to 3,000,000 L. Plastic tubes, carboys, plastic bags, and limnocorrals have been used to enclose the biota [40–42]. The effects of oil, mercury, phenolic compounds, acidification, and pesticides, among other toxicants, have been investigated in studies ranging up to 3 months [40–42].

Single Species to Multispecies Toxicity Comparisons

The results of multispecies tests have been compared to those of single-species tests conducted with the same toxicant; for example, the results from the experimental stream study of Hansen and Garton [43] were compared to those for single-species chronic toxicity tests conducted with fish, daphnids, algae, and snails. These single, cultured species were more than an order of magnitude more sensitive than the stream communities to the insecticide diflubenzuron. Other comparisons of this type are discussed by DeLaender et al. [44], Hose and Van den Brink [45], and Cairns and coworkers [34,35]. In most cases, the outcomes of these comparisons have been species and compound specific; thus, the use of toxicity test results for single species to predict effects on natural biotic assemblages without supporting data requires careful consideration. The validation of laboratory-derived toxicity data continues to receive high priority in aquatic toxicology.

Predictive Toxicology

The large number of chemicals—combined with the many different regulations, the cost of conducting test batteries, and the number of species to be protected—limits the full use of standard toxicity tests to only a relatively few chemicals and species. In the absence of empirical data, methods have been developed to predict chemical toxicities. These methods include the use of in silico or computer modeling, or predicting of toxicity based on similar chemical analogs or moieties using QSARs [16], interspecies extrapolation modeling of the acute toxicity of chemicals from one species to others [46,47], and prediction of chronic toxicity from acute toxicity data [48]. In aquatic toxicology, QSAR models have been developed based on the single chemical property of hydrophobicity (i.e., log octanol/water partition coefficient) for neutral or polar organics causing narcosis [49]. QSAR models have been limited to a few standard freshwater test species such as green algae, daphnids, and fathead minnows [49]. The USEPA has developed an Internet-based interspecies correlation estimation tool, Web-ICE, to allow prediction of toxicity to a broader range of species [47]. Web-ICE uses the known toxicity of an aquatic or wildlife species (the surrogate) as model input to predict toxicity to another species, genus, or family [47]. The acute-to-chronic ratio (ACR) is commonly used to predict chronic toxicity when only acute toxicity data are available for a chemical. ACR values have been reported for a variety of chemicals, particularly metals and pesticides, and most are 25 or less [50].

Computational toxicology is an emerging field in ecotoxicology that offers an alternative to traditional animal-intensive approaches [51]. It uses bioinformatics, in vitro screening, and computer models and combines techniques from computational chemistry, genomics, and systems biology to improve prioritization of data requirements and risk assessments for chemicals. The value of computational toxicology as a predictive tool, and its utility in ecological risk assessment, is still being determined.

The results of single-species toxicity tests are often used to predict effects in natural ecosystems, with little being known about the accuracy of the prediction. In some cases, multispecies toxicity test results are available and can be used with more confidence. In other cases, conservative correction factors are used to compensate for the limitations of the toxicity data. A variety of these correction techniques have been reported [52] and their usefulness reviewed [37,53]. One of the more simple and common methods is the use of numerical safety or uncertainty factors to estimate safe, concern, or risk concentrations [54,55]. Laboratory-derived chronic toxicity results (usually the NOAEC) can be divided by factors of

100 or 10, depending on the level of uncertainty or protection desired, to determine the concentration that, if exceeded in the ecosystem, may represent an ecological risk. The magnitude of the factor used depends on the quantity and quality of the toxicity data available for the toxicant of interest. The greater the quality and quantity of data, the smaller the safety factor applied. The technical validity and magnitude of these factors are largely unproven, although they are in general use; consequently, this issue continues to be a subject of considerable debate within the scientific and regulatory communities [56].

An additional tool related to differences in interspecific sensitivities that has received considerable attention is the use of species sensitivity distributions (SSDs). An SSD is a cumulative frequency distribution (usually a lognormal or Weibull function) of the sensitivities of a set of species to a chemical of interest. The available toxicity data (e.g., NOAEC or LC_{50} values) are assumed to be a representative sample of the entire variation of sensitivity of all species to the chemical. A concentration of the chemical of concern that will be protective of a desired percentage of all species can be calculated from the frequency distribution in a manner similar to determination of a benchmark dose. Generally, the value selected is the lower confidence interval of the 5th or 10th percentile of the distribution. A modification of this approach is used for development of water quality criteria, and SSDs are used frequently in ecological risk assessments to extrapolate individual species toxicity values to an assemblage of species. A detailed description of SSDs and their applications and limitations is available in Posthuma et al. [57] and Maltby et al. [58].

Sediment Toxicity Tests

Toxicity tests have been conducted primarily with water-column or planktonic organisms, with the objective of controlling water pollution. However, sediments act as reservoirs for chemicals that can adversely affect benthic, or bottom-dwelling, aquatic organisms and, at times, also affect organisms in the water column [59]. This concern has led to the development of a variety of assessment techniques [60], including the use of sediment quality guidelines to protect benthic organisms [61]. Test methods have been developed to support the derivation of these guidelines and other related regulatory activities, such as the disposal of dredged materials [62]. Methods have also been developed for identifying which chemicals are the cause of observed toxicity in environmental samples of sediments. The sediment toxicity identification evaluation (TIE) consists of comparative toxicity testing and chemical fractionation techniques similar to those used for effluents [63].

Sediment toxicity tests may be conducted in the laboratory with a variety of single species of freshwater and marine benthic organisms, either with clean sediments spiked with known amounts of chemicals to derive toxicity thresholds or with samples collected from the environment to determine the amount of in situ toxicity. Methods were reviewed by Traunspurger and Drews [64]. Several toxicity tests and methods for the collection and preparation of sediments used in toxicity tests have been standardized (Table 42.8).

TABLE 42.8
Examples of Standardized Sediment Toxicity Test Methods

	Sediment test procedures for marine bivalves
	Sediment pore-water toxicity

Additional test guidelines for marine sediment [65] and freshwater sediment [66,67] have also been developed. In situ methods for assessing the toxicity of sediment contaminants in aquatic environments have also been reviewed [68]. Most tests conducted to date are acute and are of 10-day duration or less. Toxicity tests usually are conducted with the whole sediment (solid phase) or pore water [69]. An example of a whole-sediment acute toxicity test is shown in Figure 42.4. In this static test, a burrowing amphipod or an epibenthic mysid is exposed to undiluted field-collected contaminated sediment, and mortality is recorded after 10 days of exposure. The mortality of amphipods is made obvious by the reduction in their burrowing entrances (Figure 42.5).

The results of a chronic toxicity test conducted with amphipods exposed to different concentrations of a contaminated sediment are shown in Table 42.9. Survival, growth, and reproductive effects of the burrowing amphipod *Leptocheirus plumulosus* were determined at the end of the 28-day toxicity test. Significant effects on the test species were noted at contaminated sediment concentrations of 10% (young production, fertility), 50% (survival), and 100% (length).

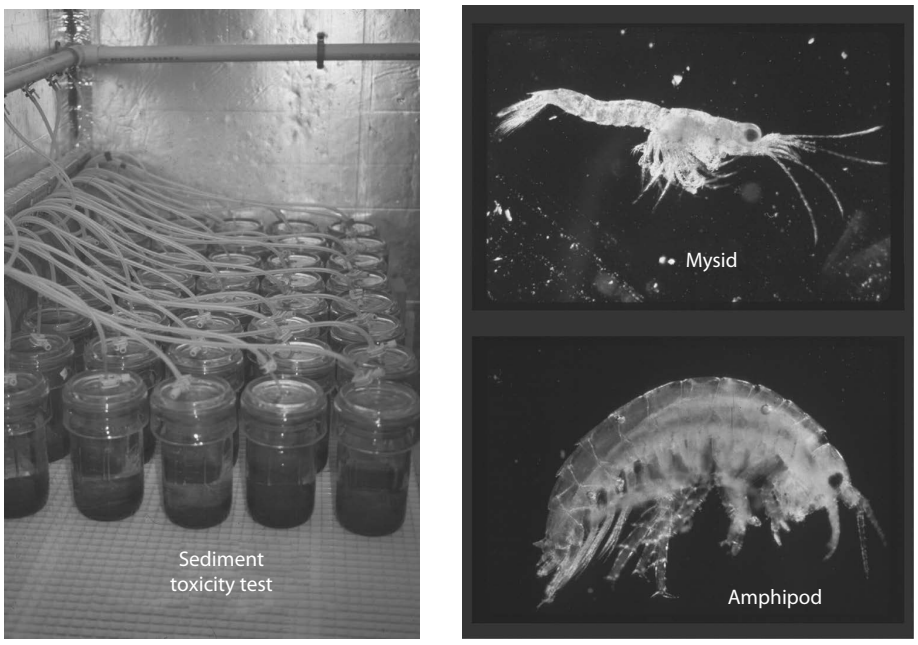

FIGURE 42.4 Example of a whole-sediment acute toxicity test conducted for 10 days with epibenthic mysid and burrowing amphipod test species.

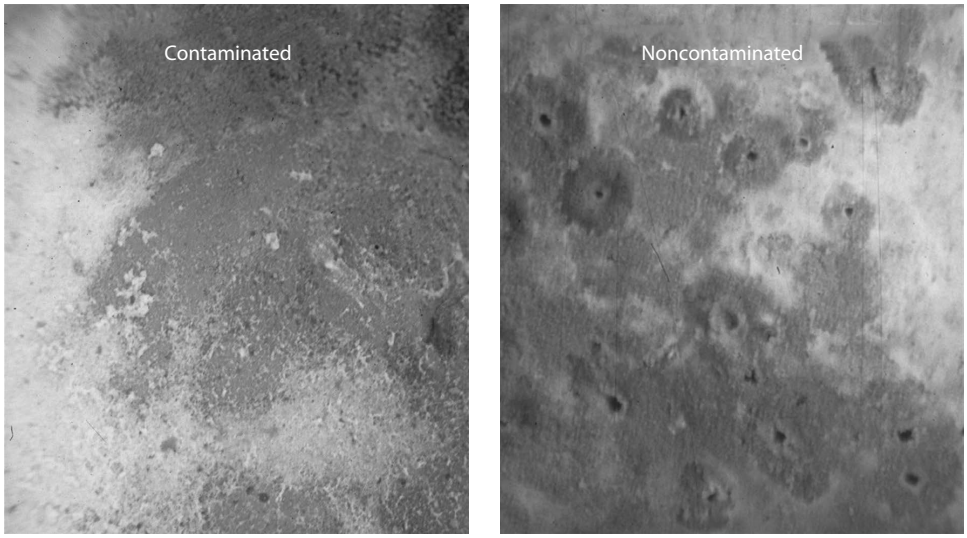

FIGURE 42.5 Burrowing entrances of infaunal amphipods exposed for 10 days in an acute toxicity test to contaminated and noncontaminated estuarine sediments. Lack of entrances indicates mortality.

TABLE 42.9
Example Results of a 28-Day Chronic Sediment Toxicity Test Conducted with the Marine Amphipod *Leptocheirus plumulosus*

Test Concentration[a]	Mean Survival (%)	Young Production (Number of Juveniles)	Fertility	Mean Length (mm)
Control	97	91	59	5.83
10	93	32	31	5.31
25	92	30	19	5.45
50	83	8	6	4.95
100	9	0	0	3.06

[a] Contaminated sediment was diluted with a noncontaminated reference sediment to obtain test concentrations.

Effluent Toxicity Tests

Toxicity tests are used in the U.S. National Pollutant Discharge Elimination System (NPDES) permitting process to determine the toxicities of municipal and industrial effluents prior to discharge into aquatic life [15,31,70]. A summary of the experimental conditions for test methods using freshwater species appears in Table 42.10. The methods for assessing the toxicity of wastewater discharge samples differ slightly from those used for pure chemicals. For example, the choice of the dilution water and the technique used to collect the effluent are important considerations. In most cases, water collected from the receiving water above the outfall is used for dilution, and composite samples of treated effluent are used. The test species (algae, invertebrates, or fish) are exposed to five effluent dilutions for 4–7 days. The tests are static renewal, except those for algae, which are static. The calculation results reported are the LC_{50} value, the NOAEC, and the LOAEC, expressed as percent effluent. The specific causes of toxicity in the effluent can be identified by using a TIE that consists of comparative toxicity testing and chemical fractionation techniques [71].

Phytotoxicity to Aquatic Plants

The majority of aquatic toxicity tests have been conducted with animal test species, because they were once thought to be more sensitive than plants. This generalization is not true for several chemical classes [72], and recently, phytotoxicity tests have been more common, although with a limited number of algal species and even fewer species of vascular plants. Example test data are listed in Table 42.11.

Standardized methods are available to determine the phytotoxic effects of chemicals and effluents (Table 42.12). Species of microalgae have been used more frequently than vascular species. The freshwater algal species used most frequently is the green microalga *Pseudokirchneriella subcapitata*, for which a relatively large database exists. Marine species include the diatom *Skeletonema costatum*, the flagellate *Dunaliella tertiolecta*, and the red macroalga *Champia parvula* [73].

Most toxicity tests conducted with algae are chronic tests, despite their short duration, because growth of the test population is measured over a significant portion of the algae's life span. These tests typically are 3–4 days in duration, although exposures can be less than 1 day if effects on photosynthesis are measured. The static exposures occur in a liquid nutrient-enriched medium under conditions of controlled pH, temperature, and light (Figure 42.6). Inhibitory and stimulatory effects on population growth are monitored during the exponential growth phase. Five test concentrations and a control are included in each study. The most common calculation reported is the 96 h IC_{50} value (concentration that reduces the parameter of interest by 50%), but algistatic (completely stops growth) and algicidal (lethal) concentrations have also been reported. In addition, the SC_{20} (stimulatory concentration) is reported if growth stimulation is observed. The SC_{20} value represents that concentration that increases algal growth 20% above that of the algal population in the control. Additional information on the use of algae in toxicity tests is available in Thursby et al. [74] and Nyholm and Källqvist [75].

Freshwater floating and rooted vascular plants have been used more frequently in toxicity tests than marine species.

TABLE 42.10
Example Experimental Conditions for Acute Toxicity Tests Conducted with Effluents and Freshwater Fish, Invertebrates, and Algae

Experimental Condition	Fish (*Pimephales promelas*)	Invertebrate (*Ceriodaphnia dubia*)	Alga (*Pseudokirchneriella subcapitata*)
Test type	Static nonrenewal, static renewal, or flow-through	Static nonrenewal, static renewal, or flow-through	Static nonrenewal
Test duration	24, 48, or 96 h	24, 48, or 96 h	96 h
Temperature	20°C ± 1°C or 25°C ± 1°C	20°C ± 1°C or 25°C ± 1°C	25°C ± 1°C
Light intensity	10–20 μE/m²/s (50–100 ft-c)	10–20 μE/m²/s (50–100 ft-c)	86 ± 8.6 μE/m²/s
Photoperiod	16 h light, 8 h darkness	16 h light, 8 h darkness	Continuous illumination
Test chamber size	250 mL	30 mL	125 or 250 mL
Test solution volume	200 mL	15 mL	50 or 100 mL
Renewal of test solutions	After 48 h	After 48 h	None
Age of test organisms	1–14 days; ≤24 h range in age	Less than 24 h old	4–7 days
No. of organisms per test chamber	10 for effluent and receiving water tests	5 for effluent and receiving water tests	1×10^4 cells/mL
No. of replicate chambers per concentration	2 for effluent tests, 4 for receiving water tests	4 for effluent and receiving water tests	3–4
Test concentrations	5 and a control	5 and a control	5 and a control
Endpoint	Mortality	Mortality	Growth (cell counts, biomass, chlorophyll fluorescence)

The duckweeds (*Lemna* spp.) are the most commonly used freshwater species due to their small size and rapid growth. Published methods are available for *L. minor* and *L. gibba* [76,77]. Tests with these species are usually 4–14 days in duration, during which effects on frond number and chlorophyll content are monitored. The results are expressed as an EC_{50} value and the NOAEC. As for algae, the tests are conducted in a nutrient-enriched medium. The test chambers can be jars, plastic cups, test tubes, or Erlenmeyer flasks.

The use of rooted vascular plants as test species in toxicity tests has been limited due to their large size, slow growth, and, until recently, lack of standardized methods. Standardized tests are now available for a few species (Table 42.12). In addition, other experimental techniques are available [77,78]. Several of these describe the use of seeds and seedlings of macrophytic vegetation to assess the toxicities of chemicals and effluents (Figure 42.6). In conclusion, the use of rooted macrophytes and their seeds in toxicity tests will increase in the future as the development of sediment quality criteria to protect aquatic life and protection of wetland vegetation increase in regulatory importance. However, for this to occur, identification of sensitive species and response parameters and validation of the laboratory-derived results is required [26,79].

Bioaccumulation Testing

A bioaccumulation study is conducted to derive information on the potential for a chemical to concentrate a toxicant in tissues of aquatic organisms [80]. This uptake and accumulation can be hazardous to the organism or can form an exposure pathway to other aquatic life, wildlife, or humans through trophic transfer in the food web. Bioconcentration tests assess the potential accumulation of a waterborne chemical, whereas bioaccumulation tests can assess multiple pathways, including diet and sediment exposures, as well as water. These tests are conducted with single chemicals and single species of algae, fish, and bivalve mollusks. A variety of fishes have been used, including the fathead minnow, bluegill, rainbow trout, and sheepshead minnow, and several invertebrate species, including oysters, scallops, and mussels. Several test methods are available to estimate the bioaccumulation potential of a compound (Table 42.13). In a typical bioconcentration test, the aquatic organism is exposed to a low level of toxicant during an uptake and depuration or clearance phase. A control is included in which the test species is not exposed to the toxicant. The uptake phase is usually for 28 days or until an apparent steady state is attained. The depuration period should continue until the concentration in

the test species is 10% of the steady-state concentration in the tissue. During both phases, the test water and test species are analyzed daily for the test chemical. All results from a bioconcentration study are based on measured concentrations. The uptake rate, the depuration rate, and the BCF (ratio of fish to water concentration at equilibrium) are computed and reported [80]. The relevance of tissue-concentrated chemicals to the survival, growth, and reproduction of the organism and its population dynamics is a continuing area of research [81–83]. Databases have been developed for interpreting tissue residue effects on aquatic organisms, and the literature has been reviewed by McEloy et al. [82].

TERRESTRIAL SYSTEMS

Standardization of toxicity testing for environmental problems in terrestrial systems has matured during the past decade. Risk-based soil quality guidelines have been developed by the Canadian Council of Ministers of the Environment [84], selected Canadian provinces [85], and several European countries [86]. The USEPA has developed ecological soil screening levels (Eco-SSLs) to standardize the approach for contaminated site assessments [87], although the supporting documentation specifically states that these are not to be used as cleanup values. Several of the USEPA regions have developed soil preliminary remediation goals (PRGs) for contaminated site cleanup for the protection of human health [88] that provide information and some guidance to assessing risks to wild plants and animals as well.

Because of the lack of applicable site-specific soil quality criteria, and the difficulty in applying such criteria to specific sites within the heterogeneous soil ecosystem, terrestrial environmental toxicology still relies on standardized toxicity tests for assessing the toxicity of new and existing chemicals to plants, wildlife, and soil ecosystem functions. These tests fall into one of two major categories: (1) a priori toxicity tests of single chemicals proposed for use or potential release in terrestrial systems and (2) site-specific assessments of extant (post hoc) contamination. Both approaches use the same suite of tests for determining plant, wildlife, and soil toxicity, and to some extent, they rely on data generated for human toxicology studies, although they differ significantly in their risk assessment approach [89]. Many of the tests discussed in detail have standard operating procedures published by the USEPA, the American Society for Testing and Materials (ASTM), the European Union (EU), or the Organization for Economic Co-operation and Development (OECD). A subset of these tests are under discussion for revision to incorporate up-to-date statistical designs and measurement of potential disruption of the endocrine system [90]; however, at the time of this writing, no revisions have been formally accepted to the protocols as they are presented here. Table 42.14 lists all the terrestrial bioassays for which detailed protocols currently are available. Additional tests are being developed, and where appropriate, references are provided to direct the reader who desires further information.

One major challenge remaining in terrestrial toxicology is extrapolation of results from test species to species of concern that have not been tested. Given the large number of terrestrial biota (mammals, birds, reptiles, amphibians, invertebrates, and soil microbes), it will never be possible to test all substances using all species, so protection levels must be established based on some method of extrapolation from the data at hand. Several methods currently are in use: (1) Calculate a fifth percentile of the distribution of species mean toxicity values [57], (2) use a fixed extrapolation factor on a calculated threshold for adverse effect based on the toxicity endpoint of interest, or (3) use the interspecies correlation estimation tool, Web-ICE, described earlier in this chapter [47]. If toxicity endpoints (e.g., LD_{50} values) are available for fewer than five species, the method of Luttik and Aldenberg [92] can be used to estimate the fifth percentile from the available data by applying the extrapolation factors derived for small samples (Table 42.15) to the geometric mean of the species tested. This method is based on pooled lognormal standard deviations. If more than one toxicity value is available for a species, the geometric mean of all available values is used as the input for the species. Further information on statistical analysis of ecotoxicity data is available in OECD [93].

Risk to wildlife species can be ascertained using methods similar to those used in estimating risks to humans, wherein dietary exposures are estimated and compared with a safe level of exposure using a hazard quotient paradigm. The safe level is often referred to as the toxicity reference value (TRV) and can be derived using various methods [94,95]. In screening approaches, TRVs have been developed using no-observed-adverse-effect-levels (NOAELs) and LOAELs and extrapolating between species using assessment factors [95]. Other approaches have used, as described, SSDs [46]; however, these often assumed minor influences in response are realized from differences in study design. Other methods use dose–response functions as a point of departure to capture the threshold of toxicity for species extrapolation (e.g., benchmark dose) [38]. This curve-fitting algorithm is

more robust than the straight-line calculation on an EC value. However, optimal study design should include at least five treatments, inclusive of a control, to best fit models used in the benchmark dose model [M.S. Johnson, unpub. data]. Few data exist for wildlife from dermal exposures, although for some substances and species, the dermal route could be significant [96]. At the present time, insufficient data exist to quantify risks for dermal exposures for most nonmammalian species. Values have been developed for inhalation exposures using allometric and route-to-route extrapolations, as for burrowing mammals in functionally confined spaces where soil vapor levels are a concern [97]. Few inhalation data are available for wildlife of other classes.

Other concerns include the extrapolation of controlled testing designs to realistic environmental conditions. The use of *ad libitum* feeding in toxicity tests is contrary to what many wildlife species typically encounter and has been suggested to result in skewing of the effect levels to lower concentrations in

rodent studies. It has been shown that limited food resources maintain healthier individuals that are able to cope with low-dose exposures [98]. This point, however, applies to gavage dosing studies and cannot be applied to feeding studies using contaminated feed. Constant temperature and humidity additionally are not typically experienced in many wild populations, and the relevance of this condition influencing the response to toxicants is poorly understood. However, given the incidence of nonspecific opportunistic infections experienced in laboratory amphibian studies, it is typically beneficial to have much cooler laboratory temperatures when housing those species (8°C–17°C) than is typical for studies using endothermic species.

Avian Tests

The USEPA requires tests with northern bobwhite (*Colinus virginianus*) and mallards (*Anas platyrhynchos*), at a minimum, for pesticide registration, so the largest database of toxicity information and testing experience for such compounds is available for these species. Relatively large databases also exist for Japanese quail (*Coturnix coturnix japonica*) (required by the EU for pesticide registration) and ring-necked pheasant (*Pashianus colchicus*) [99,100]. The test methods, however, are equally applicable to all other avian species, provided that appropriate adjustments are made in caging and feeding regimens [101,102]. Single-chemical laboratory tests for acute, subacute, subchronic, and reproductive toxicity have accepted standard methods.

Acute Toxicity Test

The acute toxicity test (LD_{50}) is required when determining effects of ingesting pesticide granules, seed treatments, or baits [13] or for comparative toxicology [101,102]. A modified version of this test has been developed for testing potential toxicity of alternative nontoxic shot pellets developed for waterfowl hunting [103]. The LD_{50} test [104] requires the use of adult birds (e.g., ≥16 weeks old for bobwhite and mallards; >6 weeks old for Japanese quail). Within a given test, all birds should be from the same hatch, unless the test is being conducted with wild birds. All birds should be of uniform weight and size, and absent of obvious signs of disease. Birds should be housed under acceptable animal husbandry practices, with a 10:14 light/dark (L/D) cycle to avoid inducing a reproductive state. Animals should be acclimated to the test environment for a minimum of 2 weeks prior to starting the test. For pesticide testing, a minimum of six birds per dose level is required, with the doses arranged by geometric progression, such that at least one dose will be below the estimated LD_{50}, one dose above, and one control group (administered carrier only). For shot toxicity studies, 10 birds of each sex are dosed with eight no. 4 shot pellets, and a similar negative control (steel shot) and positive control (lead shot) also are dosed. Birds should be fasted for 15 h prior to exposure; at all other times, they should be allowed *ad libitum* access to food and water. Chemical or shot should be administered through oral intubation into the crop or proventriculus, preferably in an encapsulated form, as birds can regurgitate liquid formulations or small pellets. The test animals should be observed for a minimum of 14 (pesticide) or 30 (shot) days after exposure, recording all signs of intoxication and number and time of mortality. For pesticide studies, if more than one bird from the control group dies during the 14-day period, the test may be considered invalid. Necropsies and histopathological studies of all birds that die during the test are encouraged. For studies of alternative shot, measurement of hematocrit, hemoglobin concentration, and other specified blood chemistries is required on days 15 and 30 after exposure, and histopathological analysis is required of liver and kidney at test termination. Additionally, analytical chemistry analysis of these or other tissues may be required to ascertain residue concentrations. The LD_{50} value is calculated, along with the slope and the 95% confidence interval, using probit analysis [28] or another acceptable statistical method.

In 2010, the OECD approved a new avian test guideline that significantly reduces the number of birds required for LD_{50} determination [105]. This approach provides for a limit test to approximate toxicity when a substance is suspected to be nontoxic (LD_{50} >2000 mg/kg-bw), using 5 or 10 birds tested at the limit dose, in addition to a control group. It also uses 24 or 34 birds, in addition to a control group, in 3–4 repeated stages of testing to approximate the LD_{50} and then refines this estimate to within acceptable limits of statistical error. For those instances where the slope of the dose–response curve is needed, as well as the LD_{50}, the design provides for additional stages and requires the use of more animals. The test requires gross examination of the internal organs of a subset of birds from all dose groups.

Other methods that are not prescribed for pesticide registration can be used to determine acute toxicity, including the stagewise probit design [106–108]. This design typically uses fewer animals and is flexible to adjust treatment exposures given results of previous stages. Furthermore, it can provide an LD_{50}, 95% confidence interval, and slope where stopping rules may preclude the development of criteria using the up/down method. Initially, four individuals of the same sex are each given different oral doses, typically at one-quarter log intervals above and below 750 mg/kg bw (assuming there is no other information on potential toxicity) [106]. After a period of observation, the next stage allows for 10 animals to be placed in treatment at dose levels set to intervals surrounding the expected partial response level. Following observation, the final stage uses another 10 animals that are again placed at treatment doses surrounding the partial-effect level. A greater number of animals should be placed in treatments that approximate the partial-effect level. All animals are observed for a period of 14 days and evaluated as mentioned previously.

Subacute Toxicity Test

The subacute avian dietary toxicity test (also known as the dietary test or LC_{50} assay) is conducted using 10- to 14-day-old bobwhite or 5- to 10-day-old mallards, although the test is not limited to these species [104,109–111]. Birds used in the test should be either wild birds or pen-reared birds that are

phenotypically indistinguishable from wild birds, preferably from colonies with known breeding history. If possible, all test birds should be from a single hatch, and only birds free of obvious injury and disease should be used. Birds must be kept in brooders of appropriate dimensions and temperature (about 35°C for bobwhite and mallards). The standard protocol does not require a certain lighting regimen; however, because the length of the photoperiod influences daily food consumption, it is recommended that a 10:14 or 12:12 L/D cycle be maintained. Water should be available *ad libitum*. A standard commercial game bird diet in mash or crumble should be used for mallard and bobwhite tests; appropriate formulations should be developed as needed for other species. If possible, the test material should be added to the diet without the use of a vehicle. If a vehicle is needed, water is preferred, but reagent-grade evaporative material (acetone, methylene chloride) can be used if necessary and completely evaporated at room temperature prior to feeding. Other acceptable vehicles include table-grade corn oil, propylene glycol, carboxymethylcellulose, and gum arabic.

In the dietary test, the toxicant is added to feed in a ratio of two parts solution to 98 parts feed by weight, and subsampling should be done to confirm uniformity of mixing. Large batches can be mixed in mechanical food mixers or similar devices. It is encouraged that feed batches be analyzed, and actual concentrations be reported along with the nominal value. The chemical should be administered in at least four concentrations spaced geometrically to produce mortality ranging from 10% to 90%. A concurrent control group and a vehicle control group (if appropriate) are required. A minimum of 10 birds is required for each concentration and control group. Birds should be acclimated to the testing conditions and fed prior to presentation of treated feed. Birds are exposed to treated feed for 5 days, followed by an observation period on clean feed for at least 3 days or until mortality ceases. There must be at least 72 consecutive hours without treatment-related mortality, and control mortality cannot exceed 10% during this period for the test to be considered valid. Throughout the test, all signs of intoxication should be recorded, including time of onset and duration. Times of all mortalities must be recorded. Average food consumption must be estimated for each pen of birds; therefore, feed must be weighed at the beginning and end of the pretreatment, treatment, and observation periods. Provisions for minimizing spillage should be reported. Necropsies and histopathological examination of all dead birds are suggested. The LC_{50} and 95% confidence interval must be reported, along with the method used to determine these statistics.

The avian dietary test can also be used as an indication of the chemical's repellency (the inherent property of a test substance that causes a reduction in feed ingestion) [112]. Frequently, sufficiently severe reduction in food consumption by the chicks occurs due to inherent properties of the chemical (e.g., bad taste) to induce starvation by the end of the 5-day treatment period, significantly confounding the results of the dietary test. Thus, the LC_{50} should be calculated based on the measured concentration of chemical in the feed and the actual amount of food consumed (the daily dietary dose [DDD]), or alternative test designs should be employed [93]. Repellency is calculated as the percent reduction in food consumption, or the highest dose where no food reduction is observed. A standard guidance document on testing for avoidance behavior has been proposed [113] that uses adult birds presented with two dietary choices (treated vs. nontreated), to avoid confounding the data with starvation-induced mortality and to present a more ecologically realistic scenario. This approach, however, remains controversial, with several experts arguing that birds can detect chemicals in feed, so more than two feed treatments are needed to generate realistic worst-case scenarios for exposure potential.

Subacute avian tests can also be performed using oral gavage procedures [86,114,115]. This method benefits from a more precise method of compound delivery and is easy to accomplish using a conventional gavage needle and syringe. Test substance and vehicle are delivered into the crop, providing a simulated slow release. Gavage methods avoid the uncertainty inherent in calculating dose based on food ingestion, given the hydroscopicity of the feed, spillage, defecation in the feed, and feed avoidance. It also avoids drastic changes in body mass that can occur as a result of food avoidance [116]. Studies have been conducted in 14- and 60-day repeated-dose designs using northern bobwhite, Japanese quail, zebra finch (*Taeniopygia guttata*), and pigeon (*Columba livia*), although the latter can produce an inefficient emetic response [114]. In such cases, investigators are encouraged to sample emesis for analytical determination of actual dose.

Reproductive Toxicity Test

Avian reproductive effects and chronic toxicity endpoints are determined according to methods described by the USEPA [104,117] and OECD [118]. The U.S. Fish and Wildlife Service [103] has modified these protocols for the testing of alternative shot to include a cold stress (ambient temperatures of 6.6°C–4.4°C) and dietary stress (a diet for mallards consisting of whole-kernel corn). Both these tests are one-generation studies. A two-generation avian reproduction test guideline using Japanese quail is currently in draft form, in support of second-tier testing of potential endocrine-disrupting chemicals [119,120]. Changes to the one-generation protocol also have been under discussion, to reduce the length of the study and increase the statistical power of the test [90].

Birds in the dietary avian reproduction study should be pen reared and phenotypically indistinguishable from wild birds. Additionally, it is recommended that the birds come from a colony that has maintained breeding records and that all birds be free of obvious disease or injury. Bobwhites should be at least 16 weeks old at the beginning of the test period, and mallards should be at least 7 months of age. Ages of other bird species should correspond to known times of reproductive maturity. Birds should be acquired in a quiescent reproductive state, so that the onset of egg laying occurs in the test facility. Birds should be acclimated to the test environment for 2–6 weeks prior to the presentation of treated feed. Birds must be maintained in pens or rooms

that conform to good husbandry practices [121], with minimum space being defined as the ability to stand upright and stretch the wings to their full extent. Birds can be housed as one pair per pen or in groups (one male and two females per pen for bobwhites or two males and five females for mallards). Generally, tests are conducted indoors; however, for some birds (e.g., American kestrels [*Falco sempervirens*] and eastern screech owls [*Megascops asio*]), it is more appropriate to house them outside, and the alternative shot protocol allows for this practice if the study is conducted in a cold-weather environment. The photoperiod must be controlled rigorously, because the onset and maintenance of reproductive activity are determined by the length of the light period. During the acclimation period and for the first 8 weeks of a test conducted indoors, the photoperiod should be set at 7–8 h of light per day. The photoperiod should then be increased to 16 h of light per day, preferably by gradually increasing the day length over a 2-week period, and should be maintained at this level for the remainder of the test. Lights should have an intensity of approximately 65 lx (6 fc) at each cage. For outdoor test environments, the tests should be initiated according to the phenology of the species tested, such that presentation of treated feed begins approximately 10 weeks prior to the anticipated onset of egg laying.

Feed preparation should follow the same guidelines discussed previously for the subacute test, with a minimum of one control and two test doses. Both test doses should be at sublethal concentrations and frequently represent known environmental concentrations. If a NOAEL determination is required, then three concentrations arranged in a geometric progression should be used in addition to the control group. The test chemical should be administered for at least 10 weeks prior to the onset of egg laying, and administration should continue until all control pens have produced 25 eggs or 6 weeks after 50% of the control hens have laid one egg. Studies designed to test alternative shot use oral gavage with one no. 4 lead pellet (positive control) or eight no. 4 pellets of either the test shot or steel shot (negative control), with a minimum of four pairs in the lead treatment group and 20 pairs in the other treatment groups. Shot is administered on 0, 30, 60, and 90 days after the start of the study.

