Contents

Preface

This is the sixth edition of *Hayes' Principles and Methods of Toxicology*. It has been revised and updated while maintaining the high standards necessary to serve as a reference to the concepts, methodologies, and assessments integral to toxicology. As was the case with the first five editions of the book, new chapters have been added that address the advances and developments in the field of toxicology. These chapters deal with the importance of dose–response, systems toxicology, food safety, the humane use and care of animals, and neurotoxicology. A number of new authors have been added and the glossary has been expanded. Every effort has been made to maintain this book as a tome useful to both graduate students beginning their educational journey as well as the more seasoned toxicologist.

In many ways, toxicology remains a paradox. The words of Paracelsus, the sixteenth-century German-Swiss physician and alchemist, continue to remind us that the line between light and dark, good and evil, poison and medicine is but a fine one that we as toxicologists have been given the awesome responsibility to divine, "Alle Ding' sind Gift, und nichts ohn' Gift; allein die Dosis macht, daß ein Ding kein Gift ist." The first chapter reminds us of the evolution of toxicology, as it has matured over the centuries from its genesis as a science focused on the discovery and use of poison as an expedient tool to commit murder to the advances that have resulted in the use of toxicants to benefit mankind as medicines.

Toxicology is much more than the science of poisons. Practitioners of toxicology need to understand the hazard and the underlying mechanisms of toxicity, as well as the principles of extrapolating experimentally derived hazard information to the assessment of risk under the conditions of exposure in the species of primary interest (humans). The vastness of the field of toxicology and the rapid accumulation of data preclude any individual from absorbing and retaining more than a fraction of the methods, techniques, and information being developed on a daily basis. However, an understanding of the principles underlying these methods is not only manageable but also essential for the practicing toxicologist, and it is to this end that this book was conceived and continues in this edition.

"Training is everything. The peach was once a bitter almond; cauliflower is nothing but cabbage with a college education." (*The Tragedy of Pudd'nhead Wilson and the Comedy of the Extraordinary Twins*—Mark Twain). And thus, we hope to provide in this edition, as before, an experience that continues to educate, elucidate, nurture the inquisitive, and foster the motivation to learn. We begin with four basic principles of toxicology—dose matters, people differ, everything transforms, and timing is crucial. The relevance of these principles is waiting to be discovered, challenged, and applied in the following chapters.

Foreword to the Sixth Edition

How do you see *toxicology*—as molecular magic, a web of biochemical circuitry, a sequence of immunological or pharmacological actions and interactions, or perhaps as clinical harms and pathological findings from which ideas about causes and mechanisms might be deduced? To you is it a set of *effects* for which causes must be found? Is it a process of evaluation of one or many risks leading to a critical and doubtless criticized judgment balancing harm and cost against benefit? Or, put more simply, is *toxicology* one of those uncomfortable disciplines that extends from the precision of basic sciences to the uncertainties of personal and societal judgments required to be accurate and yet to contain the fog of economic, political, and even philosophical debates? Is it really a combination of all these areas in which the practitioner and the student may concentrate on one aspect when a balanced view requires awareness of all the other factors affecting what they study, how it is studied, and how their discoveries and findings will be used?

These questions may seem rhetorical, but the competent toxicologist striving to exert professional skills to their best ends must always be aware of the place of his or her work as it affects people, the environment, and society in general. In this respect, toxicology is unusual in its combination of several natural sciences with the softer and often more controversial disciplines of economics, the law, and political science. To me, *toxicology* is now sufficiently mature to be seen as an example of *systems biology* in which account must be taken of many processes and their proximate and distant interactions.

To do the best job that he or she can for the present and future generations and the environment in which we live, the toxicologist requires broad awareness and understanding of why something is being investigated and how to explore it. The methods employed should reveal or exclude effects with accuracy, consistency, and economy of effort and resources, and in ways that will support subsequent risk–benefit decisions because experience and theoretical knowledge have demonstrated the validity of the procedures and the results they give. The value of the results as indicators of more fundamental biological processes must never be ignored because toxicology both borrows from and supports other sciences.

One of the several particular strengths of this book, the sixth edition, lies in the breadth of its coverage of established and newer methods and tactics for the detection and investigation of toxic effects and for studying the causes of those actions at many levels from populations to individuals and down through tissues and cells to molecules. Toxicology is a derivative science, using the understanding and techniques of other sciences to find, analyze, and evaluate harmful actions. The continuous growth of toxicology has come from its usage of and gifts to its parents of medicine, pharmacology, biochemistry, pathology, immunology, genetics and embryology, and, more recently, development of molecular biology. All those aspects and related disciplines are described here from the viewpoint of the toxicological scientist and practitioner needing awareness of the newest as well as of classical ideas and techniques.

Comparing the contents of the present and previous editions of this book illustrates the continuing but jerky progress of toxicology, sometimes accelerating thanks to new discoveries and methods developed elsewhere, as in the introduction of genetics and immunotoxicity and appreciation of the endocrine disruptors and nanomaterials, sometimes adapting to the novel issues of, for example, genetic manipulation, advanced biotherapies, and the unanticipated exposures of modern urban life, and sometimes taking account of the less than certainties pronounced by some epidemiological and environmental surveyors.

Toxicology is and must remain a vigorous and as far as possible rigorous discipline. Its practitioners and other commentators, who ought to be more aware than they sometimes seem to be of its strengths and weaknesses before making toxicological pronouncements, will find much help in this book in phrasing questions that can be answered, in deciding how best to answer them, and in helping others to understand the realities and practicalities underlying the detection, assessment, and use of toxicological knowledge for protection and as a means to probe biological mechanisms better suited to study by other sciences.

Anthony D. Dayan, MD
Emeritus Professor of Toxicology and Former Director of Department of Toxicology, St Bartholomew's Hospital Medical School, London, United Kingdom

Foreword to the Fifth Edition

Toxicology is an evolving science with ongoing development of methods, concepts, and understanding. It has been only some five years since the fourth edition of this book was published, but a wealth of novel information has been reported in the scientific literature since that time. This is especially true regarding *toxicogenomics*, a term that was coined in 1999 to describe the marriage of toxicology and genomics. Since that time, gene expression analysis has been used as mechanistic toxicology screens, for more sensitive and earlier toxicity discovery, in drug discovery and in drug and chemical safety assessments. Proteomic technologies have also recently been much applied in toxicology, allowing for the examination of the entire complement of proteins in an organism, tissue, or cell type. Using large-scale, high-throughput methods, protein expression, posttranslational modifications, and protein interactions may be studied. Also coming to the fore is metabonomics, where high-resolution ^{1}H-NMR spectroscopy is used in conjunction with pattern recognition to provide a fingerprint of the small molecules contained in a given body fluid that may be applied to define the dynamic phenotype of a cell, organ, or organism. These promising technologies are described in this edition in a new chapter on toxicopanomics.

During the last few decades, a wealth of toxicological information has become available, making it impossible for any individual toxicologist to keep abreast of all new information; for example, the TOXLINE file contains over 3 million bibliographic citations; thus, the need for comprehensive and readily accessible information resources has become apparent. Many web-based, searchable databases are now available that make it possible to retrieve information related to specific toxicological questions. This edition now contains a new chapter on information resources for toxicologists.

Already in antiquity it was well known that nature was not always benevolent and that human poisoning was possible via animal venoms and plant extracts. Such toxins were in earlier times used for hunting, waging war, and assassinations; in modern times, accidental poisoning with natural toxins is rather prevalent in many parts of the world. This fifth edition includes a new chapter on plant and animal poisons.

Because of the considerable societal pressure with respect to reducing the use of animals in toxicology, nonanimal methods are being developed in an attempt to predict what happens when animals, including humans, are exposed to toxic levels of drugs and other chemicals. Such methods include a number of cellular and subcellular systems, as well as mathematical models based on correlating a compound's chemical or structural variation with measured toxicological responses. One new chapter in this edition covers the use of nonanimal methods in toxicology.

Foreword to the Fourth Edition

Publishing a toxicology book on the entrance into the third millennium is an appropriate time to reflect on the progress that has been made in that discipline since its inception. Almost 500 years ago, Paracelsus published a treatise based on his intuitive observations; he merely argued that these observations should convince one that the dose makes the poison. Now science has advanced enough so that we can prove that Paracelsus was correct, because the law of mass action tells us that the degree of perturbation of a system is proportional to the chemical potential of a substance in that system. We still, however, must rely heavily on observational epidemiology to determine the details of exactly what dose effects what change in humans.

The fourth edition of this book is a magisterial, state-of-the-art compilation of the principles and methods that toxicologists must use to identify whether a causal relationship exists between specific doses of a chemical and an alleged adverse effect, observed primarily in humans. Proper integration of principles and methods of toxicology is extremely important since the primary purpose of toxicology is to predict human toxicity. Previous editions of this book have delineated in very useful detail the methods of toxicology and how these methods have been perfected steadily and rapidly in the last few decades. The necessarily heavy reliance on animal experimentation for determining causality in humans is obvious and certainly warranted.

This book was the first to chronicle the overall aspects of the use of animal experiments in toxicology. The exponential rate of growth of toxicology continued to be reflected in further editions of the book, which served as the authoritative and comprehensive source of methods used in this science. Proper and critical conduct of acceptable toxicological tests still continue to create the body of systemized knowledge essential to the science of toxicology.

The current edition continues this tradition but adds some very significant new chapters. These chapters are on epidemiology and exposure assessment, and a chapter on repeat dosing combines previous chapters that subdivided multiple dosing into arbitrary intervals. It is remarkable that we have returned, almost full circle, to an emphasis on direct exposure and effects in human populations after finally, firmly establishing the basic scientific foundations of toxicology. This thorough, complete compendium is a necessary addition to the library of everyone interested in this subject.

William J. Waddell, MD
Professor and Chair, Emeritus
Department of Pharmacology and Toxicology
University of Louisville, Kentucky

Foreword to the Third Edition

Until 1982 when the first edition of this book was published, there was no specific source to which a student or an investigator could turn to for a comprehensive presentation of the methods used in modern toxicology. For anyone who was trying to teach the subject, the book filled a great void for both the teacher and the student. The book appeared at a time when technical achievements in the field related to toxicology were undergoing tremendous refinements. Techniques and the tools of experimental biology, pathology, mathematics, engineering, physics, and analytical/biological chemistry, which had been barely conceived 20 years earlier, were in common use. The rapid growth of toxicology at that same time created a need for scientists from all of these fields to apply their expertise to the science of toxicology. Toxicology borrowed freely from these related sciences so a developing, modern, scientifically acceptable body of procedures became identified as the methods of toxicology. Prior to the span of a single human life, the methods of toxicology consisted of some general, short-term tests for the determination of the overall aspects of this difficult area of toxicology. The exponential rate of growth of toxicology continues, and the third edition of the book continues to be an authoritative and comprehensive source of the methods that are currently used in this science.

If toxicology can be appropriately defined as the study of the harmful effects of chemicals on biologic systems, it must then embody a systemized knowledge of the effects of chemicals that are introduced into the simplest, as well as the most complex, of all biologic systems, and methods must be available to accomplish these experiments. The availability of methods to detect the harmful effects of chemicals allows for the creation of data, but those data become useful in toxicology only after they are suitably interpreted. An additional link toward understanding the subject of toxicology is the placing of results obtained from the available methods in their proper relation and perspective to the whole picture of the role that toxicology can play for the improvement of mankind. In order to accomplish this function, the toxicologist must not only develop an understanding of the methods used but also determine the significance or insignificance of their data in the complete picture of the toxicity of each compound. My graduate school mentor, Dr. Roger Hubbard, once told me that no scientifically valid experiment creates erroneous results, but inappropriate application of those results can create erroneous conclusions. An understanding of the principles together with the methods involved in the science of toxicology prepare the critical scientist for developing an insight with regard to the proper application of experimental results. Results that are properly obtained by acceptable methodology and that are suitably weighted for the conditions under which they were obtained certainly contribute to the development of proper conclusions. In this book, very highly qualified toxicologists present the procedures in detail that are currently used and accepted in the field of toxicology. Discussions of each procedure or category of procedures enable the conduct of acceptable toxicologic tests that create the body of systemized knowledge essential to the science of toxicology. Properly applied, that knowledge serves to protect mankind and the biologic realm in general from sudden, as well as delayed, insidious chemically induced harm.

Acknowledgments

We express our warmest appreciation to the many knowledgeable individuals who have contributed knowingly and otherwise to the sixth edition of *Hayes' Principles and Methods of Toxicology*. The good contained within this tome is due in no small part to the various chapter authors; the bad resides solely with the editors. We most heartily thank each of the chapter contributors, who either revised their chapters or prepared new chapters, for keeping in mind that thoughtfully worded information is greatly appreciated, especially by the student but also by the more advanced reader. We thank Jill Jurgensen and Kathy Brailer for their skillful handling of the manuscript. Appreciation is also expressed to our publisher, Barbara Norwitz, and the staff at CRC Press.

Editors

Dr. A. Wallace Hayes is a toxicologist with over 35 years of experience in industry and academics. He holds degrees from Auburn University (PhD and MS) and Emory University (AB). Dr. Hayes was an NSF predoctoral fellow at Auburn University, an NIH individual postdoctoral fellow at the Vanderbilt University School of Medicine, and a NATO Senior Scientist at the Central Veterinary Laboratory in Weybridge, England, and was a recipient of a NIH Research Career Development Award. Dr. Hayes has held tenured professorships at the University of Alabama, the University of Mississippi Medical Center, and Wake Forest University School of Medicine. He has served on committees and expert panels for the National Academy of Sciences, the National Institutes of Health, the Environmental Protection Agency, and the Department of Defense. He has also served on a number of Generally Recognized as Safe (GRAS) expert panels. Dr. Hayes has authored more than 225 peer-reviewed publications; is the editor of *Principles and Methods of Toxicology*, *Human and Experimental Toxicology*, and *Cutaneous and Ocular Toxicology*; and serves as coeditor of the Target Organ Toxicity Series. He is the editor in chief of *Food and Chemical Toxicology*. He has also served as the past secretary-general of International Union of Toxicology (IUTOX) (two terms); as past treasurer and board member of the American Board of Toxicology; as past president of the American College of Toxicology, the Toxicology Education Foundation, and the Academy of Toxicological Sciences; and as past member of the council of the Society of Toxicology. Dr. Hayes is a diplomate of the American Board of Toxicology, the Academy of Toxicological Sciences, the American Board of Forensic Medicine, and the American Board of Forensic Examiners. He is a fellow of the Academy of Toxicological Sciences, the Institute of Biology (UK), the American College of Forensic Examiners, and the American College of Nutrition. He is also a registered toxicologist in European Registered Toxicologist (ERT) and a certified nutrition specialist (food safety). Dr. Hayes was honored by the Society of Toxicology in 2006 with the Society's Merit Award, by the Mid-Atlantic Society of Toxicology with its Ambassador Award in 2012, by the American College of Toxicology in 2012 with its Distinguished Scientist Award, and by the International Dose-Response Society in 2013 with its Outstanding Leadership Award.

Dr. Claire Kruger is president of Spherix Consulting, Inc. With more than 25 years of consulting experience, her primary area of expertise is in foods, consumer products, and pharmaceuticals, where she provides scientific, regulatory, and strategic support to clients in both the United States and international regulatory arenas. She has conducted toxicity evaluations of foods and food contaminants, as well as health risk assessments and exposure assessments of drugs, cosmetics, and pesticides. Her clients include food, drug, and dietary supplement manufacturers, agricultural producers, biotechnology companies, trade associations, and law firms.

In her role as a consultant, she has been involved in the safety evaluation of a variety of consumer products, providing oversight of product compliance with current and emerging scientific and regulatory guidance. Dr. Kruger provides evaluations of the potential health risks related to employee and/or consumer exposure to consumer products. She has worked with clients to develop product stewardship programs to ensure appropriate guidance for sourcing of ingredients and for manufacturing, distributing, and using products.

Dr. Kruger has been involved in evaluating the safety of foods, novel foods, food additives, Generally Recognized as Safe (GRAS) substances, dietary supplements, food contact substances, and food contaminants. She has developed health risk assessment and regulatory compliance dossiers for ingredients used in dietary supplements, infant formulas, medical foods, novel foods, and functional foods.

In this role, Dr. Kruger has dealt with issues relating to all aspects of food production, from manufacturing process and ingredient specifications to preclinical safety evaluation and human clinical testing. She has prepared numerous GRAS determinations and notifications and has served as an expert for many GRAS determinations. Dr. Kruger has also assessed the safety of and prepared premarket notifications for a number of dietary supplements. In addition, she has developed novel approaches for evaluating the safety of bioactive components and has employed these approaches in completing GRAS determinations for several novel bioactive products and functional foods. Dr. Kruger has also assisted clients with the identification, screening, and documentation of data for candidate ingredients to assist companies in evaluating these products for potential label claims.

>
> **Oliver Wendell Holmes, Jr.**

PREFACE

History is full of bad intentions, ignorance, and folly. Poisoning has been part of each of these for as long as humans have lived. Understanding poisons—to control them or avoid them—has therefore been an integral part of our past. As our understanding of poisons progressed, a unique field of knowledge grew into the science of toxicology. This chapter captures toxicology's *wissenschaften*, its emergence as a distinct field of study from its vague, sometimes dark, beginnings. Toxicology passed through a number of phases during its maturation into a recognized discipline. These include the use of poisons to kill, listing poisons and their effects (observation/phenomenology), guessing at possible antidotes, identifying occupational causes of disease, detection of poisons, experimentation to deduce the mechanisms of toxicity, development of rational therapeutic measures, and finally quantification of effects. As toxicology moved along this path, it evolved from harming people to helping them by protecting them from the adverse effects of chemical exposure at home, in the environment, and in the workplace.

The use, abuse, and misuse of chemical agents by individuals, groups, and societies over time form the basis of toxicology and how it developed as a discipline. This chapter will demonstrate how toxicology has developed as a science from the study of chemicals to induce harm (the art of poisoning) to a study of chemicals in order to prevent harm (the science of preventing poisoning) and benefit humankind. Toxicology has come forward to be a critical and respected member of the scientific and medical communities.

* Richard W. Lane is an employee of PepsiCo, Inc. The views expressed in this chapter are those of the author and do not necessarily reflect the position or policy of PepsiCo, Inc.

The title and emphasis of this chapter are slightly revised to focus on the deliberate and systematic examination of poisons. *Wissenschaften* is generally translated as *science* or *the sciences*, but the word also refers to the growth and development of any field of intellectual inquiry, such as literature, religion, law, and the sciences. It is the latter meaning that is used here to emphasize the emergence of toxicology as its own discipline. This chapter looks at the evolution of toxicology, the events and people that influenced and shaped its course. There will be more weight on situations that show the understanding of poisons and how the science of toxicology developed.

The observant reader will note other changes in this chapter. The most important is the absence of Dr. Joseph Borzelleca as an author. His work on this chapter over the years was seminal, and everyone in the field owes him a debt of gratitude for it. From his lead, the examination of the history of toxicology flourishes. The amount of new information and insight now available has grown substantially. The Society of Toxicology has published articles and posters. Numerous books have been published. Articles in major journals abound. Information on the Internet is sometimes overwhelming. There is even a society for this endeavor! With all this new information, some parts of the earlier versions have been revised or removed. Events after around 1970 have been omitted unless continuity is important. The style and intent of previous versions have been maintained to the extent possible, but differences are inevitable.

INTRODUCTION

Poisonings—accidental, intentional, and unintentional—form the basis of toxicology. Poisonings have occurred throughout history and is intertwined with most of the important aspects of human life, such as eating, politics, working, religion, folklore, murder, suicide, and warfare. Poisoning evokes both dread and fascination. Toxicology, the study of poisons, takes something that is inherently emotive and forces the practitioner to rationally deal with agents that can harm. By rationally applying his/her knowledge, the toxicologist can positively influence individuals' and the public's health.

A toxicologist uses his/her knowledge for the *proper* use of chemicals and mixtures. In some cases, this involved how to kill or harm. In others, the toxicologist allows the appropriate use of chemicals by establishing safe limits of exposure so that harm does not occur. In both instances, toxicology provides the basis for obtaining the desired outcome.

Initially, toxicology involved listing poisons, noting their onset of action and the nature of the harm produced (painful or painless, terminating in death or not, etc.). Observations in humans following exposure to toxic plants, minerals, or animals and recommendations for treatment—sometimes based on limited evidence—are hallmarks of the early phases of toxicology. As medicine evolved and observations about disease became more astute, epidemiology became possible, and effects could be associated with a cause. As chemistry evolved, detection of poisons became possible and toxicology moved into forensics. As the basic sciences evolved, poisons could be studied at the cellular level. The famous French physiologist, Claude Bernard, used poisons more than 150 years ago to investigate basic physiological phenomena. This marked a major turning point in toxicology as poisons were now being used as experimental agents to dissect the basis of physiology and cell biology. These studies could elucidate the mechanism of action of poisons, which could lead to the development of appropriate treatment modalities (i.e., antidotes) and/or to identifying safe exposure limits. Today, the study of poisons includes knowledge of the physiological, biochemical, and morphological effects of a chemical and understanding the mechanism of action at the organ, cellular, and molecular level. In this way, toxicology reflects the development of society: a progression from simplicity to sophistication, from crude to cultured, from elemental to elegant, from superstitious to scientific, and from taking lives to saving lives.

Poisons also cause psychological harm. The threat of poisoning can be terrifying, and poisons have generated fear throughout time, right up to today. Because poisons are tasteless or can be disguised, people have become fearful of them in any amount. The mere instance of a chemical can inflame the public, sometimes even when no physical harm can be demonstrated. There are numerous periods in history when the fear of poisoning far surpassed any physical harm. At times like those, rumors and inaccurate reports become facts. The misinformation can lead to hysteria, which can lead to countermeasures that often results in secondary problems worse than what started the problem in the first place. Unfortunately, proper communication of correct interpretation of the data is difficult and is drowned out by the clamor for action.

HARMING AND HELPING THROUGH TIME

Initially, poisoning was accidental. As man learned about toxic agents through experience, he could avoid them, a proper use of knowledge. But poisoning also could be deliberate, an abuse of knowledge. Once the value of poisons was recognized, they became very appealing solutions to difficult problems, like how to overcome superior physical force. Initially, killing involved the use of physical agents (clubs, spears) that required strength and skill, favoring large humans. How could smaller individuals level the field? Poisons were an answer. Knowledge of the poison, along with cunning, was required for success.

Once a need for poisons had been established, an industry of suppliers and practitioners developed for implementation. As people became more aware of poisons, laws were developed to prevent their use. Subtler, more sophisticated (i.e., undetectable) poisons were needed. The do-it-yourself poisoners were replaced by professional poisoners (early, applied toxicologists), who offered advice, provided materials, and perhaps even performed the required services. New agents developed by practitioners could make the

poisoning fast or slow, painful or painless. As poisoning developed into an art, its practitioners became infamous. The popularity of poisoning grew until it reached epidemic proportions in some countries. The resulting fear was enhanced by the inability to detect poisons and to prove that poisoning had occurred. Identification of the perpetrator was extremely difficult since determination of the cause of death (proof of poisoning) required analytical techniques that had not yet been developed.

Prevention of poisoning was accomplished by using bioassays (e.g., official tasters of prepared food and drink), taking precautions (only eating food of known origin, not eating foods that contained lumps or were highly seasoned), and developing tolerance/adaptation through the repeated ingestion of small doses of toxins.

Forensic toxicology began when advances in analytical techniques were applied to the detection of poisons. The Marsh test, developed in 1836 by British chemist James Marsh, allowed arsenic, the most popular poison at that time, to be identified unambiguously. More tests followed and more poisons could be identified. This had the intended effect of reducing poisonings because the poison could be identified, the perpetrators tried in court, and appropriate action taken. Practitioners became ever more sophisticated in their attempts to avoid detection, but they were no match for the chemists who continued to develop more sensitive and specific analytical methods. Once chemists turned their skills from developing poisons to detecting them, the popularity of such agents declined rapidly and poisoning became less common. Although subtle and ingenious means of poisoning are available today, forensic methods have made undetected poisoning nearly impossible.

As the use of poisons to dispatch people declined, their use as tools to understand physiological and pathological processes increased. Their redeeming value emerged. There are uses for poisons beyond harming! Agents commonly referred to as *poisons* have contributed to the health and safety of humankind and to the advancement of biological sciences, including medicine, in many ways. Claude Bernard, probably the first mechanistic toxicologist, used curare to study the neuromuscular junction. He wrote in 1878:

> Poisons can be used as agents for the destruction of life or as means to cure disease; but in addition to these uses – there is a third which particularly interests the physiologist. For him the poison becomes an instrument which dissociates and analyses the most delicate phenomena of the living machine and by careful study of the mechanism of death in different poisonings, he can gain knowledge, indirectly, of the physiological mechanism of life. (i.e. poisons can be used to explain physiological events). (Translation of P.N. Mage, 1965)

Dozens and dozens of other *poisons*, too numerous to list here, have helped us understand fundamental biology.

Further to helping mankind, knowledge of the proper use of chemical has been applied in many basic ways. Chlorine gas was one time used as a weapon of war due to its ability to cause pulmonary irritation, acute damage in the upper and lower respiratory tract, and eventually slow death by asphyxiation. Today, it is used as a disinfectant to treat public drinking water to prevent illness by dramatically reducing the threat of waterborne diseases. Its proper use has saved millions of lives. Smoke, an irritant also used in chemical warfare, is also used to preserve food. The use of pesticides, poisonous by their very design, which help feed a growing population by controlling unwanted plants and animals, has resulted in increased food production and subsequently in better nutrition, health, and longer life expectancy. Again and again, humans can use toxic compounds in a useful fashion to control their environment to their benefit.

When it became known that nondeliberate exposure to chemicals could produce adverse health effects (e.g., in the workplace and environment), efforts were directed at the prevention of the effects by defining safe conditions of exposure to protect humans and other life forms from injury. Dose–response relationships were established as correlations between the level of the chemical in blood and/or in tissues and biological activity were made. This was followed by the identification and quantification of the risk of adversity following exposure (risk identification, assessment, and management). Quantifying a risk, assigning a number to it, tends to decrease the uncertainty of extrapolation, lessen anxiety, and provide a degree of comfort. Quantification of the responses to toxic agents and the relationship of structure to biological activity are the basis for a great deal of scientific activity.

Starting from the art of poisoning, supplying and using poisons, the toxicologist now studies their mechanisms of action, develops analytical methods to identify and quantify poisons in body fluids and tissues, develops rational antidotes, establishes safe limits of exposure from carefully designed and executed studies, and quantifies and predicts adverse effects. The toxicologist now plays a critical role in the advancement of humankind.