Food and water should be presented *ad libitum* for the entire test period, and food consumption should be recorded at least biweekly throughout the study. Eggs should be collected daily, marked according to the pen from which they were collected, and stored at 16°C and 65% relative humidity. All eggs should be set in incubators once a week at a temperature and humidity suitable for the species being tested. Parental incubation and rearing of chicks may be used if suitable artificial husbandry parameters cannot be determined. Eggs should be candled on day 0 to look for cracks and on days 11 and 18 (bobwhite) or 14 and 21 (mallard) to determine fertility and embryo survival. Eggs collected on 1 day of weeks 1, 3, 5, 7, and 9 of the egg-laying period should be opened at the equator, the contents washed out, and the shells dried and measured for the thickness of the shell plus the membranes to the nearest 0.01 mm. Eggs should be transferred to a hatcher 1 day before expected pipping (day 21 for bobwhite and 23 for mallard). Hatchability for each egg batch is recorded, and chicks are placed in brooders for 14 days and fed a control diet *ad libitum*. Survival at the end of 14 days is recorded. All birds should be weighed weekly prior to the onset of egg laying and at the termination of the experiment; handling should be minimized during the egg-laying period to reduce disturbance. In addition to weight changes, reported endpoints include daily egg production per pen; type and frequency of abnormal eggs (including cracks and other gross defects); the number of incubated eggs that are fertile (fertility); the number of fertile eggs that produce hatchlings that completely free themselves from the shell (hatchability); the number of normal young surviving to 14 days of age; weight of young at 1 day and 14 days of age; eggshell thickness; and chemical residue in tissues of adults, chicks, and eggs. Alternative shot studies also require measures of hematocrit, hemoglobin concentration, and appropriate blood chemistries. Standard appropriate statistical analyses should be conducted to determine whether treated birds differ from controls or to ascertain the dose–response relationship.

Field Tests

Specific methods for examining effects of toxic substances on birds under field conditions were developed initially by the USEPA's Office of Pesticide Programs for use in obtaining pesticide registration data, but have since been discontinued for this purpose. Similar methods are being used in post hoc evaluations of contaminated sites. In pesticide evaluations, field studies were used to determine effects of specific toxic substances if preliminary laboratory studies indicated a potential hazard (e.g., high acute toxicity) and were used primarily for pesticide registration testing. These techniques have been adopted for use in determining individual-level and population-level effects of existing environmental pollution, such as at hazardous waste sites [122], although methods for field surveys of bird density, community composition, nesting success, and other ecologically relevant endpoints have a long history of use in biological assessments [123]. Integration of specific ecological methods is beyond the scope of this chapter and will not be discussed further here; the standardized controlled field studies that evaluate toxicity and/or evaluate exposure are described as follows.

The European starling (*Sturnus vulgaris*) nest-box study [124] is one means of introducing standardized testing procedures into a field study and has been adapted for other cavity-nesting passerines, because of concerns regarding the sensitivity of starlings [102]. Nest boxes encourage birds to nest within a study site and establish a large local population, with readily accessible nests from which chemical-induced reproductive, behavioral, and biochemical perturbations can be documented. The full-scale test is a 3-year procedure. The first field season serves as a pilot study (and allows birds to locate and colonize the nest boxes) in which 30 nest boxes are erected on each of 12 fields, and occupancy and reproduction are documented. Pesticide application occurs in the definitive study during years 2 and 3 in a paired block design (i.e., each

treated field is paired with a similar control field). The type of fields selected depends on the pesticide (or other chemical) to be applied and the bird species of interest; for example, starlings and bluebirds prefer grasslands (e.g., hay fields), which should be selected in preference over other field types when using these birds as a representative species. Study fields are typically 16 ha in size and should be located next to similarly cropped fields to encourage foraging and enhance exposure to test sites. Study sites must be located at least 3 km from each other to reduce the possibility that birds will leave their initial study site and forage in another study area.

Nest boxes are constructed from utility-grade lumber and measure 29 × 23 × 38 cm ($l \times w \times h$) (dimensions vary, depending on the study species). Study designs are available to reduce probability for nest-box predation [125]. The back portion of the box that attaches to the post is 58 cm long, centered so that 10 cm extends above and below the box. The box is attached to the top of a 10 × 10 cm × 3.67 m ($l \times w \times h$) post, with aluminum sheet metal tubing placed around the post starting immediately below the box and extending down about 75 cm to reduce predation. Nest boxes must be placed in the fields so that crop culture can occur with minimal disturbance; therefore, boxes are placed in a single row down the middle of the field in the same orientation as the crop rows. Boxes are separated by 10 m and are erected at least 2 months before the beginning of the breeding season.

Following the placement of the nest boxes, a period of 7 days is allowed to pass before first observations are made. This allows time for the birds to locate and use the nest boxes without disturbance. During the initial nest-building stage (by males), observations are made every 4 days. When the females arrive and during the mating period, observations are made every 3 days. When eggs have been observed in the nest, observations are made every other day. Daily observations are made from the time that hatching begins until fledging occurs. During all monitoring periods, observations are made between 11:30 a.m. and 3:00 p.m., the time when the birds are least active. The following is the reproductive information observed or calculated from nest-box observations:

- Date of nest-box selection (based on the presence of some nesting material)
- Notes on the development of the nest (e.g., amount of nest-building material, quality of the nest, presence of a nest cup)
- Date the first egg is laid (the previous day is designated the date of nest completion)
- Interval of egg laying
- Clutch size
- Number of eggs missing or broken
- Number of eggs that hatch
- Date of egg hatch
- Number of missing or dead nestlings
- Weight of 16-day-old nestlings (g)
- Number of fledglings on each day
- Date of fledging

Additional information collected includes weather data (maximum and minimum daily temperature, precipitation events, wind speed), observations of adult birds' behavior, and presence of predators in the study area. The study continues until all eggs and nestlings from the second clutch (starlings generally produce two clutches of eggs per breeding season) have hatched and fledged or died, and at least 2 weeks have passed without any more eggs being laid. If none of the eggs hatch but they remain in the nest box, the study is terminated when the last box occupied prior to the chemical application has been monitored for 12 days after the laying of the final egg in the clutch. All nestlings that are found dead in the box are analyzed for brain cholinesterase activity, liver enzyme induction, and tissue residues to verify the cause of death (choice of assay depends on the chemical being studied).

If the study being conducted is a pesticide safety study, the application rate of the pesticide should be the highest concentration proposed for registration. The timing of application depends on the age class of starling nestlings. The initial (or single) application to the fields should be performed when there is the greatest number of 1- to 14-day-old nestlings in the boxes. Pesticide application rates are verified through analysis of vegetation, spray cards, and subsampling of the pesticide holding tanks. For granular formulations, the deposition rate of the granules from the dispensing apparatus is measured. About 50 samples per field are required for an accurate representation of application rate.

The reproductive success of the nesting pairs (as summarized by the number of fledglings per field) should be analyzed initially using a two-way ANOVA randomized block design, with the number of fledglings per field as the dependent variable, to determine differences among treatment groups. It is advisable to transform data using a square-root transformation prior to analysis. If this initial test shows significant differences, then inferential statistics should be used to identify which parameters were affected.

Guidance for designing and performing avian field studies for toxicity determinations is provided by Fite et al. [126]. General guidelines are given for two kinds of studies: a general screening study to detect acute toxic effects resulting in mortality or obvious behavioral changes and a detailed, definitive study to quantify the magnitude of acute mortality, determine and measure reproductive impairment, and integrate indirect effects (e.g., food reduction) that may influence the long-term survival of the subpopulation under study. The species and location for the study are determined primarily by the known or proposed location of the pollutant and the population densities and species diversity of the bird communities. The number of replicate study plots (both reference control and treatment) required to make a determination of effect is based on the expected probability of occurrence of effect and the known variability of the system. True replicates are required, and the tendency toward pseudoreplication must be avoided [127]. Many statistical techniques are available for determining the minimum number of replicates required [128].

Information on population density, age, and sex structure, as well as survival data, can be acquired through a range of methods, including the use of mark–recapture techniques, radiotelemetry [129], line transects (for carcass searches), captures per unit effort, or counts of animal signs [110]. Various models are available that use these types of data to determine the probability of survival per unit time and intrinsic population growth rates [130,131]. Reproductive success (from time of initiation of egg laying to fledging of young) is determined through visual observations of nests (egg and fledging counts), radiotelemetry of young, and behavioral observations [129,132].

Studies can also be conducted on contaminated sites to investigate effects on open-cup nesting birds. Nests are found through spot mapping singing males on territory for many passerine species [125,133]. Mist netting can be used to age and color mark individuals for long-term assessment and observation. For persistent, bioaccumulative compounds, residues in food sources from the lower portion of the food web for species of concern can be measured to determine site-specific BAFs. Hatchlings, typically greater than 10 days old, can be used to gather food items for species-specific dietary assessments using the throat ligature technique [134]. Combined with samples for analysis of collocated soil or sediment concentrations, site- and species-specific BAFs can be determined. The throat ligature is a small wire tie that can be fitted snugly around the base of the throat. Nests are observed for evidence of parental feeding, and immediately following feeding events, food is removed from the mouths of fledglings with forceps and subsequently analyzed for chemical content. The wire tie is removed harmlessly using small diagonal cutters. Because bioaccumulation is not a linear function of exposure concentration for most chemicals, and because the process attenuates at higher doses, BAFs should be calculated for multiple areas within a contaminated site to establish the appropriate uptake function.

Additional data that should be collected when assessing effects of contaminated soils include the effects of the chemical on the food source, competitors, or antipredator behaviors of the species of concern. Information on the abundance and composition of the predator community should be gathered to ascertain whether indirect effects of food reduction or changes in community composition may be affecting the endpoint species in addition to (or instead of) direct toxicological effects. These data must be interpreted in the context of what is known about the natural history and normal phenology of the species being studied [135].

Exposure through specific (geophagy) and inadvertent soil ingestion can also be determined for species exposed to contaminants in soil through an evaluation of silica content in feces [136]. These data are particularly useful in exposure characterization for substances that do not biomagnify in food items, and can be used to refine exposure estimates and remedial criteria.

In addition to documenting direct toxic effects on the species of concern, information also is gathered during a field study about the distribution and persistence of the chemicals in the environment. Relating harmful effects on animals to the degree of environmental contamination depends on establishing that a toxic dose has reached either the animal or another species upon which its survival depends. Such information is collected by determining the tissue residues of the chemicals or their metabolites. Biosamples (e.g., blood) can be used to gather information on biomarkers of exposure or effect [94,133]—for example, suppression of brain or blood cholinesterase activity following exposure to organophosphorus or carbamate insecticides or inhibition of δ-aminolevulinic acid dehydratase (ALA-D) due to lead exposure. Both ALA-D and cholinesterase inhibition are legally acceptable indicators of harmful effects of exposure to environmental pollutants [137]. For some chemicals, the concentration of the chemical in the blood or a specific organ can be related to adverse effects, such as blood lead levels, liver lead concentrations, or concentrations of DDT or mercury in the brain [138]. These critical tissue residues can be used as highly specific risk threshold values [94,115]. Other biomarker responses have been developed and used in wildlife exposure studies for risk assessment purposes (e.g., cytochrome P450 induction, corticosteroid levels) but are not yet standardized or have questionable relevance in estimating risk [139].

Mammalian Tests

In environmental toxicology, mammalian-effects data generally are gathered as part of human health impact studies. Both the USEPA [104] and ASTM [106,140] have published general guidelines for conducting acute and subacute toxicity studies with wild mammals and reference the avian and laboratory mammal protocols for more detailed approaches. For large or relatively scarce species, a single-dose regimen may be used where a group of three or more test animals is exposed to the chemical at a dose thought to be representative of expected environmental exposures and observed for at least 10 days for signs of intoxication. Additional doses may be tested sequentially if needed to develop a dose–response curve. This follows the method described for estimating acute oral toxicity in rats by the up–down or the stagewise probit method discussed previously [106–108].

Efficacy testing of anticoagulants in rodents (particularly rats and mice) is well developed, because these animals are the target species [141]. The tests present the animals with both contaminated feed and control feed simultaneously for a free-choice scenario, using a single concentration of chemical in the feed. Exposure times vary from 8 to 20 days, depending on the species being tested, with a 7-day postexposure observation period. The higher the mortality, the greater the efficacy of the product.

Detailed protocols have also been developed for mink (*Mustela vison*) and the European ferret (*Mustela putorius furo*) as representative carnivores, due to concerns about compounds that biomagnify in the aquatic or terrestrial food chain, respectively, and therefore might be expected to cause secondary poisoning due to high concentrations in

the tissues of the target species. Both of these animals can be propagated successfully in the laboratory, and stocks of known genetic origin are available. Additionally, the mink has been shown to be extremely sensitive to polychlorinated biphenyls [142], polybrominated biphenyls [143], hexachlorobenzene [1], aflatoxins [144], and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin [145]. Three protocols are available: dietary LC_{50}, reproduction, and secondary toxicity [146]. For all three tests, animals should be of mature body weight (about 18–20 weeks of age). Either sex can be used in the subacute dietary and secondary toxicity tests; however, the two sexes must be treated as separate subgroups due to significant size differences. Test animals can be obtained from commercial sources or reared in the laboratory and should be free from obvious disease or injury. It is recommended that mink be vaccinated against canine distemper, virus enteritis, infectious pneumonia, and botulism and that ferrets be vaccinated against canine distemper and botulism. Although space requirements for most carnivores have not been standardized, adherence to the guidelines of the Fur Farm Animal Welfare Coalition [147] should provide adequate husbandry guidance. Cages measuring 61 × 76 × 46 cm ($l \times w \times h$) have proven adequate for housing individual mink or ferrets. Solid dividers should be used between adjoining cages to reduce aggression, and a nest box containing straw, shredded wood, or marsh hay must be provided for females in reproduction tests prior to parturition. No specific photoperiod is required, but the day length should not be altered from that in which the animals have been reared. A minimum of 7 days of acclimation is required, during which time food consumption should be measured and an initial body weight determined. Diets must be formulated to meet the requirements of the test species. Suggested composition of mink diets is provided by the National Research Council [148] and by Ringer et al. [146]. Fresh food and water must be provided daily *ad libitum*. Test diets are prepared by mixing the chemical directly into the feed or by dissolving or suspending in a solvent or carrier prior to mixing in the feed. If a solvent or carrier is used, it must also be added to the control-group diet. If a volatile solvent is used (acetone or hexane), the diet should be air-dried to evaporate the solvent prior to feeding. Sufficient diet should be mixed to provide feed for the entire exposure period and frozen in aliquots sufficient for 1–2 day feeding. All diets should be analyzed after mixing to determine actual concentrations and homogeneity of the test substance in the diet.

Subacute Dietary Toxicity Protocol for Ferrets or Mink

The doses for a definitive LC_{50} study [146] should be arranged in a geometric progression, with the highest dose set so an animal will consume the equivalent of an LD_{50} dose in 1-day feed. The test concentrations should then be spaced to achieve at least two concentrations, yielding between 10% and 90% mortality. This generally can be achieved with four to six different concentrations. A minimum of eight animals per dose is required. If an LD_{50} value is not available, one can be determined from a range-finding procedure. A geometrically spaced series of doses is administered by gavage to two animals per dose, and the LD_{50} is determined to be the dose at which one or two animals die during a 1-week observation period. Animals should be treated by gavage with a 3-in., 14-gauge, curved, stainless-steel animal feeding needle. If a lethal dose is not found, the highest dietary concentration should be set at 5000 mg/kg. It is recommended that the highest concentration to be tested be fed to two to four animals for several days prior to the start of the test, to be sure that it is palatable. If it is not, the highest concentration should be reduced to a level that will be eaten. The test diet is then presented for 28 days. A withdrawal period when clean feed is given should be included if animals are still exhibiting signs of intoxication at the end of the exposure period but should not exceed 14 days. Body weights should be recorded at the beginning of the treatment period and weekly thereafter. Feed consumption should also be measured weekly. Mortality, behavioral abnormalities, and other signs of toxicity should be recorded daily. A test is considered invalid if more than 12.5% of the control animals die. It is recommended that a dietary concentration group be removed from the test when food consumption values indicate that feed consumption has dropped to less than 10% of control values after the first 2 weeks of measurements or if animals lose 30% of their initial body weight. It is recommended that necropsies be performed on all animals at the time of death and on all test animals euthanized at the end of the observation period [149]. Gross and histopathological examinations of all major organs should be conducted, including measurement of organ weight. Comparison of body- and organ-weight changes and feed consumption between control and treatment groups should be made by ANOVA procedures with a posterior comparison of groups conducted by Dunnett's method [150]. The LC_{50} value is calculated by probit analysis or another standard method.

Reproduction Test Protocol for Ferrets or Mink

This test [145] primarily measures female reproductive effects, because the male is used only for the period of time needed for insemination of the female. Proven breeders should be used if possible. A minimum of 12 females per treatment group is required. One male is needed for every three females in each treatment group; males should not service females in more than one treatment group. If proven breeders are used, the number of females per group can be reduced to eight, and the number of males to two. Males are left with the females only for the duration of breeding. A minimum of two test concentrations and one control group is required. The highest test concentration must (1) produce an effect, (2) contain at least 1000 mg/kg, or (3) be at least 100 times higher than the known or expected environmental concentration. Animals are fed test diets for 8 weeks prior to breeding; during breeding, gestation, and parturition; and for 3 weeks of lactation (approximately 23 weeks in total). The test will be longer for mink than for ferrets, because mink exhibit a variable delay in implantation of fertilized ova, while ferrets do not. The gestation period for mink can range

from 42 to 60 days, whereas the ferret has a more constant gestation period of 42 days. Under natural conditions, mating attempts begin at the first of March for mink and at the end of April for ferrets.

To breed mink, a female is presented to a male (in his cage) and, if receptive, is allowed to mate. If not receptive, the female is removed and a mating attempt is tried again in 4 days. Successful mating is verified by the presence of viable spermatozoa in a vaginal aspiration taken after copulation. Following a successful mating, the female is given a second opportunity to mate to the same male either the next day or (preferably) 8 days later. In breeding ferrets, females are presented to males when in estrus (determined by extent of vulvar swelling) and left with the male overnight. They are not given the opportunity for additional matings.

When the breeding period is over, animals should be left undisturbed except for daily feedings. Body weights should be measured weekly only during the 8 weeks prior to breeding. Feed consumption should be measured weekly throughout the duration of the test. Observations of behavioral changes, mortality, or other signs of toxicity should be recorded daily. During parturition (up to 3 weeks in length), females should be checked daily for newborn. Number, weight, and sex of all newborns are recorded within 24 h of birth. It may be necessary to remove the female from the nest box to check for newborns. Offspring should be weighed again at 3 weeks of age. After this time, they will begin eating the adult diet and should be fully weaned at 6 weeks of age, at which time the test is terminated. At the end of the test, all males and at least an equal number of females are euthanized [148], and necropsies are performed for gross and histopathological examinations. A test is considered invalid if more than 20% of the control animals die during the test. The following reproductive parameters must be reported:

- *Length of gestation*—Time, in days, from last confirmed mating until parturition.
- *Number whelped, not whelped*—Number of females giving birth or not giving birth in a treatment group per number of females with confirmed matings; number whelped includes those females that die during parturition.
- *Live newborns per females whelped*—Average number of live newborns produced by all females that give birth in a treatment group; this does not include females that die during whelping.
- *Average birth weight*—Average weight within 24 h of birth of all live newborns within a treatment group.
- *Average litter weight*—Average weight of all litters (live newborns only) within each treatment group.
- *Percent newborn survival to 3 weeks*—Number of live newborns in a treatment group surviving to 21 days of age, expressed as a percentage of all live births in the treatment group.
- *Average body weight at 3 weeks of age*—Average weight of all live newborns in a treatment group on the 21st day after birth.
- *Total newborns per female whelped*—Average number of all newborn (alive and dead) produced by all females that give birth in a treatment group (including those females that die during whelping).
- *Percent newborn survival to 6 weeks*—Identical to 21-day survival but extended to 42 days.
- *Average 6-week body weight*—Identical to 21-day weights but measured at 42 days of age.

Number whelped and percent survival should be analyzed for differences among treatment groups using contingency tables and Bonferroni's chi-square test or similar statistical procedures. The remaining variables can be compared among treatment groups by ANOVA techniques with Dunnett's method [149] for comparison to controls.

Secondary Toxicity Protocol for Ferrets or Mink

This protocol [145] is used to determine the comparative toxicity of both a parent compound and its metabolites administered in the diet, such as might be ingested when consuming contaminated prey. The toxicity of the parent compound is determined following the procedures detailed in the preceding text for subacute dietary toxicity testing (LC_{50}). Secondary toxicity testing is conducted using the same protocol, with the exception that the contaminated feed consists of mink and ferret prey items that have themselves been fed the test substance. Prey animals can be any species that is readily consumed by the test animals, including fish (salmon, perch, alewife, sucker, carp, and bloater chubs), birds (chickens), and mammals (beef, nutria, rabbits, voles, pocket gophers, rats, and mice). Prey animals may be contaminated by dietary, inhalation, or dermal routes and should be exposed to the same test substance (same source and lot number) as fed to the mink or ferrets in the primary toxicity test. The concentration of the test substance to which the prey are exposed should be sufficient to generate tissue residues of parent compound or metabolite at levels known to cause 10%–90% mortality of the mink or ferret. This may need to be determined through a range-finder test with the prey species. The final body burden in the prey should allow for dilution of the tissues by the remainder of the dietary ingredients provided and for dilution by noncontaminated portions of the prey; for example, if 10 mg/kg causes a 50% lethality in the mink or ferret, and a diet consisting of 40% prey tissue is being fed, then a prey body burden of 25 mg/kg is required to yield the final dietary concentration of 10 mg/kg. Prey animals that are not killed by the test substance should be euthanized in a manner that will not interfere with the test results. The gastrointestinal (GI) tract can be removed from the carcass if the test substance is known to accumulate in tissues. This will reduce the probability of direct poisoning from consumption of undigested material in the upper GI tract; however, some compounds do not readily accumulate in tissues (e.g., organophosphorus insecticides), and poisoning of carnivore species occurs primarily from ingestion of material in the GI tract. In these instances, the GI tract can be left intact. All prey-animal carcasses should be frozen until being fed to the mink or ferret.

Other Acute, Subacute, and Subchronic Mammalian Models

Other species have been used in various study designs intended for the derivation of TRVs. *Peromyscus* spp. (e.g., white-footed and deer mice) are native to eastern and western North America, respectively, and are available from several captive-bred facilities, including genetic variants [151]. Typically, these species are not amenable to repeated-dose gavage studies, because they are high strung and difficult to handle on a daily basis; however, acute gavage studies using the up–down or stagewise probit methods can be accomplished. Repetitive exposures are best accomplished using dietary studies, although care is needed to use feed receptacles that reduce spillage and do not allow the animals to either nest or urinate/defecate in their food. Spilled feed should be weighed daily to account for unconsumed diet. Traditional polycarbonate mouse cages can be used with additional housing material for enrichment, because these species are crepuscular and nocturnal. Other small-mammal models include voles (*Microtus* ssp.) and shrews (*Sorex* ssp.), although these species require additional care in handling due to an increased tendency to bite. Cotton rats (*Sigmodon* ssp.) should not be handled by the tail, because they can shed the outer layer of skin and can also inflict a painful bite. The use of mail gloves is advised when handling any wild rodent.

Honeybees

The European honeybee (*Apis mellifera*) is important economically, due to its use for pollination of many crops (e.g., fruit trees). Methods have been developed to evaluate the effects of pesticides on honeybees [14,152–154], and these tests have been adapted for use in assessing environmental pollution in situ [155,156]. Toxicity to bees of residues on foliage is determined using individual worker bees of uniform age [14,155]. The compound of concern is applied to alfalfa foliage in the field and allowed to weather under natural conditions. Worker bees—honeybees, the alfalfa leafcutting bee (*Megachile rotundata*), or the alkali bee (*Nomia melanderi*)—are collected from the frames of established colonies, and 50–100 individuals are introduced into each test cage. Cages are constructed by cutting wire screen into 5 cm strips 46 cm long and stapling the ends to form a cylinder. Tops and bottoms of 150 × 15 mm plastic petri plates serve as the tops and bottoms of the cages. Honeybees (50–100), leafcutting bees (20–40), or alkali bees (15–30) should be placed in each cage. Ambient temperature during the 24 h test period should be 24°C–26°C (honeybees) or 29°C–31°C (leafcutting bees and alkali bees). Bees are fed during the test by providing cotton squares (5 × 5 cm) soaked with 50% sugar syrup and placed under the treated foliage.

The test compound is applied to 0.01-acre alfalfa plots in a randomized block design at applications that simulate known environmental concentrations or proposed use patterns. The test can be designed to evaluate a single dose; preferably, a geometrically spaced range of doses is used to determine an LC_{50} value. Foliage is harvested at 3, 8, and 24 h after application. If greater than 25% mortality of bees occurs when exposed to 24 h foliage, sampling should continue at 24 h intervals until mortality resulting from exposure to treated foliage is not significantly different from control groups. Foliage is chopped and mixed, and 500 mL is introduced to each cage. Mortality is determined after 24 h of exposure to the treated foliage. At least three cages of bees must be used per replicate, and each treatment, including controls, must be replicated at least three times.

The honeybee acute contact LD_{50} test is based on the protocol developed by Atkins et al. [151] for screening pesticide dust and follows the same husbandry procedures detailed previously. Worker bees of uniform age are exposed to the test substance through a dusting procedure. Twenty bees are transferred to the dusting cage and dusted for a period of 15 s. The dusted bees are then put in holding cages and observed for mortality over the next 24 h.

The honeybee subacute test [13] is designed to test the effects of a chemical on the colony as a unit. The study is intended to identify those chemicals that may cause adverse reproductive, behavioral, or other subacute effects that can be brought back to the hive by exposed foragers. This test is less developed than the tests described in the preceding text for individual bee toxicity, and consequently, it will not be detailed here, but it was discussed at a recent workshop on risk assessment for pollinators [154]. The general approach involves exposure of intact bee colonies to the test substance through feeding in pollen or sugar syrup (there is no consensus as to which component of the diet should contain the test compound). Through caging or location, the colonies are restricted to feeding only on the treated food provided. Periodic observations are made for 42 days to 4 months (42 days is the approximate time needed to complete two brood cycles). Observations include the following:

- Colony strength
- Weight of the hive
- Pollen, honey, and nectar stores
- Mortality at the hive (via the use of dead-bee traps or collecting sheets)
- Mortality of drones and pupae
- Mortality in the crop
- Presence of the same queen
- Foraging activity in the crop
- Returning foraging bees (can be counted automatically)
- Behavioral abnormalities
- Residues in pollen, nectar, pollen pellets, wax, bee bread, and dead bees
- Assessment of the brood, including an estimate of adults
- The area containing cells, eggs, larvae, and capped cells
- Disease or pest levels (as a measure of resistance)

Analysis of pollen content can also be useful in understanding exposure to soil contamination.

Soil Invertebrates

Direct measures of chemical contamination of the soil can be, and frequently are, made following traditional analytical chemistry methods; however, these methods are costly and time consuming and do not provide information about the toxicity of the soil to terrestrial organisms, particularly because synergistic, antagonistic, and additive effects of the complex mix of compounds found in contaminated soils can occur. Furthermore, chemicals in soil become bound to soil particles during the aging process and become progressively less bioavailable [157]. Chemical assays that use harsh extraction procedures to extract all the chemical from the soil do not provide a realistic estimate of exposure to soil organisms. Models are being developed to calculate porewater concentrations for varying soil types (especially with reference to pH, organic matter, and clay content) to more closely estimate actual exposure regimes. Even these methods cannot account for biological adaptations, behaviors, and microenvironment alterations; therefore, bioassays have been developed to provide direct measures of toxicity.

Plant germination and growth tests are the most commonly used methods for determining soil toxicity and are described later in this chapter. The amphibian bioassay (FETAX) described in the following text can be conducted using eluates from contaminated soils. A solid-phase version of the aquatic MICROTOX test has been developed and is used occasionally. Soil microbial function assays are available for nitrogen and carbon transformation processes [158–160] and are described briefly in the following text. Analysis of the soil transcriptome (i.e., transfer RNA) is being studied as a sensitive and more realistic in situ method for measuring functional changes in the microbial community.

Soil invertebrates play a pivotal role in the terrestrial ecosystem, providing functions such as decomposition of organic matter, as well as providing a prey base for many higher-order organisms. A well-developed, but infrequently applied, test determines an LC_{50} in soil for harvester ants (*Pogonomyrmex owyheei*) [161]. Crickets (*Acheta domesticus*), isopods (e.g., *Porcellio scaber*), millipedes (*Brachydesmus superus*), centipedes (*Lithobius mutabilis*), staphylinids (e.g., *Philonthus cognatus*), oribatid mites (e.g., *Platynothrus peltifer*), and soil nematodes also have been studied as possible toxicity test organisms for soil toxicity determinations [162,163], but none of these protocols has yet been accepted by the OECD, EU, or United States for regulatory purposes. The soil invertebrates most frequently used for toxicity testing are the oligochaetes: the potworm (Enchytraeids, such as *Cognettia sphagnetorum*) and earthworms (e.g., Lumbricidae, such as *Eisenia foetida* and *Eisenia andrei*); the Collembola (*Folsomia candida*, *Folsomia fimetaria*, and *Orthonychiurus folsomi*) also are used. Standard assays are available for earthworm survival, reproduction, and avoidance behaviors [164–166]. Both of these types of worms are found in nearly every soil type (except for xeric soils) and play an important role in soil decomposition [167]. Furthermore, they are composed of a high percentage of lipids and readily bioaccumulate contaminants from soils; a standard test is now available for bioaccumulation in oligochaetes [168], which are a significant food item for many vertebrates and, therefore, are often an important first step in the movement of soil contaminants into the aboveground food web. Standard test protocols have also been adopted by the OECD and Canada for Enchytraeid, Collembola, and predatory mite *(Hypoaspis aculeifer)* reproduction assays [169–172].

Earthworm Tests

The earthworm survival test [165,173,174] uses adult (>60 days old, 300–500 mg, with clitellum) *E. foetida* or *E. andrei* grown in a single culture chamber. Worms can be purchased from a commercial source or collected outdoors. The identification must be verified [175] to ensure that the species is *E. foetida* or *E. andrei*. Test soils are first homogenized using a blender and then mixed with artificial soil (10% 2.36 mm screened sphagnum peat, 20% colloidal kaolinite clay, and 70%-grade 70 silica sand) to prepare 700 g each of a geometric series of test soil concentrations (e.g., 100%, 50%, 25%, 12.5%, 6.25%, 3.13% w/w) plus a 100% artificial soil control. The total amount for each concentration is blended—to ensure even mixing—prior to dividing into aliquots for the test. After mixing, the soils are hydrated to 75% water-holding capacity (WHC). Standard 1-pint canning jars with screw-top lids and rings are used as test chambers. Three replicate chambers are filled with 200 g (dry weight) of soil for each dilution. Ten earthworms are placed on the soil surface, the jars are capped, and they are incubated at 20°C ± 2°C under continuous light (540–1080 lx) for 14 days. Worms are not fed during the test. Soil pH is measured at the beginning and end of the test, and the temperature of the environmental control chamber is monitored continuously. The total organic carbon of the test soils should be measured in one test jar for each test concentration and the control. Jars are examined daily for dead worms (worms are considered dead when they do not respond to a gentle touch on their front end). At the end of the 14-day period, the soil is emptied into a tray and the jar is thoroughly searched for worms. Dead worms decay very rapidly, so all 10 worms in a container may not be accounted for during the test, and it is assumed that all missing worms have died. The percent mortality for each concentration is determined, and the EC_{50} for mortality is calculated by probit analysis. Mortality is defined as a lack of response to a gentle mechanical stimulus (e.g., a touch with a small glass rod). Loss of earthworm biomass and behavioral and morphological endpoints such as coiling, segmental swellings or constrictions, lesions, rigidness, and flaccidness also can be used as toxicity endpoints.

Growth and reproduction are biological endpoints in earthworm tests of longer duration, generally 140 days [3,173,174]. Test conditions are the same as described for the 14-day study, although worms must be fed for any study with duration greater than 28 days. Control of pH, temperature, and soil moisture content is very important, because variations in these environmental parameters have been shown to significantly affect the outcome of earthworm reproduction

studies. Mortality and other sublethal observations are made at least weekly. At the conclusion of the test, the containers are emptied, and the number of adult worms remaining is tabulated. The number of cocoons formed, cocoon mass, number and growth of young worms, and rate of clitellum development are measured as reproductive endpoints.

Enchytraeid Tests

The potworm, *C. sphagnetorum*, is readily obtained from the field and is easy to culture in the laboratory on a 75 vol% sphagnum peat substrate mixed into 25 vol% LUFA 2.2 soil (LUFA is a natural soil type found in Europe that contains ~3.9% organic matter and 3.5% clay and has a pH of 5.8) [176]. Animals of similar size (i.e., with the same number of segments) are used in each study. A single study is conducted to determine percent mortality and effects on growth rate of adults and fragments. Potworms reproduce asexually, resulting in the production of three fragments: head, middle, and tail. The middle and tail fragments develop a functional mouth within 2–3 weeks, and all three fragments continue to add new segments. After another 2 weeks of adding segments, the new worms are indistinguishable from older specimens. Worms that have >30 segments are considered to be adult. Growth is defined as the increase in number of segments over the test period, reproductive success is quantified as the mean number of fragments that survive and add segments over the test period, and the fragmentation rate is defined as the average number of fragments produced per day. The chemicals of interest are dissolved in water or an organic solvent and mixed with the soil substrate, and the soil is wetted to 80% WHC 24 h before introducing the worms. For chemicals dissolved in organic solvent, the chemical is first mixed with a small amount of sand to allow the solvent to evaporate and then mixed into the final batch of soil. A food source is required due to the long duration of the test, so 1% algae (*Pleurococcus* spp.) or 0.2% baker's yeast is added to the soil substrate prior to putting ~2 g of soil into each test tube. Animals are maintained one per test tube at 15°C ± 1°C, with a relative humidity in the test chamber of 75% under constant light, after first counting the number of segments present. At weekly intervals for 10 weeks, the tubes are examined for the number and size of fragments and number and size of unfragmented worms. Animals are transferred to vials with fresh soil and food (one worm or fragment per vial) prior to returning them to the incubation chamber. Copper chloride is used as a positive control (reference); a test is considered valid if the growth rate in control animals is >1 segment/week and there is <10% mortality of controls.

Springtail Tests

Springtails, including *F. candida, F. fimetaria*, and *O. folsomi*, are common soil organisms that occupy a position in the soil food web, being consumers of fungi, detritus, nematodes, and bacteria, and are an important prey group for other invertebrate predators. Historically, *F. candida* has been the preferred species for studying the effects of contaminated soils, and an International Organization for Standardization (ISO) protocol was published in 1999 but is no longer available; Environment Canada published a more comprehensive protocol in 2007 [169]. Laboratory-cultured springtails should be used as the source of the test organism, making sure that the animals are not excessively inbred. All springtails used in a test must be derived from the same population and be of the known developmental state and the same age and size; information about the laboratory stock should be provided. Test vessels consisting of 100–125 mL wide-mouthed glass jars or beakers with plastic or metal lids are thoroughly cleaned and rinsed and filled with 20 g (wet weight) of soil. Test soils can be either negative control soils spiked with chemical or soil collected from contaminated sites. Negative control soils, in turn, can be either natural soils or artificial soils; regardless, physicochemical characteristics should be described (e.g., pH, particle size, texture, conductivity). Positive control soils consisting of soils spiked with a known toxicant should also be included. For field studies, reference soils (i.e., similar soils collected from sites known to not be contaminated with the chemicals of interest) can be included as well. Concentrations of chemicals in soils should be analyzed at the beginning and end of the test. Soils should be at 70% WHC, and any field collected should have debris and indigenous macroorganisms removed and press-sieved through mesh size 4–6 mm and thoroughly mixed. Test vessels are seeded with 10 female and 5 male organisms at 28–31 days of age for *O. folsomi*, 10- to 12-day-old juveniles for *F. candida*, and 23- to 26-day-old organisms for *F. fimetaria*. Test duration is 28 days for *O. folsomi* and *F. candida* and 21 days for *F. fimetaria*. Air temperature should be maintained at 20°C ± 2°C, with light intensity at 400–800 lx and a photoperiod of 16 h L:8 h D. Animals are fed granulated dry yeast on days 0, 7, 14, and 21 by sprinkling onto the soil surface in each test vessel. Vessels should be opened briefly at least once per week to aerate and should be rehydrated as necessary. Measurements made during the test include daily (or continuous) air temperature, percent moisture, and pH of soil in each vessel at start and end; excessive growth of fungi; feeding activity; and presence and quantity of uneaten food. Endpoints measured are number alive (percent survival) and total number of live progeny at the end of the test. Depending on the test design, concentration–response functions can be derived or differences between test soils and reference soils calculated. Tests are considered invalid if mean survival of adults in negative control soil is <70%.

Soil Microorganism Tests

Soil microbes (i.e., fungi, bacteria, actinomycetes, and protozoa) make up 80% of the living matter in soil and contribute significantly to essential soil function, such as decomposition of organic matter, nutrient cycle, and soil aggregation [177]. Because of the diversity of species and the importance of microbial functions, tests for the effects of chemicals on soil microbes use functional endpoints rather than effects on individuals or population structure. Two standardized tests are available—nitrogen transformation [159] and carbon

transformation [160]—but significant controversy remains over the relevance of these and other soil function assays. The nitrogen transformation test adds a nitrogenous substrate to reference or contaminated soils collected in the field (or clean soils spiked with chemical). Soils are incubated for 28 days and then analyzed for the production of mineralized nitrogen (i.e., amount of ammonium, nitrite, and nitrate production). The carbon transformation test is similar and measures the soil respiration rate (carbon dioxide production). A dilution series of five soil concentrations of the chemicals of concern is preferred, and at least a 20% difference between reference and treated soils is required to specify that a significant effect has occurred.

Amphibians

The frog embryo teratogenesis assay *Xenopus* (FETAX) is a standardized bioassay developed for obtaining data on the developmental toxicity of test materials. Amphibians usually are associated with wetlands, many of which are affected by chemical pollution due to their distribution in low-lying areas of the landscape and their connection to the surface and subsurface hydrology [71]. FETAX is used primarily as a measure of toxicity to amphibians of environmental samples (water, sediments, and soil eluates); however, results from this bioassay have an 85% correspondence with results from mammalian developmental toxicity tests, so the information can be extrapolated to other classes of animals with a high degree of certainty. The standard protocol, as described in the following text, is a laboratory assay. A field application (by putting the egg masses in porous containers submerged in the water at the study site, and following all other standard procedures) also has been used [178].

In FETAX [179], a range-finding and three replicate tests are performed. Each test includes both a negative control (no test material added) and a positive control (6-aminonicotinamide). The 96 h LC_{50} and 96 h EC_{50} (malformation) are determined, and the teratogenic index (TI) is calculated by dividing the LC_{50} by the EC_{50}. The FETAX protocol is designed to use embryos of the South African clawed frog, *Xenopus laevis* (Daudin), which is a tetraploid (4N) species. Other North American species can be used and are listed in the appendix of the protocol, although breeding times and methods would have to be adjusted to produce an appropriate egg mass for the test. For *Xenopus*, adult frogs that are proven breeders should be purchased and maintained in single pairs. The frogs should be bred in the same water in which the test is to be conducted (natural, nonchlorinated water known to be free of contaminants) and fed ground adult beef liver three times per week. Temperature should be kept at 23°C ± 3°C on a 12:12 L/D photoperiod. Breeding is induced in the males and females by injection into the dorsal lymph sac of 250–500 and 500–1000 IU, respectively, of human chorionic gonadotropin. Egg deposition usually occurs 9–12 h later. The eggs should be inspected for fertility, which must be >75% for the egg mass to be used in a test. Eggs are then separated from the jelly coat by gently swirling them for 1–3 min in a 2% w/v L-cysteine solution prepared in FETAX solution (625 mg NaCl, 96 mg $NaHCO_3$, 30 mg KCl, 15 mg $CaCl_2$, 60 mg $CaSO_4{\cdot}2H_2O$, and 75 mg $MgSO_4$ per liter of deionized or distilled water; final pH 7.6–7.9). Eggs should be removed from the dejellying solution and rinsed with clean water as soon as dejellying is completed or survival will be reduced. Only normally cleaving embryos should be selected for use in the test. The *Atlas of Abnormalities* [180] should be consulted to determine abnormalities during the assay. Each test must use embryos derived from a single mated pair.

FETAX is a 96 h test. Each test consists of at least five concentrations arranged in a geometric progression, three of which should fall within the 16%–84% effect range on the mortality and malformation dose–response curves. A range-finding test should be conducted first, consisting of at least seven concentrations that differ by factors of 10. Each test concentration and the positive control should have two dishes, each containing 25 embryos and 10 mL of test solution. The negative control groups must have four dishes of 25 embryos each. The positive control (6-aminonicotinamide) consists of two dishes exposed to 2500 mg 6-aminonicotinamide per liter and two dishes exposed to 5.5 mg/L. Dishes are placed in an incubator to maintain the temperature at 24°C ± 2°C. The pH of the test solutions should be 7.7 (range, 6.5–9.0). The test material is renewed every 24 h during the test. Renewal should be done by removing the old test solution with a Pasteur pipette, with the orifice enlarged and fire-polished to accommodate embryos without damage if they are picked up accidentally. Fresh solution is added quickly to minimize embryo desiccation.

Dead embryos are removed at the end of each 24 h period during the 96 h test (at the time the solutions are changed). Death at 24 h is ascertained by the embryo's skin pigmentation, structural integrity, and irritability. At 48, 72, and 96 h, a lack of heartbeat indicates death. The total number of dead embryos and numbers and types of malformations occurring at the end of 96 h are reported. The ability of the test material to inhibit growth is determined at 96 h by recording head-to-tail length. If the embryo is curved or kinked, the measurement should be made as if the embryo were straight (i.e., following the contour of the embryo). The minimum concentration of test material that significantly inhibits growth (MCIG) should be determined from these data using the *t*-test to determine significance at $p = 0.05$. The LC_{50} and EC_{50} (malformation) should be determined using probit analysis.

Postfertilization protocols using native amphibian eggs have been developed to evaluate sediment and water contamination [141]. Exposures can be extended to metamorphosis. Effects of compounds that inhibit thyroid hormone production can be particularly evident as delayed or inhibited metamorphosis [181,182]. Moreover, tests involving native species can reveal a greater sensitivity than *Xenopus*, yet their overall sensitivity to environmental contaminants has been questioned [183].

Soil contamination effects have been tested using a plethodontid terrestrial salamander species, the red-backed

salamander (*Plethodon cinereus*) [110,184–186]. Individuals are wild-caught and exposed to treated or contaminated soils in glass petri dishes. Salamanders can be housed for long exposure periods, lasting several months. Small amounts of sphagnum moss are wetted and used for humidity control and for environmental enrichment. Individuals can be maintained on mutant (flightless) *Drosophila melanogaster*, although attempts to integrate compounds within food items have not been productive due to direct toxicity to live food (Johnson, unpublished data). Animals are particularly sensitive to irritants in soil and are considered conservative models in estimating risk to compounds that are likely to penetrate via dermal routes. Excess mucus production is an early indicator of stress. Animals should be euthanized in a buffered MSS-222 solution at the end of the test exposure period and decapitated to obtain 10–20 µL of plasma obtained for determination of packed-cell volume and red and white blood cell counts. Whole animals should be fixed in formalin and embedded in paraffin, and cross sections should be cut and stained with hematoxylin and eosin for histopathological evaluation.

Ambystomid salamander species also have been tested under controlled laboratory conditions, though with variable results [96,187,188]. Wild-caught *Ambystoma maculatum* and *Ambystoma tigrinum* are fed tainted live earthworms (*Lumbricus* ssp.), although shipping-related stress can cause sepsis (red leg), which can be difficult to treat. Salamanders reared from egg masses are more successful in toxicity tests, although larval stages require specialized feed (e.g., copepods).

Plant Tests

A standard guide for conducting terrestrial plant toxicity tests has been completed and published by the ASTM [189]. Included with the guide are standard protocols for seedling emergence, root elongation, woody plant assays, and a *Brassica* life-cycle test. Additionally, a seed germination test is available [169,190–192], as is a test for vegetative vigor [164,190,193]. These bioassays were developed initially to determine hazards due to soil contamination at hazardous waste sites or in sludge disposal areas [194]; however, they also can be applied to a priori safety testing requirements. A comprehensive review of plant toxicity tests is available in Kapustka [195].

Seed Germination

The seed germination test is a 120 h static test and measures seed survival, germination, and seedling emergence. Butter crunch lettuce (*Lactuca sativa*) is the most commonly used test species, although more than 30 species have been accepted by regulatory agencies. Butter crunch lettuce seeds and many other domestic plants can be purchased from a commercial vendor. Only one lot should be used for each test, and information on the germination percentage should be provided by the seed source. Alternatively, native seeds may be field collected. Regardless of source, only untreated seeds (no applications of fungicide, repellents, etc.) should be used. The seed lot should be examined to discard trash, empty hulls, and damaged seed. Seeds are sized by stacking four wire-mesh sizing screens on top of each other with a collection pan underneath; the largest mesh screen should be on top. The seeds are poured in, and the nest of screens is shaken until no more seeds fall through the screens. The size class containing the most seed is selected and used for all of the tests. Seeds can be stored in a desiccator at 4°C in airtight, waterproof containers until used.

Test soils are first homogenized using a blender and then mixed with artificial soil (commercially available, 20-mesh, washed silica sand) to prepare 400 g each of a geometric series of test soil concentrations (e.g., 100%, 50%, 25%, 12.5%, 6.25%, 3.13% w/w) plus a 100% artificial soil control. The ASTM method [189] requires the use of boric acid as a positive control. The total amount for each concentration is blended to ensure even mixing, prior to dividing into aliquots for the test. The soils are air-dried, and 100 g of each concentration is placed in each of three replicate 150 mm plastic petri dishes labeled with the appropriate soil dilution. The petri dishes are then randomized, and 40 seeds are placed in each dish at least 1.25 cm from the edge. The seeds are pressed into the test soil with a glass rod or beaker bottom. Soils are hydrated with deionized water to 85% of WHC. Cover sand (90 g commercially available, 16-mesh sand passed through a 20-mesh screen to remove fines) is poured over the top of the soil and leveled with a ruler. The dishes are then placed in an incubator for the duration of the test. They should be incubated at 24°C ± 2°C in the dark for 48 h, followed by 16 h of light and 8 h of dark, until termination of the test at 120 h. Light intensity should be 4300 ± 430 lx. Soil pH should be measured at the beginning and end of the test (and should be between 4 and 10), and soil temperature should be measured every 24 h in one replicate of each concentration and the control. At 120 h, the number of germinated seeds in each dish is determined by counting each seedling that protrudes above the surface. The LC_{50} and its 95% confidence limits are determined by probit analysis.

Seedling Emergence

The seedling emergence test is very similar to the seed germination test. Seeds are placed in pots, rather than petri dishes, and need not be stored in the dark for the first 48 h. Soil is hydrated to WHC throughout the test. Test duration is twice the amount of time required to achieve acceptable germination for whatever test species is being used. In addition to counting the number of emergent seedlings at the end of the test, optional measures include shoot and root growth. Shoot measurements are made from the transition point between hypocotyl and root to the tallest point on the shoot. Roots are measured from the same transition point to the tip of the root. If sufficient growth is present, dry-weight measurements can be obtained. Material is harvested and placed in a preweighed drying vessel and dried at 70°C until constant weight is achieved (approximately 24 h). Weights are taken to the nearest 0.001 g.

Root elongation is a key component of the early stages of plant growth and development. The root elongation bioassay tests the toxicity of water or soil eluates (i.e., the water-soluble constituents) to seed germination [192]. It generally is used as a bioassay of hazards due to soil or water contamination at hazardous waste sites or in sludge disposal areas; however, as with the seed germination test, it also can be applied to a priori safety testing requirements. As a general rule, root elongation is more sensitive than seed germination. The test is a 120 h static test that measures seedling root growth. Butter crunch lettuce is the most commonly used and is the most sensitive species, but other plants have been used as well (e.g., cucumber, wheat, alfalfa, radish, red clover, rape). Seeds are purchased, sorted, and sized as described for the seed germination assay. Soil eluates are prepared by mixing 4 mL of deionized water per gram (dry weight) of soil. The slurry is mixed in total darkness for 48 h at 20°C ± 2°C. After mixing, the eluate is centrifuged and filtered through a 0.45 μm cellulose acetate or glass fiber filter. Water samples (or soil eluates) are diluted in deionized water to provide a geometrically spaced range of concentrations, generally using a 0.3 or 0.5 dilution factor and five concentrations. As with the seed germination study, boric acid should be used as a positive control. A sheet of Whatman No. 3 filter paper is placed in each of three replicate 100 mm plastic petri dishes, and 4 mL of the test solution is poured over the paper. Five seeds are placed in a circle on the filter paper, equidistant from the edge to the center and equally spaced from each other. The lid is placed on each petri dish, and the dishes are then set in layers in a black 33-gal plastic garbage bag within a cardboard box. Moist paper towels are placed between layers of dishes to keep the humidity level elevated. The bag and box are sealed and placed in a controlled environmental chamber at 24°C ± 2°C for 120 h. The pH and hardness of the test solutions are measured at the beginning of the test, and temperature is recorded every 24 h. At the end of the 120 h period, root lengths are measured to the nearest millimeter by placing the seedling on a glass work surface and measuring the distance from the transition point between the hypocotyl and root to the tip of the root. Swellings or deformities at the transition area should be noted. Roots can be harvested, dried to a constant weight, and weighed to the nearest 0.001 g as an optional endpoint. The percent inhibition of the treated seeds as compared to the controls is calculated, and an EC_{50} (the concentration that inhibits root growth to 50% of the control length) is calculated.

Whole-Plant Toxicity

Whole-plant toxicity is evaluated using a 5-day screening test (TOXSCREEN) conducted in hydroponic solutions [196] or a longer full life-cycle test using vascular plants in soils, such as *Brassica* [189].

Hydroponic Tests

TOXSCREEN uses whole plants such as soybean (*Glycine max*), barley (*Hordeum vulgare*), and woody perennials that have been grown in hydroponic culture for at least 28 days. Alternatively, known-age plants may be purchased commercially and adapted for hydroponic exposures [197]. Regardless, exposures occur hydroponically when young plants are transferred from nursery containers to containers filled with exposure medium. Geometrically spaced dilutions of the exposure medium or chemical concentrations within the exposure medium are used to develop a dose–response curve. Soil eluates may be used to fill exposure containers. Tests are conducted under a 16:8 L/D photoperiod (light intensity of 350 μmol/m²/s at the top of the canopy) at 25°C/21°C ± 2°C (light/dark) and relative humidity of 50%–70% for 5 days. Following the exposure period, survival, root and shoot growth, and total biomass of the plants are measured. Probit analysis is used to calculate LC_{50} values.

Woody Plant Tests

An alternative procedure to TOXSCREEN is available in the woody plant test protocol [189]. This is similar to the TOXCREEN test, but woody plants are grown in silica sand, a formulated soil, or a contaminated soil, rather than in a hydroponic solution. Plants are obtained from the field or a horticulture source, and the roots are washed gently by dipping the root mass into deionized water. Plants are kept moist and sorted according to size and stage of development, to begin the study with uniform-sized plants in similar stages of root and shoot growth. The starting conditions for all endpoints are measured and recorded. Plants are sorted randomly into treatment groups and placed in pots of sufficient dimension to contain test medium to a depth of approximately two times the root length of plants. Each replicate container should be planted with one test replicate; five replicates of each soil sample, sample dilution, and positive and negative control are required. Medium should be added to cover roots completely and to bring the level within 1–2 cm of the top of the container. Medium can be gently packed by hand but should not be compacted. Deionized water is used to bring the pots to WHC. A regular water application schedule should be followed thereafter for the duration of the test. Test duration should be approximately twice the length of time required to achieve amounts of shoot and root growth acceptable for statistical characterization. Tests are conducted under a 16:8 L/D photoperiod (light intensity of 100–200 μmol/m²/s) at 20°C–30°C and relative humidity of >50%. Measured endpoints include wet and dry shoot mass, number of new shoots or leaves, number of root initiation points, and changes in total plant weight. Additional observations on general plant condition and leaf or root malformations are also noted. Plants can be harvested, dried at 85°C until constant weight (approximately 24 h), and weighed to the nearest 0.01 g.

Full Life-Cycle Plant Test

The full life-cycle plant test evaluates the effect of test materials on germination, growth of shoots and roots, photosynthetic systems, flower development, and reproductive capabilities of plants. It is conducted using either *Arabidopsis thaliana* [195] or *Brassica rapa* [189,196] exposed to the toxic

substance for 25–36 or 36–44 days, respectively. Hydroponic exposures [198,199] occur in double-pot, static-replacement systems, in which a vermiculite-filled growth container (for *Arabidopsis*) or greenhouse potting soil (for *Brassica*) is nested above a second, larger pot that serves as a nutrient solution reservoir. Nutrients, toxics, and water move from the reservoir to the vermiculite or potting soil via polyester wicks that are draped between the two pots. Alternatively [189], *B. rapa* seeds can be planted directly into test soil, as described in the preceding text for root elongation or woody plant tests. Dilutions and eluates of test substances are made as described previously. Seeds are planted uniformly on the surface of the vermiculite or potting soil and incubated in the conditions described for TOXSCREEN and the woody plant test. Plants will germinate, grow, mature, and set seeds. Exposure to the test substance occurs from the time that seeds are planted and continues until the mature plant drops its own seeds. Observations include leaf and flower structure, total biomass, vegetative and reproductive biomass (e.g., stems and leaves vs. seeds and reproductive structures), foliar height, initial flowering date, time to flowering, stunting, chlorosis, and survival. Probit analysis is used to calculate EC_{50} values for each endpoint. ANOVA techniques can be used to determine which test concentrations produce effects significantly different from control values.

Soil-Core Microcosms

Soil-core microcosms [200] can be used to develop site-specific or regional information on the probable chemical fate and ecological effects in a soil system resulting from release or spillage of chemicals into the environment. This test is most useful in the assessment process after preliminary knowledge of the chemical properties and biological activity of the compound of interest has been obtained. The test is designed to determine impacts in agricultural or natural field soil ecosystems and may not be applicable to forest soils. Specifically, the test will determine the effect of a chemical on growth and reproduction of either natural grassland vegetation or crops, nutrient uptake and cycling, potential for bioaccumulation in the plant tissues, and potential for and rate of transport of the chemical through soil to groundwater.

Soil cores are extracted from the site or region of interest with a specially designed steel extraction tube. The steel tube surrounds an ultrahigh-molecular-weight, high-density, nonplasticized polyethylene pipe to prevent the tube from warping or splitting during extraction. The tube is 60 cm deep and 20 cm in diameter. In agricultural systems, the plowed topsoil is moved aside prior to coring and backfilled into the upper 20 cm of the tube after collection. For the natural grassland system, the vegetation is clipped before the core is extracted. The polyethylene tube containing the soil core is removed from the steel coring device and placed within a specially designed wheeled cart that holds six to eight tubes packed within insulating Styrofoam® beads. The tube sits on a Buchner funnel that is covered by a thin layer of glass wool and connected by polyvinylchloride (PVC) tubing to a flask for collection of leachates. For the natural ecosystem, the natural plant cover collected with the soil core is suitable for the test. For agricultural systems, a mixture of grasses and broadleaves (e.g., legumes) that are typically grown together in the region of interest should be planted in the soil cores. The seed application rate should duplicate standard farming practices. Microcosms should be watered with purified water on a predetermined regimen, usually established on the basis of site history. Microcosms are leached once before dosing and once every 2 or 3 weeks after dosing. Microcosms that take longer than 2 days to produce 100 mL of leachate are not used in the test. The microcosms in their insulated carts are kept in a greenhouse or environmental chamber where temperatures and photoperiods are set to simulate outdoor conditions during a typical growing season in the region of interest.

If information is available, only one concentration of the test chemical above that known to cause at least 50% change in plant growth or 50% change in bacterial growth or respiration needs to be tested. Generally, three concentrations are used, choosing one that produced a 20%–25% change in productivity. In any case, the lowest treatment level should not be less than 10 times greater than the analytical limits of detectability of the parent compound. A range-finding test using concentrations of 0.1, 1.0, 10, 100, and 1000 µg/g in the upper 20 cm of topsoil can be used to determine the appropriate dose for the definitive test. The range-finding test should last a minimum of 4 weeks, while the definitive test lasts for 12 weeks. For aqueous compounds, the test solution is mixed with water and applied as single or multiple (daily, weekly) exposures in sufficient volume to bring the microcosm to field capacity. In no case should the exposure volume be sufficient to cause leaching in any of the microcosms. Frequency of application should reflect the situation encountered in the region of interest. The use of carriers should be avoided. If the test substance does not mix with water, it should be applied evenly to the top of the unplanted microcosm and mixed into the topsoil prior to planting. If the test substance is normally sprayed on growing plants, then it should be sprayed on the plants with a nebulizer at the seedling stage. The number of replicate microcosms per dose is determined by the desired power of the statistical test and the variability between microcosms (determined in the range-finding test). Individual microcosms should be assigned to treatment groups in a randomized block design, with the cart as a blocking variable.

The parent compound should be radiolabeled with ^{14}C, either in an appropriate aromatic, cyclic carbon group or in a linear chain, to follow uptake and degradation rates. The following parameters are measured:

- Primary productivity, the total yield or yield of harvestable portion (e.g., grain), reported as oven-dried weight
- Physical appearance and abnormalities of plants
- Amounts of nutrients in leachate (e.g., calcium, potassium, nitrate–nitrogen, ammonium–nitrogen, *ortho*-phosphate, dissolved organic carbon)

- Amounts of parent compound in all plant parts, soil horizons, and leachate (by measuring radioactivity of parent compound)
- Amounts of chemical degradation products in plant material, soil, and leachate
- Soil properties, including pedologic identity (according to the USDA Seventh Approximation Soil Classification System), percent organic matter, hydraulic characteristics, cation exchange capacity, bulk density, macro- and micronutrient content, organic matter content, inorganic mineral contents, exchange capacity, particle-size distribution, and hydraulic characteristics

Data analysis should follow standard statistical techniques as appropriate, such as ANOVA for comparing biomass data or regression analysis on sequential measures of productivity. The 5% level should be considered as the level of significance with a power of 0.90 or 0.95.

AIR POLLUTION

Air pollution has the potential to seriously injure plants and animals. A good example of air-pollution effects is the change in the forest vegetation of the San Bernadino Mountains in southern California [201]. There, prolonged exposure to photochemical oxidants (smog) resulted in a shift from ozone-sensitive pine trees to more ozone-tolerant oaks and shrubs. Ozone injury in pines results in decreased photosynthesis due to foliar injury and premature needle fall, reduced nutrient retention in needles, and decreased growth. In general, gaseous pollutants have the potential to disrupt plant-leaf biochemical processes through absorption by stomata or cuticle, while trace metals and organochlorine compounds tend to accumulate in humus and organic matter. Animals are affected either by uptake through the food chain or direct exposure via inhalation [202]; however, there has been little direct measurement of toxicity to wildlife from air pollutants other than studies of the effects of smelter emissions and a documented reduction in small-mammal diversity in the ozone-impacted San Bernardino Mountains. Many species of freshwater animals have been affected by wet deposition of sulfur dioxides, also known as "acid rain." In general, fish are most sensitive to acidification, followed by invertebrates, algae, and microbes [202].

Certainly, the potential impact on biodiversity from global climate change is significant. The amount of production or the type of plant that will grow efficiently may change in response to increasing CO_2, changes in the amount and timing of precipitation, or to the amount of available solar radiation. CO_2 enrichment alone would increase the rate of plant growth, while higher temperatures would increase the rate of microbial decomposition of organic matter, adversely affecting soil fertility [203]. On the other hand, higher temperatures generally hasten plant maturity in annual species, shortening the growth stages of some plants. At the same time, midlatitude summer dryness is likely to reduce yields by 10%–30% [204].

Air-pollution levels generally are measured mechanically, through the use of biosensors or air-sampling devices in situ; however, as with chemical analysis of soils and other media, this type of monitoring does not provide information about the toxicity of air pollutants to terrestrial organisms. Lichens are particularly sensitive to low levels of some forms of air pollution. Some are killed by pollutant levels that are too low to cause visible injury to other plants; consequently, lichens are now used as qualitative indicators of air quality in parts of the United States and Europe, in particular for sulfur dioxide, hydrogen fluoride, acidic precipitation, ozone, nitrogen dioxide, heavy metals, and radioactive compounds [91]. Lichen species in the area of study are identified, and species diversity, density, and frequency are recorded, as is percent cover. Plants also are observed for obvious signs of damage. These parameters are compared with historical accounts of lichen communities to determine whether airborne pollutants have affected the plants. Additionally, some compounds (e.g., heavy metals, organochlorines) are bioaccumulated by lichens without visible signs of damage to the plants. Residue analysis of lichens has been used to map the location and distribution of these pollutants.

Studies conducted with terrestrial vertebrates suggest that some species may also constitute useful sentinels of air pollution. The common pigeon (*C. livia*) is abundant in many urban environments and has been used as a bioindicator of pollution [4,156]. Blood samples can be obtained from the birds with relative ease through jugular and brachial venipuncture, and the bird released unharmed. The blood sample subsequently is analyzed for the presence of airborne pollutants (e.g., lead). If the bird is euthanized, other more invasive measures yield more specific information (e.g., chemical concentrations in target organs).

ECOLOGICAL RISK ASSESSMENT

The toxicity tests described in this chapter ultimately become a component of the process of establishing the likelihood that adverse ecological effects are occurring or may occur as a result of exposure to one or more chemicals or other stressors. The process of ecological risk assessment has evolved rapidly in the 20 years since the USEPA issued their *Framework for Ecological Risk Assessment* in 1992 [205] and the supporting *Guidelines for Ecological Risk Assessment* in 1998 [131]. Many other countries in Europe and Australasia have adopted the same general approach for improving the quality, consistency, and applicability of assessments of the impact of environmental stressors on components of an ecosystem [176]. In 2007, the Registration, Evaluation, and Authorisation and Restriction of Chemicals (REACH) came into force in the EU, requiring a base data set on aquatic toxicity for all chemicals in commerce. This resulted in a significant increase in the amount of ecotoxicity testing being conducted, which has resulted in a large amount of new toxicological information.

Ecological risk assessment involves three stages in a continuous process: (1) problem formulation, (2) analysis of exposure and effects, and (3) risk characterization. Because

ecological risk assessment must consider effects at the population, community, and ecosystem levels, as well as to the individual species, and relevant assessment endpoints are not universally accepted, the process is generally more complex and protracted than are most human health risk assessments. Furthermore, ecological risk assessment frequently must consider the effect of mixtures of chemicals that interact in a complex chemical and physical environment that typically includes other environmental stressors. Many examples of comprehensive ecological risk assessments can be found in the scientific literature (see, e.g., [205]).

The ecological risk assessment process is illustrated in Figure 42.7. The first, and most critical, phase of the process is problem formulation. It is during this phase that the affected environmental resource and the stressors of concern must be considered within the context of the overall situation that is to be evaluated. It is frequently useful at this stage to involve risk assessors, risk managers, and stakeholders in discussions about how to proceed so the results of the assessment will be most useful to those who will have to use them. It is also worthwhile to spend some time modeling the problem, at least in a conceptual sense, so that assessment endpoints will be reasonable and achievable, and a sampling and analysis plan with appropriate measurement endpoints can be established. Here, pathways of exposure are determined for each receptor or guild, and a conceptual site model is developed. A quality assurance project plan should also be established at this stage.

During the analysis phase of the risk assessment, the exposure level or concentration of the stressor of concern on the environmental resource must be established, and the effects assessed. The effects assessment should include both potential toxicological effects, as described in this chapter, and ecological effects. Whereas toxicological effects are usually measured on individual organisms using a variety of standardized tests and are relatively easily quantified, ecological effects involve predictions about changes in populations and communities of organisms in longer-term studies, which are more difficult to conduct and interpret. Studies in microcosms, mesocosms, small ponds, and streams, as described earlier, would be most useful in this regard, but are not used routinely due to their complexity and cost, and the difficulty of interpreting the results. Food-web relationships may have to be elucidated and bioaccumulation effects determined. Finally, indirect effects of contaminants on the organisms of interest must be considered, such as changes in food availability, habitat structure, or predator abundance. The analysis of exposure and effects also must include consideration of

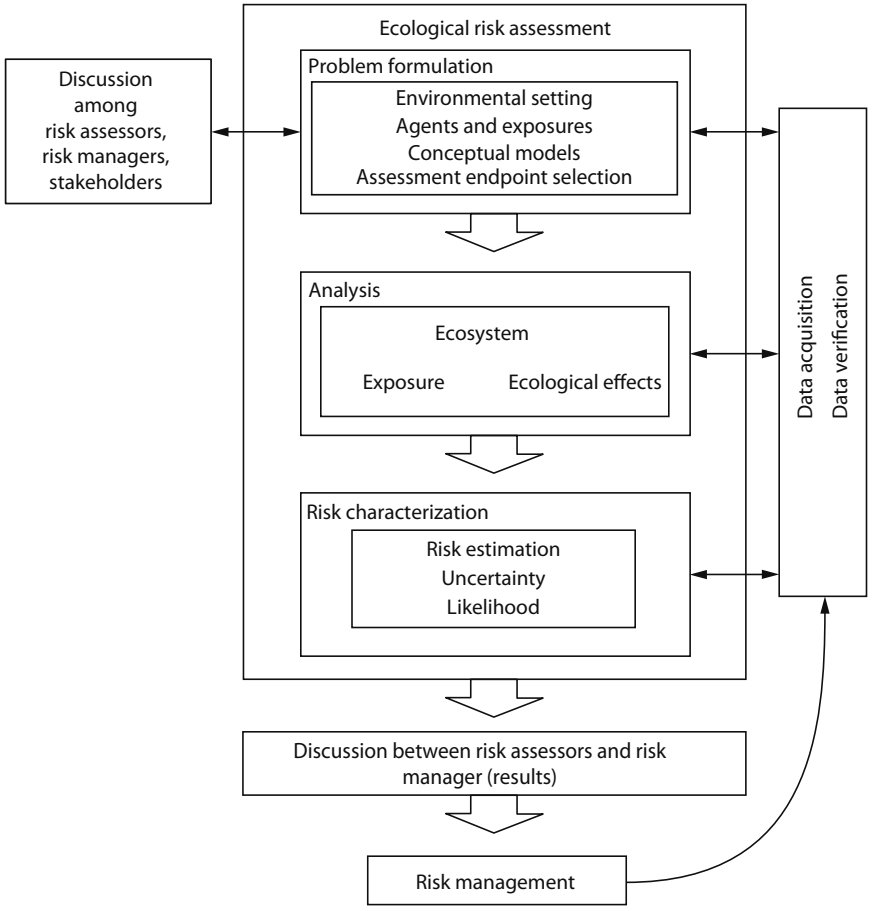

FIGURE 42.7 The ecological risk assessment process. (From USEPA, *Framework for Ecological Risk Assessment. EPA/630/R-92/001. Risk Assessment Forum,* Environmental Protection Agency, Washington, DC, 2002.)

fate and transport of the stressors. As described earlier, exposure is dependent on the bioavailability of the stressor, which depends on its chemical, physical, and environmental characteristics, and effects are entirely dependent on exposure; thus, knowledge of the physical and chemical behavior of stressors in the ecosystem is critical.

The final step in the risk assessment process is to integrate the exposure of the resource to the stressors with the observed or predicted effects within the context of the problem formulation, to estimate the degree of risk and the probability of adverse environmental changes actually being observed. Very simple systems in which statistical analyses can establish the confidence of the predicted result are rare in ecological risk assessment. The more usual cases involve a high degree of uncertainty, which in turn, requires the risk manager to establish the parameters within which regulation must be effected, frequently using a worst-case scenario. Obviously, the more quantitative and precise the assessment results presented to the risk manager, the more effective will be the management of the ecosystem. New tools that consider the heterogeneous nature of contaminated sites and the manner in which individual animals move about the area and come into contact with contaminated portions of their ranges provide a more accurate estimate of exposure and risk within a probabilistic framework [176,206]. In reality, as indicated in Figure 42.7, ecological risk assessment is a continuous, iterative process in which risk managers and risk assessors must interact in concert with stakeholders to strive for continuous improvement in understanding the ecosystem and providing for optimum functionality [13]. More detailed explanation of applications of the ecological risk assessment process can be found in Suter [207].