PREHISTORY

Poisonings—it is not unreasonable to assume that harmful plants, moldy grains, and venomous animals were accidentally encountered with dire consequences—predate recorded history and make toxicology arguably the oldest biological science. The earliest view of poisons, based on everyday life and needs, began when man had only a rudimentary view of nature. As with many aspects of everyday life, the interpretation of the effects was frequently mixed with religion and mysticism. Finding food was a matter of chance, and if you picked the wrong plant, you could be in trouble. Cause and effect were generally unknown. Early man may have thought himself surrounded by poisons. After some trial and error, the distinction between poisonous and nutritious plants became known. But even food that was wholesome at one point could be contaminated by mold and rendered injurious. Thus, there was still a great deal that was unknown and uncontrollable. Life must have seemed capricious. It is easy

to imagine how poisoning could be seen as *magic* or an act of the gods. Mysticism and superstition made up for the lack of knowledge.

To establish that poisoning occurred, it is essential to demonstrate that a particular substance caused the adverse effects. This was often very difficult because cause and effect were not always evident when there was no understanding of pathogens, chemicals, and poor nutrition. Early man had to study hard to determine exactly what had caused an illness based on underlying assumptions about the nature of man himself and the world at the time.

Once cause and effect were established, toxic substances could then be used intentionally as tools to catch prey and dispose of unwanted persons. The initial instruments for killing were physical weapons that required strength and skill for effectiveness. Later developments, such as the bow and arrow, required more skill and less physical strength, but something more was needed to feed growing families and control one's surroundings. Might poisons be what were needed to solve some problems? As early humans learned through experience that plants were beneficial and were poisonous, the poisonous ones were used as aids in hunting, such as arrow poisons like curare from the resinous extract obtained from several tropical American woody plants. Poisonous animals were also discovered and the people in South America used the secretions from amphibia to kill animals for food. The adverse effects of venomous insects and animals were probably also noted, but the practical utility of these venoms was limited.

Poisons proved to be very useful in killing animals, and it did not require a great a leap of reasoning to extrapolate from the effects seen in animals to humans. Although killing people was not sanctioned (*Thou shalt not kill*.), could humans be dispatched as readily as animals with the use of poisons? It is unknown when the first human intentionally used a substance to kill another human, but humans have an instinct to control their own destinies and to satisfy their lust for power, wealth, and pleasure. The age of poisoning, of practical toxicology, the seduction by toxicology, had begun. Poisons moved from being random problems to predictable tools. Seduced by toxicology, man would use poisons for his advancement throughout history.

OBSERVATION/RECORDING OF PHENOMENA

With the development of civilizations and writing, the known causes of toxicity could be recorded so that others could learn about them. Many early cultures had lists (catalogs) of poisons and their effects in humans, based on keen observation. Interest in plants that are harmful to health and as tools for vindication evolved, as did their beneficial use, predominantly herbs, for medicinal purposes. The cures for the problems of humankind (healing or killing) could be found in nature. With time, the lists began to include detailed descriptions of preparation, use, and effects of biologically active plant materials. Metals were used for therapies. There was some interest in the properties of animals, but most writings dealt mainly with avoiding venoms. Prevention and treatment of poisoning and envenomation emerged.

Egypt

Egyptian medicine was reputed to be the most advanced of the ancient world, and as expected, the first known list of poisons and antidotes appears in Egyptian writings. Egyptian medicine was based on the work of the gods and the presence of evil spirits in the sick person. Medicines such as herbs were mostly expected to lessen pain, while magic effected the cure. However, a portion of Egyptian medicine was based on experimentation and observation, including the effects of poisons. Menes, the first Pharaoh of unified Egypt and the founder of Memphis, the capital, was reported in Egyptian papyri to have had an interest in poisons. He cultivated and studied the effects of poisonous and medicinal plants somewhere between 3500 and 3000 BC. Unfortunately, there is no detailed written history of these activities.

The Ebers Papyrus (c. 1550 BC) is one of the oldest known writings pertaining to medicine. It contains 110 columns of hieratic (priestly) script (equivalent to about 110 pages). It reveals many customs, practices, and traditions of Egyptian doctors and describes over 800 recipes, many containing recognizable poisons such as hemlock, aconite, opium, and some of the heavy metals. The formulas also contain over 700 drugs (medicinal substances), specific indications, and dosages, together with appropriate spells and/or incantations. Forty-seven case histories are presented. Modes of administration include snuffs, inhalations, gargles, pills, troches, suppositories, enemas, fumigations, lotions, ointments, and plasters. Vehicles included beer, wine, milk, and honey. Drugs were identified on the basis of origin as plant (e.g., acacia, castor bean, wormwood, fennel, garlic), animal (e.g., honey, grease, milk, excrement), or mineral (e.g., alum, iron oxide, limestone, sodium bicarbonate, salt, sulfur). Insect and animal venoms were described.

The Egyptians had some correct general principles of toxicology, but the concept of cause and effect was missing that consequently led to poor treatments for disease. Herbs played a major role in Egyptian medicine as antidotes, as were some minerals.

The Egyptians used chemicals in the administration of justice. The penalty of the peach involved having the accused ingest the distillate from crushed pits of peaches that are high in amygdalin and forms hydrocyanic acid. If the accused died, it was a presumption of guilt. If the accused lived, it was a presumption of innocence. The practice of using chemicals in the administration of justice continued into other cultures (e.g., Greek, Roman) and persists to the present with injections of chemicals used in some state executions.

Thousands of years later, Cleopatra (c. 69–31 BC) poisoned her second brother after Caesar was murdered so she could jointly rule Egypt with her infant son. According to a recent theory by Christoph Schaefer, she likely committed suicide by hemlock, wolfsbane (aconitum), and opium, not by the bite of an asp.

China

Legend has it that the second of China's mythical emperors, Shen Nung, is the father of Chinese medicine and agriculture. He is credited with writing a 40-volume work entitled *Pen Ts'ao* or *Pun Tsao* (the Great Herbal, a Chinese *materia medica*) around 2735 BC. It contained lists of poisonous plants, plants with medicinal value (365), and drugs (265, 240 of which are of plant origin). The effects of plants and drugs and appropriate antidotes were described. Drugs and poisons were presented together, presaging the concept that the dose differentiates a poison from a remedy. Included among the drugs were iodine, aconite (also used as an arrow poison), opium, cannabis, rhubarb, alum, camphor, iron, sulfur, and mercury. Shen Nung was also reputed to have discovered a number of drugs and experimented upon himself.

Another emperor, Huang Ti (2650 BC), reportedly wrote *Huang Ti Nei Ching* (*The Yellow Emperor's Medicine Classic*), the oldest extant classic of traditional Chinese medicine. Although the *Huang Ti Nei Ching*'s authorship is attributed to the Yellow Emperor, it was more likely written by several authors over a long period of time, compiled roughly 2000 years ago. The book is divided into two sections, the second being *Lingshu* (*The Vital Axis*) and was written sometime in the second century BC with revisions taking place up to the Han Dynasty (206 BC–AD 25). This great work forms the theoretical basis of traditional Chinese medicine. As traditional Chinese medicine's history developed over the millennia, nearly all significant medical works benefited from the enlightenment of this unparalleled book. *The Yellow Emperor's Medicine Classic* demonstrates that even in ancient times, people accomplished scientific achievements that are applicable, relevant, and innovative in modern times. It still remains one of the most respected and studied texts on Chinese medicine.

Another medical text, found during an excavation of the Mawangdui tombs and dating back to 168 BC, is the *Wushier Bingfang* (*The Fifty-Two Prescriptions*). It detailed 52 ailments and 52 prescriptions, an early written reference of Chinese pharmacology.

The Chinese may have been the originators of chemical warfare. Chinese writings contain hundreds of recipes for the production of poisonous or irritating smokes for use in war, as well as providing accounts of their use. There are reports from the fourth century BC of the Chinese using bellows to pump smoke from mustard and other noxious vegetable matter into tunnels being dug by a besieging army in order to discourage the diggers. Cacodyl (tetramethyldiarsane, $As_2(CH_3)_4$), a colorless liquid possessing an intensely disagreeable garlic-like odor, in smoke is also mentioned in early manuscripts.

India

The *Rig Veda*, a Sanskrit document written between 1500 and 1200 BC, is the earliest account of Hindu medicine. It contains many references to alchemy, science, and magic in the treatment of disease. Medicinal and poisonous plants and antidotes (e.g., for snake bites) are listed. The influence of gold as a therapeutic agent and for longevity is discussed. A later work, the *Ayurveda*, the Veda of long life, is a Sanskrit document written about 700 BC. It discusses medicine and all its branches in eight parts; drugs and poisons are also mentioned.

Sushruta (c. 380–450), a Hindu surgeon, authored a medical/surgical text called *Sushruta Samhita*. The section on drugs listed 760 indigenous medicinal plants, of which many were used externally as ointments, baths, sneezing powders, and inhalations. It also listed animal and mineral remedies. The fifth section, the *Kalpa Sthana*, was the section on toxicology, dealing with the nature of poisons and their management and advanced treatments for venomous snakebites.

Greece

The Greeks borrowed heavily from the medicine of Egypt, and they took it forward through their system of philosophy, which included what we now call science. Over the centuries, this philosophy formed the theoretical basis of their attempts at a causal foundation for explaining disease.

The Greeks had lists of poisons and antidotes that were consulted by citizens and the government. They had a great deal of knowledge about plant poisons and metals, especially arsenic, antimony, mercury, gold, copper, and lead. Other and more significant contributions to the advancement of toxicology include detailed descriptions of the effects of various agents in humans, antidotes, and principles for the management of poisonings (e.g., hot oil and vomiting).

The Greeks executed criminals with poisons, with Socrates (469–399 BC) being the most famous victim of state poisoning in history. Socrates' iconoclastic attitude did not sit well with everyone, and at age 70, he was charged with heresy and corruption of local youth. Convicted, he carried out the death sentence by drinking hemlock (the state poison), becoming one of history's earliest martyrs of conscience.

Suicide and murder by poisoning was not uncommon since poisons were readily available. The Greeks also used chemicals in warfare. Solon of Athens used hellebore roots (which contains two glucosides, helleborin that is narcotic and helleborcin that is a highly active cardiac poison, similar in its effects to digitalis, and purgative) to poison the water of the River Pleistos during the siege of Kirra around 590 BC.

Pythagoras of Samos (c. 570–480 BC) may be the first Greek to have an influence on toxicology. Although best known as the mathematician who developed the theory of numbers and considered to be the founder of arithmetic, he was also a physician and scientist who was especially interested in procreation and animal physiology. His contributions to toxicology include his studies of the effects of metals (e.g., tin, iron, mercury, silver, lead, gold, copper) in the body. Since he left few, if any, writings, all of his teachings have come through his pupils.

Hippocrates (460–377 BC), known as the *father of medicine*, was born on the island of Cos, the son of Heraclides,

a physician, and Phenarete. His contributions to the advancement of medicine are legendary, due in great measure to his belief that the causes of diseases were natural and not supernatural. Writings attributed to him rejected the superstition and magic of primitive *medicine* and laid the foundations of medicine as a branch of science. Like other Greek physicians, he believed that health was the result of an equilibrium or balance in the body among the humors (blood, black bile, yellow bile, and mucus) and that disequilibrium resulted in ill health.

He apparently was the first physician of record who believed that environmental factors should be considered as probable causes of disease. In his book *Airs, Waters and Places*, he argued that environmental factors (overall weather, local weather conditions, and drinking water) can influence health. "Every disease has its own nature and arises from external causes, from cold, from the sun, or from changing winds."

Hippocrates identified about 400 drugs, mostly of plant origin, that included narcotics (e.g., poppy, henbane, mandragora [mandrake]), purgatives, and sudorifics (inducing perspiration; diaphoretics). He also advocated the use of emetics and enemas as part of the cleansing process. His contributions to toxicology include the use of sound observation, logical reasoning, and basic approaches to the management of intoxication (decrease absorption; if ingested, induce vomiting) and the use of proper antidotes.

Hippocrates recognized lead toxicity among miners and metallurgists, although no concern was demonstrated for their protection.

Diocles of Carystus (375–300 BC), also known as *the younger Hippocrates*, was one of the most prominent medical authorities in antiquity. A pupil of Aristotle, he wrote one of the earliest *materia medica* (*materials of medicine*, a reference that lists the curative indications and therapeutic actions of medicines), the *Rhizotomikon*. It is considered to be the first work on botany that included the names of the plants, their habitat, means of collection, and medical uses. His second book on plants described those used for food, and his third dealt with poisonous plants. His works indicate that serious attention to the pharmacology and toxicology of plants had begun. Along with Hippocrates, Diocles extended toxicology beyond merely listing poisons and antidotes. Rational methods for the study of the effects of poisons and the treatment of poisoning were proposed. Experimental studies to assess the biological effects of plants had begun.

> Nature does nothing without a purpose.
>
> **Aristotle**

Heraclides Ponticus of Tarentum (387–312 BC), a philosopher and student of Plato, was reported to have spent a great deal of time studying poisons and antidotes. Heraclides belonged to the *empiric* school, which rejected anatomy as useless and which relied entirely on the use of drugs. He may have been the first physician to indicate the value of opium in certain painful diseases.

Theophrastus (372–287 BC) studied in Athens under Plato and afterwards under Aristotle. He became the favorite pupil of Aristotle and one of his chief collaborators in the attempt to achieve a complete study of all the known fields of wisdom. Aristotle named Theophrastus his successor and bequeathed to him his library and manuscripts of his writings. Theophrastus was probably the most famous Greek botanist/herbalist. He wrote *De Causis Plantarum* (*About the Reasons of Vegetable Growth*) and *De Historia Plantarum* (*A History of Plants*) in 300 BC. These works may be considered the beginning of modern botany and served as an excellent text of medicinal and poisonous plants, as well as indications for the use of medicinal plants. They were an important influence on medieval science. His contributions to toxicology include a list of poisonous plants and the recognition of adulterated food.

An important figure in toxicology was Nicander of Colophon (185–135 BC), a Greek physician, poet, and grammarian who wrote, among other things, two didactic poems about poisons. They are the most ancient works devoted exclusively to poisons. The longest, *Theriaca*, is a hexameter poem (958 lines) on the nature of venomous animals and the wounds they inflict. The other, *Alexipharmaca*, consists of 630 hexameters on the properties of poisonous plants, including opium, henbane, poisonous fungi, colchicum, aconite, and conium (poison hemlock), and their antidotes. Although there were fanciful parts, much was accurate and reflected his powers of observation and his experiences. Nicander divided poisons into those that killed quickly and those that killed slowly. He recommended emetics in the treatment of poisoning. So important were these works that *theriac* has come to mean antidote against all poisons, a concept that survived into the eighteenth century.

An interesting person, although not a Greek *per se*, was Mithridates VI, or Mithridates Eupator, (132–63 BC), king of Pontus (now the northeastern part of Turkey). In 120 BC, while still a child, Mithridates became king. His mother, said to have assassinated her husband Mithridates V, ruled in her young son's stead. Afraid his mother would try to kill him, Mithridates went into hiding, at which time he started ingesting small doses of various poisons in order to develop protection. When Mithridates returned (c. 115–111 BC), he took command, had his mother imprisoned, and set about extending his dominion. Mithridates was obsessively possessed with a fear of poisons. As protection, he took poisons daily, beginning with very small doses and increasing the amounts ingested to develop a polyvalent tolerance. He drank the blood of ducks fed toxic chemicals and took mixtures of antidotes. It has been reported that he may have ingested all the known poisons and their antidotes every day of the year each day starting early in his life. Mithridatum, his universal antidote, was to be taken each morning before breakfast to effectively prevent poisoning. The term *mithridate*, meaning an antidote or preventive for poisoning containing many ingredients, immortalizes his contribution to toxicology.

Mithridates was a student of toxicology and one of the first to systematically study poisons in humans. He tested

the effects of poisons and their potential antidotes on slaves, criminals, and prisoners. He used his knowledge of poisons against his enemies when, in 67 BC, the Roman general Pompey led a large army against Mithridates. Mithridates slowly retreated over the course of a year, until he reached the southern shores of the Black Sea. Along the way, near the outskirts of the city of Trabzon, he left a large supply of locally produced honey in clay pots knowing that it would be found and eaten by the advancing Roman army. Three squadrons of Pompey's army found and ate the honey and then became violently ill. That honey, locally called *mad honey*, was left for the Romans because it was produced from the nectar of rhododendrons. Mithridates knew about the mad honey in that region because his adviser, the Greek physician Kateuas, had read about Xenophon's experiences in the same area in 401 BC when his whole army became sick after eating the local honey. The *mad honey* contained grayanotoxin. Although grayanotoxin poisoning is rarely fatal, the physical effects—vomiting, loss of coordination, muscular weakness, low blood pressure, and hallucinations—often last for 24 h or longer. Part of Pompey's army was rendered helpless to repel their attackers and many were killed. Pompey eventually prevailed over Mithridates and found the prescription for mithridatum. He sent it to Rome where efforts to improve upon it were made (described in the following).

It is said that when Mithridates saw that people supported his son over him, he attempted to take his own life, but failed because of the resistance he had built up to poison. He had to ask one of his mercenary soldiers to kill him with a sword.

Dioscorides (Pedanius Dioscorides) (AD 40–90), was born in Anazarbia in Cilicia (today's Turkey). He was a Greek physician, pharmacologist, and botanist who practiced in Rome at the time of Nero. He was a surgeon with the army of the emperor so had the opportunity to travel extensively, seeking medicinal substances (plants and minerals) from all over the Roman and Greek worlds. Dioscorides is famous for writing a text on botany and pharmacology free from superstition, *De Materia Medica* (*On Medical Matters*), that was a precursor to all modern pharmacopoeias. This five-volume set (*On Plant Materials*, *On All Manner of Animal*, *On All Manner of Oils*, *On Materials Derived From Trees*, and *On Wines and Minerals and Other Similar Substances*) became the leading text in pharmacology for 16 centuries. It covered 4740 medical uses of the materials and included descriptions of about 600 plants and 1000 simple drugs. Also discussed are the dietetic and therapeutic value of animal products (e.g., milk, honey) and mineral drugs (e.g., mercury, arsenic, lead acetate, calcium hydrate, copper oxide). He also described a surgical anesthetic made from opium and mandragora (mandrake). He was the first to recognize the toxicity of mercury. His contributions to toxicology include classifying poisons into three major classes (animal, plant, mineral), identifying antidotes, and recommending decreasing absorption to control intoxication (e.g., by inducing vomiting or purgation; cf. Hippocrates of Cos).

Galen of Pergamum (AD 129–c. 216) may be second only to Hippocrates of Cos in his importance to the development of medicine. If the work of Hippocrates represents the foundation of Greek medicine, then the work of Galen, who lived six centuries later, is the apex of that tradition. He knew all of the medical knowledge of his day, gathered it together, and wrote about it voluminously and well. Greek medicine was transmitted to the Renaissance scholars essentially in the form of Galenism. It was Galen who first introduced the notion of experimentation to medicine. Galen argued that although apothecaries knew drugs, only the physician understood both the drug and the patient and, further, that drugs are tools only for physicians (hence, few experimental nonphysician pharmacologists in Greece). He introduced rationality into drug therapy. He recommended mixtures of drugs for treating disease, which is the basis for the term *galenicals* (medicinal preparations or remedies composed mainly of herbal or vegetable matter). He further developed the theriaca, the universal antidote, to include 100 substances, which was to be administered in honey and wine. Galen warned against the adulteration of herbs and spices.

Galenic physiology continued Hippocratic concepts and was a powerful influence in medicine for 1400 years. Galen and his work *On the Natural Faculties* remained the authority on medicine until Vesalius in the sixteenth century, even though many of Galen's views about human anatomy were incorrect since he had performed his dissections on pigs, Barbary apes, and dogs. His writings were a blessing to the ancient world, but they became a curse when, for more than a millennium, they were held to be an unassailable authority and paralyzed the progress of medicine, something Galen would have greatly deplored.

Paul of Aegina (AD 625–690) was a celebrated Greek physician during the Byzantine period and was probably the *last Greek compiler.* He was the quintessential student of the best medical authorities, Hippocrates and Galen, and authored a seven-volume medical encyclopedia, *Epitome*. Book 5 deals with toxicology, specifically bites and wounds of venomous animals. He also displayed a peculiar genius in the field of surgery, and the sixth book, *A Treatise on Surgery*, influenced European and Arabic surgery into the Middle Ages. *Paul of Aegina's Medical Handbook* or *pragmateia* was transmitted and transformed through Syriac and Arabic translations, to become one of the cornerstones of the Islamic medical tradition. Paul's influence on the development of medical theory in the Islamic world and beyond makes him an important contributor to Greek and Arabic medicine.

Rome

The Romans had an intense interest in poisons. Records back to the fourth century BC indicate that poisoning was common as a means of suicide and murder. Cicero's court speeches confirm the high incidence of murder by poison in the first century BC. Poisoning during the first century AD reached a peak during the reign of the Julio-Claudian emperors. The emperors poisoned members of their families and others who displeased them. Horace tells of the professional

poisoner Canidia, who with Martina and Locusta became an infamous trio of women poisoners. Locusta in particular gained infamy as a poisoner in Rome. Convicted of multiple crimes under Claudius, she was sentenced to death. But the sentence had not been carried out when Claudius died. The new Emperor, Nero, made use of Locusta to eliminate many of his rivals, including his half brother, Britannicus. Once Britannicus was dead, Nero suspended Locusta's death sentence and made her his advisor on poisons. Nero organized a school of poisoning where she could tutor others and conduct experiments to determine how to poison and defend the Emperor against poison. Locusta became one of the first to systematically investigate the use of poisons with state sponsorship.

Reports of poisoning continued during the reign of subsequent emperors during the first century AD, and poisoning almost became a status symbol with the moral decay of Rome. Mass poisonings were recorded. Suicide by poisoning was not uncommon, but Pliny the Elder defended euthanasia by poison in the elderly when so desired. During the second century AD when tensions and fear of the previous two centuries gave way to peace and prosperity, very few deaths by poisoning were recorded.

Our understanding of poisons available during Roman times is derived from the writings of Dioscorides, Scribonius Largus, Nicander, Pliny the Elder, and Galen (note the influence of the Greeks). Poisoners preferred plant poisons rather than animal or mineral poisons. Favorites included belladonna, aconite (wolfsbane, monkshood), hemlock, hellebore, colchicum, yew extract, and opium. The specific poisons used in poisoning incidents are rarely mentioned, but it is known that hemlock in honey was the poison favored by Canidia and that Seneca drank hemlock. Ovid called aconite *mother-in-law's poison*.

The first effort at improving the mithridatum was by Damocrates, one of Nero's body physicians, and is known as *mithridatum Damocratis*. Andromachus the Elder (c. AD 60) was another archiater (the chief physician of some cities and first body physician of princes), in this case, the royal physician to Nero. He too was ordered by Nero to improve on the existing antidote. Andromachus removed some ingredients from the mithridatum and added others: squill, opium, and, the most important, vipers' flesh. It was administered in honey to Nero. This became known as *theriaca Andromachi* or Venice treacle. (The name *Theriaca* or *Tiriaca* could have come from the work of Nicander of Colophon. It is also reportedly derived from the snake called tyrus, the flesh of which was added to the mixture by Andromachus.) The *Theriaca* contained 70 substances and was used until the eighteenth century.

Mercurialism as an occupational disease was recognized by the Romans. Mining in the Spanish cinnabar mines of Almadén, 225 km southwest of Madrid, was regarded as being akin to a death sentence due to the shortened life expectancy of the miners, who were slaves or convicts. We now know that this shortened life was due to the exposure of the miners to mercury. Cinnabar, mercuric sulfide, is the principal ore of mercury and was used as a red pigment. Later, it was a source of mercury metal, which was used for centuries as the best way to extract gold and silver from their ores. When Spanish prospectors discovered rich cinnabar deposits in central California, they named the site after the mines of Almadén, Spain. The ready availability of New Almaden mercury was a crucial ingredient in the California gold rush.

Chemical warfare was used by and against the Romans. The Romans catapulted bees and hornets at their enemies. Hannibal of Carthage hurled pots of snakes on the decks of Roman ships in a sea battle during the Punic Wars, 184 BC. When the pots broke, the Romans were forced to fight both the snakes and Hannibal's forces. The Romans were not above poisoning wells when it suited them.

The first law against poisoning, *lex Cornelia de sicariis et veneficis* (concerning assassins and sorcerers), was passed in the time of Sulla (82 BC). The law not only provided for cases of poisoning but contained provisions against those who made, sold, bought, possessed, or gave poison for the purpose of poisoning.

Aurelius Cornelius Celsus (30 BC–AD 50) was the author of the first systematic Roman treatise on medicine. It is the most important historical source of knowledge of Alexandrian and Roman medicine. Little is known of Celsus. It appears that he was not esteemed as a scientist in his time, and there is dispute as to whether he was even a physician. His fame rests entirely upon his *De Medicina*, in eight books. *De Medicina* was among the first medical books to be printed early in the Renaissance (in Florence, 1478), and more than 50 editions appeared. It became very influential largely because of its splendid Latin style. It was required reading in most medical schools into the 1800s. The surgical section, which even Joseph Lister studied in the nineteenth century, is perhaps the best part of the treatise. His four classical signs of inflammation—calor, dolor, rubor, and tumor (heat, pain, redness, and swelling)—are still used today. Book 5, *Toxicology and Rabies* (note the difficulty in separating poisons from pathogens), includes the works of Nicander and Dioscorides and covered poisons and antidotes. He cited others who believed that poisons and animal venoms depressed a vital factor resulting in the loss of innate heat. His contributions to toxicology include his list of poisons and antidotes and the management of poisoning. Consistent with Hippocratic teaching, Celsus advocated eliminating the poison as quickly as possible (acrid materials applied to wounds, cupping severe wounds, suction with palms of the hand, and the use of hypertonic salt solutions). In addition, he recommended the use of appropriate antidotes including the antidote of Mithridates: 37 ingredients in honey.

Gaius Plinius Secundus, better known as Pliny the Elder (AD 23–79), was a famous Roman naturalist, historian, military tactician, philosopher, and one of the most learned men of his time, writing 160 books. His most famous and one surviving work, *Historia Naturalis* (*Natural History*),

was published in AD 77. *Historia Naturalis* consists of 37 books that covered all that the Romans knew about the natural world in the fields of astronomy, geography, zoology, botany, mineralogy, medicine, metallurgy, and agriculture. Despite its flaws, *Historia Naturalis* remains a key resource on Roman life. Pliny's contributions to toxicology include lists of poisons and their biological effects and his questioning of the value of nonspecific antidotes like mithridatics. He was also interested in adulteration of foods and developed methods for the detection of adulteration (e.g., chalk in flour, herbs, and spices).

Galen (see in the previous discussion) became the chief physician of Rome in AD 164 and is credited with systematizing Roman medical practice. Through Galen, the totality of Greek medicine became part of the Roman world, and it was the Roman medicine that was passed down to posterity as *western* medicine.

After the collapse of the western Roman Empire in the fifth century, Europe lost touch with much of its medical heritage. The center of Europe's view became the Church, which exerted profound influence on medicine. The Church viewed care for the soul as far more important than care of the body, so much so that medical treatments and even physical cleanliness were little valued. In time, illness became seen as a condition caused by supernatural forces and cures could only be effected by holy men. This pre-Hippocratic belief that disease was punishment by God and treatable only by prayer and penance meant that licensed medicine as an occupation vanished. It would be centuries before its return to Europe.