CONCLUSION

Clearly, toxicity testing under realistic environmental conditions is a much more complex enterprise than determining the effects of single chemicals on single species under controlled laboratory conditions; however, the information obtained in a well-designed, well-executed environmental study provides a valuable supplement to the toxicity data obtained in more traditional laboratory studies. Understanding the impacts of a pollutant within the environment, including the organisms that live in it, requires more complex evaluation and study. Interactions of organisms with each other and with their environment can be altered by the introduction of foreign chemicals. The impacts of such chemicals must be assessed in terms of these interactions, as well as the effect on individuals if the overall health of an ecosystem is to be properly evaluated and understood. This is the essential difference between ecotoxicology and the discipline of toxicology as it relates to human health. Toxicologists have developed rigorous methods for assessing the effects of chemicals on single species under controlled conditions; however, effects on ecosystems in which many species are involved are much more difficult to identify and measure quantitatively. Subtle changes in population-level effects are often variable and not discernible in the short term. Species diversity and functional redundancy provide resiliency within the community and greater ecosystem. Great strides have been made in the development of controlled ecosystems, in the form of microcosms and mesocosms, for this purpose. There is still much work to be done, however, to perfect the methodology to the extent that effects can truly be assessed at the ecosystem level. The truism that "the whole is greater than the sum of its parts" definitely applies.

Much progress has been made by the various environmental regulatory authorities in codifying procedures and requirements for the use of field-derived toxicology assessments for populations and communities, to evaluate the impacts of chemicals on the environment [208]. The guidelines include not only community-level toxicological data but also the requirement to understand the spatial and temporal scales of stress and the natural variability in biotic community dynamics. Ultimately, the extra costs in terms of time and money for conducting environmental toxicology evaluations and ecological risk assessments will be returned manyfold in our wiser use of natural resources and the protection of the environment in which we live.

QUESTIONS

42.1 What are the differences in experimental considerations and methods used to assess the toxicities of contaminants in surface water and sediment?

42.2 What predictive methods are available to compensate for the limitations in the chemical toxicity databases for aquatic flora and fauna? What are the advantages and disadvantages in the use of these methods?

42.3 What environmental factors affect the toxicity of anthropogenic chemicals to aquatic life? How do these physical and chemical factors differ between freshwater and saltwater ecosystems?

42.4 What methods are available for extrapolating toxicity thresholds from tested to nontested species?

42.5 What are the differences between acute, subacute, subchronic, and chronic avian toxicity studies?

42.6 What are the advantages or disadvantages in conducting field studies as compared to laboratory toxicity bioassays?

42.7 What is the real effect of ad libitum testing regimes for animals that are often food limited?

42.8 Why are no standardized rodent protocols described for ecotoxicity testing?

42.9 What is the importance of honeybee studies?

42.10 What ecological role do soil invertebrates play, and what are standard test species?

42.11 How do soil microbial assays differ from single-species toxicity tests?

42.12 Many amphibians have both an aquatic and a terrestrial life phase. What tests are available to determine the effects of soil and water contaminants on these species?

42.13 How do terrestrial plant bioassays differ from aquatic plant tests?

42.14 What are soil-core microcosms, and what is the advantage in using these types of studies?

42.15 How are terrestrial ecosystem effects of air pollution measured (including climate-induced changes from elevated CO_2)?

Glossary

50th percentile: The number in a distribution such that half the values in the distribution are greater than the number and half the values are less. The 50th percentile is equivalent to the median.

95th percentile: The number in a distribution such that 95% of the values in the distribution are less than or equal to the number and 5% are greater.

95% upper confidence limit (95% UCL) for mean: The 95% UCL for a mean is defined as a value that, when repeatedly calculated for randomly drawn subsets of size *n*, equals or exceeds the true population mean 95% of the time. Although the 95% UCL provides a conservative estimate of the mean, it should not be confused with a 95th percentile. As the sample size increases, the difference between the UCL for the mean and the true mean decreases while the 95th percentile of the distribution remains relatively unchanged at the upper end of the distribution. The Environmental Protection Agency's (EPA) Superfund program has traditionally used the 95% UCL for the mean as the concentration term in point estimates of the reasonable maximum exposure (RME) for human health risk assessment.

Absolute white blood cell and reticulocyte counts: Counts expressed as cell concentration (i.e., cells/volume of blood). Absolute counts, as opposed to relative counts (%), are preferred for interpretation and reporting.

Absorbed dose: Energy imparted to matter when radiation passes through; measured in grays or rads.

Absorption: Uptake of the chemical from the site of administration into the general circulation. Absorption may involve a number of stages (e.g., dissolution) and diffusion through membranes. Chemicals may be changed during absorption due to metabolism or degradation, such that it is possible to have complete absorption and low bioavailability.

Absorption barrier: Any of the exchange barriers of the body that allow differential diffusion of various substances across a boundary. Examples of absorption barriers are the skin, lung tissue, and gastrointestinal tract wall.

ACB: Accelerated cancer bioassay.

Acceptable daily intake (ADI): Daily intake of a chemical (e.g., food additive, pesticide) that, during the entire lifetime, appears to be without appreciable risk (affects 1 in 1 million people or less) on the basis of all known facts at the time.

Accessory cells: Cells that support T or B cells in the induction of an immune response. These cells usually express major histocompatibility complex (MHC) class II molecules.

Accuracy: A measure of the extent to which the mean estimate of a quantity approaches its true value: (1) the closeness of agreement between a test method result and an accepted reference value and (2) the proportion of correct outcomes of a test method. It is a measure of test method performance and one aspect of *relevance*. The term is often used interchangeably with *concordance* (see *Two-by-two table*). Accuracy is highly dependent on the prevalence of positives in the population being examined in the validation study.

Acid–base balance: Maintenance of pH; kidneys function in acid–base balance by the regulation of H^+, HCO_3^-, and NH_4^+ ions.

ACTH: Adrenocortical tropic hormone.

Action level: Level of unavoidable contaminants in foods and feeds considered as the upper limit of safety but which are not subjected to regulatory control.

Active ingredient: Chemical or substance component of a pesticide product that can kill, repel, attract, mitigate, or control a pest.

Acute: Characterized by a time period of short duration; commonly used to describe single-dose exposure in toxicity studies.

Acute toxicity: The adverse effects occurring within a short time of administration of a single dose of a substance or multiple doses given within 24 h.

Acute toxicity study: Usually, a single-dose study in which animals are observed for a 2-week period postdose to determine overt signs of toxicity, normally including some form of assessment of the lethal dose.

Acute-to-chronic ratio (ACR): A ratio determined experimentally or mathematically for a chemical that is used to predict chronic toxicity when only acute toxicity data are available.

Ad libitum: Available with unrestricted access; this term is commonly used in toxicity studies to describe free access by animals to feed or water.

Adenohypophysis: The anterior lobe of the pituitary gland.

ADH: Antidiuretic hormone or vasopressin; an octapeptide.

Adjunct test: A test that provides information that adds to or helps interpret the results of other tests and provides information useful for the risk assessment process.

Adjuvant: A material that enhances an immune response, it traditionally refers to a mixture of oil and mycobacterial cell fragments.

ADME: Absorption, distribution, metabolism, and excretion—the processes that determine the disposition and fate of an administered molecule.

Administered dose: The amount of a substance given to a test subject (human or animal) in determining dose–response relationships, especially through ingestion or inhalation. In exposure assessment, because exposure to chemicals is usually inadvertent, this quantity is called *potential dose*.

Advance access: The online publication of papers in manuscript form soon after they have been peer reviewed and deemed final; they appear considerably sooner than as print publications.

Adverse effect: A test compound–related effect (e.g., morphological, biochemical, developmental) that alters the function of an organ or system or alters the ability to respond to additional environmental challenges.

AEGL: Acute exposure guideline levels are values intended to provide estimates of concentrations and exposure durations (minutes to hours) above which one could reasonably anticipate observing adverse health effects. Compare to emergency response planning guidelines (ERPGs).

Aerodynamic equivalent diameter: The diameter of a spherical particle of unit density (1 g/mL) that has the same terminal settling velocity as the particle in question.

Aerosol: A suspension of either microscopic liquid or solid particles dispensed in a gas, the particles of which have a negligible falling velocity; also used to characterize a product or chemical form that contains particles that can enter the respiratory tract.

Aglycone: The xenobiotic substrate that is conjugated by glucuronosyltransferases.

Air elutriation: A process in which particles are separated on the basis of size by pitting their settling velocity against the velocity of a current of air with which they move.

Air shower: A device that uses high-velocity, ultrafiltered air to remove particulates from the surfaces of the clothing worn by personnel.

AL: Ad libitum.

Alkaloids: Nitrogenous heterocyclic compounds that protect plants from attack by microorganisms, pests, and herbivores. Any of a large, heterogeneous group of alkaline, bitter tasting, biologically active, usually water-insoluble, nitrogenous organic compounds produced by plants.

Allergic contact dermatitis: Chemically induced immunologic (delayed hypersensitivity) dermatitis.

Allergy: A state of altered immunity in which contact with an antigen (allergen) results in a hypersensitivity response.

Allogeneic: From a different genetic background. In the context of immunotoxicology, it generally refers to the use of genetically dissimilar cells in vitro assays to elicit a cell-mediated immune response.

Allometry: The study of the relationship between body size and various biological and physiological parameters, such as organ sizes, blood flow rates, and metabolic rates.

Alloxan: A chemical that can cause destruction to the pancreatic beta cell.

Alpha particle: Nucleus of a helium atom emitted by certain radioisotopes upon disintegration. Contains two protons and two neutrons.

Alveolar macrophage: A motile, phagocytic cell of the pulmonary region of the lung, essential to removal of particulate matter from the alveoli and sterility of alveolar surfaces.

Alveolus: The smallest functional gas-exchange unit of the pulmonary region of the lung. The alveolus contains a very thin epithelial and endothelial surface that allows the rapid exchange of oxygen and carbon dioxide, as well as a portal for the absorption and elimination of volatile substances from the vasculature.

Amatoxin: One of two groups of thermostable toxins isolated from poisonous species of *Amanita*; they are extremely toxic, bicyclic octapeptides that act on the RNA polymerase II system of eukaryotic cells.

American Conference of Government Industrial Hygienists (ACGIH): A professional organization made up of individuals in the industrial hygiene and occupational and environmental health and safety industry. ACGIH is best known for the development and publication of TLVs® and BEIs® as well as many foundation documents for the practice of industrial hygiene and occupational health.

American Industrial Hygiene Association (AIHA): Professional organization of environmental health and safety professionals practicing industrial hygiene in industry, government, labor, academic institutions, and independent organizations. AIHA develops and administers comprehensive education programs and publications that keep occupational and environmental health and safety professionals current in the field of industrial hygiene.

Ambient measurement: A measurement (usually of the concentration of a chemical or pollutant) taken in an ambient medium, normally with the intent of relating the measured value to the exposure of an organism that contacts that medium.

Amine precursor uptake and decarboxylation (APUD) cells: A group of apparently unrelated endocrine cells found throughout the body that have a number of similar characteristics and that make a number of hormones with similar structures (including serotonin, epinephrine, dopamine, neurotensin, and norepinephrine). Over 60 types of endocrine cells have been identified in the APUD system that can be found in the numerous organs throughout the body.

Ammonium molybdate: A metallic negative stain that is used to negative stain the Formvar backing on coated electron microscopic grids for transmission electron microscopy.

Amphibia: A class of anamniote tetrapods comprised of 2600 known species of toads, frogs, salamanders, and newts, many of which are poisonous but not necessary dangerous to humans; any life form adapted to or able to live in both aquatic and terrestrial environments.

Amyotrophic lateral sclerosis: Fatal neurologic disease characterized by progressive degeneration of upper and lower motor neurons in the brain and spinal cord.

Analytic study: A study designed to examine a priori hypothesized causal associations.

Anaphylaxis: An extreme, immediate immunologic reaction characterized by contraction of smooth muscle and dilation of capillaries due to the release of pharmacologically active substances (e.g., histamine) in response to administration of a foreign material; a local or systematic immediate hypersensitivity reaction resulting from the release of mediators following exposure to antigen. A life-threatening, often fatal response.

Androgens: Male sex steroids (e.g., testosterone).

Anemia: Reduction below normal of hemoglobin concentration; usually accompanied by a similar reduction of red blood cell count and hematocrit. Functionally, anemia is characterized by a decrease in red cell mass sufficient to cause reduced oxygen delivery to peripheral tissues.

Anemone: Any herb of the genus *Anemone*.

Anencephalus: Congenital absence of the upper part of the brain and the flat bones of the skull.

Anergy (tolerance): Unresponsiveness to antigenic stimulation; also referred to as *tolerance*.

Animal Care Program: "All activities conducted by and at an institution that have a direct impact on the well-being of animals, including animal and veterinary care, policies and procedures, personnel and program management and oversight, occupational health and safety, institutional animal care and use committee (IACUC) functions, and animal facility design and management."

Animal extremism: The practice of or belief in taking extreme action to promote beliefs regarding animal rights, including illegal activities that result in property damage, theft, and human injury.

Animal model: A living, nonhuman test system that models human biology or a disease state, due to similarities in taxonomy, physiology, etiology, or pathogenesis of disease. The model may be defined as an animal in its unaltered state, or by a method of preparation involving surgical, pharmacologic, genetic, or behavioral manipulation.

Animal rights: The belief that nonhuman animals have moral rights that are equal in consideration to humans. These beliefs may be practiced personally through lifestyle decisions, promoted publically, politically, or through extremism activity, or enacted through the legal system or legislation.

Animal welfare: The belief that animals should be provided with living conditions that provide for their physical and behavioral needs and that pain or distress should be avoided unless there is social or scientific justification for performing activities that are not in the animals' interest.

Animal Welfare Regulations: Laws that define requirements for the care and use of animals in research, teaching, testing, exhibition, breeding, commercial use, and transportation.

Animal Welfare Standards: Legal requirements or published guidelines that are not legally binding, but represent industry best practices to promote and ensure animal welfare.

Annexin V-FITC staining: Method used to assay apoptosis or necrosis. Annexin V labeled with fluorescein isothiocyanate (FITC) binds to phosphatidylserine residues of cellular membranes; cell populations with differential binding and, hence, fluorescence are detected by flow cytometry.

Anogenital distance (AGD): A primary landmark of sexual development, typically measured at birth, reflecting the linear distance between the genital tubercle and the anus. AGD is sexually dimorphic, being greater for males than females, and androgen dependent. The AGD in male rodents is decreased by development exposure to antiandrogens.

ANOVA: Analysis of variance.

Antibody: Complex molecules produced by plasma cells that recognize specific antigens. Antibodies, also called *immunoglobulins* (Ig), consist of two basic units. The antigen-binding section (Fab) contains variable regions with coding for antigen recognition. In mammals, the constant region of the molecule (Fc) may be grouped into several classes, designated IgA, IgD, IgE, IgG, and IgM, depending on the function of the molecule. Cross-linking of antibody molecules on the surface of a target leads to activation of complement, usually resulting in the destruction of the target.

Antibody-forming cell (AFC)/plaque-forming cell (PFC) assay: An assay that measures the ability of animals to produce specific antibodies against a T-dependent or T-independent antigen following in vivo sensitization. Due to the involvement of multiple cell populations in mounting an antibody response, the AFC assay actually evaluates several immune parameters simultaneously. It is considered to be one of the most sensitive indicator systems for immunotoxicology studies.

Antigen: A molecule that is the subject of a specific immune reaction. Antigens are recognized in a cognate fashion by the T-cell antigen receptor, the B-cell antigen receptor, or immunoglobulins (antibodies). Antigens generally are proteinaceous in nature.

Antigen-presenting cell (APC): Cells that are responsible for making antigens accessible to immune effector and regulatory cells. Following internalization and degradation of the antigen (generally by phagocytosis), a fragment of the antigen molecules is presented on the APC cell surface in association with a major histocompatibility complex (MHC) molecule. This complex is recognized by either B cells via surface-bound immunoglobulin molecule or by T cells via the T-cell antigen receptor. Induction of a specific immune response then proceeds. APCs include macrophages, dendritic cells, and certain B cells.

Antigenicity (immunogenicity): The property of eliciting an immune response, characterized by an interaction of a foreign material with endogenous antibodies or immune cells, in a subject that has been previously exposed (sensitized) to that foreign material.

Anti-Mullerian hormone (also called *Mullerian Inhibiting Substance*): A protein produced by fetal Sertoli cells that prevents formation of a female reproductive tract in male fetuses.

Aortic perfusion: Aorta is cannulated for inflow of the perfusate through the heart and the perfusate exits through the left atrium.

Aplastic anemia: Failure of blood cell production resulting from direct injury to pluripotent hematopoietic stem cells or their stromal microenvironment and characterized by varying degrees of pancytopenia (i.e., decreased erythrocytes, leukocytes [primarily neutrophils], and platelets) and hypocellular bone marrow.

Apoptosis: A series of biochemical events characterized by activation of a series of caspase enzymes that lead to the digestion of cellular DNA with the appearance of DNA laddering on agarose gels and morphological formation of intranuclear clumps in affected cells. This process is also known as *programmed cell death*, whereby cells die in a controlled, progressive manner that is regulated in part by the release of mitochondrial-initiating factors and cytochrome c. Programmed cell death is a normal cellular process for the removal of unneeded cells during organogenesis (e.g., cell death and replacement) that is accelerated by a number of toxic agents, including chemotherapeutic drugs. Thus, apoptosis is a single-cell phenomenon that is energy dependent and tightly regulated and generally occurs at lower doses of many toxicants and is important in morphogenesis and development. It is a genetically programmed form of cell death, distinct from necrosis, which is accidental cell death. Apoptosis helps regulate animal cell populations by eliminating cells that have been overproduced or mutated. The process is complementary to mitosis but opposite in function.

Apoptosis-inducing factor (AIF): A pro-apoptotic protein that when released from the mitochondrion stimulates activation of caspase 3.

Apparent volume of distribution: The volume of plasma (or blood) into which the body load appears to have been dissolved or distributed; equivalent to the body load, at any time, divided by the corresponding plasma (or blood) concentration. It is not a physiological volume but is important, as it indicates the volume of plasma that has to be cleared of chemical; independent of concentration and dose under first-order conditions.

Applied dose: The amount of a substance in contact with the primary absorption boundaries of an organism (e.g., skin, lung, gastrointestinal tract) and available for absorption.

Aquatic toxicology: The study of adverse effects on freshwater and saltwater biota and on the ecosystems that contain them.

Arachnida: A large class of invertebrates comprised chiefly of predaceous terrestrial forms such as scorpions, spiders, harvestmen, mites, ticks, and related forms; they are characterized by a cephalothorax that bears four pairs of walking appendages.

Arithmetic mean: The sum of all the measurements in a dataset divided by the number of measurements in the dataset.

Aspect ratio: Usually applied to fibers; the ratio of length to width.

Atherosclerosis: Nodular sclerosis characterized by irregularly distributed lipid deposits in the intima of the large and medium-sized arteries; such deposits are associated with fibrosis and calcification.

Atopy: General systemic or local hypersensitivity (i.e., allergy), often related to genetic predisposition; may be thought of as *unwanted reactivity.*

ATP-binding cassette (ABC) transporters*:* ABC transporters are transmembrane proteins that utilize the energy of ATP hydrolysis to translocate various substrates across cell membranes. This process can occur against a considerable concentration gradient. ABC transporters include P-glycoprotein (P-gp), the breast cancer resistance protein (BCRP), and the family of multidrug resistance–associated proteins (MRPs).

Atrial perfusion: Right atrium is cannulated for inflow of the perfusate, which exits through the right ventricle via pulmonary arterial cannula or an open slit.

AUC: Area under the plasma concentration time course.

Autoimmunity: Immune reactivity toward self.

Autologous blood perfusate: Blood used as perfusate comes from the same animal from which the organ was removed for perfusion.

Autolysis: Enzymatic self-digestion of cells or tissues that occurs after death. Autolysis complicates detection of pathologic changes in tissues or organs during necropsy and subsequent microscopic examination and can make valid observations during these activities impossible.

Autoradiography: The production of an image by the emission of radioactive decay energy from a radionuclide. It provides a qualitative visual image of the tissue distribution of a xenobiotic and can provide quantitative distribution data as well. Quantitative whole-body autoradiography (QWBA) is becoming a standard tool for absorption, distribution, metabolism, and excretion (ADME) studies.

Autosome: A chromosome that is not a sex-determining chromosome.

Azotemia: Accumulation of nitrogenous wastes such as urea or creatinine in the blood.

Background exposure: Exposures that are not related to the site—for example, exposure to chemicals at a different time or from locations other than the exposure unit of concern. Background sources may be either naturally occurring or anthropogenic (man-made).

Background level (environmental): The concentration of substance in a defined control area during a fixed period of time before, during, or after a data-gathering operation.

Base pair substitution: A gene mutation characterized by the replacement of one nucleotide pair for another in a codon.

B-Cell antigen receptor: A membrane-bound molecular complex responsible for antigen recognition by B cells. It comprises membrane immunoglobulin (mIg) and several accessory molecules. Functionally analogous, but structurally dissimilar, to the T-cell antigen receptor.

B Cell/B lymphocyte: Lymphocytes that recognize antigen via surface-bound immunoglobulins. B cells that have been exposed to specific antigen differentiate into plasma cells that are responsible for producing specific antibodies. B cells differentiate in the bone marrow in mammals and in an organ known as the bursa in birds.

Becquerel (bq): SI unit of radioactivity equaling one disintegration/s, approximately 2.7×10^{-11} curies (Ci).

Beer–Lambert law: This law relates solute concentration and cell path length to ultraviolet absorbance. The law can be expressed by the following equation:

$$A = \log \frac{I_o}{I_t} = abc$$

where

A is the absorbance
I_o is the original intensity incident on the cell
I_t is the reduced intensity transmitted from the cell
a is a proportionality constant (the absorptivity)
b is the path length of the solution
c is the concentration of the analyte

When c is in moles per liter, the constant is the molar absorptivity or molar extinction coefficient. When c is a 1% solution and b is a 1 cm path length, the term *specific absorptivity* is used (1%/1 cm is the most common form used).

Behavioral teratology: The functional deficits arising from exposure to neurotoxic agents during early development.

Benchmark dose (BD): The lower confidence limit on a dose associated with a specified level of response; a dose corresponding to a specified level of risk, generally in the range of 1%–10%.

Beta cells: Insulin-secreting cells of the endocrine pancreas.

Bias: Systemic error as opposed to a sampling error; for example, selection bias may occur when each member of the population does not have an equal chance of being selected for the sample.

Bifurcation: Usually related to airway anatomy, describing a branching of the parent airway into two or more smaller airways, often at acute angles.

Bile salt export pump (BSEP): An ATP-dependent efflux transporter expressed on the canalicular membrane of hepatocytes. BSEP drives and maintains the enterohepatic circulation of bile salts, and is the rate-limiting step of hepatocellular bile salt secretion. Mutations in BSEP or inhibition of its function by xenobiotics have been associated with liver disease or injury.

Bioaccumulation: The net uptake of chemicals from the environment from all sources.

Bioactivation: The enzymatic conversion of a chemical to a more toxic form (in the body or in vitro by an enzyme as a model of a process in the body).

Bioassay: A functional assay that depends on the use of living cells or cell components as an indicator system.

Bioaccumulation: General term that describes the net accumulation of a substance within the tissue of an organism, assuming steady-state conditions.

Bioaccumulation factor (BAF): The ratio of chemical concentration in an organism of interest to the concentration in its exposure medium.

Bioactivation: Enzymatic conversion of a less toxic or reactive compound to a more toxic or reactive compound. Xenobiotics may react covalently with endogenous molecules following bioactivation, sometimes resulting in toxicity to the organism.

Bioavailability: The fraction (or sometimes percentage) of the administered dose that enters the general circulation as the parent compound. A low bioavailability may be due to poor absorption or first-order conditions; the state of being capable of being absorbed and available to interact with the metabolic processes of an organism. Bioavailability is typically a function of chemical properties, physical state of the material to which an organism is exposed, and the ability of the individual organism to physiologically take up the chemical.

Bioconcentration: (1) The accumulation of a substance that partitions from water to an organism, assuming steady-state conditions. Often used to describe body burdens in aquatic organisms, can also be used for terrestrial organisms that experience exposure through soil pore water transfer. (2) The uptake of chemicals from water alone.

Bioconcentration factor (BCF): The tendency of a chemical to be more concentrated in an aquatic organism than the concentration in its environment, calculated by dividing the concentration of the chemical in the organism (wet weight) by the concentration of the chemical in the water.

Biocontainment: The process and equipment used for the purpose of preventing the unwanted release of hazardous material or organisms.

Biodegradation: The process of microbial transformation of a substance in the environment.

Biodegradation: The breakdown of chemicals in organisms or the environment, primarily by microorganisms.

Biodiversity: The variety of organisms considered at all levels, from genetic variants belonging to the same species through arrays of species to arrays of genera, families, and higher taxa; includes the variety of ecosystems that comprise both the communities of organisms within particular habitats and the physical conditions under which they live.

Bioexclusion: The process of preventing the introduction of unwanted microorganisms into animals or their immediate environment.

Biologically based dose–response model: A mathematical expression of the relationship between the incidence of severity of a biological effect and a dose that is based on the biological mechanism or mode of action.

Biologically effective dose: The amount of a deposited or absorbed chemical that reaches the cells or target site where an adverse effect occurs or where that chemical interacts with a membrane surface.

Biomagnification: (1) The increase in tissue contaminant concentration in higher trophic levels as a result of dietary accumulation. (2) The increasing concentration of a substance in organism tissues at successively higher trophic levels that occurs through trophic transfer, that is, ingestion of food items.

Biomarker: Observable change (not necessarily pathological) in the function of an organism, related to a specific exposure or event; a biochemical, genetic, or molecular indicator that can be used to screen disease or toxicity; parameters that can be used as an indicator of exposure, effect, or susceptibility and may be a metabolite, enzyme, or cell surface marker, among others.

Biotransformation: The biochemical modification of a xenobiotic once it enters an organism. Chemical modification can be enzymatic or nonenzymatic and may result in either reduced or increased toxicity. This process generally gives rise to compounds that are more readily excreted in the urine and feces and thus serves as a detoxification process; however, some xenobiotics are activated to more toxic metabolites by these enzymatic conversions.

Birth defect/congenital malformation: An abnormality identified in utero or within the first 2 years postnatal (i.e., death, growth or functional retardation, or alteration or dysmorphogenesis).

Blackfoot disease: A condition caused by long-term exposure to arsenic. The condition was first noted in Taiwan in regions containing high levels of arsenic in drinking water. The condition is characterized by poor circulation, leading to distal gangrene of the foot and other extremities.

Blood: A complex tissue composed of plasma and cellular elements with many different functions; the circulating tissue of the body; the fluid and its suspended formed elements that are circulated through the heart, arteries, capillaries, and veins; the means by which oxygen and nutrient materials are transported to the tissues and carbon dioxide and various metabolic products are removed for excretion.

Body burden: The amount of a particular chemical stored in a body at a particular time, especially a potentially toxic chemical in the body as a result of exposure. Body burdens can be the result of long-term or short-term storage—for example, the amount of a metal in bone, the amount of a lipophilic substance such as polychlorinated biphenyl (PCB) in adipose tissue, or the amount of carbon monoxide (as carboxyhemoglobin) in the blood; amount of radioactive material present in a human or animal.

Bolus dose: A quantity of test material administered all at once. This term is commonly applied to the single daily administration of a test material by oral gavage in toxicity studies.

Bond stretching frequency: This frequency is related to the masses of the two atoms that form the bond (M_a and M_b, in grams), the velocity of light (c), and the force constant of the bond (k, in dyn/cm). The frequency can be expressed approximately as

$$v\,(\text{in cm}^{-1}) = \frac{1}{2\pi c}\sqrt{\frac{k}{M_a M_b/\left(M_a + M_b\right)}}$$

The value of k is unique for a specific bond type (e.g., sp^3, sp^2, and sp bond have values of 5, 10, and 15×10^5 dyn/cm, respectively).

Bootstrap: A method of sampling actual data at random, with replacement, to derive an estimate of a population parameter such as the arithmetic mean or the standard error of the mean. The sample size of each bootstrap sample is equal to the sample size of the original dataset. Both parametric and nonparametric bootstrap methods have been developed.

Botulism: Fatal paralytic disease resulting from the consumption of food containing preformed toxin from *Clostridium botulinum*.

Bounding estimate: An estimate of exposure, dose, or risk that is higher than that incurred by the person in the population with the highest exposure, dose, or risk. Bounding estimates are useful in developing statements that exposures, doses, or risks are *not greater than* the estimated value.

Bowman's membrane: An acellular layer of collagen and ground substance that provides a functional interface between the stroma and epithelium of the cornea.

Bufotenin: A very toxic, water-insoluble genin and serotonin derivative that is synthetically produced and is found in certain toads and in very small amounts in the usual edible mushroom.

Bursa of fabricius: A structure located in the cloaca of avians, where bone marrow–derived lymphocytes mature into immunocompetent B cells prior to moving to the peripheral lymphoid organs.

***Caenorhabditis elegans*:** *C. elegans,* a nematode or roundworm, was the first animal to have its genome completely sequenced and all genes fully characterized.

Capture velocity: Air velocity at any point in front of the hood or at the hood opening necessary to overcome opposing air currents and to capture the contaminated air at that point by causing it to flow into the hood.

Cascade impactor: Instrument used to collect and sort aerosols onto discrete stages by separating the particles according to their aerodynamic size.

Case-control study: A study in which the past histories of those with a specific disease (the case) are compared with those who do not have the disease (the controls). The measure of association is the odds ratio (i.e., the odds of the cases having had some type of exposure compared to the odds of the controls having had that same exposure). In the context of exploratory data analysis, the case-control approach has sometimes been called *a disease in search of an exposure.*

Case reports and case series: A description of a single individual or group of individuals with the same or similar disease. This type of work lacks controls; therefore, any conclusions derived from such anecdotal information must be viewed with caution. Nonetheless, case reports and case series sometimes are useful for generating hypotheses.

Cause of death: The disease or injury that initiated the train of events leading directly to death, or the circumstances of an accident or violence that produced the fatal injury.

CBG: Corticosteroid-binding globulin.

CBI: Chemical-binding index.

cDNA: Complementary DNA enzymatically synthesized as a copy of mRNA.

Cell-mediated immunity (CMI): Antigen-specific immune reactivity mediated primarily by T lymphocytes. CMI may be expressed as immune regulatory activity (primarily mediated by CD4+ T-helper cells) or immune effector activity (mediated largely by CD8+ T-cytotoxic cells). Other forms of direct cellular activity (e.g., natural killer [NK] cells, macrophages) are generally not antigen specific (i.e., nonimmune) and are more accurately described as natural immunity.

Central tendency exposure (CTE): A risk representing the average or typical individual in the population, usually considered to be the arithmetic mean or median of the risk distribution.

Centrilobular cells: Collection of hepatic cells situated around the terminal hepatic venule (or central vein).

Centromere: Constriction along the length of a chromosome.

Chelating agent: An organic compound that forms multiple coordinate covalent bonds with metal ions yielding stable compounds that can be excreted. Chelating agents are used in the treatment of metal toxicity. An example is dimercaptopropanol (British Anti-Lewisite) to treat arsenic poisoning.

Chemical shift: The frequency at which a given nucleus absorbs in a nuclear magnetic resonance (NMR) spectrum. The precession frequency (v) for a given nucleus depends on its chemical environment and the shift in v from the standard value is given by the fundamental NMR equation:

$$v = \frac{\gamma_o^{btn}}{2\pi}$$

is called the *chemical shift* for that nucleus. Chemical shifts are rarely (if ever) expressed in absolute frequency units; instead, they are measured relative to ^{13}C a standard reference compound. For ^{1}H and NMR, the universally accepted reference is tetramethylsilane (TMS). The protons and carbons of TMS absorb at a lower frequency (are more shielded) than those of almost all other organic compounds, so their chemical shifts are arbitrarily set to 0 Hz, and most other chemical shifts measured relative to them are positive. Chemical shifts are expressed in dimensionless units designated δ. The chemical shift in δ units is defined according to the following relationship:

$$\delta = \frac{v_s v_{std}}{\text{Operating frequency}} \times 10^6 \text{ ppm}$$

Chemokine: Small peptide molecules related to cytokines and associated with a variety of physiological states, such as inflammation and immunoregulation.

Chemotaxis: Directed movement of cells through a concentration gradient of an attractant molecule, such as a chemokine.

Chilopoda: A class of about 2000 species of nocturnal, predatory, terrestrial arthropods that includes centipedes; they superficially resemble millipedes.

Cholestasis: Diminution or cessation of bile flow, accompanied by decreased excretion and enhanced retention of normal constituents found in bile.

Chondrichthyes: The vertebrae class comprised of cartilaginous fishes, including sharks, rays, skates, and chimaeras; there are about 300 species, some of which are venomous.

Chromatography: A process for separation of molecules on the basis of their affinities for a stationary phase and a mobile phase.

Chromophore: A structural moiety in an organic molecule that absorbs light in the useful part of the ultraviolet spectrum. Common chromophores are aromatic moieties and conjugated double-bond moieties.

Chromophoric resonance Raman label: These labels provide detailed vibrational and electronic spectral data when they are incorporated into the vicinity of a biologically important site. They usually are designed to mimic natural biochemical components and are themselves biologically active compounds. These labels are useful for obtaining information on protein–ligand interactions and have been utilized for studying enzyme–substrate complexes, where vibrational spectra of the substrate during enzyme catalysis can be obtained.

Chromosome: Microscopically visible organelle composed of DNA and proteins.

Chronic: Characterized by a time period of long duration; commonly used to describe long-term (6–12 months) exposure in toxicity studies.

Chronic toxicity study: A multiple-dose study in which animals are treated for ≥6 months to comprehensively assess the potential toxicological effects of a compound following long-term exposure; normally, these studies are required prior to phase II testing in humans.

Chylomicrons: A class of large lipoprotein structures that are created by the cells of the lumen of the small intestine and transport dietary fat by exocytosis from the small intestine to the lymphatic system, where they are eventually removed by lipoprotein lipase.

Ciguatoxins: A group of colorless and heat-stable lipophilic polyether neurotoxins produced by 300–400 tropical reef and semipelagic marine animals.

Cilia: Flexible, microscopic projections from cell surfaces that participate in the active movement of overlying mucous; effective rhythmic ciliary motion is essential for normal particle clearance of deposited particles from airway surfaces.