Middle East

At roughly the same time that Europe was moving away from medicine, a new civilization was rising to the east. Pre-Islamic medicine in the Arab region had been negligible due to the unsettled, nomadic life. As Islam spread and conditions changed, the Arabs attempted to collect all knowledge that was available. Greek medicine was one of the first sciences studied by Islamic scholars. Translators rendered the entire body of Greek medical texts into Arabic by the end of the ninth century. These translations established the foundations of Arab medicine. Based on the Greek teachings, Arab physicians came to look upon medicine as the science that helps recognize the dispositions of the human body, with the goal of preserving health and, if health was lost, assisting in recovering it. The Arabs also learned from the Indo-Persian practices further east. They built on these traditions and made significant contributions to all the health professions.

The Arabs excelled in chemistry and are credited with inventing distillation, sublimation, and crystallization. Jabir ibn Hayyan (Latinized to *Gerber*, c. 705–769) may be the father of Arab alchemy. He was an expert in chemical procedures and was the first to discover mercury. He produced arsenic trioxide (arsenious oxide, As_4O_6) from realgar (arsenic sulfide, As_4S_4), a naturally occurring, red-colored ore found in lead and iron mining, and thus made available to mankind one of the most widely administered poisons for homicide. He wrote one of the first pharmacological treatises in Arabic.

The Arab pharmacopoeia of the time was extensive and gave descriptions of the geographical origin, physical properties, and methods of application of everything found useful in curing disease. Arab pharmacists introduced a large number of new drugs to clinical practice, including senna, camphor, sandalwood, musk, myrrh, cassia, tamarind, nutmeg, cloves, benzoin, saffron, laudanum, naphtha, and mercury. They were familiar with the anesthetic effects of cannabis and henbane, both when taken as liquids and when inhaled.

The practice of pharmacy was extended by Arab physicians and eventually became a separate profession run by highly skilled specialists who were licensed. Arab pharmacies are considered to be the forerunners of modern pharmacies. To keep patients happy, make the physician's job easier, and promote more effective healing, Arab pharmacists are credited with developing or perfecting syrups and juleps (words from the Arabic, to drink, and Persian, rose water, respectively), tinctures, confections, pomades, plasters, and ointments as means of administering drugs. They were the first to wrap medicines (pellets) in silver foil.

Abu Ali Husain ibn Abdullah ibn Sina (Latinized to *Avicenna*, 980–1037), the *prince of physicians*, was born in Bokhara, Persia (today, Bukhara, Uzbekistan). He was a child prodigy whose fame as a physician was so great that by the age of 18 he was appointed physician to the prince and became physician-in-chief to the hospital in Baghdad. He was a logical thinker and an astute observer. Some have referred to him as a second Aristotle. Avicenna wanted to develop a system of medicine, to make medicine *a quasi-mathematical discipline*. This would remove uncertainty from medical decisions (cf. Hippocrates, Galen). By the age of 21, he had written a 20-volume encyclopedia. His most significant medical works were *Book of Healing*, a medical and philosophical encyclopedia, and *The Canon of Medicine*, a codification of all existing medical knowledge. *The Canon* included descriptions of some 760 medicinal plants and drugs that could be derived from them. *The Canon* rapidly became the standard medical reference of the Islamic world.

Avicenna laid out the basic rules of drug trials that are still followed today. He discussed oral and parenteral poisons and bites and stings and their treatment, and classified and discussed poisons as plant, animal, or mineral.

His contributions to toxicology include mechanisms of action of poisons including neurotoxicity and metabolic effects. He also recommended the bezoar (from the Arabic *bazahr*, from the Persian *pad-zahr counterpoison*, from *pad protecting*, *guardian*, *master* + *zahr poison*) stone as an antidote for venoms and preventive of disease. Originally, it meant *antidote*, but later, it referred specifically to a solid mass found in the stomachs and intestines of

ruminants, which was held to have antidotal qualities. His work was the authoritative text on poisons and antidotes for 500 years.

Jewish medical erudition was of the background of Greek, Roman, and Arabic works. Rabbi Moses ben Maimon (Moses Maimonides, 1135–1204) was a famous Jewish philosopher and physician, court physician to Saladin, and rabbi of Cairo. His compendium on poisons, *Poisons and Antidotes/Upon Poisoning and Its Treatment*, was translated into Latin by Armend and Blasii in 1305, into German in 1813 by Steinschneider, and into French in 1865. He taught that the simplest method to poison someone was to add a single or compound poison to a highly spiced and/or chopped dish or in a victim's glass of wine, under the reasoning that the strong flavors and uneven texture would mask the bitter taste or consistency. He described poisonous insects and animals and noted that the most dangerous bite was that of a fasting human. His treatment of poisons included ligature of the bite, sucking out the poison by means of cupping glasses or with oiled lips (another extension of Hippocratic teaching to decrease absorption), and the use of external (e.g., salt, onions, asafetida) and internal remedies (e.g., emetics). His books on health were very advanced and resemble modern medical texts. He believed in the importance of preventive medicine and stressed the importance of hygiene. He wrote a four-volume treatise upon hygiene and diet (*Sepher Rephuoth*).

The medical works of Hippocrates and Galen were returned to the West by way of the Middle East and North Africa, recovered through translation of Arab medical references in Sicily, southern France, and Spain. Avicenna's *The Canon of Medicine* had a great influence on Europe during the Middle Ages and was a standard European medical text for centuries. Its *materia medica* was the pharmacopoeia of Europe. So great was the reputation of Arab physicians that Chaucer names four in *The Canterbury Tales* and Dante, in *The Inferno*, and placed Avicenna next to two other great physicians from ancient times, Hippocrates and Galen.

Middle Ages (c. 500–1450) and the Renaissance (c. 1450–1600)

As there was little medical work in Europe during the Middle Ages, information related to drugs and poisons is meager. European works on poisons were largely based on the remnants of classical works available and on the works of the Arabs.

Academic texts on poisoning were often written by monks since monasteries were the main seats of learning in a largely illiterate population. One example is *The Book of Venoms*, written by Magister Santes de Ardoynis in 1424. This was a reasonably comprehensive account of the poisons known at the time (e.g., arsenic, aconite, hellebore, laurel, opium, mandrake, cantharides), their effects, and treatment.

Pietro d'Abano (c. 1250–1316) was a teacher of science and medicine at the University of Padua and one of the most renowned teachers and skillful physicians of his time. His famous work *Conciliator Differentiarium* attempted to reconcile Arabic medicine and Greek natural philosophy. In another book, *De remediis venenorum* (*De venenis eorumque remediis*), he classified poisons as mineral, vegetable, and animal. Unfortunately many innocuous substances were often in the lists of ingredients thought to be poisonous, these were side-by-side with many truly deadly plants and minerals. He correctly noted that poisons can be absorbed from air and through the skin (*poisoning by touch*). The book was very popular and went through 14 editions. The power of the Church was great at that time, and he was tried twice by the Inquisition on charges of heresy and practicing magic. Acquitted at the first trial, he was found guilty at the second, after his death.

During the Renaissance, a shift in the notion of illness occurred. Instead of humoral theories dating back to the Greeks that had physicians regarding each patient's disease as unique, changed to a view where disease was no longer a unique experience but a process essentially similar in all patients. Medicine began to look a bit more like how we see it today. The period of observation (recording phenomena) and categorizing and listing poisons started to give way to the period of challenge and active investigation—experimental science. God was still used to describe conditions and cures, but the grip of the Church was weakening, and interpretation and experimentation were becoming more important.

Ulrich Ellenbog's *Treatise on Industrial Hygiene*, written in 1473, is the first known work on industrial hygiene and toxicology. The book dealt with occupational diseases and injuries among gold miners. Ellenbog also wrote about the toxicity of carbon monoxide, mercury, lead, and nitric acid.

George Bauer (Latinized to Georgius Agricola, 1494–1555) was born in Saxony during the early years of the Renaissance. In 1522, he began to study medicine, first at Leipzig and then at Bologna and Padua—Italian universities at the center for science, medicine, and philosophy. He took his degree in 1526 and became a practicing physician in the ore-producing region of Bohemia. He initially hoped to discover new medical drugs from mine ores. Agricola, who is considered the father of mineralogy, observed firsthand the ill effects of the mining operations on miners. The publication of his book (1556), *De Re Metallica*, included a section on industrial hygiene as he described how the miners suffered from diseases as a consequence of their work. He attributed the diseases to the dusts, stagnant air, and gases in the mines. The book included suggestions for mine ventilation and worker protection (masks), discussed mining accidents, and described diseases associated with mining occupations such as silicosis. At the same time, he also blamed the miners for their condition because of their carelessness. He died one year before the publication of his great work.

While most of this seems sensible today, Agricola's readiness to discard received authority, even that of classical

authors, is impressive. He was among the first to found a natural science based on observation and field experience, as opposed to dogma or conjecture. His works on mining were by no means the only ones available at the time, but his were not steeped in the ideas of alchemists, of whom Agricola had a low opinion. Herbert Hoover, a mining engineer who became a U.S. president, translated *De Re Metallica* into English in 1912. Hoover regarded Agricola as the originator of the experimental approach to science, *the first to found any of the natural sciences upon research and observation, as opposed to previous fruitless speculation*.

> The universities do not teach all things.
>
> **Paracelsus**

Philippus Theophrastus Aureolus Bombastus von Hohenheim (1493–1541) was born outside the village of Einsiedeln (near Zurich), Switzerland, the son of Wilhelm Bombast von Hohenheim, a German physician/alchemist. Following the death of his mother when he was very young, Paracelsus moved to Villach in southern Austria, where his father taught chemistry, practiced medicine, and became interested in the health problems of the local miners, eventually becoming an expert in occupational medicine. Paracelsus attended the universities of Basel, Tubingen, Wittenberg, Leipzig, Heidelberg, Cologne, and Vienna, from which he received a baccalaureate in medicine in 1510, at the age of 17. He received his doctorate from the University of Ferrara in 1516. It was the custom of that time to Latinize one's name after receiving a degree and Philippus von Hohenheim chose the name Paracelsus (*para*, above, Celsus), since he considered himself greater than Celsus. He traveled throughout Europe, England, Scotland, Egypt, the Holy Land, and Constantinople, attempting to learn the most effective means of medical treatment and the latest findings in alchemy. He returned to Villach in 1524 and became town physician and lecturer in medicine at the University of Basel in 1527.

He was a keen student of human behavior who believed that practicing physicians needed to use common sense, gain experience, travel, and practice humility. As his fame spread, his lectures became very popular and students thronged to them.

Paracelsus' enduring legacy is at times puzzling, though. He was of low personal hygiene, a drunk, and seemed not to have paid his bills. He never stayed in one place too long, possibly because of enraged patients and threats of lawsuits. Cope (1957) described Paracelsus as arrogant and conceited

> almost to the point of insanity… extremely effective in [his] criticisms of the then accepted doctrines… reveled in the wildest speculations and taught [his] mad conjectures as unassailable truths… bitter and unscrupulous controversialist… mystic… his writings… so confused and obscure as to be often quite unintelligible… braggart, scorner of authority… that Paracelsus scarcely ever lectured except when he was half drunk, or attended a patient until he was wholly drunk.

Paracelsus defended himself in his *Seven Arguments, Answering to Several of the Detractions of His Envious Critics*, written in 1537.

He was part medic, part mystic. This is understandable when considering that he was a product of his times, when magic and science existed together. It was a turbulent age, with the Reformation and all that it brought. In addition, the scientific revolution was starting. At the same time, people were also reconnecting with the classical teachings from Egypt to Greece and Rome. Thus, Paracelsus was an astrologer and alchemist and mystic as well as a physician. The paradoxes that surround Paracelsus can be explained from these perspectives.

An iconoclast, Paracelsus believed all physicians who preceded him were incompetent, liars, or fakers. His disdain for established authorities, for everything that had been said by his predecessors, reached its climax on June 24, 1527, when he publicly burned the books of Avicenna and Galen in front of the university. By doing this, he discarded the old ways, in order to demonstrate that reconnection to classical medicine was not a move forward. At the same time, he attacked the medical principles of his time and trusted only his own observations, ideas, and works.

Paracelsus was a deeply religious man. He was intensely concerned with the eternity, or soul, in man and felt that a doctor was neither *pillmaker* nor businessman, but a legate of God, the supreme physician. Medicine was therefore a divine mission, and the doctor must raise his eyes from *excrements and salvepots to the stars*. The perfect physician, he felt, was a philosopher, an astrologer, an alchemist, and, above all, a virtuous man. The character of such a doctor, Paracelsus proclaimed, was far more effective than mere mechanical skill (Bettman, 1979).

His approach to medicine and the body was chemical. He taught that it was more important to learn about the chemical composition of the body than about the muscles (i.e., more chemistry/biochemistry and less emphasis on anatomy and physiology). It was the role of the alchemist to find these chemicals and convert them to effective remedies, and Paracelsus, the physician/alchemist, began to do so with simple materials, the metals. He tried to bring chemistry into therapeutics and is credited with the introduction of mineral baths, laudanum, mercury, lead, arsenic, copper sulfate, and iron into the practice of medicine.

Paracelsus' positive contributions to medicine and toxicology outweigh their incongruity with his mystical approach. He is considered by some to be the father (founder) of chemistry and/or medicinal chemistry and the reformer of *materia medica*. He forever destroyed the doctrine of the four humors as the basis for disease, and believed that diseases were specific/discrete conditions and are cured by specific/discrete treatments. He taught that observation and experience are essential for success in medicine. Although others made observations in humans (often after deliberately administering a poison), Paracelsus encouraged the use of animals. He also developed and promulgated certain basic principles of the action of chemicals

(e.g., dose–response) that still form the scientific underpinnings of modern experimental toxicology.

In the *Third Defense*, he wrote, "What is there that is not poison? All things are poison and nothing (is) without poison. Solely, the dose determines that a thing is not a poison." (Deichmann et al., 1986). This concept has been expanded to include no-effect level, threshold, extrapolation, and dose–response relationship. His other contributions include target organ toxicity, animal experimentation to study the effects of chemicals, and the use of inorganic salts in medicine. He was thoroughly seduced by the complexity of chemical–biological interactions and spent his lifetime trying to solve the mysteries of these interactions.

His principal works include *Chirurgia magna* (1536), *De gradibus* (1568), and *A Treatise on Diseases of Miners* (1567).

Paracelsus died at age 49, some say in a brawl at the White Horse Tavern in Salzburg on December 24, 1541. Despite his early death, Paracelsus permanently changed the course of medicine and toxicology.

Attempts to explain the action of toxins attracted the attention of other giants in the biomedical sciences of that time, such as Ambroise Paré (1510–1590). Paré practiced surgery in France and is considered a founding father of modern surgical practice, *the greatest surgeon of the sixteenth century*, and one of the most famous anatomists of all time. Paré is remembered mainly for innovations in treating war wounds and for the treatment of skin ulcers, but he also investigated carbon monoxide poisoning and published a report in 1575. He proved that bezoar stones could not cure all poisons. He may have been the first person to state that each chemical has a specific toxic response. Another French physician, Jacques Grevin (1538–1570), the *father of modern biotoxicology*, published his classical work, *Deux Livres des Venins*, in 1568 and further developed the concept of chemical–biological interactions.

The beginning of the Renaissance also began a period of a great number of notorious poisonings. Poisons and their effects were being studied by alchemists mainly to create the most potent concoction. Life was not valued as it is today and poisons became a leading weapon, due to their relative inconspicuousness, to remove rivals or partners. Perhaps the most notorious of the poisoners were Cesare (1476–1507) and Lucrezia (1480–1519) Borgia, the illegitimate children of Rodrigo Lenzuoli Borgia (1431–1503) who become Pope Alexander VI in 1492. They dispatched several of their rivals with a secret poison, *La Cantarella*. The exact composition of *La Cantarella* is not known, but it may have included copper, arsenic, and phosphorous, which reflected the trend in alchemy at that time to make the most potent mixtures from known toxic substances. The poor quality of historical records makes it difficult to know who actually committed the crimes, but Cesare is the primary suspect. The death of Pope Alexander VI was likely due to poisoning, but it is not known whether he drank poisoned wine intended for a cardinal, or the cardinal had him poisoned, or there was a mix-up in the kitchen!

In Venice, during the sixteenth century, a body of alchemists known as the *Council of Ten* met regularly to arrange poisonings for the state. The Council's written records have been preserved, showing they planned, voted, and carried out the demise of any chosen person for a sum of money. Victims were named, prices agreed upon, and contracts with poisoners recorded. Payment was made after the deed was accomplished. The Council seems to have had a number of poisonous ingredients available: corrosive sublimate (mercuric chloride), white arsenic (arsenic trioxide), arsenic trisulfide, and arsenic trichloride. In 1543, John of Ragusa, a Franciscan brother and mercenary poisoner, confronted the Council, declaring that with his collection of poisons, he could remove any person from society. He also added, "The farther the journey, the more eminent the man, the more it is necessary to reward the toil and hardship undertaken, and the heavier must be the payment." Perhaps, he may be considered the first consulting toxicologist. His estimate was carefully considered by the Doge and Council of Venice.

Poisoning had become such an art and so rampant that schools for poisoners were established in Venice and Rome. A publication on the art of poisoning appeared in 1589. Written by Giovanni Battista Porta (1535–1615), *Neopoliani Magioe Naturalis* describes various methods of poisoning, particularly drugging wine, as this was perhaps the most popular method at that time. Described as *a very strong poison*, Porta gives a formula for *Veninum Lupinum*. This was a concoction of aconite, yew, caustic lime, arsenic, bitter almonds, and powdered glass. Mixed with honey, it was made into pills the size of walnuts.

Even Leonardo da Vinci (1452–1519) experimented with poisons, trying to make them more potent by passage through animals and did some musing about their use for chemical warfare in the form of throwing powdered chalk and arsenic trisulfide on enemy ships.

Royalty used poisons on their rivals and on the poor, just to study the effects on humans. Catherine de Medici (1519–1589) of Florence and later queen of France tested and carefully studied the effects of various toxic concoctions on the poor and the sick, noting onset of action, potency, site of action, and signs and symptoms.

Marie-Madeleine-Marguerite d'Aubray, Marquise de Brinvilliers (1630–1676), was a French poisoner who worked with her lover Jean-Batiste de Godin de St. Croix. Brinvilliers poisoned her father, two brothers, and a sister in 1670 for their inheritance. She attempted to poison her children's tutor, Briancourt, with whom she had shared romantic relations, but his quick wits saved him. His intelligence also saved the lives of Brinvilliers' sister-in-law and sister, cloistered in a convent, whom she also tried to poison. Brinvilliers even went so far as to poison her own daughter, merely because she thought her stupid! She regretted it immediately afterward however and made her drink a great quantity of milk as an antidote. She appears to have used Tofana poison (see in the following), whose recipe she seems to have learned from her lover, who had learned it from Exili, an Italian chemist and poisoner whose real name was probably Nicolo Egidi or Eggidio, who had been his cellmate in the Bastille. Sainte-Croix betrayed her upon his death, with incriminating

documents found among his belongings. After several years on the run in England and the Netherlands, Madame de Brinvilliers was tried and convicted on all charges of poisoning. She was forced to do public penance, was put to torture, both ordinary and extraordinary, and was beheaded.

The pinnacle of this period in France occurred with Catherine Deshayes (c. 1638–1680), popularly known as *La Voisin*. La Voisin started her career by practicing fortune-telling to support her family. She practiced medicine, especially midwifery, and performed abortions. She sold aphrodisiacs to those who wished for people to fall in love with them and poison to those who wished for someone to die. La Voisin was interested in science and alchemy and financed several private projects and enterprises, some by con artists. She was part of a network of fortune-tellers in Paris who dealt with the distribution of poison. La Voisin was convicted of witchcraft and burned in public in Paris on February 22, 1680.

Throughout time, women have taken a particular interest in poison for criminal purposes, and the extent of this can be seen in an account from Rome in 1659. A society of women was formed in secret, meeting regularly at the house of a reputed witch, Hieronyma Spara. Usually married, the members of this society were issued the poison they required with instructions for its use. Spara was eventually arrested by the Papal police and tortured on the rack. She refused to confess. Nevertheless, she was hanged along with a dozen other women suspected of having been her aides.

Perhaps the most notorious poisoner of seventeenth century Italy was a woman from Palermo named Giulia Tofana (executed in Rome, 1659). She invented a poisonous mixture, *Aqua Tofana*; although some records suggest her mother invented it and passed the recipe to her. The solution was mostly arsenic and lead and possibly belladonna; it was a colorless, tasteless liquid and easily mixed with water or wine to be served during meals. It was sold in vials that bore the representation of a saint, usually Saint Nicholas of Bari. She managed to sell it under the pretense that it helped a woman's complexion. This was not a complete misrepresentation since the active ingredient was arsenic that was used to treat various skin disorders. However, the real purpose of her vials was made known to those with whom Tofana had a *rapport*. She made a good business for over 50 years selling a large production of Aqua Tofana—she employed her daughter and several other lady helpers—to would-be widows. It has been estimated that Tofana aided the murder of over 600 people between 1633 and 1651, usually husbands, making her one of the *greatest* homicidal poisoners of all time.

By the end of the Renaissance, despite the poisonings, science was flourishing; it was the beginning of the period of enlightenment. Competition among ideas allowed old thinking to be discarded. New ideas provided a path forward to allow for the development of theories that could be tested (cause and effect) and the practical application of scientific information.

Mathematics also flourished. While generally not regarded as a key part of toxicology, risk assessment has its roots in mathematics. The work on numbers by Greeks like Diophantus was lost over the centuries, but even so, he lacked zero that meant mathematics could not progress very far. Europe labored under Roman numerals for centuries. The Arabs, however, used a revolutionary numbering system. These numbers, especially zero derived from their contact with Hindus, allowed mathematics to be its own field of study. Mathematics in the form of algebra was practiced in Arab lands in the 800s. The Arabic numbering system and algebra were introduced to Europe by the Moors in Spain and the Saracens in Sicily around the year 1000. The new numbers were in general use by the thirteenth century.

The use of numbers and mathematics from the Arabs was important for two reasons. The obvious one is better quantification and accuracy. Everything in science must be quantified and the new numbers allowed that to happen. Additionally, the new numbers and mathematics allowed probability theory to be developed. Without it, the risk assessments we perform today would not be possible.

In 1654, Blaise Pascal was asked to solve a problem by a gambler: how to divide the stakes of an unfinished game when one player is ahead. It had stumped mathematicians for 200 years and Pascal turned to Pierre de Fermat for help. The outcome of their collaboration led to the theory of probability. Their solution meant that people could for the first time make decisions based on mathematics. Before this, when people made decisions, it was based on superstition, mysticism, or tradition. Probability theory allowed risk to be understood in a rational way.

SYSTEMATIC TOXICOLOGY

Felice Fontana (1720–1805), an abbot, physician, physiologist, naturalist, and professor of philosophy at Pisa and director of the Natural History Museum at Florence, investigated the physiological action of poisons, particularly of snakes. He is the first modern scientist to study venoms (*Ricerche fisiche sopra il veleno della vipera*, 1767). After a series of impressive and ingenious experiments, Fontana believed the action of the bite of the viper to be an alteration in the irritability of the fibers, which he maintained was mediated by the blood: in other words, the poison directly alters the blood, coagulating it, and this in turn alters all parts of the organism—especially the nerve fibers—that the blood would normally nourish. Through this work, he advanced the concept of target organ toxicity and secondary toxicity, that is, the symptoms of poisoning may not be the result of poisons acting on a particular organ but may occur as a result of effects on other organs/tissues. Fontana extended his toxicological experiments to other substances, especially to the laurel berry and curare. Although he did not hold a chair in chemistry, Fontana was perhaps the greatest Italian chemist of the end of the eighteenth century.

Richard Mead (1673–1754) was a British physician (medical degree from Padua) who worked at St. Thomas' Hospital and was physician to many of the leading figures of the day including King George I, George II, Isaac Newton, and Robert Walpole (the first British prime minister).

He attempted to explain the action of poisons (venoms) in his book *A Mechanical Account of Poisons* (1702). The book was well received and established Mead's reputation, although it has been said that the rules of treatment laid down are sounder than the arguments. Its publication excited so much attention that an abstract of it was printed in the *Philosophical Transactions* for 1703. Mead dissected vipers and gave an exact account of the mechanism that provides for the erection of the fang when the snake opens its mouth. He described snake poisoning and noted that the venom is only effective parenterally. He swallowed the poison and confirmed Galen's experiment on fowls, that puncture is necessary to produce the effect. Mead also considered other poisonous animals, plants including opium, and toxic natural gases. *A Mechanical Account of Poisons* was later republished with many additions in 1743.

Ellenbog, Agricola, and Paracelsus drew attention to the plight of miners, but little consideration was focused on the effects of nondeliberate exposure to chemicals in other work environments. It was the brilliant Italian physician Bernardino Ramazzini (1633–1714) who effectively and convincingly brought the entire workplace situation to the attention of the world, especially to the field of medicine. He was the first to describe in a comprehensive, systematic, and detailed fashion industrial health problems in his *De Morbis Artificium Diatriba* (*Diseases of Workers*). This is the first comprehensive work on occupational diseases and was published in 1700, although Ramazzini lectured on this topic as early as in 1690. It is considered a milestone in the history of occupational medicine. *De Morbis Artificium Diatriba* outlines the health hazards of irritating chemicals, dust, metals, and abrasive agents. The book describes the hazards of 52 occupations, such as tanners, miners, potters, masons, farmers, nurses, and soldiers. He noted the high incidence of breast cancer among nuns, which he attributed to their celibate life (which is now known to be due to the unabated presence of estrogen). In discussing the etiology, treatment, and prevention of these diseases, Ramazzini often cites Hippocrates, Celsus, and Galen and, after summarizing their observations, relates his own experience with the various diseases. By recognizing the social significance of occupational diseases, he earned the title, the *father of industrial hygiene*.

The observations of Ramazzini concerning the relationship between workplace exposure and disease were extended by the classical studies of Sir Percival Pott (1714–1788), British physician and surgeon to St. Bartholomew's Hospital (from 1749 to 1787), who achieved fame in two areas: surgery and occupational medicine/toxicology. His contributions to toxicology include describing in 1775 the relationship between squamous cell carcinoma of the scrotum (*sooty warts*) in London chimney sweeps, whose job it was to clean the residue from the chimneys and fireplaces, and the soot from burning coal. French counterparts were less prone to developing skin cancers because they bathed more frequently after working. This was the first identification of occupational chemical carcinogenesis and represents the beginning of the study of occupational cancer. He also noted the increased sensitivity of children to some chemicals. The sweeps were usually children who worked from age 8 to adulthood, although *apprenticeships* could start at age 4. Pott noted that this was an occupational disease and postulated that the cancer was caused by an ingredient in the residue from the burning coal. Pott's pioneering work resulted in *The Chimney Sweepers Act* of 1788, the year of his death.