Clastogen: An agent that causes chromosomal breakage.

Clastogenicity: Chromosome breakage and/or rearrangements.

Clearance: The volume of plasma (or blood) that is cleared of chemical per unit time; equivalent to the rate of elimination, at any time, divided by the corresponding plasma (or blood) concentration. Clearance may be dependent on the blood flow and/or the metabolic activity or extraction ratio (at steady state) of the organ(s) elimination; independent of concentration and dose under first-order conditions. The volume of plasma from which a compound is completely removed by the kidneys per unit time.

Cleft phallus: See *Hypospadia*.

Clinical assays of renal function: Assays that can be performed in humans; typically involve measurement of parameters in blood (serum and plasma) or urine; usually noninvasive.

Clinical pathology: A subspecialty of pathology that uses laboratory methods such as hematology and clinical chemistry to detect, define, or corroborate a disease state.

Cluster of differentiation (CD): The CD series is used to denote cell surface markers (e.g., CD4, CD8). These markers, used experimentally as a means of identifying cell types, serve various physiological roles.

C_{max}: Maximum achieved concentration.

Cnidaria: A large family of venomous marine invertebrates of the Indo-Pacific region often found in coral reefs.

COD: Caloric optimization diet.

Coded chemicals: Chemicals labeled by code rather than names so they can be tested and evaluated without knowledge of their identity or anticipation of test results. Coded chemicals are used to avoid intentional or unintentional bias when evaluating laboratory or test method performance.

Coded microscopic evaluation: The practice of conducting the initial histopathological evaluation with the pathologist having no knowledge of treatment status of individual animals.

Coding regions: Those parts of the DNA that contain the information required to form proteins. Other parts of the DNA may have noncoding functions (e.g., start–stop, pointing, or timer functions) or as yet unresolved functions or perhaps even *noise*.

Codon: A DNA base pair triplet coding for an amino acid or stop signal.

Coefficient of inbreeding: Refers to a mathematical relationship used to express the relatedness and is expressed in mathematical values ranging between 0 and 1.

Cohort study: This type of epidemiology study is conceptually quite similar to the approach used in most toxicology experiments. The health experience (incidence of disease or mortality) of those exposed to some agent is compared with that of a group not so exposed. In epidemiology, however, the results usually are presented in terms of a relative risk or standardized morbidity (or mortality) ratio. In the context of exploratory data analysis, the cohort approach also has been called *an exposure in search of a disease*.

Collision-induced dissociation: A method in which ions are collided with neutral molecules to produce fragmentation. This process is also referred to as *MS/MS*, as a mass spectrum is produced on an ion selected from a mass spectrum.

Colubridae: The largest and most cosmopolitan family of snakes, comprised of more than 1,700 of the known species of snakes, most of which are nonvenomous; both jaws hold solid or grooved teeth, but no enlarged or hollow fangs, and in most cases, the head is wider than the neck.

Commensal: An organism commonly found in association with animals or their environment that under normal circumstances does not produce disease.

Complement: A group of approximately 20 proteinase precursors that interact in a cascading fashion. Following activation, the various precursors interact to form a complex that eventually leads to osmotic lysis of a target cell.

Computational toxicology: The application of mathematical and computer models to predict adverse effects and to better understand the mechanisms through which a given chemical induces harm (U.S. Environmental Protection Agency definition).

Conceptus: An embryo or fetus.

Conditioned response: Response to an originally neutral stimulus, such as a sound or light, that has acquired the ability to evoke the response because it was paired with an eliciting stimulus.

Confidence interval: A range of values (above, below, or above and below) about the midpoint of the sample (e.g., the mean, median, mode) that contains (with a specified level of probability, such as 95%, or a standard deviation or error, such as 67%) the true value of the population midpoint. The 95% confidence interval (also called the *fiducial limit*) is equivalent to the $p = 0.05$ region boundary.

Confidence limit: A statistical estimate that considers the influence of experimental variation of a parameter.

Confocal microscope: An instrument capable of producing high-resolution microscopic images that can be used to study ocular tissues. A confocal microscope with scanning capability can be used to determine area and depth of corneal injury.

Confounding variable, confounder: A confounder is an alternative cause for the disease in question that is unequally distributed among those exposed and unexposed to the putative agent of interest. As a consequence, it can confound or confuse the measure of association and any resulting interpretations of cause and effect.

Congenital: Present at birth.

Coniine: A highly toxic liquid alkaloid and derivative of pyridine; it is the chief toxic agent of poison hemlock.

Conjugation: A common mechanism during phase II metabolism where an endogenous compound is added to specific functional groups of a xenobiotic; generally, this increases the excretion of the xenobiotic and decreases its potential to interact at critical sites to produce toxicity.

Conjugation reaction: A metabolic process that combines a xenobiotic having an appropriate functional group with an endogenous substrate (e.g., glucuronic acid, glutathione, sulfonic acid) to yield a product having increased water solubility compared to the parent compound facilitating urinary or biliary elimination. Often the added chemical group is recognized by specific carrier proteins.

Conjunctiva: The delicate membrane that lines the eyelid and covers the exposed surface of the eyeball. Histologically, the conjunctiva is an aqueous nonkeratinized epithelium with numerous mucous-secreting cells. In the Draize eye test, effects to the conjunctiva represent a maximum of 20 out of 110 total points.

Coprophagy: The process of eating one's own feces.

Cornea: The transparent outermost covering of the anterior portion of the eye consisting of the epithelium, the stroma, and the endothelium. In the Draize eye test, effects to the cornea represent a maximum of 80 out of 110 total points.

Correlation: The relationship or interdependence between measurable varieties or ranks—that is, the extent to which, as one set of values changes, another set also changes in the same (positive correlation) or an opposite (negative correlation) direction.

Cortical collecting duct: Originates at convergence of two initial collecting tubules and extends to the corticomedullary border; nephron segment responsible for regulating the final composition of urine.

Cosmic rays: Radiation of many sorts, mostly nuclei (protons) with very high energies, originating outside the Earth's atmosphere.

Coupling constant: The separation between nuclear magnetic resonance (NMR) spectral lines due to coupling is the *coupling constant* (J). The magnitude of coupling constants depends on the number of intervening bonds and the bond geometry. Coupling constants are expressed in units of hertz (Hz).

Critical temperature: Maximum temperature at which a gas may be liquefied by application of pressure alone. Above this temperature, the substance may only exist as a gas. The critical temperature for CO_2 is 31°C.

Cross-sectional study: A prevalence study (i.e., an epidemiology study) that examines the association between health status and other variables of interest as they exist in a defined population at one particular time. This type of research can also be useful for generating etiologic hypotheses, but these hypotheses then need to be tested in analytic studies. Conceptually, it is also the first step of the more rigorous cohort method.

Cumulative distribution function (CDF): A representation, generally a function or graph, of the cumulative probability of occurrence for a random independent variable. The CDF is obtained from the probability density function (PDF) by integration in the case of a continuous random variable and by summation for discrete random variable. Each value c of the function is the probability that a random observation x will be less than or equal to c.

Curie: Standard measure of rate of radioactive decay; based on the disintegration of 1 g of radium, or 3.7×10^{10} disintegrations/s.

Cyclone separator: A process in which particle-laden air is introduced radially into the upper portion of a cylinder so it makes several revolutions inside the cylinder. The particles in the air are accelerated outward to the cylinder walls, where they either stick and are retained (low particle loading) or are swirled down to a collection port at the bottom of the cylinder (high particle loading).

Cyclopeptides: Group of toxins, produced by the *Amanita* and *Galerina* species of mushrooms, that inhibit mammalian nuclear RNA polymerase.

Cytochrome c: A major component of the mitochondrial electron transport chain that is localized in the intermitochondrial membrane space. Increased release of this protein into the cytosol is one of the major factors activating the caspase system resulting in apoptosis.

Cytochrome P450: Heme thiolate proteins associated with the endoplasmic reticulum originally named for their absorption maximum at 450 nm. These proteins, which serve as catalysts in a variety of oxidative reactions involving both endogenous and xenobiotic lipophilic compounds, are unique in their multiplicity of isozymes, substrates, reactions, and regulatory mechanisms. This family of heme-containing enzymes is involved in the so-called phase I metabolism of xenobiotics and endogenous compounds and catalyzes myriad reactions, including oxidation, reduction, dealkylation, and hydrolysis.

Cytokine: Small peptide molecules that subserve a wide range of regulatory and effector mechanisms. These include interleukins, tumor necrosis factors, interferons, colony-stimulating factors, and other growth and regulatory factors. Often referred to as *lymphokines* in the older literature.

Cytotoxic T lymphocyte (CTL): A subset of T lymphocytes bearing the CD3/CD8 surface markers; CTLs are able to kill target cells following induction of a specific immune response. The mechanism of this lysis appears to be a combination of direct lysis resulting from the extrusion of lytic granules by CTLs, as well as the induction of apoptosis in the target cell. The target cells most frequently used for assessment of CTL activity are virally infected cells and tumor cells. Measurement of CTL activity provides an indication of cell-mediated immunity.

Datum: A single point of measurement; more than one point is referred to as *data*.

Default value: A conservative value used for a model parameter or uncertainty (safety) factor when data are inadequate to justify a different value.

Definitive test: A toxicity determination designed to provide an accurate quantitative result with low variability; a second-level test conducted following pretests or range-finding tests.

Delayed skeletal ossification: Developmental delay in bone formation.

Delayed-type hypersensitivity (DTH): A form of cell-mediated immunity in which recalled exposure to an antigen results in an inflammatory reaction mediated by T lymphocytes; usually referred to as *contact hypersensitivity.*

Deposition: The process whereby the amount and location of matter (vapor, gas, or solid) is absorbed into or onto a surface (usually described as the amount per unit area during a specified time).

Descemet's membrane: An acellular layer that lies beneath the stroma and forms the basement membrane of the corneal endothelium.

Descriptive study: A study designed to describe the distribution of certain variables (e.g., a health survey of a community that gathers data on disease status and presents the resulting information in the form of what disease was present when, where, and among whom). Although not useful for etiologic research, it can be used to generate hypotheses.

Detoxication: The enzymatic conversion of a chemical to a less toxic form or, for these purposes, the conversion of a chemical to a form that can no longer be bioactivated (distinguished from detoxification, which is the process of removing the chemical from the body by physical means).

Developmental toxicology: The study of the causes, mechanisms, and sequelae of perturbed developmental events in species of animals that undergo ontogenesis; affected endpoints include death, delayed or retarded development, dysmorphology, and functional impairment.

Diagnostic drift: The gradual changes in nomenclature or application of severity grading scales that may occur in a single study group, across several groups in a single study, or when several studies are compared.

Diastole: The dilation of the heart cavities during which they fill with blood.

Dietary reference intake (DRI): Dietary Reference Intakes is the general term for a set of reference values used to plan and assess nutrient intakes of healthy people. These values, which vary by age and gender, include:

- Recommended Dietary Allowance (RDA): Average daily level of intake sufficient to meet the nutrient requirements of nearly all (97%–98%) healthy people.
- Adequate Intake (AI): Established when evidence is insufficient to develop an RDA and is set at a level assumed to ensure nutritional adequacy.
- Tolerable Upper Intake Level (UL): Maximum daily intake unlikely to cause adverse health effects. http://ods.od.nih.gov/health_information/dietary_reference_intakes.aspx.

Diffuse neuroendocrine system (DNES): Neurones and amine precursor uptake and decarboxylation (APUD) cells produce some identical biogenic amines and peptides in cells that in some ways are

similar to nerve cells and in other ways are similar to endocrine cells. These cells are located in different organs and have a common regulatory mission. Although they do not form a specific organ, they do function to control many aspects of homeostasis and are considered to be a regulatory entity.

Diffuse neuroimmunoendocrine system (DNIES): Recently, it has been shown that there are common chemical regulatory systems present among the nervous, endocrine, and immune systems. The close relationship among the amine precursor uptake and decarboxylation (APUD) cells that produce peptidergic/aminergic neurons, the DNIES system that unties many different locations, and the peptide-producing immunocompetent cells suggests that the entire system should be combined into a single regulatory homeostatic functional system and termed the *diffuse neuroimmunoendocrine system*.

Diffusion-limited uptake: Tissue uptake is limited by the diffusion through the membranes rather than by the blood flow to the tissue.

Dinoflagellata: An order of predominately marine, free-swimming protists that have two flagella; they are a staple food of shellfish and some crabs and are thus in the human food chain. Certain species may become extremely abundant in warm coastal waters, causing certain of the toxic *red tides*, although few are actually toxic.

Diploid: Two set of chromosomes, one maternal and one paternal.

Dirty bomb: A bomb that uses conventional explosives, such as dynamite, to spread radioactive material. The best known of the radiological dispersal devices; the dirty bomb does not produce a nuclear explosion but is sometimes referred to as a *Weapon of Mass Disruption*.

Discrimination behavior: Behavior based on the ability of subjects to discriminate stimulus qualities. In the typical situation, because different stimulus properties require different behaviors, discrimination abilities can be measured by the type or location of responses.

Distal tubule: Generic term describing epithelial cell types in the cortex comprising distal convoluted tubule, connecting segment, and initial collecting tubule.

Distress: A state in which an animal, unable to adapt to one or more stressors, fails to return to physiological and/or psychological homeostasis. May be manifested as clinical signs of disease, abnormal or maladaptive behaviors, or subclinically as a pathologic condition as measured by abnormal physiological parameters or organ function.

Distribution: The reversible transfer of chemical from the general circulation into the body tissues.

DNA: Deoxyribonucleic acid, the chemical substance containing the genetic code; see also *Nucleotide*.

DNA adduct: A molecule that is covalently linked to a portion of the DNA helix.

DOCA: Deoxycorticosterone.

Donor animal: An animal from which the organ or the blood was removed.

Dosage: A general term encompassing the dose, its frequency, and the duration of dosing.

Dose: The amount of a substance available for interaction with metabolic processes or biologically significant receptors after crossing the outer boundary of an organism. The *Potential Dose* is the amount ingested, inhaled, or applied to the skin. The *Applied Dose* is the amount of a substance presented to an absorption barrier and available for absorption (although not necessarily having yet crossed the outer boundary of the organism). The *Absorbed Dose* is the amount crossing a specific absorption barrier (e.g., the exchange boundaries of skin, lung, and digestive tract) through uptake processes. *Internal Dose* is a more general term denoting the amount absorbed without respect to specific absorption barriers or exchange boundaries. The amount of the chemical available for interaction by any particular organ or cell is termed the *delivered dose* for that organ or cell.

Dose equivalent (H): Unit of biologically effective dose, defined as the absorbed dose in rads multiplied by the quality factor (Q). For all x-rays, gamma rays, beta particles, and positrons likely to be used in nuclear medicine, $Q = 1$.

Dose rate: Dose per unit time (e.g., in mg/day), sometimes also called *Dosage*. Dose rates are often expressed on a per-unit-body-weight basis, yielding units such as mg/kg/day (mg/kg per day). They are also often expressed as averages over some time period (e.g., a lifetime).

Dose reconstruction: An approach to quantifying exposure from internal dose, which is in turn reconstructed after exposure has occurred, from evidence within an organism, such as chemical levels in tissues or fluids or from evidence of other biomarkers of exposure.

Dose–response: "What is there that is not poison? All things are poison and nothing [is] without poison. Solely, the dose determines that which is not a poison" (Paracelsus). The biological response to an agent is a function of the condition of exposure, including dose, duration, and route.

Dose–response assessment: The part of risk assessment associated with evaluating the relationship between the dose of an agent administered or received and the incidence or severity of an adverse health or ecological effect.

Dose–response model: A mathematical expression that relates the incidence or magnitude of a biological effect to the dose of a chemical.

Dosimetry: Estimating or measuring the quantity of material (mainly refers to particulate) at specific target sites at a particular point in time. The quantity can be measured in terms of mass number, surface area, or volume; process of measuring or estimating dose.

DPA: Decision point approach.

DR: Diet restricted.

Draculin: Anticoagulant factor present in the saliva of vampire bats.

Duct velocity: Air velocity through the duct cross section. When solid material is present in the air stream, the duct velocity must be equal to or greater than the minimum air velocity required to move the particles in the air stream.

Dust: Solid particles that are capable of temporary suspension in air or other gases. Usually produced from larger particles or masses through grinding, crushing, or other handling. Particles may be up to 300–400 μm, but those above 20–30 μm usually do not remain airborne.

Drug: Any substance or product that is used or intended to be used to modify or explore physiological systems or pathological states for the benefit of the recipient World Health Organization (WHO).

Dysplasia: Abnormal tissue development.

Early-phase regeneration (EPR): Tissue repair response, where arrested G_2 hepatocytes are activated to proceed through mitosis (see *SPR*).

Early transient incapacitation (ETI): Transient performances deficits observed in animals and humans after a large, rapidly delivered dose of ionizing radiation. Five to ten minutes after radiation exposure, behavioral performance rapidly falls to near zero, followed by partial or total recovery 10–15 min later.

EC_{50} (effective concentration–50%): A statistically or graphically determined concentration of a chemical that reduces a sublethal response parameter of interest by 50%.

Echinodermata: Phylum of marine invertebrate coelomate animals that includes starfish and sea urchins. Approximately, 85 of the nearly 6000 species are known to be venomous or poisonous.

Ecotoxicology: The study of adverse effects to organisms other than humans from exposure to natural or synthetic toxic substances in the environment.

Ecological risk assessment: The process used to establish the likelihood that adverse ecological effects are occurring or may occur as a result of exposure to one or more stressors.

Ectopic or cryptorchid testis: Malposition or displacement of the testis outside the scrotum. Typically, such testes are found within the peritoneum or inguinal canal; however, abdominal sites outside the peritoneum have been observed.

Effect concentration (EC): Concentration of a substance in media predicted to cause a measurable change in a defined proportion (e.g., 50%) of a population of organisms.

Effective dose-50% (ED_{50}): The dose of radiation or a chemical agent that would result in a given response in 50% of the population; see also *Median effective dose*.

Elapidae: A family of front-fanged, highly venomous, aquatic, burrowing, terrestrial, and arboreal snakes that includes cobras, kraits, mambas, coral snakes, death adder, the Australian copperhead, and the African garter snake; they are characterized by a pair of comparatively short, stout, permanently erect, deeply grooved fangs at the front of the mouth, and the tail is cylindrical and tapered.

Electrocardiogram: A bioelectric potential originating in the myocardium and recorded on the surface of the body; represents the sum of the electrical depolarizations of the myocardium syncytium as the wave of depolarization sweeps across the heart.

Electron paramagnetic resonance (EPR): An analytical technique that is used to study the structure and properties of free radicals. EPR spectroscopy is similar in principle and practice to nuclear magnetic resonance (NMR) spectroscopy. Whereas NMR uses energy in the radiofrequency region of the electromagnetic spectrum, EPR uses energy in the microwave region.

Elimination: The irreversible transfer of the chemical from the circulation to the organs of elimination and its subsequent removal from the body by metabolism or excretion.

Emergency response planning guidelines (ERPGs): ERPGs are values intended to provide estimates of concentration ranges for 1 h exposures above which one could reasonably anticipate observing adverse health effects. Compare to acute exposure guideline levels (AEGLs).

EMIT: Enzyme-multiplied immunoassay technique.

Empirical distribution: A distribution obtained from actual data possibly smoothed with interpolation technique. Data are not fit to a particular parametric distribution (e.g., normal, lognormal) but are described by the percentile values.

Empirical dose–response model: A mathematical model that is selected from plausible models based on agreement with experimental data.

Enantiomer: A type of stereoisomer, an enantiomer is one of a pair of isomers that are nonsuperimposable mirror images of each other. Although chemically identical (except for optical rotation), enantiomers may demonstrate widely different pharmacological and toxicological properties.

Endobiotics: Chemicals that are normally present in the biochemistry of a cell; these include chemicals that are normally found with the biochemistry of anabolic and catabolic metabolisms.

Endocrine disruptor: Chemicals or naturally occurring substances that can alter the endocrine system. Reference to chemically induce alternations in any of a wide range of endocrine functions.

Endometrium: Inner lining of the uterus that is shed during menstruation.

Endoscopy: In vivo inspection of the internal surface of a hollow organ with an instrument.

Endpoint: The biological or chemical process, response, or effect assessed by a test method.

Engineered nanoparticle: A form of nanoparticles that are designed and fabricated by material scientists for specific physical, chemical, optical, magnetic, catalytic, or morphological properties not evident in the macroscale.

Engineering standards: Specifications that do not provide for interpretation and modification of prescribed methods or procedures, even if acceptable alternative methods are available or unusual circumstances occur. This term is most commonly used in conjunction with prescribing conditions for the care and use of laboratory animals.

Enteric endocrine system (EES): An endocrine system that helps control digestive function. Over 25 hormones have been identified as affecting the gastrointestinal tract, with single-hormone-secreting cells located throughout the lumen of the stomach and small intestine.

Enteric nervous system (ENS): A nervous system that helps control digestive function; it is located primarily in the wall of the gastrointestinal tract and is an interdependent part of the autonomic nervous system that can be affected by sympathetic and parasympathetic nervous impulses. It is also referred to as the *second brain* because it can operate the gastrointestinal tract in the absence of external stimuli.

Enterohepatic circulation: Bile salts are necessary for the absorption of lipids when ingested and present in the small intestine. The bile salt forms micelles that are integral in the absorption of longer chained lipids. When the micelles are spent, they are eventually reabsorbed in the ileum of the small intestine to be returned throughout the circulatory system to the liver where the bile salts are resecreted through the bile ducts into the small intestine to again form micelles.

Environmental fate: The destiny of a chemical or biological pollutant after release into the environment. Environment fate involves temporal and spatial considerations of transport, transfer, storage, and transformation.

Environmental enrichment: Providing animals with sensory and motor stimulations, through structures and resources that facilitate the expression of species-typical behaviors and promote psychological well-being.

Enzyme: A biological catalyst (for these purposes, proteins).

Enzyme-linked immunosorbent assay (ELISA): A type of immunoassay in which specific antibodies are used to both capture and detect antigens of interest. The most popular type is the *sandwich* ELISA, in which antibodies are bound to be a substrate such as a plastic culture plates. These antibodies bind antigenic determinates on molecules (or alternatively on whole cells). Unrelated material is washed away and the plates are exposed to an antibody of a different specificity; this antibody is coupled to a detector molecule.

Epididymis: The duct that conveys sperm from the testis to the vas deferens. It consists of caput (head), corpus (body), and cauda (tail) regions that support sperm transit, maturation, and storage prior to ejaculation.

Epitope: The portion of an antigen that is recognized by an antibody or T-cell antigen receptor; also known as the *antigenic determinant*.

Epigenetics: Refers to any change in gene expression that is stable between cell divisions but do not involve changes in the DNA sequence of the organism. Mechanisms involved with epigenetic changes include methylation of cytosine residues in the DNA, remodeling of chromatin structure, regulatory processes mediated by small RNA molecules, and other gene silencing pathways. However, one of the most significant challenges with this area of research is understanding the *normal* epigenome in regard to the distinction between adaptive and adverse epigenetic changes. Without detailed characterization of the epigenome, including stable and variable methylation sites, it is not possible to evaluate whether an epigenetic alteration is an adverse effect from exposure to an exogenous agent or is part of the normal epigenetic variability. As described in a workshop by the National Academy of Sciences' Standing Committee on Use of Emerging Science for Environmental Health Decisions "Use of Emerging Science and Technologies to Explore Epigenetic Mechanisms Underlying the Developmental Basis for Disease," epigenetic testing is not yet sufficiently validated for the regulatory process because (1) no single test is ideal for epigenetic effects, (2) normal methylation patterns and long-term effects are not well understood, and (3) standardized tiered screening scheme to prioritize chemicals is lacking.

Epizootic: Refers to the initial period following introduction of a microorganism into a naïve population, during which time it undergoes rapid spread within the population and is often associated with a high incidence of clinical signs or disease.

Essential test method components: Structural, functional, and procedural elements of validated test methods that should be included in the protocol of a proposed mechanistically and functionally similar test method. These components include unique characteristics of the test method, critical procedural details, and quality control measures. Adherence to essential test method components is necessary when the acceptability of a proposed test method is being evaluated based on performance standards derived from a mechanistically and functionally similar validated test method. (*Note*: Essential test method components were previously referred to as *minimum procedural standards*.)

Estrogen: Female sex steroid (e.g., estradiol).

Exencephaly: An open brain resulting from failure of the neural tube to close.

Exon: Actively transcribed DNA in a eukaryotic gene.

Exposure: Contact of a chemical, physical, or biological substance with the outer boundary of an organism. Exposure is quantified as the concentration of the agent in the medium in contact integrated over the time duration of contact.

Exposure assessment: The determination or estimation (qualitative or quantitative) of the magnitude, frequency, duration, and route of exposure; the qualitative or quantitative estimate (or measurement) of the magnitude, frequency, duration, and rote of exposure. A process that integrates information on chemical fate and transport environmental measurements, human behavior, and human physiology to estimate the average doses of chemicals received by individual receptors. For simplicity in this guidance, exposure encompasses concepts of absorbed dose (i.e., uptake and bioavailability).

Exposure concentration: The concentration of a chemical in its transport or carrier medium at the point of contact.

Exposure pathway: The physical course a chemical or pollutant takes from the source to the organism exposed.

Exposure point concentration (EPC): The contaminant concentration within an exposure unit to which receptors are exposed. Estimates of the EPC represent the concentration term used in exposure assessment.

Exposure route: The way in which a chemical enters an organism after contact (i.e., by inhalation, ingestion, or dermal absorption).

Exposure scenario: A set of facts, assumptions, and inferences about how exposure takes place; this information aids the exposure assessor in evaluating, estimating, or quantifying exposures.

Extra risk: $(P - P_o)(1 - P_o)$

where

P is the total risk

P_o is the background (spontaneous) risk in control animals or unexposed humans

Extrapolation: Using data or results from one set of conditions (e.g., animal experimental results) to predict results for a different set of conditions (e.g., humans).

Extravascular hemolysis: Destruction of red blood cells by cells of the mononuclear phagocyte system (e.g., splenic macrophages); may be a normal process for removal of senescent red blood cells or part of a pathological process for removal of abnormal red blood cells or red blood cells coated by immunoglobulin (i.e., immune-mediated hemolysis).

Eye corrosion: Irreversible ocular tissue damage following exposure to a material. Eye corrosion represents gross tissue destruction, which generally occurs rapidly after exposure.

Eye irritation: Reversible inflammatory changes in the eye and its surrounding mucous membranes following direct exposure to a material on the surface of the anterior portion of the eye.

Face velocity: Air velocity at the hood opening.

FACS analysis: Flow-assisted cell sorting; analytical method applied to data from flow cytometry experiments.

False negative: A substance incorrectly identified as negative by a test method.

False negative rate: The proportion of all positive substances falsely identified by a test method as negative (see *Two-by-two table*). It is one indicator of test method accuracy.

False positive: A substance incorrectly identified as positive by a test method.

False positive rate: The proportion of all negative substance that are falsely identified by a test method as positive (see *Two-by-two table*). It is one indicator of test method accuracy.

Favism: A hemolytic disease in individuals deficient in glucose-6-phosphate dehydrogenase resulting from consumption of fava beans.

Fertility: The ability to conceive and produce a live offspring. The fertility index should be calculated separately for male and female animals and is generally calculated as the ratio of the number of animals pregnant divided by the number of animals inseminated.

Fetal alterations (malformations, variations, and developmental delays): Any morphological change identified in a term conceptus, including frank malformation, minor deviations from normal development, and reversible delays or accelerations in development, regardless of the potential effect on subsequent viability or quality of life.

Fiber: A particle that has a length-to-width ratio of 3:1 and a length greater than 5 μm. These can be naturally occurring, man-made mineral, or synthetic organic fibers.

Fibrosis: An abnormal accumulation or proliferation of fibrous connective tissue, usually in the lung.

First-order process: A process for which the rate of reaction is proportional to the available concentration—for example, diffusion, metabolism (at low concentrations), and filtration.

Fixation: Preparation of a histologic or pathologic specimen for the purpose of maintaining the existing form and structure of its constituent elements. Maintenance of the normal form and structure of tissues and organs is critical to the evaluation of pathologic effects during microscopic examination. Common fixatives, such as formaldehyde, result in the precipitation of proteins. This fixes them in place and preserves the morphology of the specimen.

Face velocity: The measured air speed at an inlet or outlet of a ducted air system.

Flame ionization detector (FID): An instrument that measures real-time concentrations of organic vapors at

low levels from parts-per-billion (ppb) up to 50,000 parts-per-million (ppm). FIDs use the energy of a hydrogen flame to ionize gases and produce ions that can be measured as a weak current through an imposed electrical field. The resulting electrical signal is proportional to the amount of gas in the sample.

Flammability: The ability of a material to ignite and burn readily.

Flash point: The lowest temperature at which vapor is given off in sufficient quantity so the air–vapor mixture above the surface of the solvent will ignite momentarily in a flame.

Flavin-containing monooxygenases (FMOs): Enzymes containing flavin adenine dinucleotide that belong to a family of proteins that are important in the NADPH-dependent metabolism of exogenous compounds. FMOs catalyze the addition of a single oxygen atom to nucleophilic nitrogen, sulfur, and phosphorus centers of a variety of xenobiotics.

Flavonoids: Phenolic plant pigments belonging to flavone, flavanone, isoflavone, anthocyanidin, chalcone, or aurone groups.

Flow cytometry: Method to separate populations of fluorescent-labeled cells according to differences in a specific property.

Fluid mosaic membrane model: The accepted models for the description of the biological membrane. This model is a noncontinuous phospholipid bilayer that forms planar bimolecular films that separate two aqueous compartments with hydrophobic cores. Proteins are an integral part of the membrane and span the entire thickness of the lipid layer.

Folliculogenesis: Maturation of the ovarian follicle, a densely packed shell of somatic cells that contains an immature oocyte.

Food poisoning: A predominantly gastrointestinal disease resulting from the consumption of food containing any of the ever-increasing number of toxigenic microorganisms or the preformed toxins produced by them.

Formication: The unpleasant sensation of tiny insects (ant) crawling on the skin.

Fourier transformation (FT): A mathematical operation that converts information from the time domain to the frequency domain. FT can be applied to a variety of spectral techniques, including mass spectrometry, nuclear magnetic resonance, electron paramagnetic resonance, and infrared spectroscopy.

Fractional excretion: The excretion of a substance in urine relative to the rate it is filtered into the urine; an index of reabsorptive function.

Frameshift: A gene mutation characterized by the addition or deletion of one or more base pairs in a gene.

Free radical: A molecule that is inherently unstable and highly reactive with other components of living systems and produced by sufficient exposure to ionizing radiation.

Frequency distribution: A graph or plot that shows the number of observations that occur within a given interval. Usually presented as a histogram showing the relative probabilities for each value, it conveys the range of values and the count (or proportion of the sample) that was observed across that range.

FSH: Follicle-stimulating hormone.

Fugu: A puffer fish that can lead to severe tetrodotoxin poisoning if improperly prepared.

Fume: Minute solid particles arising from high-temperature or combustion processes with subsequent condensation of vapors and often accompanied by a chemical reaction, such as oxidation. Metal vapors commonly condense to create fume; exposure to fresh metal fumes can cause metal fume fever. Fumes exist initially as very small (<100 nanometers [nm]; 10^{-9} m) particles but form larger (~1 μm) particle clusters through agglomerative growth.

Functional observation battery: A set of standardized observations, typically performed with rodents, designed to assess neurobehavioral functions such as reflexes.

Functionalization: The addition to or uncovering of functional groups that are required for subsequent phase II metabolism; for example, hydroxylation of a hydrocarbon provides a functional group from which a conjugate can be formed during phase II metabolism.

Functionalization reactions: Enzymatic reactions that introduce a new functional group into a xenobiotic molecule, either by addition of a new functional group (e.g., hydroxylation) or by removal of a masking group (e.g., *N*-demethylation). Functionalization reactions are also commonly referred to as phase 1 reactions.

Gametogenesis: Production of sperm or ova.

Gamma rays: High-energy, short-wavelength electromagnetic radiation emitted from the nucleus of an atom.

Gas: A substance that exists in the gaseous state at standard temperature and pressure.

Gas chromatography–mass spectrometry: A method for introducing analytes volatized into the gas phase into the mass spectrometer through a chromatographic system where a carrier gas passes through a column packed with a solid-phase material.

Gastrointestinal transit: The rate of passage of the luminal contents of the gastrointestinal tract in the oral to anal direction, ordinarily measured with a nonabsorbable marker.

Gavage: Method of oral administration of a solution or suspension using a suitable stomach tube or feeding needle attached to a syringe. In toxicity studies, gavage is a common method of test material administration by the oral route.

Gene: Generally described as the smallest functional unit of an organism's genome.

Gene pool: The total genetic information contained in the reproductive cells of a species.

Genome: The total number of genes contained in the hereditary material of an organism; the chromosomal DNA information.

Genomics: The techniques available to identify the DNA sequence of the genome; field of study involving analysis of genetic material (i.e., DNA, RNA). Genomics can be studied at the cellular level in a population; automated methods, such as DNA microarray, have been developed for high-throughput analysis.

Genotoxic: Property of an agent making it capable of damaging or altering an organism's genetic composition.

Genotoxicity: Alteration of nucleic acids and associated components at subtoxic exposure levels, resulting in modified hereditary characteristics or DNA inactivation.

Genotype: The nucleotide composition of an organism's hereditary material; the full set of genes carried by an individual organism. Note that this term is more limited than the genome, as the genome also contains noncoding DNA and genes.

Geometric mean: The nth root of the product of n values.

Gestation/pregnancy: The interval in a pregnant animal from conception (fertilization) to the beginning of parturition.

GH: Growth hormone or somatotropin.

Globally Harmonized System (GHS): A UN initiative aiming to harmonize the classification, labeling, and SDS format of chemicals so as to promote international trade and the protection of health and environment.

Glomerular filtration rate: The volume of plasma separated from the vascular space across the renal glomerulus, expressed per unit time. The filtrate is further modified by the nephron tubule to become the final urine that is eliminated from the body. The rate at which plasma is filtered through the glomerular capillary bed into the tubular lumen is defined as the difference between the hydraulic and oncotic pressures across the glomerular capillary wall multiplied by an ultrafiltration coefficient and the surface area available for filtration.

Glycone: The activated form of glucose used in glucuronidation. The term is sometimes used for other activated forms of the endogenous compound used in xenobiotic conjugation reactions.