With the Industrial Revolution, which occurred between 1760 and 1830, workers no longer owned the means of production. The demand for goods had grown to a point whereby the only means of meeting it was through mass production. This production was achieved through the invention of machines, such as James Hargreaves' spinning jenny, which could do the work of several individual workers. With the machines came the textile mills and factories, which in turn generated a proportionate increase in the exposure to chemicals needed for processing textiles such as acids, alkalis, soaps, and mordants (substances that fix a dye in and on textiles and leather by combining with the dye to form a stable, insoluble compound). As more workers were used to increase production, exposures to chemicals and dusts increased. The factory owners realized the benefits of increased production, but the risks were borne by the workers—not an acceptable or sustainable risk/benefit relationship. Charles Turner Thackrah (1795–1833) developed an interest in the diseases he came to see among the poorer classes of people living in the city of Leeds. His observations led him to develop some of the basic principles of occupational hygiene to improve the health of his patients. He advocated the elimination of lead as a glaze in the pottery industry and ventilation and respiratory protection to protect knife grinders and suggested a change in the work practices of tailors and in the design of their work stations to eliminate their cramped postures that he felt contributed to their high prevalence of tuberculosis. He published a book in 1831 entitled *The Effects of the Principal Arts, Trades and Professions, and of Civic States and Habits of Living, on Health and Longevity, with Suggestions for the Removal of many of the Agents which produce Disease and Shorten the Duration of Life*. Although Ramazzini recognized the relationship between a worker's occupation and health, Thackrah's work occurred in the heart of the Industrial Revolution, England. Thackrah was the first physician in the English-speaking world to establish the practice of industrial medicine. His writing led to a raised public awareness of the abominable working conditions of the new working class such that public outcry and the efforts of reformers led to the passing of the *Factory Act* in 1833 and the *Mines Act* in 1842.

Forensic toxicology, the application of analytical techniques to the detection of poisons, had its beginning with Joseph Jacob Plenck (c. 1735–1807), who noted in his text, *Elementa Medicinae et Chirurgiae Forensis*, that the only proof of poisoning is the identification of the poison in the organs of the body. This remains a basic principle of forensic toxicology. Unfortunately, it was not accepted by the medical or scientific communities until the work of Orfila (see in the following). Plenck also wrote a treatise, *Icones Plantarum*

Medicinalium secundum systema Lynnaei cum enumeratione virium et usus medici, *chirurgici et diaetetici*, dealing with the therapeutic use of about 800 plants. It centered on 111 plants with diuretic properties that still appear in many pharmacopoeias. Plenck is a forerunner of modern dermatology and also worked in ophthalmology.

Fredrich Accum (1769–1838) is largely forgotten these days but contributed to important changes in society by raising awareness of food safety. The application of analytical chemistry to matters of food and drug safety formally began with Accum, although earlier attempts were made by Theophrastus, Cato, Pliny the Elder, Dioscorides, and Galen. Born in Buckeburg, Germany, Accum moved to London in 1797 as a pharmacist. In Accum's time, it was common to add all sorts of materials to food to make it cheaper to produce and yet still pass as a quality product. He was the first to use analytical chemistry to detect adulterants in food and published *A Treatise on Adulterations of Food and Culinary Poisons* in 1820, a very successful book that was acclaimed worldwide. Accum and fellow campaigners fought against food fraud and paved the way for the 1875 *Sale of Food and Drugs Act* in Britain. He also published *An Attempt to Discover the Genuineness and Purity of Drugs and Medicinal Preparations.* Accum also had an entrepreneurial bent and was successful in his business of selling laboratory chemicals and equipment. He equipped the first chemistry laboratories of both Harvard and Yale. He left England and returned to Germany because of unsubstantiated charges of embezzlement directed against him related to his position as a librarian.

ANALYTICAL AND MECHANISTIC TOXICOLOGY

> In physical science the first essential step in the direction of learning any subject is to find principles of numerical reckoning and practicable methods for measuring some quality connected with it. I often say that when you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely in your thoughts advanced to the state of *Science*, whatever the matter may be.
>
> **—Sir William Thomson, Lord Kelvin (1883)**

Advances in chemistry, physiology, pathology, and clinical medicine in the eighteenth and nineteenth centuries resulted in significant advances in toxicology. The time had come for analytical techniques to be formally incorporated into toxicology. Up until this time, it had been difficult to establish poisons as the cause of death since they could not be identified in tissues, the only scientifically valid proof.

Analytical (forensic) toxicology had its formal origins in the outstanding work of Mathieu Joseph Bonaventure Orfila (1787–1853). He was born on the island of Minorca, Spain, and educated in Valencia and Barcelona. He studied chemistry and medicine in Paris, receiving his medical degree from the University of Paris in 1811. Upon graduation, he became a private lecturer on chemistry. In 1813, when he was only 26, he published his monumental two-volume work, *Traité de Toxicologie: Traité des poisons tires des regnes mineral, vegetal at animal ou toxicologie generale considerée sous les rapports de la physiologie, de la pathologie et de la médecine légale* (Crochard, Paris). This classic work, the first of its kind, effectively combined forensic and clinical toxicology with analytical chemistry. It is a vast mine of experimental observation on the symptoms of poisoning of all kinds, on the effects poisons have in the body, on their physiological action, and on the means of detecting them. It earns Orfila the title, *father of forensic toxicology.* It is the first book devoted entirely to toxicology and established toxicology as an experimental science separate from pharmacology. He summed up everything known about poisons at the time and classified poisons into six categories: corrosives, astringents, acrids, narcotics, narcotico-acids, and septica and putrefacants. He presented the chemical, physical, physiological, and toxic properties of each chemical, methods of treatment, and chemical tests for their identification. An English translation of his work first appeared in 1816, and American editions were published in 1817 and 1826. In 1816, Orfila published *Eléments de chimie médecale* and in 1818, *Secours à donner aux personnes empoisonnées ou asphyxiées.* He provided a rational basis for some antidotes. He demonstrated the toxicity of strychnine in numerous experiments on dogs. At that time, strychnine was widely used in prescriptions and in tonics and was considered by practitioners of medicine to be a safe drug (Magendie, discussed in the following, later established the mechanism of action of strychnine). He later published *Leçons de médecine lègale* (1821), *Trait des exhumations juridiques* (1830), and *Recherches sur l'empoisonnement par l'acide arsenieux* (1841). Orfila's books were translated into many languages and this helped internationalize toxicology.

Becoming professor of medical jurisprudence in 1819, Orfila helped develop tests for the presence of blood and used a microscope to assess blood and semen stains. Four years later, he was professor of chemistry in the faculty of medicine at Paris. In 1830, he was nominated dean of that faculty, a high medical honor in France. Orfila was a capable physician and excellent analytical chemist. He assessed the various tests for poison detection and had found them to be highly unreliable. He was also an experimental toxicologist and administered known doses of poisons to animals, carefully observed the effects produced, examined organs for evidence of toxicity, and chemically analyzed tissues and body fluids to establish relationships between dose, response, and tissue levels. He was able to demonstrate conclusively and quantitatively that poisons are absorbed from the gastrointestinal tract and accumulate in tissues. He refined Rose's method for arsenic detection (in 1806, Valentine Rose showed how arsenic could be detected in human organs) to achieve greater testing accuracy. It was Orfila who showed with tests on animals that after ingestion, arsenic is distributed throughout the body. He consulted on many criminal cases due to his fame as an analyst and to his prominent university position. In one case, Madame Lafarge was accused of poisoning her

husband with arsenic and put on trial. Chemical tests conducted shortly after death were inconclusive. During the trial in 1840, Orfila had the body exhumed and found traces of arsenic in the man's organs (using the Marsh test, developed in 1836; see below). Madame Lafarge was found guilty and sentenced to the penitentiary for life. *L'affaire Lafarge* may have been the first trial in history in which convincing forensic evidence was successfully used in a court case.

Orfila's significant contributions to toxicology include the chemical detection of poisons in tissues and fluids, thereby permitting better diagnoses, furthering the concept of target organ toxicity by evaluating tissues grossly and histologically, relating symptoms to specific tissue injury, and extending the concept of dose–response. His investigations were also the forerunner of modern toxicokinetics and dynamics. His influence on modern toxicology is equal to that of Paracelsus and Bernard. His books were published in many languages and used in many countries. Few branches of science can be said to have been created and raised at once to a state of high advancement by the labors of a single man as Orfila did for toxicology.

Isidore Geoffroy Saint-Hilaire (1805–1861), a French zoologist, noted for his work studying anatomical abnormalities in humans and animals and coined the term *teratology* in 1832. His father had initiated studies on chicken eggs, but it was Isidore who first published an extensive work on teratology, *Histoire Générale et Particulière des Anomalies de l'Organisation chez l'Homme et les Animaux*, organizing all known human and animal malformations. Many of the principles governing abnormal development were described for the first time, and many hundreds of names for specific malformations are still in use.

James M. Marsh, an English chemist, developed a method for the detection of arsenic so sensitive that it can be used to detect minute amounts in foods or stomach contents (1836). Until the test was developed, arsenic, usually in the form of arsenic trioxide (As_2O_3), was a highly favored poison, for it is odorless, easily incorporated into food and drink, and untraceable in the body. Although there were tests developed to detect arsenic, they were insufficient for use in court.

In 1832, John Bodle was brought to trial for poisoning his grandfather by putting arsenic in his coffee. James Marsh, a chemist working at the Royal Arsenal, was asked by the prosecution to try to detect its presence. He performed the standard test by passing hydrogen sulfide through the suspect fluid. Marsh detected arsenic as a yellow precipitate, arsenic trisulfide (As_2S_3), but it did not keep well, and by the time it was presented in court, it had deteriorated. The jury was not convinced and Bodle was acquitted.

Angered and frustrated by this, especially when Bodle later confessed that he had killed his grandfather, Marsh decided to devise a better test. Marsh's test has a sample placed in a flask with arsenic-free zinc and sulfuric acid. Arsine gas forms and is led through a drying tube to a hard glass tube in which it is heated. Igniting the gas converts arsine to arsenic, which is deposited as a *mirror* just beyond the heated area on any cold surface held in the burning gas emanating from the jet. This test was sensitive enough, specific enough (antimony gives a similar result, but the deposit is insoluble in sodium hypochlorite, whereas arsenic will dissolve), and rigorous enough that it held up in court. The introduction of analytical methods for metallic poisons was such that it reduced their popularity, and practitioners turned to alkaloids isolated from plants.

The first half of the 1800s was an era of high-profile poisonings in Great Britain that left the public almost in a panic. The ready availability of poisons and the accessibility of scientific knowledge due to increased literacy and scientific education led the public to believe that poisoning was something new. The press fanned the panic by capturing and embellishing every detail. Additionally, poisoning seemed to pose a special problem to the new social order because of the rise of life insurance. People could now be murdered for money, not for being highly placed in society or a powerful ruler. One of the most famous examples of poisoning as a commercial transaction was the case of Dr. William Palmer, also known as the *prince of poisoners*. He was an English doctor convicted for the 1855 murder of his friend John Cook and executed by hanging the following year. He had poisoned Cook with strychnine. Before that, Palmer made large sums of money from the deaths of his wife and brother from collecting their life insurance. But the public's fascination with the case was of his suspected poisoning several other people including his brother, his mother-in-law, and four of his children who died of *convulsions* before their first birthdays.

This public outcry in the early 1800s stimulated the development of forensic toxicology in Great Britain. The result was the evolution of toxicology and medical and legal practices. Some of these changes are apparent today. For example, the registration of deaths by a physician, the banning of the sale of poisons by chemists (pharmacists), and rules of evidence in courts. A realistic appraisal of the situation, however, is that the hype was greater than the poisonings and there really was no poisoning epidemic in Britain at that time.

Alfred Swaine Taylor (1806–1880), British physician and the founder of British forensic medicine, is also the founder of modern medical jurisprudence, a natural continuation to the development of forensic toxicology. He received a diploma from the Apothecaries Society in 1828, his certificate to practice from the Royal College of Surgery in 1830, and presented the first course in medical jurisprudence in England in 1831 at Guy's Hospital. He was probably the most famous expert witness of his time and published his *Manual of Medical Jurisprudence* in 1842. It became very popular, and the 10th edition was published in 1879. His books on medical jurisprudence and on poisons became the standard works throughout the world. He codified the legal precedents, judicial rulings, and anatomical and chemical data that bore on the subject.

Sir Robert Christison (1797–1882), a noted Scottish physician with a medical degree from Edinburgh, studied toxicology under Orfila. He was appointed to a Chair of Medical Jurisprudence at the University of Edinburgh in 1822. In 1832, he transferred to a Chair of Materia Medica at the same

institution, which he held for the next 45 years. He published *A Treatise on Poisons* in 1829. He became a recognized authority on poisons, and in the course of his inquiries, he did not hesitate to experiment on himself. He took large doses of calabar bean (the seed of the woody vine *Physostigma venenosum* of western African and source of physostigmine; African natives used this as an ordeal: if the accused person eats the bean and vomits within half an hour, he is judged innocent, but if he succumbs, he is found guilty). Christison's attainments in medical jurisprudence and toxicology procured him the appointment of medical officer to the crown in Scotland, and from that time until 1866, he was called as a witness in many celebrated criminal cases. His works helped develop the basis for expert witnessing. He strove to provide a sound scientific basis for toxicology.

Christison was approached by the Scottish firm of W. and G. Young that wanted a harpoon that would kill a whale quickly to prevent it from diving under the ice. In 1831, the Youngs, harkening back to times before history, asked him to invent a harpoon that would utilize poison as the killing agent. Christison accepted the challenge and chose pure prussic acid (hydrogen cyanide) because of its extreme potency. Christison's harpoon contained two glass cylinders of the liquid, together containing almost 60 g. In 1833, the *Clarendon* was sent out with prussic acid harpoons. According to Christison, the harpoon gun was fired for the first and only time. The harpoon was buried deeply in the whale, which immediately *sounded*, or dived perpendicularly downwards. But in a very short time, the rope relaxed, and the whale rose to the surface quite dead. Apparently, the men were so appalled by the horrific effect of the harpoon that they declined to use any more of them. Christison was required by the Youngs to keep his invention secret, and he remained silent until 1860 (although the crewmen must have discussed it because a U.S. patent was granted for a prussic acid harpoon very similar to the Christison design in 1835). After the Youngs had died and their heirs were no longer involved in whaling, they released Christison from his promise of silence. In 1860, Christison explained his harpoon design in an article, *On the Capture of Whales by Means of Poison*, in the *New Edinburgh Philosophical Journal*.

Other forensic toxicologists of note include Henry Coley, a New York City resident who published *A Treatise on Medical Jurisprudence: Part I. Comprising the Consideration of Poisons and Asphyxia* in 1832. Included in this book were mineral acids, caustic alkalis, ammonia, nitrates, phosphorus, cyanide, metals, and alkaloids, as well as their chemistry, uses, signs and symptoms of poisoning, cause of death, postmortem findings, and treatments. Theodore George Wormley (1826–1897) published *Microchemistry of Poisons*, the first American toxicology textbook (1867), which became the standard on the subject worldwide. A.W. Blyth published *Poisons: Their Effects and Detection*, an excellent analytical toxicological text (1884). Rudolph A. Witthaus and Tracy C. Becker edited a four-volume text, *Medical Jurisprudence*, *Forensic Medicine and Toxicology*, which became the standard reference text in the field (1894–1896). Walter S. Haines and Frederick Peterson wrote *A Textbook of Legal Medicine and Toxicology* (1903). Alexander O. Gettler (1883–1968), who probably influenced the development of forensic toxicology in America more than anyone else, began working in the Office of the Chief Medical Examiner in New York City in 1918.

The advances in forensic toxicology paralleled advances made in analytical techniques. Toxicology was beginning to be recognized as a scientific discipline. However, true understanding of the basic mechanisms of action of chemicals and drugs lagged. Little had been done to answer the basic question, *How do poisons kill?* But that changed as mechanistic toxicology began with the classical studies of two of the most famous physiologists in medical history: François Magendie and his pupil Claude Bernard. Although important contributions had been made by others, they were not as systematic, fundamental, and far reaching as those of Magendie and Bernard.

François Magendie (1783–1855) contributed significantly to the advancement of physiology, medicine, and toxicology. His interest in the functioning of the nervous system led him to establish the mechanisms of action of emetine and strychnine, leading to the scientific introduction of these compounds into medical practice. He also experimented on the effects and uses of morphine, quinine, and other alkaloids, for which he is sometimes called the founder of experimental pharmacology. He was the first, or one of the first, to observe and describe anaphylactic shock.

Magendie's most famous pupil was Claude Bernard (1813–1878). Bernard was the son of a Burgundian vinegrower who studied pharmacy and enjoyed science, but wanted to be a playwright. His friends told him to study medicine and fortunately for humankind he accepted their advice. In 1834, Bernard enrolled in the Paris School of Medicine, and after a few years, he obtained a position at a lab at the Collège de France, where he worked under Magendie. He enthusiastically endorsed Magendie's philosophy that physiologists must discover the laws of *vital manifestations* or physiological functions and that observation and experimentation were the only methods of investigation. He received his degree in 1843. In 1854, he accepted the newly created chair of physiology at the Sorbonne. When Magendie died in 1855, Bernard took over his post at the Collège de France. He held the positions at the Sorbonne and the Collège de France concurrently until 1868.

In his work in experimental physiology, Bernard insisted that an experiment should be designed to either prove or disprove a guiding hypothesis. He also maintained that an experiment should produce the same results again and again, so long as the starting conditions are the same. These two points are integral parts of the modern scientific method.

His specific contributions to toxicology include furthering the concept of target organ toxicity, establishing approaches to defining the mechanism of action of drugs and other chemicals (i.e., curare, nicotine, carbon monoxide), demonstrating that the basic principles of pharmacology and toxicology are identical, and showing that drugs and other chemicals can modify the function and structure

of tissues. He believed that *the physiological analysis of organic systems can be done with the aid of toxic agents* (a new use for poisons!). His works were published in 18 volumes. One of his most famous, *An Introduction to the Study of Experimental Medicine,* was published in 1865 and translated into English in 1949. It is a clear and penetrating presentation of the basic principles of scientific research. Bernard introduces his idea of homeostasis in this book and he explains how and why it works and how humans, as well as animals, could not live without it. It is a classic in the field of experimental biology and a *must* reading for all students of biology and medicine.

It can be argued that toxicology as we know it today began with Bernard. Paracelsus took some important first steps, but much of his work is instructional only in hindsight. Orfila made the crucial introduction of analytical chemistry and jurisprudence. But Bernard completely changed the focus of toxicology from a science of poisoning to a biomedical science that could help to explain basic physiological processes. Substances that were used to induce harm were now being used to help mankind.

> One must break the bonds of philosophic and scientific systems as one would break the chains of scientific slavery. Systems tend to enslave the human spirit.
>
> **Claude Bernard (Introduction to *l'Etude de la Medecine Experimentale*, 1865).**

Magendie's and Bernard's work stimulated others to establish the mechanisms of action of toxic agents experimentally and to publish textbooks. For example, the Florentine physician and scientist Ranieri Bellini Pisano (1817–1878) promoted research in toxicology and pharmacology. He authored the first experimental toxicology text, entitled *Lezioni Sperimentali di Tossicologia*. He was also the founder of the Istituto Tossicologico Fiorentino.

The discipline of toxicology was also advanced by the outstanding research efforts of such noted northern European pharmacologists as Rudolf Buchheim (1820–1879), the founder of modern pharmacology; Oswald Schmiedeberg (1838–1921), another of the founders of modern pharmacology and toxicology and a student of Buchheim; and Rudolf Kobert (1854–1918), a student of Schmiedeberg, who published a number of textbooks in the 1890s (e.g., *Practical Toxicology for Physicians and Students*). A contemporary, Louis Lewin (1850–1929), the father of psychopharmacology, published on the toxicology of alcohols, chloroform, opiates, and plant-derived hallucinogens and also wrote a toxicology text (1929).

The mechanistic studies of Bernard were furthered by the brilliant German chemist, microbiologist, and immunologist Paul Ehrlich (1854–1915), who significantly advanced toxicology and pharmacology. His keen interest in chemistry and biological structure and function led him to propose the concept of a receptor as the sensitive site for chemical–biological interaction—that *chemical substances in organisms had specific points of attachment*—and once these were known, specific remedies could be developed. He subsequently identified several receptors. His most famous remedy was the use of arsenic in the management of syphilis (Compound 606, arsphenamine). His successful bout with tuberculosis stimulated his interest in immunity (as did his association with R. Koch), and he subsequently formulated the concepts of active and passive immunity. In addition to his originating the concept of receptors, his contributions to toxicology and pharmacology include underscoring the importance of mechanistic studies and structure–activity relationships. He shared the Nobel Prize in Physiology or Medicine with E. Metchnikoff in 1908.

The epidemiological study of chemical carcinogenesis that began with Pott in 1775 continued in 1822 when Dr. John Ayrton Paris (1785–1856) surmised that arsenic fumes might be the cause of the frequent occurrence of scrotal cancer in copper and tin smelter workers in Cromwell, England. In 1875, Richard von Volkmann (1830–1889) observed occupational skin tumors among workers in the tar and paraffin industry at Halle, Germany. In 1876, Joseph Bell (1837–1911) of Edinburgh suggested that shale oil was responsible for certain skin cancers in Scotland. Bladder cancer among aniline dye workers was first described by Dr. Ludwig Rehn (1849–1930) of Germany in 1895; this was the first recognition that chemicals could cause cancer away from their first point of exposure.

The experimental study of chemical carcinogenesis began in 1915 when Katsusaburo Yamagiwa and Koichi Ichikawa at Tokyo University produced malignant epithelial tumors by application of coal tar to the ears of rabbits. This was the first demonstration of chemical carcinogenesis in an animal model and was an experimental proof of Pott's hypothesis 140 years before. In 1922, R.D. Passey produced malignant growths by painting the skin of mice with coal tar ether extracts. In 1925, James Murphy and Ernest Sturm produced a high incidence of lung tumors in mice when coal tar was applied to the skin without local irritation. In 1932, Cook et al. published findings that pure hydrocarbons cause cancer in mouse skin. In 1935, Sasaki and Yoshida showed that *o*-aminoazotoluene caused liver tumors in rats. In 1938, W.C.H. Hueper, F.H. Wiley, and H.D. Wolfe first reported successful induction of bladder cancer in dogs by repeated injections of 2-naphthylamine.

As a true understanding of toxicity began to develop, there was still the practical aspects of toxicology to be handled. The need for laws to protect the public from unscrupulous purveyors of foods and drugs became apparent in the United States in the late 1800s. Harvey Washington Wiley (1844–1930), physician and chemist, served as Chief of the Bureau of Chemistry of the United States Department of Agriculture from 1883 to 1912. His main goal was to provide effective food and drug legislation to protect an unsuspecting public. Wiley issued a number of bulletins summarizing his studies of the effects of food chemicals in human subjects, tested in his *Poison Squad* from 1902 through 1907. His efforts culminated in the Pure Food and Drug Act (1906). After serving at the Department of Agriculture,

Wiley was Director of Foods Sanitation and Health for *Good Housekeeping* magazine from 1912 to 1930. He wrote many books on food composition, food adulteration, and nutrition.

In the 1910s and 1920s, the United States Radium Corporation produced *glow in the dark* watch dials painted with radioluminescent paint consisting of zinc sulfide and radium 226. The paint was applied with a small brush. Many of the young women employed in this work *pointed* the brushes by licking them between applications and ingested a small quantity of radium each time. Most people thought radium was a miracle elixir that could cure cancer and many other medical problems. A few knew it was harmful including the owners of the United States Radium Corporation and scientists who were familiar with the effects of radium because the scientific and medical literature contained ample information about its hazards. Radium accumulated in the bone marrow of the women, eventually producing bone cancer. This is one of the first instances of an occupational hazard from radioactivity. Alice Hamilton (see in the following) worked on the case to obtain just compensation for the workers. The Consumers League and the news media as represented by Walter Lippmann served in the process as well. Radium watches were manufactured into the 1950s, but with strict controls.

Despite the rise of toxicology as a science to help, there remained a certain element of mankind who wanted to use chemicals to harm. Advances in chemistry allowed people to use new agents for chemical warfare. These were generally gaseous compounds intended to indiscriminately debilitate or kill hundreds or thousands of people. It seems to be the worst scenario for toxicology: the knowledge gained by advances intended to help man were deviously twisted to harm. Early chemical warfare agents were crude destroyers of tissues, but later agents became quite elegant in their wickedness.

Chlorine was the first lethal chemical used in modern warfare. At 5 p.m. on April 22, 1915, German troops at Ypres discharged 180,000 kg of chlorine gas from 5,730 cylinders creating a gas cloud that blew with the wind. It either killed the French and Algerian troops in the opposing trenches or caused them to flee, opening a gap in the Allied line. On April 24, the Germans conducted a second chlorine gas attack at Ypres, this time against Canadian troops. On May 31, chlorine was employed on the eastern front, by the Germans approximately 50 km southeast of Warsaw. This attack employed 12,000 cylinders, releasing 264 tons of chlorine along a 12 km line. All totaled, there were nearly 200 chemical attacks during World War I using gas released from cylinders. The largest attack occurred in October 1915 when the Germans released 550 tons of chlorine from 25,000 cylinders at Rhiems. The effect of chlorine on the lungs has been described in many places. Chlorine is now considered obsolete as a chemical warfare agent.

Fritz Haber (1868–1934), perhaps Germany's greatest chemist, is known by most toxicologists for *Haber's law* used mainly in inhalation work (concentration × time = constant biological response). Yet he was a Nobel laureate for his discovery of a process for synthesizing ammonia from nitrogen and hydrogen. Inexpensive ammonia-based fertilizers led to an agricultural revolution through increased food production worldwide and saved millions from starvation. He developed a synthesis of nitric acid from ammonia that allowed the development of explosives and insecticides. He was also the chief of the German chemical warfare service during World War I and personally directed the first chlorine gas attack at Ypres, Belgium, in April 1915. In fact, Haber is often referred to as the father of chemical warfare. While not a toxicologist, he greatly influenced the course of the field through his work on insecticides and agents of chemical warfare. His legacy is as complex as toxicology itself.

As World War I continued without signs of end, many compounds were tested for utility as chemical warfare agents. In addition to chlorine, phosgene, diphosgene, chloropicrin, hydrogen cyanide, cyanogen chloride, and mustard were produced and used in large quantities. Mustard gas (bis(2-chloroethyl) sulfide) was first used in an artillery attack on July 12, 1917, by the Germans. This agent caused the most casualties of any agent used during World War I.

It is estimated that close to 1,300,000 casualties were produced by approximately 125,000 tons of chemical warfare agents used by the combatants, but the official figures likely underestimate the true number. Furthermore, it is unclear to what degree the official figures include individuals who were injured in gas attacks but who developed serious effects only after the war. However, considering there may have been 10,000,000 battle deaths from the war, it is arguable as to whether chemical warfare was more or less horrific than the other methods used.