Glycosides: Chemicals of varied structure linked to a mono- or disaccharide by a β-glycosidic linkage; an acetal that yields sugar and a nonsugar on hydrolysis and is found more commonly in plants than in alkaloids. Toxicity varies from nontoxic to extremely toxic.

Glucuronidation: A biosynthetic conjugation reaction involving membrane-bound uridine diphosphoglucuronosyl transferases that catalyze the transfer of glucuronic acid, in the form of endogenous uridine diphosphoglucuronic acid, to a xenobiotic functional group (e.g., hydroxyl, carboxylic acid) to yield a product that has increased water solubility and properties that enhance its renal and biliary elimination.

Glutathione S-transferase (GST): A family of phase 2 (biosynthetic) enzymes that catalyze conjugation of the endogenous tripeptide glutathione with electrophilic atoms in xenobiotic substrates. The GSTs involved in xenobiotic metabolism are found in the cytosolic compartment of cells, whereas a membrane-bound form is involved in biosynthesis of endogenous compounds.

Gonadotropin-releasing hormone (GnRH): A neuropeptide that regulates the release of the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

Gonadotropins: Usually considered to be follicle-stimulating hormone (FSH) and luteinizing hormone (LH); collectively includes FSH and LH.

Good laboratory practices (GLPs): Regulations promulgated by the U.S. Food and Drug Administration (FDA) and the U.S. Environmental Protection Agency (EPA), as well as principles and procedures adopted by the Organization for Economic Cooperation and Development (OECD) and Japanese authorities, that describe record keeping and quality assurance procedures for laboratory records that will be the basis for data submission to national regulatory agencies.

Graded response: A response to a stimulus or a treatment that can be determined quantitatively on a continuous scale. In acute toxicity studies, body weight and feed consumption are examples of measurements of graded responses.

Gray (Gy): SI standard unit of absorbed dose; 1 Gy equals 1 joule of energy per kilogram of absorber or 100 rads.

GTT: Glucose tolerance test.

Haber's rule: The Haber relationship expresses the constancy of the product of exposure concentration and duration ($CT = k$). This relationship does not hold over more than small differences in exposure time. The hypothesis states that equal values of ($C \times T$) produce equal biological effects, where C is the concentration of a chemical and T is the duration of exposure.

Half-life: The time taken for the plasma (or tissue) concentration to change by 50%; half-life is a characteristic of first-order reactions and is independent of concentration and dose.

Half-life, biologic: Time it takes an organism to eliminate half of the radionuclide by biologic processes.

Half-life, effective: Time required for the activity of a radionuclide in a biologic system to be reduced to half its initial value as a consequence of both radioactive decay and biologic elimination.

Half-life, physical: The time necessary for a radionuclide to decay to half of its initial activity.

Haploid: A single set of eukaryotic chromosomes.

Hapten: Low molecular weight molecules that are not antigenic by themselves but are recognized as antigens when bound to larger molecules such as proteins.

Hazard: The inherent property of a single chemical or mixture to cause adverse effects if an organism is exposed to it; the potential for an adverse health or ecological effect. A hazard potential results only if an exposure occurs that leads to the possibility of an adverse effect being manifested.

Hazard analysis and critical control point (HACCP): A system designed to assess various stages of food processing critical in controlling microbial contamination and to propose and implement procedures aimed at minimizing the microbial burden in foods.

Hazard identification: A qualitative assessment of the types of adverse effects caused by a particular chemical, including (but not limited to) an evaluation of quality of the studies, identification of susceptible subpopulations, and assessing the relevance of humans of the effects observed in animals.

Hazardous substance: Any substance or mixture of substances that is toxic, corrosive to an irritant; has the potential to cause substantial personal injury as a result of handling or use.

Heinz body: Irreversibly denatured hemoglobin attached to the inner cell membrane of the red blood cell; caused by oxidizing agents.

***Heloderma*:** A genus of lizards comprised of two species of heavy-bodied lizards with short stout legs; the body is covered by tubercular scales.

Henry's law constant: The relationship between the solubility of a gas in a liquid to the pressure of the gas above the liquid at equilibrium, which describes the tendency of a chemical to escape from solution.

Hepatic first-pass effect: Virtually, all of the substances ingested into the circulatory system are transported directly to the liver where the substances can be metabolized via phase I and phase II reactions prior to their entry into the general circulatory system.

Hepatocytes: Liver cells.

Hepatotoxicity: Toxicity to the liver.

Heterologous blood perfusate: Blood used as perfusate that comes from another animal or a different species than the source of the organ being perfused.

Heterologous expression: Production of a recombinant protein in an artificial host system.

Heterologous expression systems: Systems that allow expression of a gene in a different organism.

Heterozygous: Two different alleles on a chromosome pair.

Hexagonal lobule: Classical morphological configuration of the functional unit of the liver as described by Kiernan in 1833.

High-end exposure (dose) estimate: A plausible estimate of individual exposure or dose for those persons at the upper end of an exposure or dose distribution, conceptually above the 90th percentile but not higher than the individual in the population who has the highest exposure or dose.

High-end risk descriptor: A plausible estimate of individual risk for those persons at the upper end of the risk distribution, conceptually above the 90th percentile but not higher than the individual in the population with the highest risks. Note that persons in the high end of the risk distribution have high risk due to high exposure, high susceptibility, or other reasons; therefore, persons in the high end of the exposure or dose distribution are not necessarily the same individuals as those in the high end of the risk distribution.

Hippocampus: Radiosensitive area of the brain involved in learning and memory functions.

Histopathology: The study of morphological changes in tissues at the light-microscopic levels.

Holozoic nutrition: Obtaining nutrients or nourishment through the ingestion of large complex organic materials or whole organisms.

Homozygous: Two similar alleles on a chromosome pair.

Hormesis: A U-shaped dose–response relationship in which adverse effects do not increase monotonically with dose but decrease initially as dose increases and then rise with higher doses. (An inverted U-shaped dose–response is observed with beneficial effects.) A dose–response relationship characterized by a low-dose stimulation and a high-dose inhibition. This type of biphasic dose–response has specific quantitative features of the magnitude and width of the stimulation and the relationship of the stimulation to the response threshold.

Host defense: The ability of an animal to protect itself against disease associated with exposure to infectious organisms, foreign tissues and chemicals, and neoplasia. Host defense may be either nonspecific or specific (immune) in nature.

Host resistance: The ability of an organism to defend immunologically against infection. Host resistance may be decreased in response to an immunosuppressive insult.

HTE: Human time equivalents.

Human health risk assessment: Process by which data on the metabolism and toxicity of a chemical are used to estimate the potential hazard to humans of exposure; often involves the extrapolation of data from laboratory animals (e.g., rats or mice) to humans; used by regulatory agencies to define safe levels of exposure of human populations to potentially toxic chemicals.

Humane endpoint: The earliest point in an animal experiment when reliable data can be collected to meet experimental goals before the animal experiences.

Humoral-mediated immunity (HMI): Specific immune responses that are mediated primarily by humoral factors (i.e., antibodies and complement). The induction of humoral immune responses generally requires the cooperation of cellular immune mechanisms.

Hybridization: The formation of a double strand from two different, more or less complementary, single nucleic acid strands.

Hydroponic: Referring to a nutrient solution capable of supporting plant growth without the support of inert material.

Hydrozoa: One of three classes of the phylum Cnidaria (referred to as Coelenterata in the past) in which the stomodaeum is absent and the mesoglea has few or no cellular elements and is usually metagenetic. Most species are marine.

Hyperplasia: A histopathologic finding characterized by an abnormal increase in the number of cells in a tissue or organ. Hyperplasia generally results from increased cell division but can result from decreased cell death.

Hypertrophy: A histopathologic finding characterized by an abnormal increase in the size of cells in a tissue or organ; for example, accumulation of fat vacuoles within a cell can increase its size.

Hypospadia: In males, a congenital malformation in which the urethra remains open on the undersurface of the penis. An extreme expression of this malformation results in cleft phallus, with a cleft running the entire length of the penis.

Ibotenic acid: A neurotoxic isoxazole that, when paired with muscimol, is largely responsible for the toxicities of *Amanita* species and certain other poisonous mushrooms.

IACUC: Institutional Animal Care and Use Committee.

ICH: International Conference on Harmonization.

IDDM: Insulin-dependent diabetes mellitus, type 1.

Idiosyncrasy: A specific (and usually unexplained) reaction of an individual to, for example, a chemical exposure to which most other individuals do not react at all (e.g., some people react to their very first aspirin with a potentially fatal shock). General allergic reactions do not fall into this category.

Immune reserve: The concept that the immune response exhibits multiple redundancies capable of modulating acute reductions in certain immune functions. This reserve would theoretically prevent a severe reduction in host resistance following temporary immunosuppression of selected parameters (e.g., NK cell function).

Immunoassay: An assay that utilizes specific antibodies as reagents. Examples include enzyme-linked immunosorbent assays (ELISAs) and radioimmunoassays (RIAs).

Immunochemistry: The use of antibodies in analytical or preparative procedures.

Immunologic contact urticaria (ICU): Contact urticaria is an immediate-type reaction, on an immunologic basis, such as in latex contact.

Immunostimulation: Enhancement of immune function above an established baseline (control) response. Immunostimulation may be beneficial (e.g., therapeutics designed to restore a depressed immune response) or detrimental (e.g., the induction of allergy/hypersensitivity or autoimmunity).

Immunosuppression: Depression of immune function below an established baseline (control) response. Immunosuppression may result from inadvertent exposure to immunosuppressive agents, deliberate (therapeutic) immunosuppression, or exposure to certain infectious agents. An important consideration in immunotoxicology is determining the degree or nature of immunosuppression necessary to alter host defense. Immunosuppression can be said to result in a state of immunodeficiency.

Immunotoxicity: The condition in which a drug, chemical, or physical agent alters the structure or function of the immune system.

Immunotoxicology: The discipline of synergistically applying cardinal principles of both immunology and toxicology to study the ability of certain materials to alter the normal immune response.

Impaction: A particle deposition process related to particle inertia whereby particles contact airway surfaces by their inability to follow the air stream around directional changes from airway bends or bifurcations.

Implantation: The embedding of the early embryo in the lining of the uterus.

Imposex: A condition caused by low concentrations of organotin compounds (e.g., tributyltins and triphenyltins) characterized by the superimposing of male sex organs on otherwise normal dioecious female gastropods. The resulting pseudohermaphrodites are incapable of reproduction.

Intravascular hemolysis: Lysis of red blood cells within circulation; if severe enough, release of hemoglobin into the plasma may be recognized as hemoglobinemia and free hemoglobin filtered into urine may be recognized as hemoglobinuria.

IO: Institutional Official for the animal care and use program.

***In silico*:** An expression used to mean performed on computer or via computer simulation.

In situ perfusion: Vascularly isolated and perfused organs are left in the animal body with the neighboring tissues.

In vitro hemolysis: Rupture or lysis of red blood cells during blood collection or handling causing the release of intracellular substances (e.g., hemoglobin, enzymes, electrolytes) into serum or plasma. If severe enough, it may be responsible for artifactual test results.

In vivo nuclear magnetic resonance (NMR) spectroscopy: A technique of value for measuring alterations in specific P-31 species within cells in real time using a surface coil and large-bore, high-resolution NMR magnets.

Incidence: The number of new cases of a particular disease in a defined population during a specified period of time. The term *incidence* is sometimes used

synonymously with *incidence rate*. Note that, in the medical literature, *prevalence* and *incidence* are often used incorrectly as equivalent terms.

Induction: As used with respect to xenobiotic metabolisms, induction refers to the process where exposure of an organism to a xenobiotic results in increased activity of specific biotransformation enzymes. Generally, but not always, induction results in more rapid metabolism of the inducing agent. Induction, as used in this context, does not require de novo protein synthesis but may result from other mechanisms.

Inflammation: A nonspecific host defense mechanism. It is characterized primarily by the infiltrating of leukocytes into the peripheral tissue, followed by release of various molecules that elicit nonspecific physiological defense mechanisms.

Inhalable: A particle size characteristic denoting that the substance can enter the respiratory tract; however, particles may not be sufficiently small to enter beyond the nose and into the airways and pulmonary regions. Contrast with *respirable*.

Inhalation: The breathing in of a substance in the air (gas, vapor, particulate, dust, fume, or mist).

Inhibin: A glycoprotein produced by Sertoli cells and by the pituitary that acts as a negative regulator of follicle-stimulating hormone (FSH) secretion.

Initiated Cell: A normal body (stem?) cell that has undergone the first transformation step in the process of cancer development to an intermediate state but that is not malignant.

Innate immunity: Host defense mechanism that does not require prior exposure to an antigen; various effector mechanisms have been described, including cellular cytotoxicity mediated by macrophages or NK cells, complement, and activity gamma delta T cells.

Insecta: A very large class of invertebrate animals representing more than 75% of known animal species. They have three main body parts: head, thorax, and abdomen.

Instillation: Slow introduction of a fluid (for a fluid-containing particulate) directly into the trachea of an experimental animal; this is a surrogate method for the introduction of fluid or particulate into the lungs following inhalation.

Insufflation: Introduction of particulate (without fluid) directly into the trachea (or bronchioles) of an experimental animal. This is a surrogate method for the introduction of material into the lungs following inhalation.

Intake: The process by which a substance crosses the outer boundary of an organism without passing an absorption barrier (e.g., through ingestion or inhalation; see *Potential dose*).

Interception: A particle deposition process related to a particle trajectory and the physical proximity to airway surfaces, resulting in particle contact and deposition. Interception is a particularly important deposition process for inhaled fibers.

Internal dose: The amount of a substance penetrating across the absorption barriers (the exchange boundaries of an organism) via either physical or biological processes. This term is synonymous with *Absorbed Dose*.

International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use: An initiative intended to establish similar criteria to support the worldwide registration of drugs. Representatives from regulatory agencies and pharmaceutical companies from the United States, Europe, and Japan have been the primary participants.

International Union of Toxicology (IUTOX): An international organization representing toxicology societies worldwide.

Intestinal first-pass effect: Evidence suggests that not only do the small intestines provide for absorption of various substances, but it can also play a significant role in phase I and phase II metabolism reactions of certain substances prior to their absorption into the circulatory system.

Intralaboratory repeatability: The closeness of agreement between test results obtained within a single laboratory when the procedure is performed on the same substance under identical conditions within a given time period.

Intralaboratory reproducibility: The first stage of validation; a determination of whether qualified people within the same laboratory can successfully replicate results using a specific test protocol at different times.

Intravascular hemolysis: Rupture or lysis of red blood cells within the vascular system causing release of intracellular substances (e.g., hemoglobin) into the plasma. If severe enough, it may be recognized by hemoglobinema and/or hemoglobinuria.

Intron: Noncoding spacer DNA in a eukaryotic gene.

Intubation: Placement of a tube into a hollow organ. Intubation is used to place various materials into animals for toxicology studies. If the organ is in the stomach, the process is generally referred to as *gavage*.

Inulin: A polysaccharide (molecular weight, ~5000) that is not metabolized by mammalian cells and is too large to enter cells. The clearance of inulin is used to measure glomerular filtration rate. Inulin is used in vitro as an indicator of extracellular space.

IOCA: *In ovo* carcinogenicity assay.

Ionization: The formation of ions from neutral molecules. This is accomplished in mass spectrometry by a variety of methods, including bombardment with electrons, gas-phase chemical reactions, and ion desorption methods.

Infrared (IR) fingerprint region: This frequency region of the IR spectrum ranges from 910 to 1430 cm^{-1} and contains bending and stretching absorptions of characteristic groupings in an organic molecule. The region is abundant in absorption bands, and their frequencies and intensities are unique for a specific compound; hence, the absorption pattern in this region of the IR spectrum is utilized as a fingerprint for the recognition of an unknown molecule by comparison with the fingerprint frequencies of an authentic standard. It is important to note that polymorphic forms of the same compound may show significant differences in the fingerprint region; therefore, comparisons should be made in the solution in the same solvent. If solid-state spectra are utilized, the unknown and authentic standard should be crystallized from the same solvent under similar conditions.

Iris: The structure of the eye that is anatomically located posterior to the cornea. The iris forms the pupil of the eye and functions in regulating the amount of light that reaches the retina. In the Draize eye test, effects on the iris represent a maximum of 10 out of 110 total points.

IRMA: Immunoradiometric assay.

Irradiation: Exposure to radiation.

Irritant dermatitis: Chemically induced, nonimmunologic contact dermatitis; a complex syndrome of many types.

Ischemia: Local anemia due to mechanical obstruction (mainly arterial narrowing) of the blood supply.

Islet of langerhans: Specialized cells (beta cells) in the pancreas that secrete insulin.

Isoenzymes: Enzymatically active proteins that catalyze the same reactions and occur in the same species but differ in their physicochemical properties (also, *isozymes* or *isoforms*).

Isolated epithelial cells: In vitro preparation of single tubular epithelial cells, typically isolated by enzymatic (e.g., collagenase) digestion. Cells from specific nephron regions can be enriched by various separation methods; useful for short-term (up to 4 h) metabolic or cellular function studies.

Isolated perfused kidney: In vitro preparation involving the whole kidney. A cannula is inserted into the renal artery, and fluid is pumped into the kidney. The technique can be used to assess renal physiology and determine drug clearance. A chief advantage is that the model maintains an intact organ structure but does not include extrarenal tissues or factors; viability is maintained for up to 2–4 h.

Isolated perfused organ: Vascularly perfused organ is physically removed from the donor animal and maintained in an artificial chamber usually kept at physiological temperature.

Isolated perfused tubules: Intact tubules from specific nephron cell types are usually isolated by mechanical means and are perfused with micropipettes; useful for short-term (up to 2 h) metabolic, transport, and acute toxicity studies.

Isolated perfused ventilated lung: Vascularly perfused isolated lungs are also ventilated using mechanical devices.

Isolated tubular fragments: In vitro preparation of fragments of nephron segments, typically isolated by enzymatic (e.g., collagenase) digestion. The segments from specific cell types can be enriched by various separation methods; useful for short-term (up to 4 h) metabolic or cellular function studies.

ITO cells: Fat-storing cells found in the liver; also called *lipocytes* or *stellate cells*.

Juxtaglomerular apparatus: A specialized area of the glomerulus where the distal tubule from the nephron has contact with the arterioles entering and leaving the glomerulus; one factor in the control of renal blood flow.

Knockout animals: Genetically engineered animals in which one or more genes, usually present and active in the normal animal, are absent or inactive.

Kriging: A statistical interpolation method that selects the best linear unbiased estimate of the parameter in question. Often used as geostatistical method of spatial statistics for predicting values at unobserved locations based on data from the surrounding area. Information on the fate and transport of chemicals within the area lacking data can be incorporated into Kriged estimates.

Lactate dehydrogenase leakage: Assay for cellular necrosis that measures the fraction of cytosolic enzyme lactate dehydrogenase (LDH) released from cells due to membrane premeabilization; assays are performed by measuring NADH oxidation spectrophotometrically.

Lactation: The secretion of milk from the mammary glands and the period of time that a mother lactates to feed her young.

Large intestine: The region of the gastrointestinal tract from the ileum to the anus that consists of the cecum, the colon, and the rectum.

Laser capture microdissection: A potentially useful technique for excision of tissue area of interest (e.g., a tumor) via laser dissection from surrounding normal tissue so differences in gene or protein expression patterns may be compared by 2D gel electrophoresis patterns.

Latin hypercube sampling (LHS): A variant of the Monte Carlo sampling method that ensures selection of equal numbers of values from all segments of the distribution. LHS divides the distribution into regions of equal sampling coverage; hence, the values obtained will be forced to cover the entire distribution. It is more efficient than simple random sampling, as it requires fewer iterations to generate the distribution sufficiently.

LCB: Limited carcinogenicity bioassay.

LC_{50}: See *Median lethal* dose.

LD_{50}: Lethal dose of radiation or chemical agent that has been determined to cause death in 50% of a defined population; expressed in terms of weight of test substance per unit of test animal (mg/kg). See *Median lethal dose*.

$LD_{50/30}$: Median lethal dose (MLD or LD_{50}) required to kill 50% of the population of organisms within 30 days.

Leukopenia: Any situation in which the total number of leukocytes in the circulation is less than normal.

Leydig cells: Cells located in the interstitial compartment of the testes between the seminiferous tubules that synthesize testosterone; androgen-secreting cells present in the interstitium of the testes.

LH: Luteinizing hormone.

Limit of quantification (LOQ): The concentration of analyte in a specific matrix for which the probability of producing analytical values above the method detection limit is 99%.

Limit study: A study in which a single, maximal dose level of test material is administered to the test animals. Limit studies are conducted when administration of test material at higher dose levels is not required either because exposure at higher levels is not physically possible or because the test material has been shown to be of extremely low toxicity.

Linear energy transfer (LET): The amount of energy transferred by a unit dose of radiation per unit pathway traveled through matter (keV/micron of path); varies with the type of radiation. Alpha particles are high LET radiation with 10–100 s of keV/micron of path, whereas x-rays and gamma rays are low LET radiations (tenths to 10 keV/micron).

Linear extrapolation: The process of estimating a value at conditions not directly measurable using a linear relationship between the biological effect and the dose or duration of exposure. (Technically, when a measure of the background effect is available, an *interpolation* is being performed.)

Linear kinetics: With linear kinetics, there is a linear relationship between dose and plasma concentrations and body loads. Linear kinetics are characteristic of first-order reactions because the rates of reactions increase as the concentration or body load increases; therefore, parameters such as bioavailability, clearance, apparent volume of distribution, and half-life are independent of dose (see definitions in text).

Linear model: A model in which the change in a biological effect is proportional to the change in dose or duration of exposure.

Lipid peroxidation: The chain reaction formation of the mediators of lipid degradation by ionizing radiation.

Lipophilicity: The tendency of a chemical to partition into a lipid medium or a fat solvent, such as hexane, from an aqueous medium.

Liquid chromatography–mass spectrometry: A method for introducing analytes dissolved in solution into the mass spectrometer through a chromatographic system in which a liquid mobile phase passes through a column packed with a solid-phase material.

Liver acinus: Functional unit of hepatocytes as defined by Rappaport; consists of a small parenchymal mass arranged around an axis consisting of a terminal portal venule, a hepatic arteriole, a bile ductile, lymph vessels, and nerves.

LOAEL: Lowest observed-adverse-effect level.

Low-dose extrapolation model: A model that uses information on observed dose–response relationships combined with mechanistic understanding to predict the dose–response relationship below the range of observable data.

Lymph: A clear, transparent, sometimes faintly yellow and slightly opalescent fluid that is collected from the tissues throughout the body. It flows into the lymphatic vessels and is eventually added to the venous blood circulation.

Lymphoproliferation: Proliferation of lymphocytes in response to stimulation with cellular activators, including antigens or mitogens. Because the proliferation of lymphocytes is one of the initial consequences of cellular activation, lymphoproliferation is often used as a nonspecific in vitro measure of immunoresponsiveness. This assay is sometimes referred to as the *blastogenesis assay.*

Mab: Monoclonal antibody.

Macrocirculation: Comprised of the heart, great vessels (both arterial and venous), and larger arteries and veins.

Malformation: Structural defect due to abnormal development.

Magic angle spinning: A nuclear magnetic resonance (NMR)–based technique enabling the analysis of intact tissue. The term *magic angle* is derived from the fact that, when samples are spun rapidly at 54.7° relative to the applied magnetic field (the so-called magic angle), line-broadening effects that would ordinarily obfuscate a proton spectra of a solid sample can be reduced.

Major histocompatibility complex (MHC): A complex of genes coding for tissue compatibility markers. Two major classes are recognized: class I (present on all nucleated cells) and class II (present on B cell, T cells, and macrophages). MHC molecules appear to direct the course of immune reactivity and are presented in association with antigen by antigen-presenting cells. The human equivalent is termed *human leukocyte antigen* (HLA).

Malabsorption: Impairment in the uptake of ingested substances from the gastrointestinal lumen into the bloodstream because of defects in luminal digestion, mucosal transport, or gastrointestinal transit.

Margin of safety (MOS): The difference, normally expressed as fold difference, between the dose (or exposure level) that results in toxicity and the dose that results in the desired pharmacological activity.

Mass cell: A polymorphonuclear, granule-containing cell with a major role in hypersensitivity reactions.

Mass median aerodynamic diameter (MMAD): Standard method of characterizing the size distribution of a particulate atmosphere. It represents the size when 50% of the particles are larger (or smaller) than the stated size; aerodynamic diameter that divides the particles of a sample in half, based on their weight.

Mass spectrometry: An analytical technique that determines the mass of ionized molecules and their fragments and adducts.

Mass spectroscopy (MS): An analytical technique where charged particles (ions) are created from sample molecules that are then analyzed to provide information about the molecular weight of an ion and its chemical structure.

Mating performance: The ratio of mated (inseminated) animals to the number cohabited, generally expressed mathematically as the ratio of the number of female animals inseminated divided by the number cohabited with a cohort male.

Maximally exposed individual (MEI): The single individual with the highest exposure in a given population (also, most exposed individual). This term has historically been defined in various ways, including as defined here and also synonymously with worst-case or bounding estimate. Assessors are cautioned to look for contextual definitions when encountering this term in the literature.

Maximum tolerated dose (MTD): The dose that causes no more than a 10% reduction in body weight and does not produce mortality, clinical signs of toxicity, or pathologic lesions that would be predicted to shorten the natural life span of an experimental animal for any reason other than the induction of neoplasms.

MCL: Mononuclear cell leukemia.

Mean: The average value. In a normally distributed sample, this has the same value as the median (the middle value) and the mode (the most frequent value).

Measure of association: A term that represents the strength of association between variables. The relative risk, odds ratio, and standardized mortality ratio (SMR) are measures of association commonly used in epidemiology.

Median effective dose: A statistically derived single dose of a substance that can be expected to produce a particular effect in 50% of the study population (ED_{50}). The ED_{50} is expressed in terms of weight of test substance per unit weight of test animal (mg/kg).

Median lethal dose: A statistically derived single dose of a substance that can be expected to cause death in 50% of the study population (LD_{50}; LC_{50}). The LD_{50} is expressed in terms of weight of test substance per unit weight of test animal (mg/kg). The LC_{50} is expressed in terms of weight of test substance per unit volume (mg/L).

Median value: The value in a measurement dataset such that half of the measured values are greater and half are less.

Mesocosm: The replication of a subpart of a functioning ecosystem to study food web effects of toxic substances. A mesocosm may be replicate small field enclosures or ponds, or may be developed in artificial streams, tanks, or terraria in the laboratory; they typically include vertebrates as part of the food web.

Mee's lines: Horizontal white lines on the fingernails that occur after exposure to arsenic. The lines appear after the exposed nail bed grows to the exterior.

Mercapturic acid: *N*-acetylated cysteine *S*-conjugates of a xenobiotic derived from further metabolism of glutathione–xenobiotic conjugates. Most mercapturic acids are relatively inert and get excreted in the urine, though some may undergo bioactivation in the kidney, resulting in toxicity.

Messenger ribonucleic acid (mRNA): The substance carrying genetic information from the DNA to the protein production site.

Metabolic activation: The process by which relatively stable substrates are converted to highly reactive, generally electrophilic products with the capability of producing damage to critical cellular macromolecules. The term is occasionally used to refer to the metabolism of therapeutically inactive prodrugs to the active form of the drug.

Metabolome: The set of all low molecular weight compounds synthesized by an organism; the total quantitative collection of small molecular weight biochemical metabolites present in a cell, tissue, or organism that are involved in growth, energetics, maintenance, pathology, and other biochemical functions.

Metabolomics: The study of the dynamic expression, production, relative concentration, and variation of small molecular weight, endogenous biochemicals and metabolites in living systems. Characteristic changes in these discrete biomarkers before and after exposure to xenobiotics and in pathological processes may be useful for detecting and understanding toxicological mechanisms, histopathology, and environmental stressors.

Metabonome: The constituent metabolites in a biological sample.

Metabonomics: The techniques available to identify the presence (and concentrations) of metabolites in a biological sample.

Metal fume fever: An acute condition of short duration caused by exposure to fresh fumes of zinc and other metals. The condition is characterized by fever and chills, occurring 4–12 h after exposure. Recovery usually is complete within 1 day.

Metalloid: Any element with both metal and nonmetal characteristics (e.g., arsenic, boron, tellurium).

Metallothionein: Any inducible low molecular weight, cytosolic protein with a high cysteine content (approximately 30%) and characteristically deficient in aromatic amino acids and histidine. The presence of numerous cysteinyl thiol groups permits high-affinity binding of several metals (e.g., cadmium, lead, mercury, or zinc).

Metals: A grouping of elements generally characterized by opacity, ductility, luster, being electropositive with a tendency to lose electrons, and having the property of conducting heat and electricity. Heavy metals may be further defined as any element having a density greater than 5 g/cm^3, and those of toxicological significance preferentially bind to ligands containing sulfur or nitrogen (arsenic, cadmium, chromium, lead, and mercury).

Methemoglobin: A form of hemoglobin in which the ferrous ion (Fe^{2+}) of hemoglobin has been oxidized to the ferric state (Fe^{3+}); methemoglobin is unable to carry oxygen.

Methylation: A biosynthetic conjugation reaction involving methyltransferases that catalyze the transfer of a methyl group primarily from *S*-adenosyl methionine to oxygen, nitrogen, or sulfur atoms of xenobiotics. Unlike other conjugation reactions, methylation reactions do not enhance water solubility.

Micelles: These are discrete aggregates of 20–50 molecules of bile salts that mediate the absorption of fatty acids longer than 12 carbon molecules across the lumen of the small intestine. The water-soluble part of the molecules faces outward while the nonpolar nuclei face inward. Micelles are able to dissolve the aqueous component of the chyme allowing fatty acids to accumulate in the center of the micelle. The micelles are subsequently transported to the lumen, where the fatty acids are deposited and absorbed, and the micelles are then recirculated in the chyme to repeat the process.

Microarray: A series of molecular probes, immobilized on a solid substrate, such as nylon or glass, which can be used to detect the presence of specific biomolecules, such as RNA, DNA, or protein, in a biological sample.

Microcirculation: The business end of the circulation, where delivery of oxygen and nutrients and the removal of carbon dioxide and metabolites take place.

Microcosm: A small model or piece of an ecosystem contained in a test chamber and used to study the effect of contaminants on a biotic community in a controlled environment.

Microenvironment method: A method used in predictive exposure assessments to estimate exposures by sequentially assessing exposure for a series of areas (microenvironments) that can be approximated by constant or well-characterized concentrations of a chemical or other agent.

Microenvironments: Well-defined surroundings, such as a home, office, automobile, kitchen, or store, that can be treated as homogeneous (or well characterized) in the concentrations of a chemical or other agent.

Microexposure event (MEE) analysis: A method accessing risk based on the aggregate sum of a receptor's contact with a contaminated medium. MEE analysis simulates lifetime exposure as the sum of many short-term or microexposures. MEE approaches can be used to explore uncertainty associated with the model time step in probabilistic risk assessment (PRA)—for example, the use of a single value to represent a long-term average phenomenon, seasonal patterns in exposures, or intraindividual variability.

Microisolation cage: An animal cage usually constructed of plastic that completely surrounds the animals contained therein such that air entering and exiting the cage must pass through an integrated filter designed to stop the passage of unwanted microorganisms or fomites. Most commonly, such caging is maintained using sterile techniques to prevent the introduction of unwanted microorganisms.

Microperfusion: Technique to determine the function of a specific nephron segment. The segment is isolated from the glomerular filtrate between a wax and oil block, and the segment is then perfused in situ with a solution of controlled composition through a micropipette; the solution is then quantitatively collected from the same nephron segment.

Micropuncture: Specialized technique used to analyze the effects of drugs or chemicals on single nephron function in the intact kidney. It involves the insertion of a micropipette into the lumen of a specific nephron segment of interest; experiments are performed under microscopic control.

Microsomes: (1) The operational definition of microsomes is the 105,000 *g* pellet produced from a tissue homogenate after removal of nuclei, mitochrondria, and cell debris by centrifugation at 9000 *g*. Microsomes are the remnants of the endoplasmic reticulum after cellular disruption. The outer surface of microsomal vesicles represents the cytosolic side of the endoplasmic reticulum. (2) Small vesicles of endoplasmic reticulum containing numerous xenobiotic metabolizing enzymes formed during mechanical disruption of cells or tissues. Microsomes can be isolated from crude tissue homogenates by differential centrifugation and are a common in vitro model for studying xenobiotic metabolism.

Midzonal cells: Collection of hepatic cells situated between the periportal area and the centrilobular area of the lobule.

Milk sickness: Potentially fatal neurologic disease resulting from the consumption of unpasteurized milk containing the neurotoxin tremetol, derived from animals grazing on toxic plants, white snakeroot, or rayless goldenrod.

Misclassification: A type of bias in which an individual or attribute is assigned a value that is incorrect. The misclassification may be *nondifferential* (the same in all study groups) or *differential* (not equivalent across groups). Each type of misclassification may impact the results, the former usually underestimating the true measure of association and the latter often overestimating it.

Mists: Similar to fogs, a suspension of liquid particles in gas. These can be formed from condensation of vapors or from atomization of liquids (e.g., sprayers). Mists are characterized by particles larger than about 40 μm; fogs are categorized by their smaller size.

Mitochondrial membrane permeability transition (MPT): An increase in the permeability of the mitochondrial membrane due to a loss of membrane potential resulting in the release of a number of proteins such as cytochrome c and apoptosis-inducing factor (AIF).

Mitogen: Molecules capable of inducing cellular activation; may include sugars or peptides. The ability of a cell to respond to stimulation with mitogen (generally assessed by cellular proliferation) is believed to give an indication of the cell's immune responsiveness.

Mitogen-activated protein (MAP) kinase pathway: The MAP kinase pathway is a key cellular signaling pathway resulting in transcriptional activation and mitogenic proliferation. It consists of several enzymatic activation steps and can be stimulated by a number of agents, including cytokines and radiation exposure. It is believed to account for the accelerated repopulation of cells occurring after radiation exposure, which can affect the success of radiation therapy.

Mitogenesis: The induction of mitosis or cell transformation. The stimulation of cell proliferation, a natural recovery process in response to severe toxicologic insult that does not normally occur at reasonable multiples of human exposure levels, can account for the carcinogenic response toward nongenotoxic compounds that may not be meaningful in the clinical setting.

Mixed-function oxidase: A descriptive term for the cytochrome P450 enzyme system, reflecting the differing fates of the oxygen atoms derived from molecular oxygen consumed in the reaction. One oxygen atom is incorporated into the xenobiotic substrate and the other is reduced to water.

Mixed lymphocyte response/reaction (MLR): An in vitro assay that measures the ability of lymphocytes to proliferate in response to exposure to allogeneic cells. The proliferation represents the initial stage in acquisition of CTL function; the assay thus serves as a measure of cell-mediated immune function. Sometimes referred to as *mixed lymphocyte culture* (MLC).

MOE: Margin of exposure.

Mole viper: A viper of the genus *Atractaspis*.

Mollusk: Any member of the phylum Mollusca that includes cones, snails, mussels, clams, and oysters, as well as octopi and squid.

Monocyte/macrophage: Bone marrow–derived mononuclear cells that serve a wide variety of host defense needs, acting as both nonspecific phagocytic cells and as regulators of other immune and nonimmune host resistance mechanisms. A variety of forms exist, including monocytes (found in the blood), macrophages (found in peripheral tissue), Kupffer cells (liver), Langerhans cells (skin), microglia (brain), veiled cells (lymph), and others.

Monte Carlo technique: A repeated random sampling from the distribution of values for each of the parameters in a generic (exposure or dose) equation to derive an estimate of the distribution of (exposures or doses in) the population.

Moribund status: The condition of an animal as a result of the toxic properties of a test substance where death is anticipated. For toxicity determinations, animals killed for humane reasons are considered in the same way as animals that die.

Morphology: Pertaining to the form or structure of a cell, organ, or whole animal.

Motor activity: Spontaneous locomotion in a specified enclosure designed to provide quantitative indices of movement.

MOU: Memorandum of understanding.

MRA: Mutual recognition agreement.

MSH: Melanocyte-stimulating hormone.

MTD: Maximum tolerated dose.

Mucociliary transport: Mucous lining of the nasal passage extending from the respiratory epithelium to the pharynx. The purpose of mucociliary transport is to move waste solids up from the deeper lung to the pharyngeal area to be swallowed. Particle matter entrained in a mucous layer over ciliated airways is moved along to the nasopharynx for removal from the respiratory tract by expectoration or swallowing.

Mucosa-associated lymphoid tissue (MALT): Lymphoid tissue associated with the mucosal layer in various tissues, believed to act as a primary defense at secretory surfaces. It acts, to a limited extent, independently of the systemic response. Various tissues comprise this system, including gut-associated (GALT), nasal-associated (NALT), and bronchus-associated (BALT) lymphoid tissues.

Mullerian duct: Involves a protein secreted by the fetal testes that causes the potential female Mullerian tract to regress.

Multistage model of carcinogenesis: A model that describes the carcinogenesis process as a series of mutations or mutation-like events over time that result in a malignant growth.

Murine: Of the mouse.

Muscarine: Extremely toxic alkaloid that causes muscarinism following ingestion; an extremely toxic parasynthetic poison.

Muscimol: An extremely toxic central nervous system (CNS) depressant and gamma-aminobutyric acid (GABA) agonist that is isolated from the mushroom *Amanita muscaria* and causes visual damage, mental confusion, spatiotemporal dislocation, and memory loss in humans.

Mutagenesis: The production of genetic alterations by exposure to chemicals or radiation. This can result in irreparable DNA damage and subsequent tumor development.

Mutation: A stable change in the nucleotide sequence of a gene.

Mycotoxins: A group of more than a hundred toxins produced by various fungal organisms in food and feed commodities.

Myocardium: The middle layer of the heart, consisting of cardiac muscle.

NADPH-P450 reductase: A flavoprotein responsible for mediating the reduction of cytochrome P450.

Nanoparticles: Particles, either of man-made or biological origin, with at least one dimension less than 100 nm; also referred to as *Ultrafine Particles*, which have all dimensions in the nanometer range.

Nasopharyngeal: Region of the respiratory tract serving as the entry port for inspired air (including the turbinates, epiglottis, glottis, pharynx, and larynx).

National Institute for Occupational Safety and Health (NIOSH): U.S. Federal Agency created by the Occupational Safety and Health Act of 1970. NIOSH, a part of the Centers for Disease Control and Prevention, is responsible for conducting research and making recommendations for the prevention of work-related injury and illness.

Natural immunity: Host defense mechanisms that do not require prior exposure to an antigen. Various effector mechanisms have been described, including cellular cytotoxicity mediated by macrophages or NK cells, complement, and activity of gamma delta T cells.

Natural killer (NK) cells: A population of lymphocytes distinct from T and B lymphocytes; also referred to as *large granular lymphocytes* (LGL). NK cells exhibit cytotoxicity against virally infected cells and certain tumor cells. They are notable in that they do not require prior exposure to antigen to express cytotoxicity toward their targets. Assessment of NK activity provides a measurement of nonspecific host resistance.

Necropsy: Postmortem examination of a nonhuman body. A similar term, *autopsy*, generally is used to refer to postmortem examination of a human body. Necropsies are conducted in toxicology studies following spontaneous death or euthanasia of animals to detect potential pathologic effects of test material administration.

Necrosis: Form of cell death involving numerous cells; generally occurs at higher doses of toxicants. Necrosis in vivo often involves infiltration of macrophages and other inflammatory cells.

Neoantigen: A new antigen that appears on cells during malignant transformation, viral infection, or other process by which a naturally occurring antigen is modified.

Neoplasia: The pathologic process that results in the formation and growth of abnormal tissue (neoplasm). Neoplasms usually form a distinct mass of tissue (tumor) that may be benign or malignant; the growth of the tumor exceeds and is uncoordinated with that of normal tissue and persists in the same excessive manner after cessation of the stimulus that evoked the change.

Nephrotoxicity: Toxicity to the kidney observed in vivo.

Neurohypophysis: The posterior lobe of the pituitary.

Neuropsychology: A clinical discipline that specializes in the application of psychological tests to ascertain aberrations of neurobehavioral function.

New biological entity: A complex high molecular weight material that cannot be fully characterized by standard chemical analysis and which may require immunologic, biochemical, or bioassay techniques to measure the quantity present and to assess activity.

Nictitating membrane: An important ocular structure in many species of animals (but not humans or primates) that aids in protecting the cornea and conjunctiva when the eyeball is retracted; also called the *third eyelid*.

NIDDM: Non-insulin-dependent diabetes mellitus, type 2.

NME: New molecular (chemical) entity.

No-observed-adverse-effect level (NOAEL): A number applied to the highest dose that did not elicit an adverse effect in a properly designed and executed toxicological study.

Nongenotoxic carcinogen: A substance that causes cancer, not by primarily damaging the genetic material but by mechanisms that stimulate cell proliferation, thus increasing the chances for natural mutations to be reproduced, or by the selection of specific cell populations that may derange in a later stage.

Nonimmunologic contact urticaria (NICU): Contact urticaria is an immediate-type reaction, on a nonimmunologic basis.

Nonlinear kinetics: With nonlinear kinetics, a linear relationship does not exist between dose and plasma concentrations or body loads. Nonlinear kinetics is typically due to saturation of absorption, distribution, or elimination.

Nonparametric statistical methods: Methods that do not assume functional form with identifiable parameters for the statistical distribution of interest (distribution-free methods).

Nonregenerative anemia: Anemia characterized by decreased production and delivery into circulation of newly formed red blood cells (reticulocytes).

Normal equivalent deviate (NED): Units of deviation from the mean; probability of response on a transformed scale (e.g., 50% response equals a NED of 0).

Nose-only exposure: Experimental mode of inhalation exposure in which only the nose of the animal is placed in contact with the test atmosphere (variant is head-only).

No-threshold dose–response relationship: A dose–response relationship that assumes that any dose carries some probability of an effect.

NTEL: Nontumorigenic effect level.

Nuclear magnetic resonance (NMR): A technique to identify atoms in a sample by measuring the signal given off by relaxation of, for example, protons previously aligned in a strong magnetic field.

Nuclear magnetic resonance (NMR) spectroscopy: An analytical technique that is used to study the structure of molecules. NMR spectroscopy takes advantage of the behavior of atomic nuclei in the presence of a strong magnetic field. When samples are placed in a magnetic field and irradiated with energy in the radiofrequency (RF) range, they absorb RF energy. The exact frequency absorbed by an atomic nucleus in the sample molecule differs depending on the environment of the nucleus (its position within the molecule). A plot of intensity of RF absorption vs. frequency is called an *NMR spectrum* and is characteristic of the structure of the sample molecule.

Nucleotide: In this case, the basic building block of DNA and RNA: a base–sugar–phosphate complex. Three nucleotides form a codon that codes for one amino acid.

Null allele: An inactive form of a gene.

Occupational exposure limit (OEL): Broadly defined as a limit on magnitude and duration of an individual's exposure to an airborne chemical.

Octanol–water partition coefficient (K_{ow}, P): The ratio of the concentrations of a chemical in the water phase and the *n*-octanol phase after the chemical is equilibrated between equal volumes of the two solvents.

Odds ratio: The ratio of two odds. In case-control studies, it is an *exposure odds ratio* (i.e., the odds of exposure among the cases as compared to the odds of that same exposure among the controls). Although less seldom used, an odds ratio is sometimes calculated for a cohort study, but it is a *disease odds ratio* (i.e., the odds of disease among the exposed vs. the odds of that same disease among the unexposed).

Oligonucleotide: A chain (usually of less than 100 units) of individual nucleotide residues used as a molecular probe to detect or quantify the presence of specific DNA or RNA molecules.

Oocyte: Female germ cell in the ovary; precursor of ovum.

Open access publishing: Making publication available at no charge in public repositories, typically web based.

Open microscopic evaluation: The practice of conducting the initial histopathological evaluation with the pathologists having access to all available information about the animals from which the tissues were derived.

Opportunistic organism: Refers to an organism, most commonly a microorganism, that under a particular set of biological conditions can cause disease when normally it coexists with its host without producing disease.

Organelle: A subcellular structure with a specialized function within the cell.

Organic anion transport: Movement of negatively charged compounds across renal cellular plasma membrane; involves both reabsorption (lumen to plasma) or secretion (plasma to lumen) and is mediated by specific carrier proteins.

Organic cation transport: Movement of positively charged compounds across renal cellular membrane; involves both reabsorption (lumen to plasma) and secretion (plasma to lumen) mediated by specific carrier proteins.

Organogenesis: Formation and development of organs.

Orthologs: Genes that are believed to have evolved from a common ancestral gene. Orthologs may have a high degree of sequence homology, but their protein products do not necessarily have a high degree of functional homology.

OSHA: U.S. federal agency created by the Occupational Safety and Health Act (OSHA) of 1970. OSHA, a part of the Department of Labor, assures safe and healthful working conditions by setting and enforcing standards and by providing training, outreach, education, and assistance.

Osmium tetroxide (OsO_4): A toxic metallic cellular stain used in transmission electron microscopy.

Osteichthyes: The class of vertebrate animals that contains venomous fishy bones, characterized by the presence of an endoskeleton chiefly of bone. They are the dominant fishes; they invade all types of waters.

Osteomalacia: Inadequate or delayed mineralization of bone, resulting in an increased softness of the bone. It is the adult equivalent of rickets.

Osteoporosis: A loss in both the mineral and matrix phase of bone; associated with an increased tendency to fracture.

Outlier: A value that is far separated from other members of a sample. Outliers may be due to faulty sampling techniques (the values actually belong to a different population) or an error in measurement, or they may be real and very meaningful.

Overload: A term used in inhalation toxicology to describe a condition where the normal particle clearance mechanisms of the test system have been overwhelmed by the high inhaled particle concentrations, leading to particle accumulation in the lung and inflammation.

Oxalate: Any salt acid that contains the $(COO)_2^{2-}$ radical found in numerous plants and some fungi.

Oxidation: The net loss of electrons, which may also involve the addition of oxygen to a molecule.

Oxidative stress: Imbalance between prooxidants and antioxidants.

Oxygen enhancement ratio (OER): The ratio of the dose of radiation required to produce a given biological effect in the absence of oxygen (anoxia or hypoxia) compared to the same dose of radiation exposure required in the presence of oxygen. The OERs for low linear energy transfer (LET) radiation, such as x-rays or gamma rays, usually range from 2.8 to 3.0. Living systems are more radiosensitive when irradiated in the presence of oxygen.

Oxytocin: A peptide secreted by the neurohypophysis.

P-glycoprotein (P-gp): An ATP-dependent efflux transporter expressed on various cell types such as intestinal enterocytes, hepatocytes, renal proximal tubular cells, and blood–brain barrier endothelia. The activity of P-gp limits intestinal absorption and entry of molecules that are substrates into tissues such as the liver, kidney, and brain.

Palate: Roof of the mouth, consisting of the hard palate, soft palate, and uvula.

Pain: An unpleasant sensory or emotional experience associated with actual or potential tissue damage. It typically involves a noxious stimulus or event that activates nociceptors, which convey signals to the central nervous system, where they are processed and generate multiple responses.

Parturition: The action or process of giving birth to offspring.

Permissible exposure limits (PEL): Enforcible, regulatory limits on the amount or concentration of a substance in the air established by OSHA. PELs are based on an 8 h time-weighted average (TWA) exposure.

Photo ionization detector (PID): An instrument that measures real-time concentrations of organic vapors at low levels from parts-per-billion (ppb) up to 50,000 parts-per-million (ppm). PIDs use the energy of an ultraviolet lamp to ionize gases and produce ions that can be measured as a weak current through an imposed electrical field. The resulting electrical signal is proportional to the amount of gas in the sample.

Placenta: Organ within the pregnant uterus through which the fetus derives its nourishment.

Pluripotency: Refers to a stem cell that has the potential to differentiate into any of the three germ layers: endoderm (interior stomach lining, gastrointestinal tract, the lungs), mesoderm (muscle, bone, blood, urogenital), or ectoderm (epidermal tissues and nervous system).

^{31}P NMR spectroscopy: A technique involving the use of a nuclear magnetic resonance spectrometer tuned to following phosphorous-31 resonance in a variety of phosphorylated molecules such as ATP.

p53: A 53,000-molecular-weight tumor suppressor/transcriptional regulating protein that is commonly mutated in cancers. It participates in cell cycle regulation, transcription, and apoptosis. Activation of p53 after radiation exposure leads to radiation-induced cell cycle delay.

Pachymetry: A means of obtaining quantitative measurements of corneal thickness using either optical or ultrasonic methods. Derived from the Greek words *pachys* (thick) and *metry* (process of measuring).

Pancytopenia: Reduction of all three formed elements of blood: red blood cells, white blood cells, and platelets.

Paracelsus: The founder of modern toxicology.

Paracrine: A type of cellular regulation in which a substance exerts a regulatory influence primarily on cells in close proximity as opposed to the endocrine system, which exerts regulatory action at locations distant from the release.

Parenteral: Introduction into the body by a route other than the alimentary canal (e.g., subcutaneous intravenous, intramuscular injection).

Particle: A small, discrete object.

Particulate: An adjective for particle-related properties.

Partition coefficient: Ratio of concentration or relative distribution of a chemical in two matrices at equilibrium.

Partitioning factors: Factors that determine which individuals and results are used to construct a reference interval (e.g., species, strain, sex, age, instrument, method).

Parturition: The interval in a pregnant animal during which delivery of an offspring occurs; it is initiated at the first signs of labor and completed at the birth of the last offspring in the litter, in multiparous animals.

Pathogenesis: The cellular events and reactions and other pathologic mechanism occurring in the development of disease.

Pathology: The medical science, and specialty practice, concerned with all aspects of disease but with special reference to the essential nature, causes, and development of abnormal conditions, as well as the structural and functional changes that result from the disease processes.

Pathology data review: A quality assurance review of pathology data to ensure the quality of the materials and procedures used to generate histopathological data.

Pathology peer review: The procedure whereby a second pathologist reviews a subset of tissues and other data from the initial pathology evaluation to verify the accuracy of toxicologically significant microscopic findings.

Pathology Working Group (PWG): A panel of expert pathologists assembled to review a specific question concerning pathology study results.

PCNA: Proliferating cell nuclear antigen.

PCR: Polymerase chain reaction.

Performance: The accuracy and reliability characteristics of a test method (see *Accuracy*, *reliability*).

Performance standard: A set of specifications that define an outcome in detail and provide criteria for assessing that outcome. The term is most commonly used in conjunction with prescribing conditions for the care and use of laboratory animals. These standards are based on validated test methods, which provide a basis for evaluating the comparability of a proposed test method that is mechanistically and functionally similar. Included are (1) essential test method components; (2) a minimum list of reference chemicals selected from among the chemicals used to demonstrate the acceptable performance of the validated test method; and (3) the comparable levels of accuracy and reliability, based on what was obtained for the validated test method, that the proposed test method should demonstrate when evaluated using the minimum list of reference chemicals.

Perfusion-limited uptake: Tissue uptake limited by the rate of blood flow to the tissue.

Peripheral blood leukocyte (PBL): Leukocytes derived from the peripheral circulatory system in humans. Due to the accessibility, these cells are often used in ex vivo assays of the human immune function.

Periportal cells: Collection of hepatic cells situated around the portal triad (branch of the portal vein, a hepatic arteriole, and a bile duct).

Peroxisome: Membrane-bound cell organelles present in cells of animals, plants, fungi, and protozoa that contain oxidative enzymes responsible for the formation and degradation of hydrogen peroxide. These organelles are involved in lipid, sterol, and purine metabolism, as well as peroxidative detoxification. Nongenotoxic chemicals that cause hepatic peroxisome proliferation can cause liver tumor development in rodents. This phenomenon has not been shown to be relevant to humans.

Persistent light eruption: Photoallergic contact dermatitis that flares with ultraviolet exposure continuing past cessation of photoallergen exposure.

Personal measurement: A measurement collected from an individual's immediate environment using active or passive devices to collect the samples.

Pfiesteria: An unclassified marine organism associated with human illness from a toxin not yet identifiable.

Phagocytosis: Process of ingestion by phagocytes whereby the cell membrane of the phagocyte engulfs bacteria and delivers them into the cell, where enzymatic digestion occurs; the active process of particle indigestion by cells (generally macrophages). Once within phagocytic vesicles (phagosomes), particles are subjected to hydrolytic enzymes secreted by macrophages.

Pharmacodynamics: The study of the biological and physiological effects of chemicals and their mechanisms of actions.

Pharmacogenetics: The study of inherited differences in xenobiotic metabolism. This includes genetic mechanisms of species differences and interindividual and interpopulation differences in the genotype and phenotype of cytochrome P450s and other xenobiotic metabolizing enzymes.

Pharmacokinetics: The study of the movement of a chemical (drug) in the body (absorption, distribution, metabolism, excretion). This study involves the time course of absorption, disruption, metabolism, and excretion of a foreign substance (e.g., a drug or pollutant) in an organism's body.

Phase 1 clinical trials: The first stage of clinical testing. These single- and multiple-dose studies are normally conducted in healthy male volunteers to assess the safety and systemic exposure of new drug candidates.

Phase 2 clinical trials: The second stage of clinical testing. These trials are designed to assess safety and efficacy in the target patient population; the length of these trials is determined by the time required to demonstrate clinical endpoints suggestive of efficacy.

Phase 3 clinical trials: Expanded controlled and uncontrolled trials. These trials are performed after preliminary evidence suggesting effectiveness of the drug has been obtained in phase 2 and are intended to gather additional information about the effectiveness and safety that is needed to evaluate the overall benefit–risk relationship of the drug. Phase 3 studies also provide an adequate basis for extrapolating the results to the general population and transmitting that information to physicians. Phase 3 studies usually include several hundred to several thousand people.

Phase 4 clinical trials: These are postmarketing trials that may be requested by regulatory agencies upon their review of the New Drug Application (NDA) or in response to effects that become evident as more patients become exposed to the drug. Sponsors may also choose to conduct these studies to support a line extension strategy (e.g., new formulations, expansion of the patient population).

Phase I metabolism: The first step in drug metabolism. Its purpose is to aid the elimination of foreign compounds from the body. The main reactions involved are oxidation, reduction, and hydrolysis but could also be hydration or isomerization. The aim of phase I is to add or unmask a reactive functional group to which phase II metabolic enzymes can add a highly water-soluble molecule. This is desired because the more water soluble a compound, the more readily it is excreted by the kidneys. Although some compounds can be eliminated solely as a result of phase I drug metabolism, most go on to be involved in the conjugation reactions of phase II metabolism. Also, phase I is not a necessary precursor to phase II metabolism for some foreign molecules.

Phase II metabolism: Conjugation reactions by which covalent bonds are formed between chemicals (both xenobiotics and endogenous) and small, polar, endogenous compounds (e.g., glucuronic acid, sulfate, glutathione, glycine); these reactions often, but do not always, follow phase I reactions.

Phenotype: The total of observable features of an organism, as the result of interaction between the genetic material (genotype) and the environment.

Photoallergic contact dermatitis: Allergic contact dermatitis dependent on ultraviolet (typically UVA) exposure.

Photoirritant (phototoxic): Acute irritant dermatitis dependent upon ultraviolet (typically UVA) exposure.

Physiological leukocytosis: Increased white blood cell count associated with endogenous catecholamine release, usually resulting from excitement or fear (fight-or-flight phenomenon) or pain.

Physiologically based pharmacokinetic (PBPK) model: A mechanistic model that describes quantitatively the uptake, distribution, metabolism, and excretion of a chemical; the model can also be used to quantify the dose of an active metabolite received by the target tissue.

Phytotoxin: A plant toxin composed of complex proteins that are produced by a relatively small number of plants and are structurally similar to bacterial toxins.

Pica: Compulsive ingestion of nonnutritive items, such as dirt, flaking paint, plaster, ashes, or laundry starch. Individuals with pica often have greater exposure to toxicants (e.g., ingestion of lead in paint chips).

Pinocytosis: Cellular process of actively engulfing a liquid.

Pit viper: Any snake of the family Crotalidae that had a depression or pit between the nostril and the eye.

Plasma: The liquid portion of blood in vivo. Plasma is obtained from blood collected with an anticoagulant and centrifuged to separate it from the cells.

Plenum velocity: Air velocity in the plenum. For good air distribution with slot-type hoods, the maximum plenum velocity should be one-half of the slot velocity or less.

Point estimate: A quantity calculated from values in a sample to represent an unknown population parameter. Point estimates typically represent a descriptive statistic (e.g., arithmetic mean, 95th percentile).

Point estimate risk assessment: Familiar risk assessment methodology in which a single estimate of risk is calculated from set point estimates. The results provide point estimates of risk for the central tendency exposure (CTE) and reasonable maximum exposure (RME) exposed individuals. Variability and uncertainty are discussed in a qualitative manner.

Point-of-control measurement of exposure: An approach to quantifying exposure by taking measurements of concentration over time at or near the point of contact between the chemical and an organism while the exposure is taking place.

Poison: Any substance (chemical, physical, biological) that is harmful or destructive to a biological (living) system.

Polymerase chain reaction: A method in which a region of a nucleic acid is selectively amplified by cycles of nucleotide polymerization; a technique enabling a rapid multiplication of selected parts of a DNA or RNA strand.

Polymorphisms: Multiple phenotypes of an organism determined by different alleles; in this context, the existence of an interindividual difference in DNA sequence coding for one specific gene. The effects of such a difference may vary dramatically, ranging from no effect at all to the building of inactive proteins or not even building the protein. Two structurally distinct genes for the same protein; polymorphic genes can be produced by mutations that result in nucleotide sequence differences that can lead to the production of proteins that differ functionally or that may not have altered functionality.

Polynomial dose–response model: A dose–response model in which the response is expressed mathematically as the sum of quantities containing increasing powers of dose.

Polytocous: The production of litters of offspring.

Post-implantation: Occurring after the early embryo embeds into the lining of the uterus.

Pre-implantation: Occurring before the early embryo embeds into the lining of the uterus.

Pseudopregnancy: The appearance of clinical and/or subclinical signs and symptoms associated with pregnancy when the organism is not actually pregnant.

Porifera: An animal phylum of some 5000 species of the simplest, multicellular life forms, most of which are marine.

Positron-emitting isotopes: These isotopes have relatively short half-lives (10–100 min) and decay exclusively by emission of a positron. They produce readily detectable, tissue-penetrating, γ-ray photons and are thus commonly used in tomographic techniques (position emission tomography, or PET). Examples of such isotopes are ^{11}C, ^{13}N, ^{15}O, and ^{18}F. Because of their brief existence, positron-emitting isotopes usually have to be manufactured close to the site where they are to be used.

Potential dose: The amount of a chemical contained in the material ingested, air breathed, or bulk material applied to the skin.

Power: The effect of the experimental conditions on the dependent variable relative to sampling fluctuation. When the effect is maximized, the experiment is more powerful. Power can also be defined as the probability that there will not be a type II error (1-beta). Conventionally, power should be at least 0.07.

Preanalytical variables: Factors that occur prior to analysis of samples and influence clinical pathology results.

Preanalytical variation: Variability in test results caused by factors that occur before the test is performed.

Precision: A measure of the agreement among replicate measurements of an analyte; a measure of the reproducibility of a measured value under a given set of conditions.

Prediction model: In alternative method development, the tool that is used to predict the endpoint of interest; the prediction model is an algorithm that defines how to convert results from the alternative method into a prediction of the in vivo toxicity. A formula or algorithm is used to convert the results obtained using a test method into a prediction of the toxic effect of interest. A prediction model contains four elements: (1) a definition of the specific purpose for which the test method is to be used, (2) specifications of all possible results that may be obtained, (3) an algorithm that converts each study result into a prediction of the toxic effect of interest, and (4) specifications as to the accuracy of the prediction.

Predictivity (negative): The proportion of correct negative responses among substances testing negative by a test method (see *Two-by-two table*). It is one indicator of test method accuracy. Negative predictivity is a function of the sensitivity of the test method and the prevalence of negatives among the substances tested.

Predictivity (positive): The proportion of correct positive responses among materials testing positive by a test method (see *Two-by-two table*). It is one indicator of test method accuracy. Positive predictivity is a function of the sensitivity of the test method and the prevalence of positives among the substances tested.

Prevalence: The number of cases of a designated disease that exist at a particular point in time is the *point prevalence*. Various types of *period prevalence* represent the number of existing and new cases of a disease that are extant at the beginning of or at any time during a defined period of time. In the medical literature, both types of prevalence, particularly the latter, may erroneously be called *Incidence*, especially if the data are presented as a *prevalence rate*. Prevalence is also defined as the proportion of positive or negative substances in the population of substances tested (see *Two-by-two table*).

Prevalidation: In alternative methods development, the preliminary phase to validation in which the purpose of a test and its capabilities, limitations, interlaboratory transferability, and predictability are determined; the process during which a standardized test method protocol is developed and evaluated for use in validation studies. Based on the outcome of those studies, the test method protocol may be modified or optimized to increase intra- or interlaboratory reproductivity for use in further validation studies.

Primary cell culture: Isolated epithelial cells, tubules, or tubular fragments are used as seed material to grow renal cells under defined conditions on a solid matrix. It is a primary cell culture when seed material is directly derived from fresh tissue. It typically grows to confluence in 5–7 days and has limited ability to be passaged, depending on the species.

Primary enclosure: The cage, pen, or stall that forms the immediate limit of an animal's environment in a research facility.

Primary response: The immune response following initial contact with an antigen, resulting in the establishment of immunologic memory; synonymous with *immunization*.

PRL: Prolactin.

Probabilistic risk assessment (PRA): A risk assessment that uses probabilistic methods to derive a distribution of risk or hazard based on multiple sets of values sampled for random variables.

Probability density function (PDF): A representation, generally a function, graph, or histogram, of the probability of occurrence of an unknown or variable quantity. The sum of the probabilities for discrete random variables and the integral for continuous random variables (i.e., the area under the curve) is equal to 1.0. PDFs can be used to display distributions used as input to a probabilistic assessment or the distribution of risks that forms the output of that assessment.

Probit: Inverse cumulative distribution function of the normal distribution; it is the normal equivalent deviate (NED) plus 5 (e.g., 50% response equals a probit of 5).

Proliferation: Process of cell growth. Uncontrolled proliferation can result in cancer.

Proprietary test method: A test method for which manufacture and distribution are restricted by patents, copyrights, trademarks, etc.

Proteome: The entire protein complement of a biological sample.

Proteomics: The techniques available to identify the proteins in biological samples; field of study involving analysis of protein levels in cells or populations; automated methods developed for high-throughput analysis.

Protocol: The precise step-by-step description of a test method, including listing of all necessary reagents and all criteria and procedures for generating and evaluating test data.

Proton (^{1}H) nuclear magnetic resonance (NMR) spectroscopy: Nuclear magnetic resonance is a phenomenon that occurs when the nuclei of certain atoms are immersed in a static magnetic field and exposed to a second oscillating magnetic field. Proton NMR spectroscopy is the use of NMR phenomenon or protons (there are other magnetic nuclei) to study physical, chemical, and biological properties of samples.

Proximal tubules: Initial cell types of the tubular epithelium connected to glomerulus. They are subdivided into two overall segments—proximal convoluted (S1) and proximal straight (S2, S3) tubules. S1 cells are found in the cortex; S2 cells are found in the cortex and outer stripe of the outer medulla; and S3 cells are found in the outer stripe of the outer medulla. These are major sites in the nephron for drug metabolism, transport, reabsorption, and secretion of amino acids, glucose, organic anions, and organic cations.

Psilocybin: A hallucinogenic that is much less potent than Lysergic acid diethylamide (LSD) but much more potent than mescaline. It is moderately toxic to humans by ingestion and intraperitoneal routes and is probably toxic by all routes of exposure.

Psychophysics: A group of methods formulated to guide the testing of sensory capacities.

PTH: Parathyroid hormone.

Pulmonary: Region of the respiratory tract serving primarily as the air-exchange region composed of respiratory bronchioles, alveolar ducts, and alveoli.

Quality assurance: A management process by which adherence to laboratory testing standards, requirements, and record-keeping procedures is assessed independently by individuals other than those performing the testing.

Quality control: Procedures for establishing, monitoring, and evaluating the quality of the analytical testing process of each method to assure accuracy and reliability of test results for test subjects or patients.

Quantal response: A response to a stimulus or a treatment that can be referred to as *all or none* (it either happens or it does not happen). In acute toxicity studies, mortality is an example of a quantal response.

Racemate: Compound containing a 50:50 proportion of enantiomers.

Rad: Radiation-absorbed dose of ionizing radiation. One rad = 100 erg/g.

Radiation: Energy propagated through space or matter as waves (gamma rays, ultraviolet light) or as particles (alpha or beta rays).

Radiological dispersal device (RDD): Mechanism designed to scatter radioactive material into the environment. The amount and type of radioactive material used will determine the number of causalities, the extent of evacuations, and the area of contamination.

Radionuclide: An element, either in the environment or internal, which emits ionizing radiation.

Radioprotective agents: Chemical compounds that, when administered before irradiation, protect the organism against radiation damage.

Radiosensitizer: Substance that enhances the radiation response of biologic systems.

Radiotolerance: The eventual lack of sensitivity to radiation.

Random: Each individual member of the population has the same chance of being selected for the sample.

Randomization: Process used in toxicity studies to ensure a homogeneous population and minimize errors due to sampling bias. Randomization can be done by assigning animals to treatment groups using computer-generated random numbers or through the use of tables of random numbers.

Rate: An expression of the frequency with which an event occurs in a defined population; a measure of the *absolute risk* for the disease in that population. In a rate, the numerator is a subset of the denominator; therefore, all rates are ratios but not all ratios are rates. A rate usually has a time dimension. For a prevalence rate, it is the implied or explicit time at which the data were collected. For an incidence rate, it is the time over which the new events took place. For convenience, the denominator of either type of rate usually is presented as some power of 10 (i.e., the number of cases per 100 or per 1,000 or, for rare events, per 100,000 or even per 1,000,000).

Rate difference: The difference between two rates. In the situation where etiology has been established, the rate difference between the disease incidence in the exposed and unexposed groups is sometimes called the *excess rate* or *attributable risk*.

Raw data: Any laboratory worksheets, records, memoranda, notes, or exact copies thereof that are the result of original observations and activities from a study. This may include manually recorded information, printouts from automated instruments, computer printouts, photographs, microfilm or microfiche copies, and magnetic media (including dictated observations).

RCB: Rodent cancer bioassay.

RD_{50}: The concentration of airborne substance that produces 50% decrease in the respiratory rate in rodents, usually mice. This is the numerical output of a sensory irritation study.

REACH (Registration, Evaluation, and Authorization of Chemicals): This is a far-reaching European legislation replacing all previous patchy EU toxic substances control legislations. REACH aims to comprehensively regulate the manufacture, import, and commerce of hazardous substances and their preparations in the European Union.

Reactive or secondary thrombocytosis: Increased platelet counts observed in conjunction with generalized bone marrow stimulation as may occur with hemolysis, blood loss, and many types of acute and chronic inflammation.

Reasonable maximum exposure (RME): The highest exposure that is reasonably expected to occur at a site. The intent of the RME is to estimate a conservative exposure case (i.e., well above the average case) that is still within the range of possible exposures.

Reasonable worst case: A semiquantitative term referring to the lower portion of the high end of the exposure, dose, or risk distribution. The reasonable worst case has historically been loosely defined, including synonymously with *maximum exposure* or *worst case*, and assessors are cautioned to look for contextual

definitions when encountering this term in the literature. As a semiquantitative term, it is sometimes useful to refer to individual exposures, doses, or risks that, while in the high end of the distribution, are not in the extreme tail. For consistency, it should refer to a range that can conceptually be described as above the 90th percentile in the distribution but below about the 98th percentile.

Receptor: The sensitive site for chemical–biological interaction.

Recirculating perfusion: Perfusate flows from a reservoir through the organ being perfused and returns to the same reservoir.

Recommended exposure limit (REL): An occupational exposure limit that has been recommended by NIOSH. RELs are time-weighted average (TWA) concentrations for up to a 10 h workday during a 40 h workweek.

Red cell generative response: A response to reduced red cell mass characterized by an appropriate increase in erythropoiesis and correlative changes in related parameters.

Red cell mass parameters: Parameters that provide an estimation of whole-body red cell mass and include RBC count, hemoglobin concentration, and hematocrit.

Rederivation: Refers to a process that utilizes removal of term fetuses with subsequent cross-fostering onto mothers of the right microbiological status or the use of embryo transfer procedures to change the microbiological status of animals.

Reduction alternative: A new or modified test method that reduces the number of animals required.