In one sense, what started in World War I was simply a continuation of the use of smokes and irritants against one's enemies. In another, it changed the way chemicals and toxicology would be viewed. A line had been crossed and the use of toxicology to deliberately and indiscriminately inflict harm was part of governmental programs. The next 50 years produced some of the most lethal chemicals and combinations of chemicals imaginable.

A number of materials developed during World War I were not terribly lethal, though they were quite irritating. These are lacrimators that irritate the mucous membranes of the eyes and cause a stinging sensation and tears. They also irritate the upper respiratory tract, causing coughing, choking, and general debility. The effects are short lived and rarely disabling, and lacrimators are used today by law enforcement. Tear gas has gained widespread acceptance as a means of controlling civilian crowds and subduing barricaded criminals. The most widely used forms of tear gas have been *o*-chlorobenzylidene malononitrile and 2-chloroacetophenone. Proponents of their use claim that when used correctly, the effects of exposure are transient and of no long-term consequence. But exposure is difficult to control and indiscriminate and may not always be used correctly. Lethal injury has been documented. In 1969, 80 countries voted to include tear gas agents among chemical weapons banned under the Geneva Protocol.

The Nazis continued the work on chemical warfare that was started in World War I. They produced 12,000 tons of tabun (ethyl *N*,*N*-dimethylphosphoramidocyanidate; the first of the so-called *G-series* nerve agents, also known as GA) between 1942 and 1945. Thankfully, it was never used. The ultimate chemical genocide occurred during World War II when the Nazis used cyanide (in the form of Zyklon B—liquid hydrocyanic acid adsorbed into a highly porous material), carbon monoxide, and even engine exhaust to kill millions of people deemed to be *undesirable*.

Mechanistic studies led to a better understanding of the toxic action of many chemicals and to the development of specific antidotes. A classic example is the development of British anti-Lewisite (BAL) (dimercaprol) as an antidote for Lewisite ($CHCl{=}CHAsCl_2$), an arsenic-based gas that was synthesized too late to be used in World War I. Still fearful of its use in World War II, Rudolph Peters (1889–1982) headed the Oxford University laboratory that searched for antidotes to chemical warfare agents and developed BAL in 1940 based on the work of Carl Voegtlin (1879–1969), a developer of the *arsenic receptor* in chemotherapy and the first director of the National Cancer Institute (1938–1943).

Understanding the mechanism of poisoning by organophosphorus compounds, the basis for many insecticides and chemical warfare agents, also led to a rational antidote. Atropine, a drug that blocks muscarinic acetylcholine receptors, counteracts the vomiting and diarrhea, excessive salivation, bronchial secretions, sweating, and bronchospasm. It is administered intravenously, if possible, in high doses at frequent intervals until signs of intoxication diminish. Pralidoxime chloride (2-PAM), codiscovered in 1955 by Davies and Green and Wilson and Ginsburg, reactivates nerve agent–inhibited cholinesterase. Diazepam or another anticonvulsant may be administered in severe cases to control seizures and thereby prevent seizure-induced brain damage.

A biochemical mechanism for cyanide antagonism was described by Chen et al. (1933, 1934). They suggested using a combination of amyl nitrite, sodium nitrite, and sodium thiosulfate. Nitrite converts hemoglobin to methemoglobin, which in turn competes effectively for cyanide with the mitochondrial cytochrome oxidase complex. Cyanide is then removed from cyanomethemoglobin by intravenous sodium thiosulfate, which serves as a sulfur donor for rhodanese (thiosulfate sulfur transferase). Rhodanese accelerates cyanide detoxification by forming the nontoxic metabolite thiocyanate. This therapy represented the development of one of the first antidotes based on knowledge of toxicological mechanisms. This combination of antidotes has stood the test of time and still represents one of the most efficacious antidotal combinations for the treatment of cyanide intoxication.

The LD_{50} test was first introduced in 1927, when it was used for the standardization of not only important but also highly toxic and possibly fatal drugs such as insulin, digitalis extracts, and diphtheria toxins (Zbinden and Flury-Roversi, 1981). Because the potency of these drugs might vary among different sources or batches, it was essential to have precise measurements. Accurate chemical methods were not yet available, so lethality was used as an indicator of potency. Over time, however, it came to be forgotten that the method was designed for biological standardization of highly active pharmacological agents for which no chemical analytical method was available. Eventually, determination of the LD_{50} was used to assess the acute toxicity of chemicals other than drugs, and many regulatory authorities required an LD_{50} test for all chemicals: food additives, cosmetics, pesticides, and industrial chemicals. In some countries, new drugs required acute LD_{50} data in rats, mice, dogs, and occasionally also in monkeys by the oral, subcutaneous, and intravenous routes. Recently, this was seen as an inappropriate use of animals, and acute toxicity is determined much differently today due to this awareness.

Josef Warkany (1902–1992) of Cincinnati Children's Hospital Research Foundation was the first to demonstrate that exposures to environmental chemicals and dietary deficiencies and excesses can be responsible for the production of congenital malformations. Until that time, it was widely believed that birth defects were due to chance or *God's will*. Warkany was born and educated in Vienna, Austria. In 1932, he accepted a 1-year fellowship at Cincinnati's Children's Hospital Research Foundation and ended up staying for 60 years. In the late 1930s, Warkany and Rose Cohen Nelson attempted to produce endemic cretinism in rats. Though they failed, they obtained a syndrome of congenital skeletal malformations that was even more interesting. More than 3 years of painstaking research was needed to show that the skeletal malformations were not caused by a dietary iodine deficiency in the mother before birth, as in endemic cretinism, but instead were due to a riboflavin deficiency in the diet fed the pregnant animals. At that time, medical scientists believed that malformations were always genetic in origin, and most were reluctant to believe that the environment could have such a dramatic effect on fetal development. For his work in this area, Dr. Warkany is known as the *father of teratology*. His 1300-page textbook *Congenital Malformations* is a medical classic.

Although there are more notorious poisons, alcohol may be responsible for more deaths than any other. Professor Rolla Harger (1890–1983) at Indiana University developed the *drunkometer* in 1937 for testing drivers presumed to be under the influence. This was the first practical roadside breath-testing device intended for use by the police, which was important as prohibition had ended in the United States in 1933 and at the same time cars became more available and attained higher speeds. The *drunkometer* collected a motorist's breath sample into a balloon and then the sample was pumped through an acidified potassium permanganate solution. If there was alcohol in the sample, the solution changed color. The greater the color change, the more alcohol there was present in the breath. The *Breathalyzer*® was invented by Robert Borkenstein in 1954, which encouraged the development of police alcohol testing programs worldwide.

Occupational medicine and industrial toxicology were identified by Agricola and Paracelsus, systematized and advanced by the pioneering efforts of Ramazzini, and

further advanced by one of America's foremost physicians, Alice Hamilton (1869–1970). Hamilton researched occupational diseases, publicized the hazards of industrial chemicals to workers, and wrote several books on industrial toxicology. She was the foremost female occupational physician and industrial hygienist, the first woman faculty member of the Harvard Medical School, and the only woman to serve on the Health Committee of the League of Nations. She graphically described the history of industrial toxicology/occupational medicine in the United States in her autobiography, *Exploring the Dangerous Trades* (1943). Others who contributed significantly to industrial toxicology include Cecil Drinker (1887–1919) also of Harvard who believed that toxicological information was accumulating very rapidly, that mechanisms of toxicity were being elaborated, and exposure to chemicals was increasing due to advances in manufacturing. Ethel Browning (1891–1979) of Great Britain received her doctorate in medicine in 1927 and wrote the *Toxicity of Industrial Organic Solvents* in 1937. Interestingly, this was the first book on this subject and was written when Browning had no personal occupational medical experience. Her other publications included *Ionizing Radiations* (1959), *Toxicity of Industrial Metals* (1961), and, her greatest work, *Toxicity and Metabolism of Industrial Solvents* (1965).

The increased exposure of consumers to unknown chemicals started to raise concern. In 1933, more than a dozen women were blinded, and one woman died from using a permanent mascara called Lash Lure. It contained *p*-phenylenediamine, an untested chemical. *p*-Phenylenediamine caused blisters, abscesses, and ulcers on the face, eyelids, and eyes of Lash Lure users. It led to blindness for some and in one case, the ulcers were so severe that a woman developed a bacterial infection and died. Although the factual basis of the story was disputed by the industry and has never been confirmed, the so-called incident provided a *smoking gun* to those who saw a need for protective action.

Another crucial incident at that time (1937) was when a Tennessee drug company, S.E. Massengill Co., manufactured sulfanilamide dissolved in diethylene glycol to create elixir sulfanilamide. The food and drug laws in the United States did not require toxicological testing before sale. When 105 people died in 15 states, the trail led back to the elixir.

These events caused the U.S. Congress to pass legislation for a new Food, Drug, and Cosmetic Act in 1938. Lash Lure was the first product seized by the U.S. Food and Drug Administration (FDA) under its new authority. The Lash Lure tragedy showed that a better way to test for eye and skin irritation was needed.

In 1944, John M. Draize, an FDA scientist, standardized the scoring system of a preexisting test for ocular irritation. Frequently referred to as the *Draize test*, a liquid or solid substance is placed in one of a rabbits' eyes, and changes in the cornea, conjunctiva, and iris are observed and scored compared to the untreated eye. Despite differences between the rabbit eye and the human eye, the Draize test, when performed by trained personnel, has proven quite accurate in predicting human eye irritants, particularly slightly to moderately irritating substances, which are difficult to identify using other methods. The Draize test performs its primary function of assessing both the damage and potential for recovery after exposure to irritants very well. Draize et al. (1944) also standardized the scoring of skin reactions as a method to evaluate skin irritation or corrosion using rabbits.

By this time, the discipline of toxicology was now recognized by the scientific community and society as a distinct entity, separate from pharmacology and drawing upon the chemical, biological, and physical sciences. The stage was set for the application of toxicological principles and findings to protect the public—from consumers to workers—from the adverse effects of chemical exposure.

POST–WORLD WAR II

As society developed following World War II, it recognized the value of toxicology and its demands on the science grew. Much of this demand was a result of the enormous growth of the chemical industry. New synthetic chemicals were being produced, and new uses were discovered for older chemicals. The amounts of chemicals produced were greater than ever. The production, use, and disposal of chemicals were not always conducted in the best interest of man or the environment. Advances in analytical chemistry and the biomedical sciences also dramatically impacted toxicology. This led to new laws and regulations and a new type of activism. Given the importance of the issues, academic, industrial, and governmental research laboratories and private research foundations advanced the frontiers of toxicology by seeking the molecular basis for toxic action. Some of the issues raised outstripped the capacity to generate data and form coherent theories. Some of the questions being asked of toxicology helped move the field forward, while others were beyond the scope of any science.

Basic Science

Almost all the work in the field of xenobiotic biotransformation grew from the research of a Welshman, Richard Tecwyn Williams (1909–1979). His early work on the ring structure of glucuronic acid by isolating bornyl glucuronide from the urine of dogs fed borneol allowed him to crystallize the conjugate and use it as a source material for his elucidation of its pyranoid structure. This work in 1931 stimulated his interest in the biotransformation of foreign compounds and led to a series of papers on the fate of phenols, terpenes, and sulfonamides. Williams became convinced that the biotransformation of compounds was just as important as the metabolism of natural body constituents. During the late 1930s, Williams began writing a book on the detoxification of foreign compounds but, because of the war, it was not published until 1947. It was a slim volume summarizing much of the work that had been done to date. In the 1950s, studies on a broad range of compounds added considerably to the systemization of the biotransformation routes of xenobiotics, culminating in publication of an expanded

Detoxification Mechanisms in 1959 that provided a systematic approach to biotransformation based on organic chemistry classification. Williams also expanded his concepts of the principal biochemical reactions whereby drugs and other foreign compounds are biotransformed in two distinct phases: one of oxidation, reduction, and hydrolysis and the other of conjugation reactions.

With the aid of ^{18}O and mass spectroscopy, Howard S. Mason et al. in 1955 found proof that enzymes can use molecular oxygen to oxygenate their substrates. At the same time, Osamu Hayaishi at the National Institutes of Health made a similar discovery of oxidative transformations. This class of oxygenases had requirements for both an oxidant (molecular oxygen) and a reductant (reduced NADP) and hence was given the trivial name *mixed-function oxidases*. In 1958, Klingenberg and Garfinkel independently announced the discovery of a carbon monoxide–binding pigment (hemoprotein) with an absorbance maximum at 450 nm in the microsomal fraction of rodent liver. This pigment was characterized as a cytochrome with typical absorption bands by Omura and Sato in 1964 through the use of detergent solubilization of microsomes and interaction with isocyanide ligands. Rosenthal, Cooper, and Estabrook in 1965 studied the biotransformation of codeine, monomethyl-4-aminopyrine, and acetanilide and found them to be inhibited by carbon monoxide, and the inhibition could be reversed by yielding the same action spectrum, demonstrating that cytochrome P450 is the oxygen-activating enzyme in xenobiotic biotransformation as well as in steroid hydroxylation. From the isolation of membrane-bound P450 by Lu and Coon in 1969 to the first crystallization of a mammalian P450 in 1999 by Eric Johnson and coworkers, this area of research has established the important role of P450s in the disposition of drugs and other xenobiotics.

A key figure in the xenobiotic biotransformation was James R. Gillette (1928–2001), who worked with Bert LaDu, Jr. at the Laboratory of Chemical Pharmacology/Heart and Lung Institute at the NIH where B.B. Brodie was chief. Gillette's studies on cytochrome P450 were influential and he succeeded Brodie as chief of the Laboratory in 1972.

James A. and Elizabeth C. Miller (1915–2000; 1920–1987) made seminal discoveries related to the biotransformation of synthetic and naturally occurring chemicals to toxic and/or carcinogenic electrophilic metabolites and to the regulation of xenobiotic metabolism. Their work began in the late 1940s when they demonstrated that a foreign chemical could be biotransformed to intermediates that covalently bind to macromolecules. The administration of hepatocarcinogenic aminoazo dyes to rats resulted in the covalent binding of metabolites to protein in the liver. Little or no covalent binding occurred in nontarget tissues that did not exhibit tumorigenesis. The Millers found that factors influencing the in vivo binding of aminoazo dyes to protein also influenced hepatocarcinogenicity, which led them to suggest that covalent binding of metabolites to liver macromolecules was required for carcinogenicity. This line of thinking was extended to carcinogenic polycyclic aromatic hydrocarbons when they found that metabolites covalently bound to protein only in the skin.

James Miller demonstrated the oxidation of a foreign compound in a cell-free system by enzymes that were later identified as cytochrome P450. He demonstrated that liver microsomes reduced the azo linkage of 4-dimethylaminoazobenzene and that NADPH was required for catalytic activity. He also reported that flavin adenine dinucleotide was required for azo dye reductase activity, and these results provided a mechanistic explanation for the protective effect of riboflavin on the carcinogenicity of aminoazo dyes. These observations suggested that a dietary vitamin can inhibit the carcinogenicity of a chemical by influencing its biotransformation, an early example of cancer chemoprevention. In the 1950s, Miller continued to make fundamental discoveries on the properties of enzyme systems that biotransform foreign chemicals. He discovered that the *N*-demethylation of an aminoazo dye by liver homogenate was an oxidative process. This study provided the basis for subsequent investigations that demonstrated the NADPH-dependent oxidative metabolism of drugs and carcinogens by liver microsomes. In 1957, the Millers made the important observation that the demethylase system was inhibited by carbon monoxide. Although they did not pursue this line of research, these early observations and the other studies described earlier helped pave the way for the discovery of cytochrome P450.

The Millers discovered that foreign chemicals can induce the synthesis of liver enzymes that biotransform the compound administered and other foreign chemicals. Studies on microsomal enzyme induction provided a mechanistic understanding of the inhibitory effects of certain polycyclic aromatic hydrocarbons on aminoazo dye carcinogenesis. This work was followed by that of Allan Conney in 1956, who showed that the increase in metabolism could be antagonized by inhibitors of protein synthesis. The induction of these enzymes is important toxicologically because it leads to an accelerated biotransformation of drugs and environmental chemicals in vivo and so alters their action and toxicity.

In the 1960s, the Millers elucidated the molecular events leading to the activation of 2-acetylaminofluorene, aminoazo dyes, aflatoxin B_1, safrole, estragole, and ethyl carbamate to chemically reactive products that react with macromolecules in cells. The later studies were the start of research on the biotransformation of naturally occurring carcinogens in our diet. Studies on the activation of several structurally diverse carcinogens led to the important unifying concept by the Millers who proposed in 1969 that most carcinogenic and mutagenic chemicals are not carcinogenic or mutagenic per se, but that these compounds must undergo biotransformation to reactive electrophilic intermediates that exert their toxic effects by covalently binding to critical sites on DNA, RNA, and protein. This discovery laid the foundation for subsequent research indicating a relationship between the mutagenicity of chemicals after activation and initiated a new era of carcinogenesis research that led to the

development of rapid mutagenicity tests for the screening of potential human carcinogens.

Other early studies in the field of carcinogenesis took a different approach. In the 1940s, J.C. Mottram (1880–1945), Isaac Berenblum (1903–2000), and Philippe Shubik (1921–2004) studied the development of tumors in mouse skin that gave rise to the two-stage, initiator–promoter model. Cancer models involving two or more stages helped researchers understand carcinogenesis at the level of the whole organ and served as a basis for the classical model of carcinogenesis, which now includes initiation, promotion, and progression. The initiation phase has traditionally been described as involving the induction of mutations and escape from DNA repair. Cell proliferation in the promotion phase plus additional genetic events and angiogenesis in the progression phase are needed for the process of carcinogenesis to result in cancer. Roswell Boutwell, Stuart Yuspa, Henry Hennings, Thomas Slaga, and others have contributed to this field.

Peter Armitage and Richard Doll (1912–2005) used the two-stage model for investigating the age distribution of human cancer incidences in 1954 and 1956 using a simple power function of age. Later, Armitage and Doll and Suresh H. Moolgavkar found better equations to fit cancer incidence data. Richard Peto and Doll used epidemiologic data to estimate the fundamental causes of human cancer.

Ernst Wynder (1922–1999), born in Germany and raised in New Jersey when his family fled to escape Nazi persecution, attended medical school at Washington University, St. Louis. During a summer internship at New York University, his curiosity was piqued during the autopsy of a two-pack-a-day smoker who had died from lung cancer. Wynder began collecting case histories of lung cancer victims, first in New York City and then in St. Louis. His research brought him to thoracic surgeon Evarts Graham, who, despite initial skepticism about Wynder's premise, granted access to his extensive case records and agreed to sponsor the medical student. In 1950, the *Journal of the American Medical Association* published Wynder and Graham's *Tobacco Smoking as a Possible Etiologic Factor in Bronchiogenic Carcinoma: A Study of 684 Proven Cases*. Wynder and Graham's retrospective study was not the first to link smoking and cancer (in 1950, Doll also demonstrated that smoking causes cancer), but its sophisticated design, impressive population size, and unambiguous findings demanded action. During the next decade, hundreds of reports were published linking cancer and smoking, including large prospective studies and animal investigations. The preponderance of evidence led to the publication of the Surgeon General's Report on Smoking and Health in January 1964, the first official recognition in the United States that cigarette smoking causes cancer and other serious diseases. This seminal report prompted a series of public health actions and changed societal attitudes toward the health hazards of smoking.

Another husband–wife team in the area of carcinogenesis was John and Elizabeth Weisburger, who both started at the National Cancer Institute in 1949. John studied the mode of action of chemical carcinogens in general and arylamines in particular. Some of these chemicals were important occupational carcinogens, and more recently, it has been discovered that they occur in cooked meats, as the cooking process generates heterocyclic amines. These products undergo a two-step biochemical activation to DNA-reactive chemicals, *N*-oxidation usually in the liver, followed by *N*,*O*-acylation in target organs such as the liver, the intestinal tract, the mammary gland, and the pancreas. Between 1961 and 1972, as director of the Bioassay Segment of the Carcinogenesis Contract Program Management Group of the National Cancer Institute, John Weisburger was also involved with testing methods for environmental and industrial compounds including the role of dose levels and the species and strains of animals to be used in these tests. He introduced the F344 rat and the B6C3F1 mouse as the standard animal models. With the discovery that many carcinogens are mutagens, he organized national programs to develop rapid in vitro bioassay systems to test for carcinogenicity. When he left NCI to become director of research at the American Health Foundation in 1972, the NCI Bioassay Program was transferred to the NIEHS in North Carolina, where it continues today as the National Toxicology Program.

Elizabeth Weisburger identified biochemical pathways of malignant growth and mechanisms of carcinogenesis and synthesized reference metabolites and analogs of a research carcinogen. In 1951, she was appointed to the NCI Laboratory of Biochemistry. Ten years later, along with John, she formed a research group to test for carcinogenic activity in environmental and industrial compounds. Elizabeth stayed at NCI and became head of the Laboratory of Carcinogen Metabolism. She was appointed assistant director for chemical carcinogenesis in the NCI Division of Cancer Etiology in 1981, where she remained until her retirement in 1988.

During the late 1960s and early 1970s, many questions were being raised about rodent carcinogenicity testing. A breakthrough in thinking occurred in 1975 when Dr. Bruce Ames and his colleagues at the University of California in Berkeley developed an easy, exquisitely sensitive biological method for measuring the mutagenic potency of chemical substances. This bacterial mutagenesis system is commonly known as the *Ames test*. The great interest in the Ames test was based on the proposition that any substance that is mutagenic to bacteria may be carcinogenic because the DNA bases are the same in all cells. The test is based on inducing growth in genetically altered strains of the bacterium *Salmonella typhimurium* that are unable to synthesize the amino acid histidine from the ingredients in its culture medium. When a test material is applied to the bacteria in the presence and absence of mammalian microsomal enzyme systems, some undergo a back mutation (*revert*) such that the bacteria can grow like the original *wild* (unaltered) strains without histidine and can be seen as visible colonies. By simply counting the colonies after a standard time under standard growing conditions, the mutagenic

potential of the parent compound and its metabolites can be estimated.

The test initially gave the impression that it correlated very highly with rodent carcinogenicity. This correlation diminished as more data became available. For example, many substances that caused cancer in laboratory animals did not elicit a positive response in the Ames test and vice versa. The Ames test alone does not demonstrate cancer risk, but the mutagenic potency does correlate with the carcinogenic potency for certain types of chemicals. Further, the ease and low cost of the test make it valuable for screening substances in the environment and new substances in the laboratory. It also sets a new paradigm by distinguishing between genotoxic carcinogens and nongenotoxic carcinogens.

James G. Wilson (1915–1987) introduced a slicing technique (freehand slicing) that standardized the examination of fetuses from teratology studies, especially the soft tissues. Fetuses used for the Wilson's soft tissue sectioning technique are first fixed in Bouin's solution, which is a mixture of saturated picric acid, formaldehyde, and glacial acetic acid. This fixes the tissues, hardens the soft tissues, and softens the bones in order to preserve the specimens and make it possible to slice them cleanly into thin sections with a razor blade. All the internal organs can be examined and any abnormalities or developmental variations documented. The sections can be saved for further examination, if desired. This technique has its limitations (e.g., the original coloration of the tissues is lost), but its simplicity made it very popular and it has been accepted internationally. In 1973, Wilson outlined the four major manifestations of abnormal development: growth alterations, functional deficits, structural malformations, and death.

The growth in toxicology continued to attract more students and practitioners, and this resulted in more research. As with other recognized, independent scientific disciplines, toxicologists realized a need for a learned society to provide a forum for the exchange of the burst of new scientific information. The Society of Toxicology was founded in 1961. This was the first international society for and by toxicologists. Since its founding and as a result of the tremendous growth of toxicology, almost every developed country has its own version—a testimony to toxicology's importance and growth. The need for appropriate journals in which to publish, and thus disseminate, the results of investigations was acute and noted by the Society. The journal, *Toxicology and Applied Pharmacology*, was founded by Fred Coulston; this was followed by *Fundamental and Applied Toxicology*, which is now *Toxicological Sciences*. These have been the official journals of the Society. The Society has published a wonderful, informative book covering its first 50 years (SOT, 2011). The excellent biographies in that book are easily available and have permitted me to remove some of the people mentioned in earlier editions of this chapter.

Other important journals included *Food and Chemical Toxicology* (originally *Food and Cosmetic Toxicology*, founded by Leon Golberg) and *Regulatory Toxicology and Pharmacology*. Board certification began in the early 1980s to assure a minimal level of competency among people calling themselves toxicologists.

Regulatory

Arnold J. Lehman (1900–1979) earned his doctorate from the University of Washington in Seattle in 1930 and his medical degree from Stanford University in 1936. He taught at a number of universities before joining the U.S. FDA as director of the Division of Pharmacology in 1946. He and his staff published *Procedures for the Appraisal of the Safety of Chemicals in Foods, Drugs and Cosmetics* in 1955, the first attempt by the agency to provide guidelines for toxicological studies. He and his colleagues, most notably O. Garth Fitzhugh (1901–1994), laid the foundations of an acceptable daily intake (ADI) of a material in 1952. They developed the concept of safety factors (a number applied to the highest dose that did not elicit an adverse effect in a properly designed and performed toxicological study, the no-observed-adverse-effect level [NOAEL]) for use in extrapolating animal data to man.

Government toxicologists have made significant contributions especially in the area of safety evaluation, including the quantification of risk. Regulatory agencies demand adequate data of high quality to serve as the basis for establishing safe exposure levels. To assist toxicologists concerned with the safety of food and color additives, the U.S. FDA issued a series of guidelines in 1982, often referred to as *Redbook*, to standardize the necessary toxicological studies to establish the safety of materials added to foods. These guidelines are designed to encourage sound science and the conservation of resources while providing adequate data for determining safe exposure limits for consumers. The extent of testing was and is often determined by the nature of the chemical, its chemical and physical properties, and the extent of exposure. The Organization for Economic Cooperation and Development (OECD) issued guidelines generally consistent with those in the *Redbook* that are now accepted internationally.

Following the disclosure that some contract laboratories had falsified data used to support the safety of regulated materials, FDA and EPA instituted good laboratory practices (GLPs) in 1978 to assure the proper conduct of all toxicology studies to be submitted for regulatory review. The *Redbooks* and GLPs moved sound science into regulatory toxicological research.

At the international level, the World Health Organization (WHO), through the efforts of Frank Lu, Gaston Vettorazzi, and John Herrman, applied sound toxicological thinking to establishing safe exposure conditions for food chemicals and pesticides. They more thoroughly developed the concept of an ADI based on sound toxicological data and the proper use of appropriate safety factors. This concept, recognized and effectively used worldwide, has resulted in few significant problems with food chemicals including pesticides evaluated in this manner. The evaluations are conducted through the

auspices of the International Programme on Chemical Safety and implemented by the Joint FAO/WHO Expert Committee on Food Additives (first meeting in 1956) and the Joint Meeting on Pesticide Residues (first meeting in 1961).

Problems and Responses

Despite the successes of toxicology in understanding the mechanisms of toxicity and being incorporated into regulations, a number of incidents occurred that influenced society and caused toxicology to take on new responsibilities.

After issues arose about the improper use of food colors and other food additives in the 1950s, the U.S. Congress passed significant revisions to the Food, Drug, and Cosmetic Act requiring the approval by the FDA of all new food and color additives based on safety before they could be added to foods. A noteworthy part of the law was the *Delaney clause* that stipulated that no additive could be deemed safe (i.e., given an FDA approval) if it were found to induce cancer in man or experimental animals. Scientists agreed that the FDA had sufficient authority in the general safety clause to ban carcinogens but proponents justified the clause on the basis that some cancer experts were not able to determine a safe level for any carcinogen.

While well intentioned, the Delaney clause has created problems for the food and chemical industries and for regulatory officials since enacted. The trouble began on November 6, 1959, when FDA announced that residues of the pesticide amitrole, a rodent carcinogen, had been found in cranberries and recommended that the public stop buying cranberries. Tainted supplies were withdrawn and new inspection procedures put in place. The scare passed quickly but a year's sales were wiped out since people eat little cranberry sauce except at Thanksgiving and Christmas. Notwithstanding publicity critical of the FDA, this action had beneficial results, particularly in convincing farmers that pesticides must be used with care. The use of amitrole was phased out during the 1960s. Nonetheless, the cranberry scare of Thanksgiving 1959 left an indelible residue of suspicion and worry about chemicals in the public's mind.

A month after the cranberry scare, federal officials learned that diethylstilbestrol (DES) a nonsteroidal synthetic estrogen now known to have delayed carcinogenic effects in humans had been shown to cause cancer in laboratory animals. At that time, DES was widely used as an additive in chicken feed, and DES residues were measurable in chickens sold in grocery stores. Officials banned DES from chickens and the DES story faded from the newspapers. DES was still permitted as a feed additive for beef and sheep because residues had not been measured in those animals due to analytical difficulties. Some criticized the FDA claiming that it had stopped sampling to avoid getting squeezed between the meat industry and the Delaney clause. The politics of toxicology were becoming apparent.

The environment presented other problems. One of the worst post–World War II examples of pollution was in Minamata, Japan. This small factory town was dominated by the Nippon Chisso Corporation. From 1932 to 1968, Chisso dumped an estimated 27 tons of mercury compounds into Minamata Bay. The town consists of mostly farmers and fisherman, so as Chisso Corporation dumped this mercury into the bay, thousands of people whose normal diet included fish from the bay unexpectedly were ingesting mercury. In May 1956, four patients suffering from an unknown disease were brought to the city hospital. They all had in common severe convulsions, intermittent loss of consciousness, repeated lapses into crazed mental states, and then finally permanent coma. Death was usually preceded by a very high fever. It was discovered that the same type of patients had been seen in the fishing villages surrounding Minamata City and that 17 people died after showing the same signs and symptoms. The illness became known as the *Minamata disease*, and eventually, it was determined to be caused by methyl mercury. The same syndrome was discovered again at Niigata City, Japan, in 1965. The probable cause of the disease in Niigata was methyl mercury from effluent from the Showa Denko Company's Kase factory, located on the upper reaches of the Agano River. The second Minamata disease was recognized at an earlier stage so fewer cases were reported. Both incidents were attributed to the production of acetaldehyde using mercury as catalyst. Methyl mercury had been produced by plankton and accumulated in fish and shellfish. Those who ate the contaminated seafood developed methyl mercury poisoning. The long-term effects were sensory disturbances and constriction of the visual field, incoordination and walking difficulties, dysarthria, hearing problems, and tremors. These cases of organic mercury poisoning were the first known to occur through the food chain transfer of an environmental pollutant.

In the pharmaceutical area, in the early 1960s, thalidomide was an approved drug used by some pregnant women in Europe and Canada as a sedative/hypnotic to treat morning sickness. Thalidomide was not approved in the United States, despite intense pressure from the manufacturer, because Dr. Frances Kelsey of the FDA insisted there was insufficient proof of the drug's safety in humans. Women who took the drug in early pregnancy delivered children with a widely varying but recognizable pattern of limb deformities. The most well known was absence of most of the arm with the hands extending from the shoulders, phocomelia. Another frequent arm malformation called radial aplasia was absence of the thumb and the adjoining bone in the lower arm. Similar limb malformations occurred in the lower extremities. The affected babies almost always had both sides affected and often had both the arms and the legs malformed. In addition, the drug caused malformations of the eyes and ears, heart, genitals, kidneys, digestive tract (including the lips and mouth), and nervous system. The first published suggestion of teratogenicity in man was W.G. McBride's letter in *The Lancet* in 1961. Thalidomide was soon recognized as a powerful human teratogen and banned worldwide. Taking even a single dose of thalidomide during early pregnancy could cause major birth defects. It is estimated that more than 10,000 children around the world were born with major malformations.

As a result of the thalidomide tragedy, teratology studies became a requirement for new drugs and recommended for certain other chemicals.

Rachel Carson's (1907–1964) *Silent Spring*, published in 1962, provided the first look at the widespread ecological degradation. It touched off an environmental awareness that still exists. The book focused on chemicals used in agriculture that sometimes led to high levels in the environment. Carson argued that those chemicals were more dangerous than radiation and that for the first time in history, humans were exposed to chemicals that remained in their bodies from birth to death. Well written and presented with thorough documentation, the book alerted a large audience to the environmental and human dangers of the indiscriminate use of chemicals. *Silent Spring* became a bestseller with international impact, spurred revolutionary changes in the laws affecting our air, land, and water and remains a landmark work.

Following the publication of *Silent Spring*, rising concern about the environment swept across universities. The intensity of the discontent compared with that over the U.S. war in Vietnam. A national day of observance of environmental problems was held in the spring of 1970, Earth Day. This was a nationwide grassroots demonstration on behalf of the environment. The American people finally had a forum to express their concern about what was happening to the environment, and they did so with exuberance. Earth Day is now an annual observance. As a result of Carson's book and the ensuing activism, and in recognition of the problems in the land, air, and water, President Richard Nixon established the United States Environmental Protection Agency, which was launched on December 2, 1970. It has developed new testing methods intended to protect man and the environment.

New occupational issues began to emerge during the 1960s. In the United States and elsewhere, asbestos, thought to be an inert material, was widely used for its heat-resistant characteristics in a wide range of building materials (roofing shingles, ceiling and floor tiles, paper products, and cement products), friction products (automobile clutch, brake, and transmission parts), heat-resistant fabrics, packaging, gaskets, and coatings. Its usage peaked during World War II and into the 1970s. During the late 1960s, evidence emerged indicating that some asbestos fibers were a health risk. Breathing high levels of asbestos fibers for a long time could result in asbestosis, a disease that can eventually lead to disability and death. Breathing asbestos also increased the risk of lung cancer, mesothelioma, and possibly cancers in other parts of the body. Starting in the 1980s, the concern about asbestos resulted in the spawning of a new industry, asbestos removal and abatement.

In the late 1960s, there were implications of a cover-up by the chemical industry about the adverse effects of vinyl chloride, a major commodity. Early research conducted by producers and users of vinyl chloride focused on its toxicological properties. Later studies investigated chronic toxicity and carcinogenicity in which carcinogenic responses were observed in rodent inhalation studies. This occurred at almost the same time that case reports were published on a finding of a rare cancer, hepatic angiosarcomas, in workers exposed to high levels of vinyl chloride. More stringent occupational exposure limits were instituted, and further research on vinyl chloride was initiated, including epidemiological studies of workers, animal carcinogenicity bioassays, and mechanistic investigations. The studies firmly established an association between prolonged exposure to high levels of vinyl chloride and angiosarcomas of the liver. More detailed investigation showed that workers who inhaled high levels of vinyl chloride for several years had altered liver function, nerve damage, poor blood flow in the hands, and unusual immune reactions. Animal studies showed that long-term exposure to vinyl chloride might adversely affect male reproductive organs. Vinyl chloride is now classified as a known human carcinogen.

The carcinogenicity findings revealed marked differences in potency between humans and rodents. Research on the metabolic kinetics and molecular dosimetry of vinyl chloride and its biotransformation products provided a basis for reconciling the species differences in potency and provided a mechanistic basis for the very specific carcinogenic response, hepatic angiosarcomas. The research conducted on vinyl chloride may be viewed as a success story for mechanistic-based findings and their importance in establishing appropriate health protective standards. Seminal work by Perry Gehring (1936–2003) and Phil Watanabe of Dow Chemical and others brought a new level of understanding and importance of the role of biotransformation and pharmacokinetics in toxicity. More stringent exposure standards have been effective in protecting workers. Moreover, the research approach used with vinyl chloride has served as a template for evaluating the toxicity and carcinogenicity of other chemicals.

As a result of workplace problems involving asbestos, vinyl chloride, and other chemicals, the U.S. Congress passed the Occupational Safety and Health Act of 1970, a new effort to protect workers from harm. The Act established for the first time a nationwide, federal program to protect almost the entire work force from job-related injury, illness, and death. The Occupational Safety and Health Administration (OSHA) was established within the Labor Department to administer the Act, effective April 28, 1971. Building on the Bureau of Labor Standards, the new agency took on the difficult task of creating a program that would meet the legislative intent of the Act.

Dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin and its congeners) first achieved notoriety in the 1970s when it was discovered as a contaminant in some batches of Agent Orange, an herbicide used to defoliate trees in large areas of Vietnam. In addition to Agent Orange, dioxin is unintentionally produced by the manufacture of certain industrial chemicals, the chlorine bleaching process of pulp, the burning of certain wastes, and forest fires. Dioxin is highly lipophilic,

resists environmental degradation, and, in some species of animals, is very acutely toxic. It also causes cancers in animals and humans. It continues to generate concern because of its widespread distribution as an environmental contaminant (although levels have been declining for decades), its persistence within the food chain, and its toxicity. For these reasons, it has driven many aspects of food, environmental, occupational, and, interestingly, forensic toxicology, even though interpretation of its effects at low levels has been controversial. It is interesting to note that humans appear to be among the least sensitive species studied.

Most of our information about the effects of dioxin in humans comes from occupational accidents. Workers exposed to dioxin after a March 8, 1949, explosion at a Monsanto plant in Nitro, West Virginia, developed skin lesions (chloracne), eye irritations, headaches, dizziness, and breathing problems in the immediate aftermath of the incident. On July 10, 1976, an explosion at an Icmesa factory in Seveso, Italy, released 1.3 kg of dioxin into the air. The residents of the area were not evacuated immediately after the accident. Studies later confirmed that the residents exhibited the highest levels of dioxin ever found in human serum and that the soil in the area was heavily contaminated. Epidemiological studies of the residents of Seveso for over a quarter of a century indicate increases in certain cancers. Because of exposure to Agent Orange, the Veterans Administration set up the Agent Orange Registry, a health examination program for Vietnam veterans who were concerned about the possible long-term medical effects of exposure to Agent Orange. The National Academy of Sciences, in its 1994 report on Agent Orange, concluded that individual dioxin levels in Vietnam veterans are usually not meaningful because of background exposures to dioxin, poorly understood variations among individuals in dioxin metabolism, relatively large measurement errors, and exposure to herbicides that did not contain dioxin. Thus, the Veterans Administration will treat a number of diseases presumed to have resulted from exposure to herbicides like Agent Orange: chloracne or other acneform disease occurring within one year of exposure to Agent Orange, Hodgkin's disease, multiple myeloma, non-Hodgkin's lymphoma, acute and short-term peripheral neuropathy, porphyria cutanea tarda, prostate cancer, respiratory cancers, and some soft tissue sarcomas.

Environmental contamination by dioxin has been extremely controversial. Dioxin was implicated in vague illnesses in Love Canal, New York. Love Canal, near Niagara Falls, was a development built on and around a chemical waste site. Some epidemiologists claimed high rates of cancers and birth defects in the town, and the residents were evacuated in 1980. Some houses were torn down and the rest boarded up. Careful studies subsequently showed diseases in Love Canal were exactly what would be expected in a community of that size. Some parts of the area are now repopulated. A few years later the entire town of Times Beach, Missouri, was purchased by the federal government and bulldozed because of dioxin in the soil of unpaved roads. The buyout caused the only biological effect ever identified at Times Beach: huge populations of wild turkey and deer in the area of the former town. In 1996, the EPA announced the purchase of 158 homes and 200 apartments in the Escambia section of Pensacola, Florida, and relocated residents because dioxin-like chemicals are present in the soil of a former wood treatment plant. The EPA, worried about the chemicals possibly contaminating groundwater, dug up the soil and covered it with plastic. The residents demanded that their homes be purchased and that they be relocated, but refused examinations by U.S. Public Health Service doctors.

Even though there is little hard evidence of adverse effects in humans from dioxin in the environment, toxicology has been challenged by the public to deal with it. The controversy over dioxin involves the extrapolation of exposure to high levels (such as animal studies and occupational or accidental exposure) to the low levels generally found in the environment. For most people, the major exposure to dioxin is from food, mainly dairy and meat. This knowledge has led to increased surveillance of the food supply with resulting decreases in levels. Levels in the environment have been lowered 10-fold through new manufacturing methods and controlled incineration. Nonetheless, the concern remains.

Safety and Risk Assessment

Predicting what will happen in the future is the hallmark of any science. Given the same starting conditions, what happened before should happen again. Reproducibility may occur in the laboratory, but the public does not care about laboratories. The questions they pose are about different species, different routes of exposures, different exposure levels, and different exposure periods. How, then, can toxicologists explain to the public what may or may not happen under conditions that have not been tested and without theories that are as solid as in other sciences?

The emergence of modern safety assessment can be traced to the early 1950s with the concept of the NOAEL and ADI by Lehman and Fitzhugh and others. The basic premises have not changed in 60 years. For example, to determine the ADI, take the NOAEL (the highest dose tested that causes no adverse effects in a test species in a properly designed and executed study) and divide it by an appropriate safety/uncertainty factor (generally 100, to account for inter- and intraspecies differences). The resulting value, expressed as mg of chemical/kg body weight/day, is an amount that can be safely consumed for a lifetime by all segments of society. This has withstood the test of time and has effectively protected the public.

Risk assessment for carcinogens took a different route in the 1960s. It uses information from lifetime studies in male and female rats and mice administered a material at the maximum tolerated dose (MTD) and extrapolates the findings to millions of people exposed at levels many orders of magnitude lower. Unfortunately, standardizing risk assessments

has also resulted in inflexibility, applying numerous levels of conservatism, and frequently the inability to properly characterize likely risks because of the layers of default assumptions causing calculations to be unrealistic.

These efforts were often based upon theories that were not always well tested. For example, the most basic tenet of toxicology, the dose–response relationship with its origins dating back to Paracelsus, is apparently not as well understood and appreciated as toxicologists might think. What exactly is a dose, and is the nature of the response linear or curved? Is there a threshold for every effect? Further, is the response always in one direction, that is, as the dose is increased, is the severity of the response increased? Should hormesis be considered in risk assessment? How risk assessments are eventually conducted, by science or dogma, will greatly influence public policy. Much more research into these basic concepts of toxicology and risk assessment are needed.

Intentional Poisonings

One might think that intentional poisonings would disappear as analytical and forensic procedures improved, but they continued. Most were the standard poisons used for centuries (arsenic, cyanide), but some were more clever. In the end, only a few made any impact on the study of toxicology.

Some intentional poisonings were worse than ever. Chemical weapons more lethal than their predecessors, continued to be produced in a number of countries. In the United States, chemicals for lethal injection were being used as a means of execution. Three classes of drugs that are generally used in lethal injections are a general anesthetic to induce unconsciousness (e.g., sodium thiopental), a paralyzing agent to stop breathing (e.g., pancuronium bromide), and a cardiotoxic agent to stop the heart (e.g., potassium chloride).

Training

> Even while they teach, men [they] learn.
>
> **Seneca**

As toxicology became a recognized scientific discipline, many training programs began at prestigious universities. Although it was difficult to develop programs that could address all the many facets of toxicology including chemistry and biochemistry, physiology and pharmacology, pathology, statistics, and epidemiology, excellent ones were developed.

The need for a standard, modern textbook became evident. Although several texts were available, none appeared adequate. This issue was addressed by Louis J. Casarett (1927–1972) and John Doull. Casarett received his doctorate in 1958 from the University of Rochester, where he studied respiratory toxicodynamics and morphological changes following exposures to potentially toxic materials, especially polonium. In 1967, he moved to the University of Hawaii, where he developed a program in toxicology. His research involved drugs of abuse and pesticides. Doull received both his doctorate in pharmacology and his medical degree from the University of Chicago. He remained at Chicago for a number of years and then moved to the University of Kansas Medical Center, where he established one of the more outstanding programs in toxicology. Casarett and Doull published *Toxicology: The Basic Science of Poisons* in 1975. Since then, a number of other excellent texts address various aspects of the principles and practices of toxicology, including *Hayes' Principles and Methods of Toxicology*.

Many corporations developed centers of excellence in toxicology to study product and workplace safety and produced scientists of great renown. Some of these laboratories include DuPont's Haskell Labs (established in 1935), Dow Chemical (VK Rowe, Perry Gehring), and Union Carbide/Carnegie Mellon Bushy Run (Carroll Weil).

As reports about pollution were threatening to overshadow the benefits of chemicals to society, industry's challenge was to overcome lack of knowledge about the health effects of chemicals. So 11 major chemical companies in the United States created the Chemical Industry Institute of Toxicology (CIIT) in 1974 to address growing concerns about the effects of chemicals on environmental and human health. They hired Leon Golberg (1915–1987) as its first president. CIIT (now The Hamner Institutes for Health Sciences) moved the understanding of toxicology to new levels of expertise in the area of mechanism of action.

Contract toxicology laboratories also made a significant contribution to toxicology by providing unique opportunities for those interested in the pragmatic aspects of applied toxicology, namely, the conduct of appropriate tests to establish safe conditions of exposure. These studies must consider both the latest developments and advances in toxicology and the needs of regulators internationally. This is especially challenging in an era of increased international trade and harmonization. Laboratories, such as Hazleton Laboratories (now Covance) founded by Lloyd Hazleton, Food and Drug Research Laboratories founded by Ben Oser, Biodynamics (now Huntingdon Life Sciences, United States) founded by Tom Russell, and International Research and Development Laboratories (now MPI) founded by Frank Wazeter, produced trained toxicologists that populated a number of influential positions in academia, industry, and government.

Toxicology was also advanced within trade associations as they assisted both industry and regulatory authorities in establishing safe limits of exposure by using the best science possible. These associations include the Flavor and Extract Manufacturers Association (FEMA), Cosmetic Toiletry and Fragrance Association (CTFA) (now the Personal Care Products Council), and the International Association of Color Manufacturers (IACM). Toxicologists were also involved with organizations to promote the basic science, such as the International Life Sciences Institute

(founded by Alex Malaspina and John Kirschman) and applied science such as the Toxicology Forum (founded by Philippe Shubik with the support of industry, academia, and governments).

Through these efforts, toxicologists were trained and then kept up with developments in the field past their formal education.

> Toxicology is the ultimate Renaissance science.
>
> **Gillett (1987)**

Toxicology continues to grow. Its critical position in society and the uniqueness of the issues it faces continue to attract and even seduce some of the brightest minds. There is something for everyone: from the molecular to the macro, from the gene to the whole animal to the human. Toxicology's strengths derive from the integration of the chemical and biological sciences and supporting disciplines. Toxicology is also one of the few sciences in which academic, industrial, and regulatory scientists can and do effectively interact to protect the public. The importance of toxicology is recognized by governments worldwide. Toxicology has evolved from listing poisons to protecting the public, from simply identifying effects (qualitative toxicology) to identifying and quantifying human risks from exposure, and from observing phenomena to experimenting and determining mechanisms of action of toxic agents and rational management for intoxication. As Claude Bernard noted:

> Where then, you will ask is the difference between observers and experimenters? It is here: we give the name observer to the man [human] who applies methods of investigation, whether simple or complex, to the study of phenomena which he [she] does not vary and which he [she] therefore gathers as nature offers them. We give the name experimenter to the man [human] who applies methods of investigation, whether simple or complex, so as to make natural phenomena vary, or so as to alter them with some purpose or other, and to make them present themselves in circumstances or conditions in which nature does not show them. In this sense, observation is investigation of a natural phenomenon, and experiment is investigation of a phenomenon altered by the investigator.
>
> **Bernard (1865)**

Toxicology has come a long way! As science continues to advance, toxicology will continue to draw from these advances in its constant quest to protect the public from harm.

QUESTIONS

1.1 Analytical (forensic) toxicology had its formal origins in the outstanding work of what Spaniard?

1.2 The penalty of the peach was used by what ancient society?

1.3 What is the name of the early U.S. regulator noted for studying/testing the effects of food additives in his *Poison Squad*?

1.4 Name the two U.S. regulators who laid the foundation of an ADI of a material in 1952.

1.5 Who wrote *Silent Spring?*

FURTHER READINGS

This is not meant to be an exhaustive list of citations for all the details in the chapter. Rather, it is a list of some key books and articles the reader may wish to consult to gain a fuller appreciation of the history and meaning of toxicology.

2 Use of Toxicology in the Regulatory Process

Barbara D. Beck, Mara Seeley, and Edward J. Calabrese

CONTENTS

BACKGROUND

Regulatory toxicology is that area of toxicology directed at protecting public health by regulating exposure to potentially harmful materials. Historically, regulatory toxicology has developed in a manner that has reflected humankind's ability to relate exposure to certain agents to adverse health effects. Thus, because effects were observable and could be easily associated with exposure, early regulatory attention generally focused on preventing the acute effects of chemical agents. Food and drugs were the focus of early regulation

due, no doubt, to the relative ease in associating acute health effects with exposure to materials in the diet or medications. Hutt[1] notes that adulteration of the food supply was a serious problem in the ancient world, and he quotes Pliny the Elder, writing in the first century AD, as saying, "So many poisons are employed to force wine to suit our taste – and we are surprised that it is not wholesome!"

Occupational exposures were another early focus of regulation, due again to the fact that the relationship between exposure and effect was often observable. Early industrial hygiene efforts were typically intended to prevent overt or frank effects of materials in the workplace. Some of the first observations of effects from chronic human exposures to certain chemicals were made in occupational settings. Hutt[1] notes that, during the sixteenth century, Paracelsus wrote about diseases characteristic of miners. Certain chronic occupational hazards affected the exposed individual at the point of contact, which made the connection between agent and effect easy to discern. The first epidemiological study linking human cancer to a specific cause is attributed to Sir Percivall Pott, who in 1775 identified occupational exposure to soot as being responsible for scrotal cancers in young British chimney sweeps.[2]

The development of regulatory toxicology during the twentieth century up through the present has continued to shadow the ability to detect both chemicals and effects. That is, as it has become possible to detect chemicals at lower and lower levels as well as smaller biochemical and physiological changes, regulatory attention has turned to what appear to be *new* problems. For example, small increases in airway resistance following exposure to certain air pollutants are currently used as one basis for regulating these air pollutants; historically, no one would have been aware of these subtle effects. Similarly, guidelines for occupational exposures to benzene have decreased by two orders of magnitude—from 100 parts per million (ppm) in 1927 to the current Occupational Safety and Health Administration (OSHA) standard of 1 ppm. In contrast, ambient criteria (which are typically not mandated standards) for nonoccupational benzene exposures in some states can be much lower. For example, the ambient annual guideline for benzene is 0.04 parts per billion (ppb) in New York state, a concentration that is below many ambient background samples.[3]

Because of the dramatic increase in our ability to detect smaller effects and lower concentrations, programs to regulate chemicals in the environment have increased at an astronomical rate during the last 40 years. Factors contributing to the recent increase in regulatory activity include the following:

- The realization of the vast number of chemicals that humans have dispersed into the environment and to which humans have been exposed. As of 2007, more than 80,000 commercial chemicals in commerce had been identified and listed under the Toxic Substances Control Act (TSCA).[4] Advances in analytical chemistry have allowed ppb levels of chemicals to be detected in *pristine* areas, as well as in wildlife, food products, and human body tissues. This message was delivered initially by Rachel Carson in 1962 with the publication of Silent Spring, which described the impact on the environment, particularly birds, of use of pesticides. Today, the U.S. Centers for Disease Control and Prevention (CDC)[5] conducts biomonitoring studies (i.e., the National Report on Human Exposure to Environmental Chemicals)* of human serum and urine, demonstrating the presence of more than 200 multiple exogenous chemicals in biological media, including anthropogenic compounds (such as polychlorinated biphenyls [PCBs]) and chemicals that have both natural and anthropogenic sources (such as lead and cadmium).[5]
- The realization that historical chemical management practices might today be associated with low-level risks, even though such practices were consistent with the state of knowledge at the time. For example, during the 1970s, residents of Love Canal, a neighborhood of Niagara Falls in New York state, realized that they had unknowingly been exposed to chemicals that had migrated into their basements from a nearby site formerly used as a landfill. The Comprehensive Emergency Response, Compensation, and Liability Act (CERCLA), also known as Superfund, was enacted shortly after the Love Canal incident (see Table 2.1 and NYS DOH).[6]
- The establishment over the past 50 years of causal relationships between certain diseases and chronic chemical exposures, such as leukemia and benzene[7] or mesothelioma and asbestos.[8]
- The reduction in illness and mortality due to microbial diseases and the improved standard of living, which have focused increasing attention on other causes of ill health.

The rapid increase in the number and complexity of regulatory programs to address potential health effects from chemical exposures is also a result of the increased scientific uncertainty about toxicology and risk that has evolved with our increased understanding of these subjects (i.e., the more that is learned, the more clear how much more there is to learn becomes). As the complexities of toxicology have become better understood, more complex procedures for characterizing toxic responses have been developed, such as the use of probabilistic risk assessment methods, refined analyses of mode of action (MoA), or identification of key events on a causal pathway for toxicity.[9]

When the Delaney Clause (forbidding the addition to food of any substance found to induce cancer in animals or humans) was passed in 1958,[10] the public generally believed that the intent of the law—to provide a *zero-risk* food supply—was achievable. No one foresaw that, 20 years later, scientists would have identified more than 500 animal carcinogens,

* Often referred to as the *NHANES* study.