Reference chemicals: Chemicals selected for use during the research, development, prevalidation, and validation of a proposed test method because their response in the in vivo reference test method or the species of interest is known. Reference chemicals should represent the classes of chemicals for which the proposed test method is expected to be used and cover the range of expected response (negative, weak to strong positive). Different sets of reference chemicals are likely to be required for the various stages of validation. After a proposed test method has been recommended or accepted as valid for its intended purposes (i.e., has been recommended as a validated test method to federal agencies), a representative subset of chemicals used during the validation process may be selected to validate a mechanistically and functionally similar test method. To the extent possible, this subset of reference chemicals should (1) be representative of the range of responses that the validated test method is capable of measuring or predicting, (2) have produced consistent results in the validated test method and in the reference test method or the species of interest, (3) reflect the accuracy of the validated test method, (4) have well-defined chemical structures, (5) be readily available, and (6) not be associated with excessive hazard or prohibitive disposals costs. This list of reference chemicals would represent the minimum number of chemicals that should be used to evaluate the performance of proposed mechanistically and functionally similar test methods with established performance standards. If any of the recommended chemicals are unavailable, other chemicals for which adequate reference data are available could be substituted. If desired, additional chemicals representing other chemical or product classes and for which adequate reference data are available can be used to more comprehensively evaluate the accuracy of the proposed test method.

Reference concentration (RfC): Air concentration of a chemical exposure (expressed in mg/m^3) that is associated with minimal or no risk of adverse effects, even in susceptible subpopulations.

Reference dose (RfD): An estimate of a daily exposure to a human population, including sensitive groups, that is likely to be without appreciable risk of deleterious health effects during a lifetime.

Reference interval: The central interval of test values (usually the central 95th percentile) obtained from a defined group of apparently healthy individuals using defined methods (see *Partitioning factors*). In contrast, a reference range is the entire range of values from those individuals, including minimum and maximum values.

Reference toxicant: Chemicals of known toxicity that are used to determine the health of a population of a test species.

Refinement alternative: A new or modified test method that refines procedures to lessen or eliminate pain or distress in animals or enhances the well-being of animals.

Regenerative anemia: Anemia characterized by increased production and delivery of newly formed red blood cells (reticulocytes) into circulation; typically associated with hemorrhage or hemolysis.

Regional particle deposition: Particles ≤1 μm deposit by diffusion in the alveolar region of the respiratory tract; particles 1–5 μm deposit by sedimentation in the tracheal/bronchial/bronchiolar/alveolar regions; particles between 5 and 30 μm are deposited primarily by inertial impaction in the nasopharyngeal region.

Reinforcement schedule: A designated relationship between a specific behavior, such as pressing a lever in an experimental chamber, and the delivery of a reinforcer, such as a feed pellet.

Relative biological effectiveness (RBE): The ratio of a dose of a test radiation (e.g., neutron, gamma, x-ray) required to produce the same reference biological endpoint as the dose of a standard radiation of 250 kVp x-rays.

Relative risk: The ratio of the absolute risk of disease or death (the incidence rate) among the exposed population to the risk of disease among the unexposed; a measure of association that sometimes is called the *risk ratio*, *rate ratio*, or *RR*.

Relevance: The extent to which a test method correctly predicts or measures the biological effect of interest in humans or another species of interest. Relevance incorporates consideration of the accuracy or concordance of a test method.

Reliability: A measure of the degrees to which a test method can be performed reproducibly within and among laboratories over time. It is assessed by calculating intra- and interlaboratory reducibility and intralaboratory repeatability.

Remediation action level (RAL): A concentration such that remediation of all concentrations above this level in an exposures unit will result in the 95% upper confidence limit being reduced to a level that does not pose an unacceptable risk to an individual experiencing random exposures. The RAL will depend on the mean, variance, and sample size of the concentrations within an exposure unit as well as considerations of short-term effects of the chemicals of concern.

Renal cell lines: Immortalized cultures of renal cells, derived from specific nephron cell types but often expressing properties of multiple cell types. They can be maintained indefinitely.

Renal cellular repair and regeneration: Process by which the renal epithelium synthesizes new cells to replace those damaged by chemical toxicants or in various pathological states.

Renal slices: In vitro model involving slicing renal tissue. Typically obtained with a razor and a glass microscope slide, the slices can be obtained from the cortex, outer or inner stripe of outer medulla, or the inner medulla. They are useful over the short term (up to 60 min) in metabolic and transport studies.

Replacement alternative: A new or modified test method that replaces animals with nonanimal systems or one animal species with a phylogenetically lower one (e.g., a mammal with an invertebrate).

Reproducibility: The consistency of individual test results obtained in a single laboratory (*intralaboratory reproducibility*; see *Intralaboratory reproducibility*) or in different laboratories (*interlaboratory reproducibility*) using the same protocol and test samples.

Reproductive toxicology: The study of causes, mechanisms, and sequelae of adverse effects on the reproductive system, including alterations to the reproductive organs, related endocrine system, or pregnancy outcomes, and manifested as adverse effects on sexual maturation, gamete production and transport, cycle normality, sexual behavior, fertility, gestation, parturition, lactation, pregnancy outcomes, premature reproductive senescence, or modifications in other functions dependent on the integrity of the reproductive system.

Residual analysis: Analysis of the difference between experimental and simulated data as a function of time or other controllable variables. The residuals should be random if the model is adequate.

Residual body: A lobe of cytoplasm containing residual organelles (e.g., mitochondria, Golgi apparatus, endoplasmic reticulum, ribosomes, lipid droplets) that detaches from the elongated spermatid at spermiation. Residual bodies are eliminated from the seminiferous epithelium by Sertoli cell phagocytosis.

Resinoid: Any substance that contains or resembles a resin.

Respirable: Inhalable materials that are capable of getting to and being deposited in the gas-exchange region of the lung; a particle size characteristic whereby the substance can enter the pulmonary region of the respiratory tract. These are generally low-micrometer- to submicrometer-sized particles. Contrast with *Inhalable*.

Respiratory system: Complex arrangement of organs designed primarily for the intake of oxygen and the elimination of carbon dioxide; divided into the proximal or upper airway (nose, pharynx, larynx, trachea, nonalveolarized bronchioles) and the distal or lower airway (alveolar bronchioles, alveolar ducts, alveolar air sacs).

Respiratory tract: The entire breathing system, including mouth, nose, larynx, trachea, lungs, and associated nerves and blood supply.

Retention (of particulate material): Quantity of particles present at specific respiratory tract sites that is the net difference between deposition and clearance processes; refers to particle matter and represents the quantity of particles present at specific respiratory tract sites. Retention is the net difference between deposition and clearance processes.

RIA: Radioimmunoassay.

Ring tail: A condition seen in rodents in which annular constructions of the tail occur that may lead to necrosis of all or part of the tail. This condition is presumed to be associated with abnormal environmental conditions.

Risk: Proportion or probability expressed on a scale of 0–1, or 0%–100%, that individuals process or develop a specified biological effect by a given time for a defined set of exposure conditions; the probability or degree of concern that exposure to an agent will cause an adverse effect in the species of interest.

Risk characterization: A component of risk assessment that describes the nature and magnitude of risk, including uncertainty. In assessments of Superfund sites, it includes the summary and interpretation of information gathered from previous steps in the site risk assessment (e.g., data evaluation, exposure assessment, toxicity assessment), including the results of a probabilistic analysis.

Robust: Having inferences or conclusions little affected by departure from assumptions.

Rodent lifetime: Generally taken to be 2 years for risk estimation.

Roentgen (R): Quantity of x- or gamma radiation per cubic centimeter of air that produces one electrostatic unit of charge.

Roentgen equivalent man (REM): Unit of dose equivalent; the absorbed dose in rads multiplied by the *Q* of the type of radiation.

Rough endoplasmic reticulum (RER): The endoplasmic reticulum component that contains bound ribosomes and is largely responsible for protein synthesis.

Route of exposure: Portal of entry of a chemical into the body: oral, inhalation, dermal, or injection.

S9 mix: A 9000 *g* supernatant fraction from a tissue homogenate (e.g., liver).

Safety factor: A number or factor that considers inter- and intraspecies variability, sensitivity, and extrapolatability. It is applied to a NOAEL to establish an acceptable daily intake (ADI). See *Uncertainty factor.*

Safety pharmacology: The study of the pharmacologic effects of a drug candidate that are unrelated to the desired pharmacologic effect. These studies are generally conducted at doses similar to the anticipated therapeutic dose.

Standardized aquatic microcosm (SAM): A defined aquatic microcosm (3 L vessel) containing 15 species in a well-defined medium of trace metals and vitamins and 200 g of sand to which chitin and cellulose are added.

Sample: In statistics, the collected set of data points that (if properly collected) are representative of the population (all of the values there are).

Saponins: Steroidal or terpenoid glycosides from plants and animals capable of reducing surface tension and disruption of cell membranes.

Saturation dose: Dose that overwhelms a toxification or detoxification mechanism such that no additional changes in the effect are incurred above that dose.

Sawfly: Insects, the larvae of which are hepatotoxic when ingested by ruminant livestock.

Schedule-controlled operant behavior: An approach to the study of behavioral function that relies on manipulation of reinforcement schedules.

Scombroid poisoning: An allergic fish poisoning resulting from the consumption of inadequately processed fish containing histamine and saurine formed from bacterial action.

Screen/screening test: A rapid, simple test conducted for the purposes of a general classification of substances according to general categories of hazard. The results of a screen generally are used for preliminary decision-making and to set priorities for more definitive tests. A screening test may have a truncated response range (it may be able to reliably identify active chemicals but not inactive chemicals).

Screening tests: In acute toxicity testing, tests designed to define the range of toxicity using fewer animals per dose level or fewer dose levels.

Sea snakes: Members of the Elapidae family that spend most of their lives in oceans.

Secondary enclosure: The room or space in which a primary enclosure is located.

Secondary phase regeneration (SPR): Tissue repair response where hepatocytes are mobilized from G_0/G_1 to proceed through mitosis (see *Electron paramagnetic resonance*).

Secondary response: The immune response that occurs after initial contact with an antigen (the primary response). The secondary response is quicker, of higher affinity, and more pronounced. For humoral-mediated immune reactions, the secondary response is associated with antibody class switching.

Secondary toxicity: The toxicity of a chemical determined by feeding the test animals (especially ferrets or mink) with prey that have been fed the test chemical.

SEL: Safe exposure level.

Selection and selection bias: The process by which subjects are included in a study. If systematic differences exist between those who are selected for a study and those who are not, selection bias may occur. The bias may be introduced by the subjects themselves through self-selection (into or out of the study), as a result of the sources of the subjects, or by the study investigators.

Seminiferous epithelium: The Sertoli cells and developing male germ cells within the seminiferous tubules in the testes.

Sensitivity: The number of subjects experiencing each experimental condition divided by the variance of scores in the sample; the proportion of all positive chemicals that are classified correctly as positive in a test method. It is a measure of test method accuracy (see *Two-by-two table*).

Sensitivity analysis: Evaluation of the effect of changes in the value of a particular parameter on the estimates of a state variable provided by a mathematical model. Sensitivity is expressed as the magnitude of change in the endpoint of interest (e.g., tissue dose) as a function of change in the value of a particular model parameter.

Sertoli cell: A somatic cell present in the seminiferous epithelium of mammals. Solidly attached to the basement membrane of seminiferous tubules, it produces important regulatory glycoproteins, including anti-Mullerian hormone, inhibin, and androgen-binding protein and is essential for male germ cell development. Junctions between Sertoli cells form the blood–testis barrier.

Serum: The liquid portion of blood that remains after a clot has formed. Serum is obtained from blood collected without anticoagulant and centrifuged to separate it from the cells.

Serum responsiveness: Cell proliferative reaction to the addition of serum to tissue culture medium after prior deprivation.

Severity grading of lesion: The semiquantitative application of a defined severity score to specific microscopic lesions, usually to denote the extent of tissue involvement or degree of tissue damage.

Shuttle vector: A DNA transfer agent capable of moving genes into or out of a cell.

SI units: International system of units; SI refers to *Système International d'Unites*. Radiation units include Joule/kilogram, Gray, Sievert, and Becquerel.

Sievert (Sv): SI unit of dose equivalence; the absorbed dose in grays multiplied by the *Q* of the type of radiation. One Sv = 100 rems.

Signature sequencing: Sequencing of a short stretch of cDNA close to the end of the complementary mRNA. Sequence stretches of some 20 nucleotides are sufficiently discriminative to identify the transcript of an individual gene in a mammalian tissue.

Significance level: The probability that a difference has been erroneously declared to be significant, typically 0.05 and 0.01, corresponding to 5% and 1% chance of error.

Simulation: System behavior predicted for specific exposure conditions by solving the set of differential and algebraic equations of a model.

Single nucleotide polymorphism: Interindividual variation in the genetic code at the level of one single building block (see *Nucleotide*, *polymorphisms*).

Single-pass perfusion: Perfusate flows from a reservoir through the vasculature of a perfused organ; it is collected and not reused so the perfusate goes through only once.

Single-wall carbon nanotube (SWNT): An engineered nanoparticle consisting of carbon atoms arranged in a single tubular structure with a very high aspect ratio. The diameter of the nanotubes is less than 100 nm but the tube lengths can be several micrometers.

Skin notation: Hazard warnings used worldwide to alert workers and employers to the health risks of dermal exposures to chemicals in the workplace.

Slit-lamp biomicroscope: An instrument used to study ocular tissues that consists of a microscope and high-intensity light source. It allows the eye to be illuminated and observed from different angles and can detect lesions not observable by gross examination.

Slope: The difference in the incidence or magnitude of an effect divided by the difference in dose that created the effect.

Slot velocity: Air velocity through the openings in a slot-type hood. It is used primarily as a means of obtaining uniform air distribution across the face of the hood.

Small intestine: The region of the gastrointestinal tract from the pyloric sphincter of the stomach to the cecum that consists of the duodenum, the jejunum, and the ileum; the primary site of absorption of ingested substances.

Smokes: A complex mixture of solid or liquid particles, such as soot, liquid droplets, or mineral ash particles from incomplete combustion of organic materials. Smoke particles are generally ~0.5 μm.

Smooth endoplasmic reticulum (SER): The endoplasmic component of the cell that does not contain bound ribosomes and is strongly associated with drug-metabolizing enzyme systems such as those mediated by cytochrome P450.

Society of toxicology (SOT): The preeminent professional society for toxicologists in the United States.

Soil aging: The changes that occur in the interaction of chemicals with soil during which the chemicals are bound to soil particles and become less bioavailable.

Soil sorption constant (K_{oc}): The extent of partitioning of an organic chemical between the solid and solution phases of a water-saturated soil or sediment.

Somatotropin: Growth hormone.

Species sensitivity distributions: A cumulative frequency distribution (CFD) of toxicity responses for a given substance, describing the range of concentrations that results in a measured effect for a selected set of species. A CFD describes the frequency with which a variable assumes values less than or equal to some number. Distributions can be developed for species within or among taxonomic categories and can be limited to single endpoints (e.g., mortality) or be inclusive of all measured endpoints. A desired level of protection can be selected, most frequently the 5th percentile (HC_5).

Specific activity: The radioactivity per unit mass of material. Specific activity is used to quantify radionuclides. Specific activity can be given in Curies per mole (Ci/mol) or Becquerels per mole (Bq/mol).

Specific gravity: The ratio of the density of a substance to the density of a reference material at a specified temperature. Water is the reference standard for liquids and solids (density 1 g/mL at 4°C).

Specificity: The proportion of all negative chemicals that are classified correctly as negative in a test method. It is a measure of test method accuracy (see *Two-by-two table*).

Spermatid: The haploid germ cell, arising from meiotic divisions of spermatocytes, that differentiates within the seminiferous epithelium into a spermatozoon.

Spermatocytes: Germ cells in the seminiferous epithelium derived from spermatogonia that subsequently undergo two meiotic divisions to form round spermatids.

Spermatogenesis: The process of germ cell division and differentiation that begins with the multiplication of spermatogonia and ends with the release of elongated spermatids into the lumen of the seminiferous tubules (spermiation).

Spermatogenic cycle: A complete sequential progression of the cellular associations (or stages) of spermatogenesis. The stages follow one another through an entire cycle, returning to the original stage and repeating the cycle approximately 4.5 times until spermatogonia become elongated spermatids and undergo spermiation.

Spermatogonia: The diploid germ cells in adult males that divide by mitosis to produce additional stem cell spermatogonia and spermatocytes.

Spermiation: The process by which elongated spermatids are released from the germinal epithelium into the seminiferous tubule lumen.

Spermiogenesis: Last phase of spermatogenesis during which elongated spermatids are formed from round spermatids.

Spina bifida: A congenital defect in which part of the vertebral column is absent, allowing the spinal membranes to protrude; a result of failure of the neural tube to close properly.

Spin trapping: The most commonly used indirect method for detecting free radicals. The technique involves adding a spin trap (usually a nitrone or nitroso compound) to the sample prior to radical generation. When the radical is generated, it reacts rapidly with the spin trap, producing a secondary radical or *spin adduct*, which is more stable than the parent free radical and can be detected by electron paramagnetic resonance (EPR).

Standard deviation: The most widely used measure of dispersion of the points in a frequency distribution about the midpoint (usually the mean). It is equal to the square root of the variance. For a normally distributed population, the region within one standard deviation of the mean contains 67% of the distribution.

Statistical heterospectroscopy: A statistical technique for combining nuclear magnetic resonance (NMR)- and mass spectroscopy (MS)-based metabonomic data. It provides a focus on metabolites that change consistently across the platforms on a sample-to-sample basis.

Statistical significance: An inference that the probability is low that the observed difference in quantities being measured could be due to variability in the data rather than an actual difference in the quantities themselves. The inference that an observed difference is statistically significant is typically based on a test to reject one hypothesis and accept another.

Steady state: A situation in which the rate of change is equal to zero.

Steatosis: Accumulation of lipid within hepatocytes (fatty liver).

Stem cell: A multipotential self-renewing cell in the bone marrow that serves as the precursor for all hematopoietic cell lineages, including those of the immune system.

Stereoisomers: A general term for isomers that differ only in the orientation of the atoms in space. Enantiomers, isomers that differ in their optical rotation, are a subclass of stereoisomers.

Stomach: Saclike region of the gastrointestinal tract from the esophagus to the duodenum consisting of the cardia, fundus, corpus, antrum, and pylorus; the site of hydrogen ion secretion from parietal cells of the gastric glands that activates pepsin-mediated proteolysis.

Stress–response leukogram: Typically, an increase in neutrophil count and decreases in lymphocyte and eosinophil counts following exogenous corticosteroid administration or when stressful conditions result in increased production of endogenous corticosteroids.

Solute carrier (SLC) transporters: SLC transporters are primarily unidirectional uptake transporters, although some function in a bidirectional manner. SLC transporters include over 300 members organized into 47 families, including both facilitative and secondary active transporters. Solutes, or substrates, that are recognized and transported across membranes by SLC transporters include charged and uncharged organic molecules as well as inorganic ions.

Sulfonation: A biosynthetic conjugation reaction involving cytosolic and membrane-bound sulfotransferases that catalyze the transfer of sulfate, in the form of endogenous 3′-phosphoadenosine-5′-phosphosulfate, to a xenobiotic functional group (e.g., hydroxyl) to yield a product that has increased water solubility and properties that enhance its renal and biliary elimination.

Subchronic: Characterized by a time period of intermediate duration; commonly used to describe exposure between acute and chronic durations in toxicity studies (usually 3 months).

Subchronic toxicity study: Multiple-dose study in which animals are treated for less than 6 months. They are intended to elucidate the target organs for toxicity and demonstrate dose–response relationships. They are normally required prior to any clinical testing.

Substitute method: A new or modified test method proposed for use in lieu of a currently used test method, regardless of whether that test method is for a definitive screening or adjunct purpose.

Substrate probe: Individual isozymes may show significant differences in substrate specificity. A substrate that is metabolized by a specific isozyme and does not show significant overlaps with other isozymes can be used to probe for the presence and activity of the isozyme. Substrate probes can be used in vitro and in vivo. Use of substrate probes may not be as accurate as certain other techniques for isozyme identification but are sometimes more practical.

Syncytium: A multinucleated protoplasmic mass formed by the secondary union of originally separate cells.

Synergism: Refers to a response that is greater than a multiplicative response observed in chemical interaction studies.

Syncytiotrophoblast: Epithelial covering of the highly vascular embryonic placental villi that invades the wall of the uterus to establish nutrient circulation between the embryo and the mother.

Systems biology: Is a research approach that integrates computational sciences, applied mathematics, and experiments to allow for the analysis and interpretation of complex datasets generated by systematically perturbing defined biological systems.

Systems biology verification and industrial methodology for process verification in research (IMPROVER): IMPROVER is a methodology that aims to provide a measure of quality control of industrial research and development by verifying the soundness of the methods used.

Systole: Contraction of the heart, especially of the ventricles, by which blood is driven through the aorta and pulmonary artery to transverse the systemic and pulmonary circulation, respectively.

T_3: Triiodothyronine.

T_4: Thyroxine.

T_{max}: Time to maximum achieved concentration.

T-cell receptor (TCR): The heterodimeric surface molecule on T cells that serves to recognize antigen. It always occurs in conjunction with the CD3 surface antigen, which is responsible for transmembrane signaling following antigen recognition.

T cell/T lymphocyte: Lymphocytes primarily responsible for the induction and maintenance of cell-mediated immunity, as well as regulating humoral-mediated immunity and certain nonimmune effector mechanisms. A variety of T-cell subtypes have been described, including T-helper cells, T-cytotoxic cells, T-suppressor cells, and T-inducer cells.

Tannins: Heterogeneous polyphenols of plant origin.

Target tissue dose: Concentration of a chemical in the tissue or organ where the biological effect occurs.

TBG: Thyroid-binding globulin.

TeBG: Testosterone-binding globulin.

TEF: Toxic equivalency factor.

Telomere: The terminal portion (end) of a chromosome.

Teratology: The study of the causes, mechanisms, and sequelae of perturbed developmental events in species of animals that undergo ontogenesis; in the past, the definition was limited to malformation, but the term is now generally accepted to be synonymous with developmental toxicology.

Teratogenesis: Process by which birth defects arise.

Test article: Any food additive, color additive, drug, biological product, electronic product, medical device, pesticide, or other chemical substance to be subjected to studies.

Test material: Any chemical substance to be subjected to studies. This does not include electronic products or medical devices.

Test method: A process or procedure used to obtain information on the characteristics or a substance or agent. Toxicological test methods generate information regarding the ability of a substance or agent to produce a specified biological effect under specified condition. Used interchangeably with *test* and *assay* (see also *Validated test method*).

Test system: Any animal, plant, microorganism, and subparts thereof (e.g., in vitro organ systems) or physical matrix (e.g., soil or water) to which a test or control article is administered or added for study.

Testosterone: The primary male sex hormone produced by Leydig cells in the testis that, along with the metabolite dihydrotestosterone, is responsible for male reproductive tract development, maintenance of spermatogenesis, secondary sex characteristics, and sexual behavior.

Tetrodotoxin: An extremely toxic, highly lethal, crystalline neurotoxin that acts on both the central and peripheral nervous systems, causing nerve and skeletal muscle paralysis by selectively blocking the regenerative sodium conductance channel.

TFM: Test facility manager.

Therapeutic index (TI): The ratio of LD_{50}/ED_{50}. The therapeutic index is used to establish the safety margin of biologically active materials such as drugs. The higher the index, the greater the margin of safety.

Thermal neutral zone: The temperature or range of ambient temperatures at which an animal does not expend energy to heat or cool itself.

Thin ascending limb: Cell type of epithelium found in the inner medulla only in long-looped nephrons; begins after bend of Henle's loop.

Thin descending limb: Cell type of epithelium found in the inner medulla in long-looped nephrons and in the inner stripe of the outer medulla in short-looped nephrons. The thin descending limb follows proximal straight tubules as one follows nephrons from glomerular to urinary poles.

Threshold dose: Dose below which a specified biological effect does not occur for specified exposure conditions. This refers to a condition when a dose must exceed a specific amount before the agent can induce an effect.

Threshold dose–response relationship: A dose–response relationship that assumes that adverse effects occur only when a threshold dose is exceeded.

Threshold limit values (TLV): Airborne concentration of a substance that would be anticipated to produce no adverse health effects in nearly all workers exposed 8 h per day, 5 days per week, for a working lifetime. TLVs are established by the American Conference of Governmental Industrial Hygienists.

Threshold limit value (TLV®): An occupational exposure limit established by the American Conference of Government Industrial Hygienists. TLVs® are based on an 8 h time-weighted average (TWA) exposure.

Thrombocytopenia: A condition in which there is an abnormally small number of circulating platelets.

Thymus: Central lymphoid organ located in the thorax. Its function is to generate immunocompetent T cells from lymphocytes originating in the bone marrow.

Time-weighted average (TWA): The average concentration of a chemical in air (or exposure to a physical agent) for a normal 8 h workday and 40 h workweek to which a worker is exposed. TWA is calculated using the duration of exposure to different concentrations of the chemical during a specific time period.

Tissue time constant: The product of partition coefficient and volume divided by blood flow rate.

Tolerance level: The maximum legally permissible concentration of residues of a pesticide in food.

Toxic: Substance that has the capacity to produce personal injury via ingestion, inhalation, or absorption through any body surface.

Toxic neutrophils: Neutrophils with morphologic changes indicative of greatly accelerated neutrophil production, regardless of cause.

Toxicant: An agent that can result in the occurrence of a structural or functional adverse effect in a biological system.

Toxicodynamics: The process of interaction of chemical substances with target sites and the subsequent reactions leading to adverse effects.

Toxicokinetics: The process of the uptake of potentially toxic substances by the body, the biotransformations they undergo, the distribution of the substances and their metabolites in the tissues, and the elimination of the substances and their metabolites from the body. Both the amounts and the concentration of the substances and their metabolites are studied. The term has essentially the same meaning as *Pharmacokinetics*, but the latter term is usually restricted to the study of pharmaceutical substances.

Toxicological pathology: The science that integrates the disciplines of pathology and toxicology and is concerned with the effects of potentially noxious substances.

Toxicological profiles: Prepared by the Agency for Toxic Substances and Disease Registry, these profiles include extensive toxicological information for substances found at the National Priorities List (NPL) and other sites.

Toxicology: The study of the adverse effects of biological, chemical, or physical agents on living organisms and the ecosystems, including the prevention and amelioration of such adverse effects.

Toxicology data network (TOXNET): A major group of publicly available databases from the National Library of Medicine.

Toxin: A poison derived from a biological source.

Toxinology: The study of toxins.

Tracheobronchial: A region of the respiratory tract serving to deliver inspired air to deeper portions of the lung, comprised of a series of branching ducts beginning at the trachea and ending at the terminal bronchioles.

Transcript profiling: See *Transcriptomics.*

Transcription: The formation of messenger RNA (mRNA), complementary to a string of DNA.

Transcriptome: The messenger RNA (mRNA) from actively transcribed genes.

Transcriptomics: The techniques available to identify the messenger RNA (mRNA) from actively transcribed genes.

Transgenic: Referring to an organism in which new DNA is introduced into the genome. Some transgenic animal models have been suggested to complement the assessment of the potential for compounds to cause tumor development.

Transgenic animals: Genetically engineered animals carrying genes from a different species.

Translocation: Transfer of a portion of one chromosome to another chromosome.

Translational systems toxicology: Aims to extrapolate human response based on the results from animal and in vitro studies. It emphasizes the use of cell-based assays to provide more relevant data on the effects of short- and long-term exposure to toxicants.

TRH: Thyroid-releasing hormone; a tripeptide secreted by the hypothalamus.

Trophoblasts: Cells forming the outer layer of a blastocyst, which provide nutrients to the embryo and develop into a large part of the placenta.

Trypan blue exclusion: Assay for cellular necrosis; the vital dye trypan blue is only taken up by cells whose membranes have been permeabilized. The cell viability is estimated by counting the fraction of stained (i.e., blue) cells on a light microscope.

TS: Test substance.

TSH: Thyroid-stimulating hormone.

Two-by-two table: The two-by-two table can be used to calculate accuracy (concordance) ($[a + d]/[a + b + c + d]$), negative predictivity ($d/[c + d]$), positive predictivity ($a/[a + b]$), prevalence ($[a + c]/[a + b + c + d]$), sensitivity ($a/[a + c]$), specificity ($d/[b + d]$), false-positive rate ($b/[b + d]$), and false-negative rate ($c/[a + c]$).

			New Test Outcome	
Positive			**Negative**	**Total**
Reference test	Positive	a	c	$a + c$
Classification	Negative	b	d	$b + d$
	Total	$a + b$	$c + d$	$a + b + c + d$

Two-dimensional gel electrophoresis (2D gel electrophoresis): A series of electrophoretic techniques that separates proteins (gene products) on the basis of isoelectric points in one dimension followed by separation on the basis of molecular mass in the second dimension. This technique is useful for obtaining an overall assessment of both up- and downregulation of specific gene products as the result of cellular responses to chemical exposures. This technique separates proteins (gene products) in two dimensions on the basis of isoelectric point in the first dimension and on the basis of molecular mass in the second dimension. It is a powerful technique for proteomic research, particularly when coupled with computerized image analysis systems for quantification.

Tyndall phenomena: The abnormal cloudy appearance of the anterior chamber of the eye when light passes through the pupil; also called *aqueous flair.* It is the result of protein leakage from the iris into the aqueous humor causing the scattering of light and producing cloudiness.

Type I error (false positive): Concluding that there is an effect when there really is not an effect. Its probability is the alpha level.

Type II error (false negative): Concluding that there is no effect when there really is an effect. Its probability is the beta level.

Ultrafine particles: Particles that have all dimensions in the nanometer range; contrast with *Nanoparticles.*

Ultrastructural cytochemistry: A series of in situ techniques for localizing organelle-specific enzymes, such as acid phosphatase for lysosomes and peroxidase for peroxisomes, at the ultrastructural level.

Ultrastructural morphometry: A series of techniques for quantifying changes in organelle systems from electron micrographs in situ; these techniques provide useful correlative information when used in combination with biochemical measurements of chemical-induced alterations in organelle system functionality. The technique is based on the systematic evaluation of large numbers of transmission electron micrographs followed by the statistical analysis of changes in various organelle compartments induced by exposure to toxic agents. Data generated by this technique may be expressed as volume density (*Vv*) of an organelle compartment, surface density (*Sv*), or numerical density (*Nv*).

Uncertainty: Lack of knowledge about specific variables, parameters, models, or other factors. Examples include limited data regarding the concentration of a contaminant in an environmental medium and lack of information on local fish consumption practices. Uncertainty may be reduced through further study.

Uncertainty factor: A factor applied to a no-observed-adverse-effect level (NOAEL) or the lowest-observed-adverse-effect level (LOAEL) that is used to derive a reference dose or reference concentration. The aim of the uncertainty factor is to account for a lack of information on inter- and intraspecies variability, study deficiencies, or an incomplete database. The value, generally from 1 to 10, based on scientific data or judgment, allows for the unknown potential differences in doses or durations of exposure that produce effects in different individuals, different species, or different routes of exposure or are due to an inadequate database on which to base a decision.

Upper respiratory tract: The mouth, nose, sinuses, and pharynx.

Urinalysis: Assays on chemical and biophysical parameters of urine; includes measurement of parameters such as levels of metabolites, protein, glucose and creatinine excretion, urinary enzymes, and urinary specific gravity.

Urinary enzymes: Enzymes secreted into urine used to measure renal function; can often be used as biomarkers of cell-type specific toxicity and function.

Urticaria: Hives; an eruption of itching wheals (welts).

UVR: Ultraviolet radiation.

Validated test method: An accepted test method for which validation studies have been completed to determine the accuracy and reliability of this method for a specific purpose.

Validation: The process by which the reliability and accuracy of a procedure are established for a specific purpose.

Vapor: Gaseous forms of substances that normally are in the liquid or solid state; the gas-phase components of a substance that is a solid or liquid at standard temperature and pressure.

Vapor pressure: The amount of pressure exerted by a saturated vapor above its own liquid in a closed container.

Vaporization: The transfer of a chemical from a solid surface or a solution to a gas, dependent upon the chemical's diffusivity, water solubility, and vapor pressure.

Variability: The range of values expected among individuals of a given population; a term used to describe the natural variation in human (or test animal) responses to chemical exposures. It is also used to describe variation in exposures to chemicals in the environment. Variability represents true heterogeneity, diversity, or a range that characterizes an exposure variable or response (e.g., differences in body weight). Further study (e.g., increasing sample size *n)* will not reduce variability, but it can provide greater confidence in quantitative characterizations of variability.

Vasopressin (antidiuretic hormone, ADH): An octapeptide secreted by the neurohypophysis.

Vehicle: A substance to which a test material is added to provide a consistency or form suitable for its intended

use. In toxicity studies, test materials are added to vehicles to prepare solutions (e.g., water), suspensions (e.g., methyl cellulose), ointments (e.g., petrolatum), triturates (e.g., milk, sugar), and other forms to facilitate administration to the animals.

Venom: An animal toxin.

Viperidae: True vipers; a diverse genus of venomous snakes, many of which are large and extremely dangerous, even deadly.

Vipers: Snakes of the families Viperidae and Crotalidae.

Water solubility: The maximum amount of a chemical that may be dissolved in a given quantity of pure water at a given temperature.

Weapon of mass disruption: A terrorist weapon designed to frighten and disrupt the population.

Whole animal studies: Studies in which physiological function and toxicity are determined in vivo.

Whole-body exposure: Experimental mode of inhalation exposure in which the entire animal is placed within the test atmosphere.

Wolffian duct: Embryonic duct from which the male reproductive duct system, accessory sex glands, and external genitalia are derived.

Xenobiotic: A substance that is foreign to a biological system; a substance (usually) not present in the reference organism; a chemical species, synthetic in origin, that is toxic or damaging to a biological system.

X-ray microanalysis: The in situ localization of trace elements within organelles at the ultrastructural level using the electron beam of either a transmission or scanning electron microscope to displace electrons from specific energy shells (K, L, M) with the resulting release of characteristic x-rays that may be monitored by energy-dispersive or wavelength-dispersive spectrometers.

Zero-order process: A process for which the rate is constant and independent of dose or concentration; characteristic of enzymatic processes under saturating concentrations.

Zonation, hepatic lobule: Quantitative (or qualitative) distribution of enzymes in liver lobules based on morphological configuration.

Zonation, metabolic: Differences observed between enzyme activities in periportal and perivenous regions of the liver.

Zoonotic: Refers to the ability of an organism to be transmitted between species of animals; most commonly used in reference to the ability of an organism to be exchanged between animals and humans.

Zygote: A fertilized ovum.