TABLE 2.1
Federal Laws Related to Exposures to Toxic Substances

Legislation	Agency	Area of Concern
Food, Drug, and Cosmetics Act (1906, 1938, amended 1958, 1960, 1962, 1968, 1976, 1996 (also known as the FQPA), 1997)	FDA	Food, drugs, cosmetics, food additives, color additives, new drugs, animal and food additives, and medical devices
FIFRA (1948, amended 1972, 1975, 1978, 1988, 1996)	EPA	Pesticides
Dangerous Cargo Act (1952)	DOT, USCG	Water shipment of toxic materials
Atomic Energy Act (1954)	NRC	Radioactive substances
Federal Hazardous Substances Act (1960, amended 1981)	CPSC	Toxic household products
Federal Meat Inspection Act (1967); Poultry Products Inspection Act (1968); Egg Products Inspection Act (1970)	USDA	Food, feed, color additives, and pesticide residues
National Environmental Policy Act (1970, amended 1975, 1985, 1989, 1996, 1997)	EPA	Ecosystems and natural resources
OSH Act (1970, amended 1974, 1978, 1982, 1983, 1984, 1986, 1987, 1990, 1992, 1995, 1996, 1997, 1998, 2002)	OSHA, NIOSH	Workplace toxic chemicals
Poison Prevention Packaging Act (1970, amended 1981)	CPSC	Packaging of hazardous household products
CAA (1970, amended 1974, 1977, 1990)	EPA	Air pollutants
Hazardous Materials Transportation Act (1972)	DOT	Transport of hazardous materials
CWA (formerly Federal Water Pollution Control Act; 1972, amended 1977, 1978, 1981, 1987)	EPA	Water pollutants
Marine Protection, Research, and Sanctuaries Act (1972)	EPA	Ocean dumping
Consumer Product Safety Act (1972, amended 1981)	CPSC	Hazardous consumer products
Lead-Based Paint Poison Prevention Act (1973, amended 1976)	CPSC, HEW, (HHS), HUD	Use of lead paint in federally assisted housing
Residential Lead-Based Paint Hazard Reduction Act (1992)	EPA	Use of lead paint in all housing
Safe Drinking Water Act (1974, amended 1977, 1986, 1996)	EPA	Drinking water, contaminants
Resource Conservation and Recovery Act (1976, amended 1984)	EPA	Solid waste, including hazardous wastes
TSCA (1976); Asbestos Information Act (1988)	EPA	Hazardous chemicals not covered by other laws, includes premarket review
Federal Mine Safety and Health Act (1977)	DOL, NIOSH	Toxic substances in coal and other mines
Comprehensive Environmental Response, Compensation, and Liability Act (1981); Superfund Amendments and Reauthorization Act (1986); Emergency Planning and Community Right-to-Know Act (1986)	EPA	Hazardous substances, pollutants and contaminants
Radon Gas and Indoor Air Quality Research Act (1986)	EPA	Indoor air
Oil Pollution Act (1990)	DOT	Oil pollution
Pollution Prevention Act (1990)	EPA	Toxics use reduction
Bioterrorism Act (2002)	FDA, CDC, USDA, EPA	Biological agents and toxins used in acts of war
Consumer Product Safety Improvement Act (2008)	CPSC	Children's product safety; CPSC reform

been able to detect chemical concentrations between two and five orders of magnitude lower than could be detected in the 1950s, and found that many naturally occurring chemicals in food could be considered animal carcinogens.[11] Enormous quantities of chemical toxicity data are now being made available via the Registration, Evaluation Authorisation and Restriction of Chemicals (REACH) program in Europe—as of 2008, information had been submitted on more than 100,000 chemicals,[12] creating enormous challenges for development of new methods and interpretation of findings.

CURRENT REGULATORY FRAMEWORK

While this chapter focuses on regulatory approaches in the United States, the authors recognize the importance of *globalization* of risk assessment and risk management procedures. Therefore, some examples of regulatory frameworks outside the United States—although by no means exhaustive—will be presented as well.

At the federal level in the United States, four agencies bear most of the direct responsibility for the regulation of toxic chemicals—the Consumer Product Safety Commission (CPSC), the Environmental Protection Agency (EPA), the Food and Drug Administration (FDA), and OSHA. Table 2.1 describes the acts that empower these and several other federal agencies.

It is clear from Table 2.1 that there is a broad range of chemical exposures with which federal regulatory authorities are concerned. Chemicals may be regulated on the basis of environmental medium (e.g., air, water), activity (e.g., food manufacture, chemical transport, ocean dumping), and type of exposure environment (e.g., workplace, residential).

TABLE 2.2
Advantages and Disadvantages of Epidemiological Studies

Advantages	Disadvantages
Exposure conditions realistic	Costly and time consuming
Occurrence of interactive effects among individual chemicals	Post facto, not protective of public health[a]
Effects measured in humans	Difficulty in defining exposure, problems with confounding exposure
Full range of human susceptibility frequently expressed	Difficult to see less than twofold increase in risk except in very large populations
	Effects measured can be relatively crude (morbidity, mortality)

[a] Use of biomarkers in epidemiological studies, rather than disease endpoints, can allow such studies to be public health protective.

While the statutes in Table 2.2 represent approximately 100 years of federal legislative history, 20 of the 26 have been written (and some earlier statutes have been updated) since 1970, illustrating the relatively recent increase in public concern about chemical exposures.

The language of each statute provides the implementing agency with the basis for issuing regulations under the law. Some statutes instruct the agency to limit chemical release or exposure by requiring the use of certain control technologies. Some statutes require the agency to develop and implement risk-based standards, while others require balancing risks with the costs of regulating (or the benefits of not regulating) a certain chemical. The latter two types of statutes are the most likely to involve regulatory toxicology in their implementation.

Section 307 of the Clean Water Act (CWA) is an example of a statute that requires technology-based standards for pollution control. Under this portion of the CWA, industries discharging to surface water must use the best available control technology to limit their pollutant discharges; installation of the appropriate control technology is required from the discharger to obtain a National Pollutant Discharge Elimination System (NPDES) permit.

Other statutes specify the standard for safety that regulations and standards issued under the law are supposed to provide. A commonly cited example of a law that required health-based, or risk-based, standards for pollution control is Section 112 of the 1970 Clean Air Act (CAA), which required the EPA to set emission standards for hazardous air pollutants under the National Emissions Standards for Hazardous Air Pollutants (NESHAPS) program that would *protect public health* with an *ample margin of safety*. Implementation of this standard of safety for carcinogenic air pollutants proved to be so troublesome that, between 1970 and 1990, NESHAPS were set for only seven air pollutants. The difficulty in setting the risk-based standards was that the statute provided no indication of what an *ample* margin of safety was or how such a concept might be applied to carcinogens, given that the agency considered carcinogens to act by a no-threshold mechanism.* The 1990 amendments to the CAA replaced the health-based NESHAPS standards with specific technology-based standards for controlling hazardous air pollutants. The 1990 amendments state that after installation of the control technology, health-based standards must be set to further control emissions where unacceptable risks remain.

The Federal Food, Drug, and Cosmetic Act (FFDCA) is another example of a law requiring health-based standards for limiting the public's exposure to chemicals. Section 409 of the FFDCA requires the sponsor of a food additive to demonstrate to a reasonable certainty that no harm to consumers will result when the additive is put to its intended use. This statute contains the Delaney Clause (discussed earlier), a special provision that forbids the use of any food additive that has been found to induce cancer in humans or animals. Essentially, the Delaney Clause specifies that the acceptable risk from carcinogens as food additives is zero. This bright line has proven to be very difficult for the FDA and (until passage of the Food Quality Protection Act [FQPA] in 1996) EPA to implement, because the law does not allow the implementing agencies to specify de minimis, or acceptable, levels of risk.

The EPA regulates pesticides under both the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the FFDCA. Under the FIFRA, the agency was required to balance the risk from a given pesticide with the benefit associated with its use. However, the EPA was also bound by the *zero-risk* Delaney Clause under the FFDCA with regard to pesticides that may concentrate in processed foods above the level allowed on the raw agricultural commodity. This dichotomous standard (known as the *Delaney Paradox*) forced the EPA to regulate to zero-risk pesticides that may concentrate on foods during processing while regulating using risk–benefit analysis for the same pesticides on raw agricultural commodities.[13] In 1992, a Circuit court ruled that the Delaney Clause does not allow the EPA to permit the use of carcinogenic pesticides under the FFDCA, even if their use is associated with negligible risk.[14] The Delaney Clause has also been difficult for the FDA to implement as more chemicals (including naturally occurring chemicals in foods) have been determined to be carcinogens. As such, the FDA has searched for ways to establish acceptable risk levels from food additives. In 1988, the U.S. Court of Appeals for the District of Columbia struck down an effort by the FDA to interpret the Delaney Clause as allowing the agency to set a *de minimis* risk level for two color additives for use in cosmetics and drugs.[15]

Other laws require the implementing agency to balance the risks and benefits of alternative regulatory choices. For example, Section 408 of the FFDCA, which, until the

* With respect to risks from no-threshold mechanisms, decisions must be made as to acceptable risk, in which case the *ample margins of safety* concept is difficult to apply, other than via an expression of permissible risk.

FQPA of 1996, required tolerances for pesticide residues on raw agricultural commodities to be set at levels necessary to protect the public health while considering the need for *an adequate, wholesome, and economical food supply*.[13] "Evaluation of Noncancer Effects" section of the TSCA requires the EPA to consider the potential benefits of using a chemical and the economic consequences of restricting its use when determining whether the manufacture, distribution, use, or disposal of a substance presents an unreasonable risk of injury to health or the environment.

Language in the Occupational Safety and Health Act (OSH Act) specifies that the agency (i.e., OSHA) must "adequately assure(s) to the extent feasible…that no employee will suffer material impairment of health or functional capacity."[16] This statutory language also requires balancing of risks and costs, but the dual requirements of *feasibility* and *that no employee will suffer* may, because of the absolute nature of the language, be impossible to reconcile in certain situations.[17]

While the narrative terms *unreasonable risk* or *ample margin of safety* have not been clearly or consistently defined across agencies or statutes, agencies have generally interpreted this language as requiring a qualitative—and, frequently, quantitative—estimate of the health risks associated with an exposure and the reduction in risks resulting from regulatory action. A major factor in the increased use of risk analysis by regulatory agencies was the 1980 Supreme Court decision in Industrial Union Department vs. American Petroleum Institute. In this case, the OSHA proposed lowering the occupational standard for benzene from 10 to 1 ppm on the bases that benzene was a carcinogen, any reduction in exposure would result in a reduction in risk, and 1 ppm was technologically feasible. The Supreme Court did not find for the union, stating, "Before he can promulgate any permanent health or safety standard, the Secretary [of Labor] is required to make a threshold finding that a place of employment is unsafe – in the sense that significant risks are present and can be eliminated or lessened by a change in practices."[18] The Court left the decision of what constitutes a *significant risk* to the OSHA. This landmark decision has had a major impact on agencies in addition to the OSHA, resulting in an increase in the development and use of tools to quantify risks from exposure to environmental chemicals.

The FQPA of 1996, which addresses risks from pesticides in food through the setting of tolerance limits, is primarily risk-based, with limitations on the extent to which the EPA can consider benefits. This is in contrast to the risk–benefit balancing requirements of the FFDCA noted earlier. Only in certain narrow circumstances under the FQPA can the EPA set pesticide tolerance levels that do not meet health-based criteria. Specifically, the circumstances comprise those situations where the use of a given pesticide prevents even greater risks from occurring to consumers (a risk–risk balancing) or where the lack of the pesticide would result in "a significant disruption in domestic production of an adequate, wholesome, and economical food supply." In addition, the FQPA eliminates certain aspects of the *Delaney Paradox* discussed earlier. Tolerance limits for pesticides in raw agricultural products and processed foods, for carcinogens and noncarcinogens (the Delaney Clause considered carcinogens only), are now to be based on health only. There are several other important provisions of the FQPA: the requirement that EPA specifically consider exposures and risks to infants and young children in setting pesticide tolerance limits, allowing an up to tenfold additional safety factor; the need to consider all pathways of exposure (e.g., drinking water, soil/dust ingestion) to a pesticide in setting tolerance limits for that pesticide in food; the need to consider the cumulative risk for multiple pesticides that act via a common mechanism of action when setting a tolerance limit for any single pesticide of the *common mechanism* class; and the establishment of a very ambitious comprehensive screening and testing program for pesticides that exert estrogenic and, possibly, other endocrine-related effects. The FQPA represents a landmark piece of legislation, not only in terms of the regulatory implications but also with respect to the advancement in scientific understanding required for its implementation.[19] For example, the EPA's ambitious Endocrine Disruptor Screening Program, which resulted from this statute, has posed significant technical and financial challenges in achieving its goals of evaluating potentially hundreds of chemicals for endocrine activity.[12]

Since the prior version of this chapter, the Consumer Products Safety Improvement Act (CPSIA) of 2008[20] represents a major statutory update in U.S. chemical regulation. This statute contains new testing and documentation requirements for children's products, with particular emphasis on lead and phthalates. It is unusual in its specificity (e.g., *defining* a child as up to 12 years of age and establishing numerical criteria for lead in children's products), and it allowed the U.S. Congress, in certain provisions, to supersede the type of technical role usually delegated to the implementing agency.

The combined effect of the use of risk assessment to help make regulatory decisions and the significant uncertainty that accompanies most quantitative estimates of toxicological risk has resulted in considerable debate about the practice of risk assessment. The EPA, FDA, and other agencies have been criticized by the Office of Management and Budget (OMB) and some representatives of the regulated community for being too conservative in their risk assessment procedures.[21] In contrast, environmental advocacy groups such as Greenpeace have claimed that "[i]n the real world, quantitative risk assessments are used almost exclusively to justify pollution."[22] Others have noted that "current risk estimates are by no means routinely exaggerated, either for the entire populations they apply to or for highly exposed or highly susceptible individuals within those populations."[23] Much of this difference in interpretation is perhaps due to the fact that risk estimates are frequently defined and presented inadequately. It is not uncommon for risk assessors to provide single value estimates of risk that may apply to some unknown percentage of the population. Because the variability in the exposure and dose–response characteristics of a population are so large, the risk estimates for a small, highly exposed or sensitive subpopulation may be very different from the estimates

of the most likely risks for the entire population. Although the risk assessment results are supposed to be qualified and uncertainty discussed, the risk number is often used without appropriate qualification. To address this problem, in 1994, the EPA prepared guidance to risk assessors on the need to provide fuller, more explicit descriptions of risk when providing such information not only to risk managers but also to the general public.[24] More recently, EPA developed guidance to enhance the approaches to and practices of risk assessment at the agency. These broadly applicable principles address a number of issues, such as the need for enhanced transparency in data selection and choices for risk assumptions, as well as clarifying the purpose of a particular analysis (e.g., screening vs. comprehensive assessment) and ensuring that the level of analysis is commensurate with the overall purpose.

In addition to the agencies discussed earlier, governmental and nongovernmental agencies can influence the regulatory process as well. The American Conference of Governmental Industrial Hygienists (ACGIH) sets exposure limits based solely on health protection for approximately 600 workplace chemicals. These exposure limits, known as threshold limit values (TLVs),[25] do not carry any regulatory weight, but it is not uncommon for workplaces to adhere to TLVs for chemicals that the OSHA does not regulate or that have an exposure limit that has not been revised since the inception of the OSHA in 1970. The TLVs have also been used by several state environmental agencies to derive acceptable ambient levels for toxic air pollutants.

Agencies in the Department of Health and Human Services (DHHS) that influence the regulatory process include the National Cancer Institute; the National Institute of Environmental Health Sciences, in particular the National Toxicology Program (NTP); the National Institute for Occupational Safety and Health (NIOSH) and the Center for Environmental Health (part of the CDC); and the Agency for Toxic Substance and Disease Registry (ATSDR).[26] These agencies affect the regulatory process in several ways, ranging from decisions on which chemicals to test in long-term cancer bioassays to defining principles for evaluating carcinogens and conducting site-specific (as with a hazardous waste site) and chemical-specific risk assessments. International organizations such as the World Health Organization (WHO) and the International Agency for Research on Cancer (IARC) also have a significant role in the use of information by regulatory agencies.

The primary focus of this chapter is on the use of regulatory toxicology at the federal level in the United States. However, state governments have also been active in regulating exposure to toxicants in the environment. For example, in 1986, voters in California overwhelmingly adopted Proposition 65, the Safe Drinking Water and Toxic Enforcement Act of 1986 (known commonly as Prop 65). This act contains two major provisions—one prohibiting the "discharge or release [of] a chemical known to the state to cause cancer or reproductive toxicity into water" and the other, a labeling requirement, mandating that no person expose another individual to any carcinogen or reproductive toxin without providing *clear and reasonable warning*. Exemptions for the discharge requirements are provided for carcinogens at discharge levels that will pose a lifetime cancer risk to a person drinking the water of less than 1×10^{-5}, or, for reproductive toxicants, discharges resulting in exposure levels less than 1000 times smaller than the *no observable effect level* (NOEL) for reproductive effects.

Some states in the United States have also developed their own risk assessment procedures and health-based standards, particularly in those situations where federal criteria are lacking, federal approaches and analysis have been viewed as outdated, or state and federal agencies have different interpretations of science. For example, several states have developed their own maximum contaminant levels (MCLs)* for chemicals in drinking water. In some cases, the state criteria can be more than an order of magnitude more restrictive than the federal limit (see, e.g., Cadmus).[28] For example, the federal drinking water limit for cis-1,2-dichloroethylene (cis-1,2-DCE) is 70 ppb (1 ppb = 1 μg/L), whereas the California standard is 6 ppb. Both values are based on noncancer liver toxicity in animals, with the differences mainly due to varying interpretations of toxicological findings.

Of particular interest with respect to non-U.S. agencies are risk assessment and risk management approaches undertaken by the European Commission (EC). The precautionary principle was first presented in Principle 15 from the Declaration of the 1992 Rio Conference on the Environment and Development, which states "in order to protect the environment, the precautionary approach shall be widely applied by States according to their capability. Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation."[29]

The precautionary principle has engendered much debate. For example, under what conditions is action to mitigate risks appropriate? Under what conditions is development of a new technology considered so potentially *risky* that restrictions on development are warranted?[30] The REACH program in the European Union (EU) may be said to embody elements of the precautionary principle. This program requires companies that manufacture or import more than one ton of a particular chemical substance per year to register the chemical in a central database. Specifically, the regulation "is based on the principle that it is up to manufacturers, importers and down-stream users of substances to ensure that they manufacture, place on the market, import or use such substances that do not adversely affect human health or the environment."[31] Thus, overall, the emphasis of the precautionary principle is on demonstrating that a chemical *does not* present a significant risk and risk management action is unnecessary. This is a subtle, but important, difference from other approaches taken by the EC, which typically require demonstration that

* MCLs are health-based standards, as mandated under the Federal Safe Drinking Water Act.

a chemical *does* present a significant risk and, hence, risk management action may be necessary.

In addition to its influence on expansion of the precautionary principles, REACH has created important new challenges for the toxicology community. REACH has advanced to the stage where submissions on approximately 144,000 compounds have been received, dwarfing original expectations.[12] Toxicologists must now interpret toxicity findings from numerous submissions, creating potential concerns for the lack of sufficient technical support, the potential for false-positives, and the need to resolve differences in interpretation among submissions for the same compounds.

RISK ASSESSMENT PARADIGM

In response to a directive from the U.S. Congress, the FDA contracted with the National Research Council (NRC) of the National Academy of Sciences (NAS) to evaluate the risk assessment process in the federal government and make recommendations on how the process could be improved. As a result of this effort, the Committee on the Institutional Means for Assessment of Risks to Public Health published a book in 1983 titled *Risk Assessment in the Federal Government: Managing the Process*.[32] The book summarized past experiences and, although it did not propose new ways to evaluate risks from environmental chemicals, it has nevertheless had an important effect on the use of scientific information by regulatory agencies in its codification of the risk assessment process. The book has been particularly influential in two areas: (1) the separation of the risk assessment process from the risk management process and (2) the classification of the risk assessment process into four broad components—*hazard identification, dose–response assessment, exposure assessment,* and *risk characterization*.

More recently, the Committee on Risk Assessment of Hazardous Air Pollutants (established by the NRC under the direction of the EPA) and the Presidential/Congressional Commission on Risk Assessment and Risk Management (CRARM) reevaluated risk assessment and risk management approaches. The findings of the NRC committee were published in a 1994 book titled *Science and Judgment in Risk Assessment*,[33] and the findings of the CRARM were published in a 1997 report titled *Risk Assessment and Risk Management in Regulatory Decision-Making*.[34] While the separation of risk assessment and risk management and the four components making up the basic risk assessment paradigm remain key underlying principles, both committees recommended refinements in risk assessment and risk management approaches. For example, the NRC committee highlighted the importance of an iterative approach to risk assessment to reduce uncertainties, with each iteration incorporating fewer default assumptions and more specific information, balancing the use of *better science* with the constraints of the available resources.[33] The CRARM proposed a framework for risk management that encourages early and frequent involvement of all groups affected by the risk management problem and decision-making based on the context of broader, real-world goals of risk reduction and improved health status.[34]

Risk assessment is defined as the "systematic, scientific characterization of potential adverse effects of human or ecological exposures to hazardous agents or activities," and it involves assessment of the strength of the evidence as well as evaluation of the uncertainties associated with risk estimates.[34] In contrast, risk management is "the process of identifying, evaluating, selecting, and implementing actions to reduce risk to human health and ecosystems."[34] Risk managers choose actions that will mitigate risks, considering not only the information derived from risk assessment but also cultural, ethical, political, social, economic, and engineering information in the decision process.

The distinction between risk assessment and risk management has been an important characteristic in framing how risk analyses have been conducted and results applied.[32] There have been concerns that risk management issues on the risk assessment process, such as the economic significance of a product, can seriously undermine the credibility of the risk assessment. This concern is exemplified in the separation between the NIOSH and OSHA. The NIOSH, part of the DHHS, is responsible for recommending health-based standards for workplace exposures to OSHA, part of the Department of Labor. As the federal agency responsible for setting and implementing standards for workplace exposures, the OSHA is required to consider feasibility in the choice of exposure limits. It is not uncommon to find that permissible exposure limits (PELs) set by the OSHA are less strict than recommended exposure limits (RELs) set by the NIOSH.[35] In some cases, the differences may reflect the date when a particular value was set. However, other factors, such as differences in scientific interpretation or considerations of technical feasibility, may explain the differences. For example, the OSHA PEL for benzene is 1 ppm, whereas the NIOSH REL is 0.1 ppm.

The distinction between risk assessment and risk management is not nearly so clear in practice. This is because each component of a chemical risk assessment is associated with considerable uncertainty. In the face of this uncertainty, regulatory officials have generally resorted to erring on the side of caution by including health-protective assumptions. For example, the choice of a linear no-threshold model for carcinogens, which leads to a higher estimate of risk than other models, represents a risk management decision as much as a science policy decision. That is, the approach is conservative and provides the regulator with a greater level of confidence that the true risk to the human population is likely less than that expressed through the model. This approach has historically been justified as consistent with prudent public health policy when uncertainty is so great that it is difficult to provide a precise estimate of risk (i.e., in the face of uncertainty, it is easier to say the risk is less than x than to say the risk equals y). However, this practice can lead to inconsistent levels of protection for different chemicals and may direct resources away from the more significant risks.[36] For example, the potential cancer risks associated with chemical disinfectants

should be compared to the risks of waterborne microbial diseases when making decisions about treating public drinking water supplies; yet, such risk–risk trade-offs cannot be accurately weighed if health-protective assumptions have been used to different extents in the underlying risk assessments.[37] The practice of using health-protective assumptions in conducting risk assessments has been described by some as an inappropriate application of risk management to the risk assessment process.[21]

In 2009, an NRC panel provided recommendations for a more nuanced approach to the integration of risk assessment and risk management. The NRC panel expressed concerns that the risk assessment process at the EPA had, in several cases, become slow and inefficient; certain analyses, such as the risk assessment for trichloroethylene (TCE), could take years—if not decades. Similarly, concerns were expressed for the risk management process; disconnects were identified between the available scientific data and information needs of risk managers. To improve the process, the NRC panel recommended a framework, reproduced here in Figure 2.1, to enhance the utility of risk assessment in risk management. Importantly, the framework seeks to increase the level of upfront planning in the conduct of a risk assessment to ensure that the findings are more relevant. For example, consideration of exposure under existing conditions and under various control options could be incorporated into dose-response risk assessments.

Although risk assessments are commonplace at many federal and state agencies, there are no uniform guidelines that specify how regulatory officials should calculate chemical risks. There are also no uniform criteria that indicate how the findings of a risk assessment should influence regulatory decisions.[38] As a result, cancer potency estimates (i.e., the estimated upper bound on lifetime cancer risk associated with the lifetime daily dose of a chemical) developed by different regulatory agencies for the same chemical can vary substantially.[39] Differences in cancer potency estimates for chemicals can also vary among European agencies.[40] Furthermore, the level of risk sufficient to trigger regulatory action can vary considerably among agencies and even among different programs within a single agency.[41]

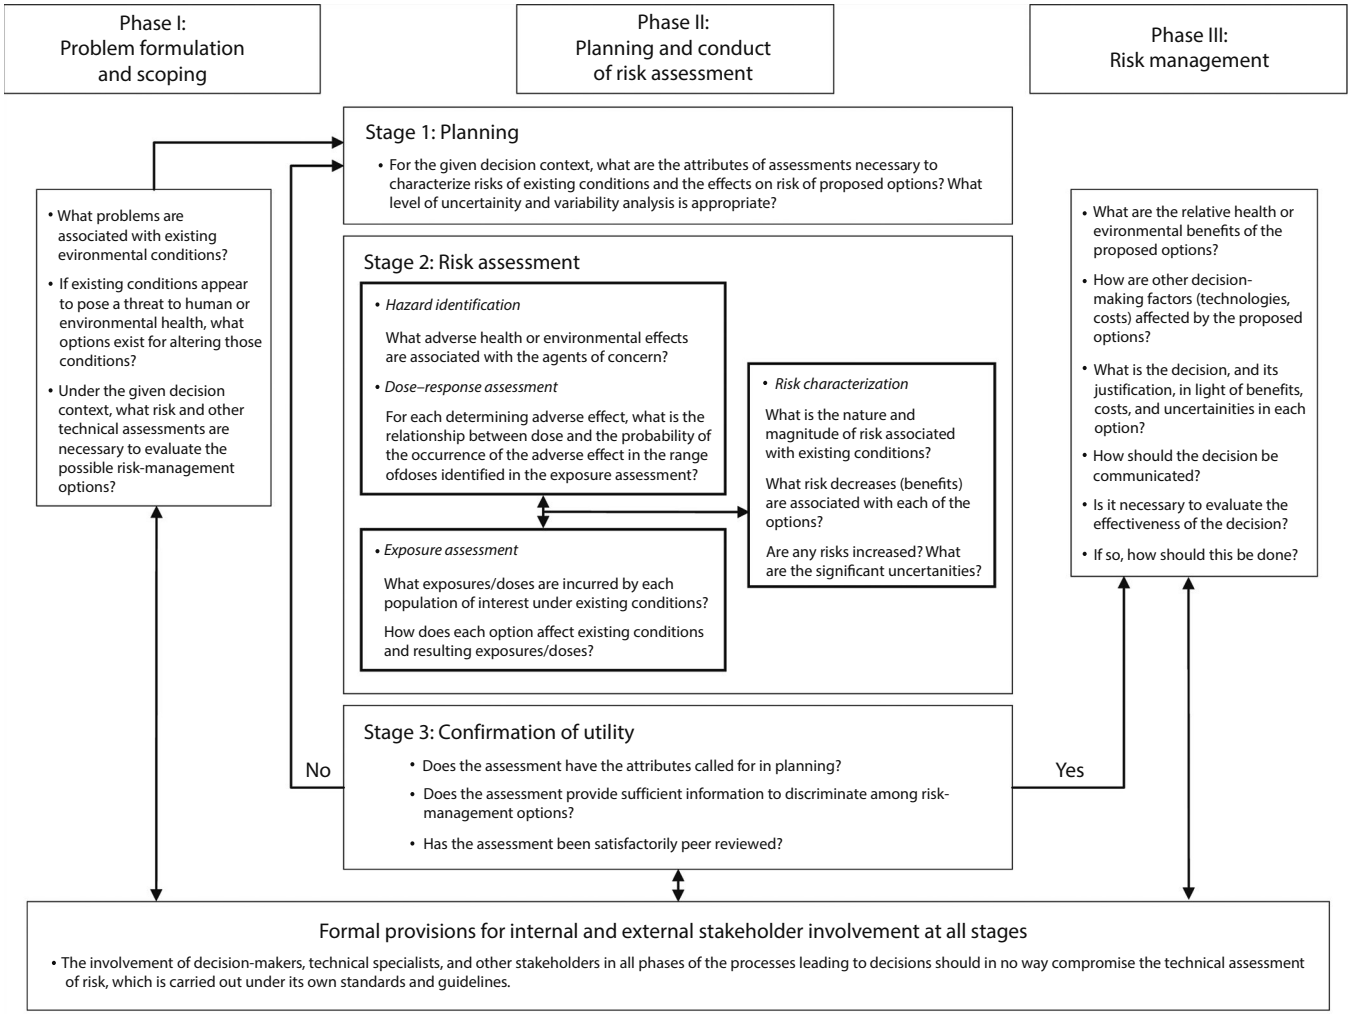

FIGURE 2.1 A framework for risk-based decision-making that maximizes the utility of risk assessment. (Reprinted from National Research Council, *Science and Decisions: Advancing Risk Assessment* [*The Silver Book*], National Academies Press, Committee on Improving Risk Analysis Approaches Used by the U.S. EPA, Washington, DC, Copyright 2009. With permission from National Academy of Sciences.)

As described earlier, risk assessment is commonly broken down into four components. The first component of risk assessment, *hazard identification*, involves an evaluation of whether a particular chemical can cause an adverse health effect in humans. The hazard identification process can be considered to be a qualitative risk assessment. It involves identifying the potential for exposure as well as the nature of the adverse effect expected. The types of information used in hazard identification include all categories described in the previous section. In hazard identification, the risk assessor must evaluate the quality of the studies (choice of appropriate control groups, sufficient numbers of animals, etc.), severity of the effect described, relevance of the toxic mechanisms in animals to those in humans, and many other factors.

The result is a scientific judgment that the chemical can, at some exposure concentrations, cause a particular adverse health effect in humans. The result is not a simple yes-or-no evaluation but a weight-of-evidence estimation of the likelihood that the particular chemical has the potential to cause the particular effect. For example, a recent animal study[42] demonstrated that intratracheal instillation (vs. inhalation) of diacetyl can result in lesions similar to bronchiolitis obliterans, a serious lung disease associated with workplace exposure to butter flavorings. Because diacetyl is a constituent in butter flavorings, the animal study added to the weight of evidence that it may be the relevant constituent for bronchiolitis obliterans in humans exposed to butter flavorings.

The hazard identification process has been codified mainly for carcinogens, as exemplified in the classification schemes from a variety of agencies, including the IARC,[43] EPA,[9] and OSHA.[44] These schemes are discussed in more detail later in this chapter.

Dose–response evaluation, the second component of the risk assessment process, involves quantitative characterization of chemical potency. In other words, the relationship between the dose of a chemical administered or received and the incidence or severity of an adverse health effect in the exposed population is evaluated. Characterizing the dose–response relationship involves understanding the importance of the intensity of exposure, the concentration × time relationship, whether a chemical has a threshold, and the shape of the dose–response curve. The metabolism of a chemical at different doses, its persistence over time, and an estimate of the similarities in disposition of a chemical between humans and animals are also important aspects of a dose–response evaluation. While the 1983 NAS report considered dose–response estimates mostly in terms of carcinogens, the evaluation of the dose–response relationships has long been a key component of pharmacology and toxicology for many chemicals.[32]

In *exposure assessment*, the third component of the risk assessment process, a determination is made as to the amount of a chemical to which humans are exposed. Data can be very limited for exposure assessment. Measures of chemicals in environmental media (such as air or soil) or in food may be available; however, the extrapolation of those levels to a dose received by humans has many uncertainties. Models exist that can describe the movement of chemicals through a particular medium, and assumptions can be made regarding inhalation, ingestion, or dermal contact rates and the bioavailability* of the chemical. This information can then be used to derive an estimate of the dose taken up by humans. Host factors, such as exercise, the use of certain consumer products, or the consumption of particular foodstuffs, will complicate the exposure assessment.

The use of biological monitoring—measurement of volatile organic chemicals in exhaled breath, for example[45]—as well as personal sampling devices, such as respirable particulate monitors,[46] represents ways in which the uncertainties of exposure assessment can be reduced. As noted earlier in this chapter, the CDC NHANES biomonitoring study provides significant new information on hundreds of chemicals measured in blood and in serum. In some cases, as with blood lead testing, such information can help reduce the uncertainty in quantifying exposure and extrapolating from exposure to dose. However, for other chemicals with more limited toxicological and epidemiological information, the biomonitoring information is difficult to interpret from the perspective of individual- or population-level risk.

The last stage of the risk assessment process, *risk characterization*, involves a prediction of the frequency and severity of effects in the exposed population. That is, the information from the dose–response evaluation (what dose is necessary to cause the effect?) is combined with the information from the exposure assessment (what dose is the population receiving?) to produce an estimate of the likelihood of observing the effect in the population being studied. Many risk assessments, particularly for cancer, performed in the regulatory arena produce a single-number estimate of risk (e.g., lung cancer risk of one in a million). These are often designed to represent the risk to the reasonable maximally exposed (RME) individual in a potentially exposed population.

Within any potentially exposed population, substantial *variability* exists in exposure rates, intake and uptake rates, and sensitivity to the effect. This variability is such that the risk to the most highly exposed and sensitive portion of the population may be orders of magnitude higher than the risks to the majority of the population. For example, some individuals in a given population may never eat locally caught fish, while other individuals may subsist on it. The fish intakes of these respective individuals will consequently vary by orders of magnitude. Information should generally be provided on both the risk to individuals and the aggregate risk of the exposed population. Point estimates of risk to a single individual in the population can be misleading when no information is provided to indicate whether that individual's exposure is typical of 50% or 0.001% of the exposed population.

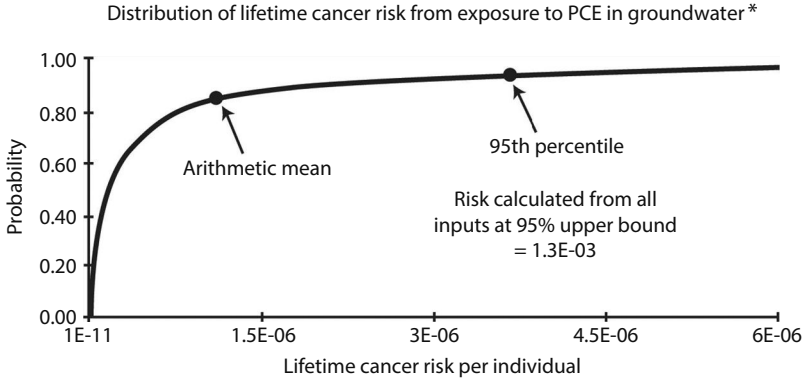
In addition to population variability, there is also significant *uncertainty* present in risk estimates, due to uncertainty in many of the risk assessment components (e.g., model and measurement error). It is critical that the

* In other words, absorption of a chemical in the relevant exposure medium as compared to absorption in the medium from the underlying toxicity study.

risk characterization step of the risk assessment process describes the biological and statistical uncertainties in the final estimation and identifies which component of the risk assessment process (hazard identification, dose–response, or exposure) involved the greatest degree of uncertainty. For example, the dose–response evaluation is generally highly uncertain. This is often due to the model error in extrapolating from animals to humans or short-term to lifetime exposures. Information may not be available to characterize the active species, mechanism of effect, effective dose, or absorption, metabolism, and excretion rates. Because the degree of uncertainty varies greatly among risk assessments for different chemicals, lack of consideration of uncertainty can lead to inappropriate levels of concern for different chemicals.

The Monte Carlo uncertainty analysis techniques have been applied to the risk assessment process as one method of attempting to more fully characterize the distribution of potential risks in a population. Rather than using single values to represent input parameters such as contaminant ingestion rates, body weights, and chemical potencies, the Monte Carlo analysis uses probability density functions to characterize the input parameters and produce a probability density function for risk.[48–51] Figure 2.2 shows a probabilistic exposure and risk model[52] produced by a Monte Carlo analysis for chloroform exposure in swimming pools. This analysis indicated that the 95% estimated cancer risk for males was nearly 3×10^{-4}, with the inhalation pathway being responsible for the bulk of the estimated risk. In contrast, the median risk was approximately tenfold lower, demonstrating a relatively skewed distribution of risks. Although these techniques provide more information on the distribution of potential risk than a single number risk estimate, they are limited by the availability of information with which to characterize the input probability density functions. Particularly uncertain are estimates of chemical potency, which can vary by orders of magnitude depending upon different interpretations regarding carcinogenic mechanisms.

The Committee on Risk Characterization, convened by the NRC, made recommendations for improving the risk characterization process in its 1996 book titled *Understanding Risk, Informing Decisions in a Democratic Society*.[53] Rather than simply presenting numerical risk results and associated uncertainties, a risk characterization also should convey the information in a clear and easily understandable way that is useful to risk managers in making informed decisions. In addition, risk characterization should address the concerns of interested and affected parties. Therefore, the rigorous scientific analyses involved in risk characterization must be performed in conjunction with frequent deliberations with all stakeholders. As explained by the NRC committee, "developing an accurate, balanced, and informative synthesis" involves "getting the science right,…getting the right science,…getting the right participation, [and] getting the participation right."[53] The EPA adopted similar values in its 1995 risk characterization guidance.[54]



* Based on the uncertainity in data used to calculate the source concentration, exposure, metabolized dose, and cancer potency

Selected input parameters and distributions

Parameter	Units	Distribution type	Min	Max	Arithmetic mean	Arithmetic std. dev.	Geometric std. dev.
PCE concentration in water	mg/L	Empirical			0.0003	0.00035	2.5
Breathing rate per unit body weight	m^3/kg-day	Lognormal			0.4	0.5	2.7
PCE metabolized cancer potency	kg-day/mg	Empirical			0.11	0.14	4.8
Exposure time in house	h/day	Uniform	8	20	14		
Skin permeability	m/h	Uniform	0.004	0.01	0.007

TOXICOLOGY INFORMATION USED IN THE REGULATORY PROCESS

Three main categories of scientific information are employed by agencies in the evaluation and regulation of toxic chemicals in the environment: (1) epidemiology, (2) controlled clinical exposures, and (3) animal toxicology. In vitro and in silico (i.e., computer-based such as structure–activity relationships) studies are typically used by regulatory agencies to support the interpretation of information from the three major categories and are only used occasionally as a primary source of information. However, with the need to generate data on more and more chemicals, it is expected that in vitro and in silico information may be used increasingly as a source of information, perhaps even of a primary nature, in risk assessment and risk management. This approach was examined in the 2007 NRC report, *Toxicity Testing in the Twenty-first Century: A Vision and a Strategy*.[55] This groundbreaking analysis describes identification and understanding of cellular response networks (as reflected in Figure 2.3) and how such networks are perturbed by chemical exposure as critical to enhancing the testing of chemicals and interpretation of such tests. High-throughput tests of cells and cell lines are expected to become more critical to the advancement of toxicology, with targeted testing in animals complementing such findings.

Epidemiology, studies of clinical exposures, and animal toxicology provide qualitatively different information, with unique advantages and limitations. Environmental epidemiology studies, which attempt to associate disease or other adverse health outcomes with an environmental exposure, have the advantage of measuring an effect in humans at exposure conditions that are by definition realistic. The first demonstration that benzene was a carcinogen came from epidemiological studies of rubber workers.[7] It was not until several years after these studies[57] that benzene was shown to cause cancer in animal studies. Studies of the London smog pollution episode in 1952 demonstrated that high levels of pollution from coal combustion could cause mortality, particularly in the very young, the elderly, and those individuals with preexisting cardiopulmonary disease.[58] Evaluation of similar effects in animal studies would be difficult, given the complexity of the exposure in London and the lack of good animal models for susceptible populations, such as asthmatics. In general, epidemiology has been particularly helpful in the evaluation of working environments or other environments where exposure concentrations are relatively high.

Several factors limit the use of epidemiological studies by regulatory agencies. One of the major limitations is the lack of well-defined exposure information, for both chemical species and actual concentrations. For example, the lack of accurate total exposure information limits the ability to quantify the effects of ambient air pollution in the United States. As an example, the Total Exposure Assessment, a Columbia and Harvard (TEACH) study quantified indoor, outdoor, and personal exposures of inner-city residents to a number of pollutants, including formaldehyde, dichlorobenzene, and benzene.[59] This study demonstrated that, depending upon the contaminant, outdoor exposure levels may underestimate, overestimate, or relatively well predict personal exposures. For example, due to the importance of indoor sources, outdoor measures of formaldehyde typically underestimated personal exposures. As discussed earlier in this chapter (e.g., the CDC biomonitoring study), the use of biological markers of exposure, such as measurements of arsenic levels in

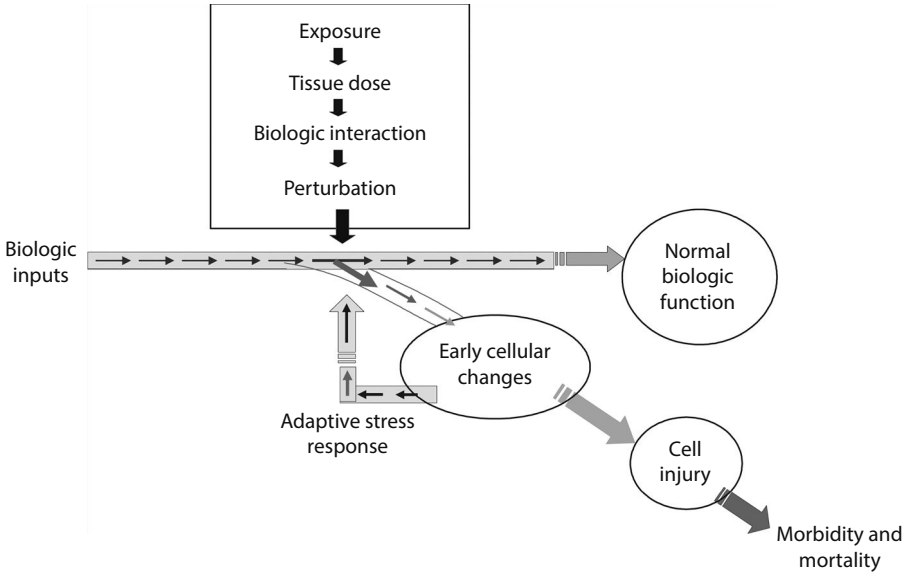

FIGURE 2.3 Biologic responses viewed as results of an intersection of exposure and biologic function. urine or pesticides levels in blood, can provide more accurate information about exposure and help reduce uncertainties in the results of epidemiological studies. Still, the linking of some findings to risk may be limited by lack of adequate health information.

It is also difficult to define the causal element in epidemiological investigations, particularly when complex exposures are involved. For example, several indicators of pollution were measured during the London smog episodes that occurred between 1958 and 1972. Initial evaluations focused on the role of total particulate and SO_2 as causative agents for the elevated mortality levels; however, subsequent analyses of the London studies, as well as studies from other cities, indicate the importance of acid sulfates on mortality.[60] Large-scale epidemiological studies have demonstrated associations between various indicators of air quality, in particular particulate matter of 2.5 μm or less ($PM_{2.5}$), but debate continues regarding the nature and magnitude of causality due to the complexity of PM composition and difficulties in replicating the findings in animal studies (see, e.g., Valberg).[61]

Another limitation is that epidemiological studies are frequently of worker populations, and such studies can be difficult to apply to prediction of health effects in the general population. Occupational studies, in general, focus on healthy adult male workers. The general population is more heterogeneous than the worker population and, for some pollutants, may exhibit a greater range in susceptibility. In general, only more recent epidemiology studies have considered adverse health effects of chemicals specific to women and children, such as developmental, reproductive, or hormonally mediated effects, including cancer. An example of the limitations of occupational epidemiology involves studies of peripheral nerve function in lead-exposed workers that underestimates risk of lead exposure in young children, for whom the primary concern is neurobehavioral effects resulting from relatively low-level exposures.[62,63]

Epidemiology studies are frequently limited by the need for a relatively large increase in disease incidence (twofold or more), given the sample sizes generally available for such investigations. Enterline[64] notes that it would require a large population (1000 deaths, using the Peto model) to detect a 50% excess in deaths from lung cancer at an asbestos level of 2 fibers/cm^3 air.

Controlled clinical studies of humans exposed to pollutants address some of the difficulties of epidemiology studies. The exposures can be controlled and quantified, effects are observed in humans, and exposed populations can be chosen to consist of susceptible individuals, such as asthmatics or exercising individuals. Thus, changes in airway resistance in asthmatics exposed to SO_2 during exercise[65,66] have been important in the EPA's evaluation of the National Ambient Air Quality Standard (NAAQS) for SO_2,[67] because these effects reflect the response of the susceptible population, using an appropriate exposure concentration and a relevant averaging time. Given the subtlety of these changes (nonsymptomatic bronchoconstrictions) and the fact that they occur only in a selected subset of the general population (asthmatics constitute about 4% of the total population), these effects would not have been detectable in the general population.

One of the advantages of controlled clinical exposure studies—that they are performed with humans—is also a major limitation. Since these studies must be limited to short-term effects that are readily reversible, they cannot be used to evaluate the potential of a chemical to cause chronic disease. There is debate within the scientific and regulatory communities as to the circumstances under which data from controlled human studies, even considering that such studies present negligible risk to the participants, may be used by agencies in decision-making. For example, intentional dosing studies in human subjects (e.g., cholinesterase inhibition tests in individuals exposed to organophosphate pesticides) were considered by the NAS[68] to be acceptable under some circumstances (e.g., when there was a *reasonable certainty* of no adverse effects to the participants and the studies addressed an important question that could not be answered with animal studies); others[69] have questioned the appropriateness of such testing, particularly because of concerns over testing on children. In addition, because of the nature of the changes observed in clinical exposure studies, the health significance of the indicators is open to discussion. For example, perchlorate, a chemical used in treatment of certain thyroid disease and also found as a groundwater contaminant, inhibits iodide uptake at the thyroid. Studies in humans[70] have demonstrated that doses greater than 0.007 milligrams of chemical per kilogram of body weight per day (mg/kg-day) are required to inhibit iodide uptake. However, the inhibition of iodide uptake must be of sufficient magnitude and for sufficient duration (e.g., in adults, up to 75% inhibition over several months may be required to inhibit thyroid hormone synthesis) before impacts on thyroid hormone synthesis (the physiologically relevant effect) may occur.[71] A recent controlled human exposure by Braverman and coworkers of volunteers exposed to perchlorate at daily doses up to 3 mg for up to 6 months demonstrated no impact on thyroid function. Thus, the clinical significance of low-level inhibition of iodide uptake for a modest period of time may be limited.

Another issue with the use of clinical studies is that, although some susceptible populations (e.g., mild asthmatics) can be tested, individuals with a greater degree of impairment (e.g., asthmatics who require continual medication) are usually not considered to be appropriate subjects for these studies because of the greater potential for harm during exposure. Later sections in this chapter address the questions of severity of effect on susceptible populations in greater detail.

Animal toxicology studies constitute the third major source of information for assessing the toxicity of chemicals. Animal toxicology studies allow the investigator the greatest degree of control over the exposure conditions, population exposed, and effects measured. One can readily evaluate

subtle effects of acute and chronic exposure using this type of study. For example, hexavalent chromium (CrVI) in water has been shown to induce gastrointestinal tumors in rodents via the ingestion pathway.[72] Recent studies of rodents have yielded important insights on initial events in tumor production, including evaluating the role of oxidative injury and assessing progression of histopathological lesions in relationship to changes in gene transcription. These mechanistic findings would be very difficult to identify with other experimental approaches, and they provide relevant information in the extrapolation from the high-dose rodent studies to much lower human exposure levels.[73] In animal experiments, the ability to manipulate the experimental conditions permits the evaluation of many variables on the response to toxic chemicals. For example, the role of metabolism in susceptibility to polycyclic aromatic hydrocarbon-induced carcinogenesis has been evaluated in studies of genetic variants in mice.[74,75] Such studies can be important in predicting modifiers of toxicity in humans and identifying susceptible human populations.

The use of *omics*, including toxicogenomics (i.e., changes in gene transcription, protein synthesis) and metabolomics (i.e., changes in metabolite profiles) as a consequence of toxicant exposure in animals and cells in vitro can be quantified and measured even at a cellular level, allows for even more refined understanding of molecular responses to chemicals in animal models (see, e.g., NAS[12]). Toxicogenomics may allow for a better characterization of the linkage between chemical exposure and toxicological effects on a number of levels, such as identifying biomarkers of susceptibility, improving the understanding of a chemical's MoA, and identifying changes prior to histopathological events. For example, transcriptional changes have been observed after low- and high-dose acetaminophen exposure, prior to the development of histopathological changes.[76,77] Recent efforts, as exemplified in the aforementioned 2007 NRC report, seek to further the use of such methodologies not only in toxicity testing but also in the risk assessment process itself. An example of such an application is the work by Bercu and coworkers.[78] These investigators identified a point of departure (POD) (i.e., the most sensitive effect dose or no-effect dose) for two nongenotoxic carcinogens based on genomic changes in rodents treated for seven days or less. The changes, which were consistent with the proposed MoA, identified threshold doses potentially applicable to a risk assessment framework yet within a much shorter time frame than associated with animal bioassays.

The limitations of animal studies fall into two broad categories: (1) those due to uncertainties in extrapolating from animals to humans and (2) those due to uncertainties in extrapolating from the high exposures in animal studies to the lower exposures typically experienced by humans. Interspecies extrapolation is complicated by the greater homogeneity of laboratory animals than humans, controlled conditions of housing and diet, innate genetic factors, and other variables. The relevance of di-2-ethylhexyl phthalate-induced hepatocarcinogenesis in rodents to humans has been questioned on the basis of differences in peroxisomal proliferation in the liver in the two species as a consequence of differences in peroxisome proliferator-activated receptor (PPAR) alpha binding.[79,80] Similarly, high exposure concentrations typically used in animal studies may result in saturation of detoxification pathways and thus may produce effects that are not relevant to effects produced at ambient exposure concentrations, where detoxification pathways are not saturated. Increased numbers of macrophages and impairment of alveolar clearance are observed in rats exposed to relatively high concentrations of diesel particulates.[81] The significance of such particulate overload to humans, who are exposed to ambient levels of diesel particulates much lower than those employed in the animal studies, remains a source of discussion and debate.[82]

Historically, in vitro studies, analysis of structure activity relationships, and other short-term test procedures have been used to help set priorities for chemical testing. For example, structure activity relationships have been used to predict mutagenicity, lethality, and carcinogenicity.[83–85] This type of information can be useful, for example, in selecting compounds for longer-term testing in animals or eliminating chemicals being considered for potential industrial or pharmaceutical applications due to toxicological concerns.

Short-term tests have typically been used indirectly in the regulatory process to support decision-making rather than as a decision-making basis per se. For example, evidence that a chemical is a point mutagen in an in vitro test system might be used to support the classification of a chemical as a possible human carcinogen or the use of a linear dose–response model for carcinogenesis. More recent efforts, as reflected in the 2007 NRC report *Toxicity Testing in the Twenty-first Century*, seek to use short-term tests, such as characterizing toxicity pathways, more directly in the risk assessment process.

Metabolism, pharmacokinetic, and mechanistic studies can also provide information to reduce uncertainties in the use of toxicology information. Metabolic studies showing that a critical reactive metabolite in rodents is also formed in humans could reduce uncertainties in extrapolating from animals to humans, while mechanistic studies could indicate whether a subtle effect observed in a clinical study is a precursor for later, more serious health endpoints—and therefore of concern as a biomarker of effect.

A summary comparing the differences between epidemiology, controlled clinical exposure, and animal toxicology studies is provided in Tables 2.2 through 2.4.

It can be concluded from the preceding discussion that there is no *best* source of information for regulatory agencies. The rational approach, therefore, is to examine all available sources of reliable information in the evaluation of toxic chemicals. Some kinds of information may be especially useful in *hazard identification*, the likelihood that a chemical will be toxic to humans, whereas other types of information will be more appropriately applied to the estimation of the *dose–response relationship.*

TABLE 2.3
Advantages and Disadvantages of Controlled Clinical Studies

Advantages	Disadvantages
Well-defined, controlled exposure conditions	Costly
Responses measured in humans	Relatively low exposure concentrations and short-term exposures
Potential to study subpopulations (e.g., asthmatics)	Limited to relatively small groups (usually <50 individuals)
Ability to measure relatively subtle effects	Limited to short-term, minor, reversible effects
	Usually most susceptible group not appropriate for study

TABLE 2.4
Advantages and Disadvantages of Animal Toxicological Studies

Advantages	Disadvantages
Readily manipulated exposure conditions	Uncertainties in relevance of animal response to human exposure
Ability to measure many types of responses	Controlled housing, diet, etc., of questionable relevance to humans
Ability to assess effect of host characteristics (e.g., gender, age, genetics) and other modifiers (e.g., diet) of response	Exposure concentrations and time frames often very different from those experienced by humans
Potential to evaluate mechanisms	

EVALUATION OF CARCINOGENS

Background

The public demand for zero risk has made the regulation of carcinogens a formidable challenge. Within the scientific community, there is ongoing debate on how to define a potential human carcinogen, as well as on how to estimate cancer risks under practical conditions of chemical exposure. This uncertainty is due largely to the fact that mechanisms of carcinogenesis for many chemicals are still poorly understood, and different carcinogens act in different ways to induce cancer. The task of regulating carcinogens has been complicated, rather than simplified, by many of the mechanistic discoveries of recent years. The simple picture of the 1950s, when only a relatively small number of chemicals were thought to be carcinogens, has been replaced by the realization that chemical carcinogenesis takes place in multiple stages, some with reversible steps, which have different dose–response relationships. Essential nutrients and hormones can be carcinogenic in some circumstances. The same chemical can promote or inhibit carcinogenesis, depending on the circumstances of exposure.[86,87] Public pressure to regulate carcinogens, even where very little toxicological information exists, has in many instances compelled regulatory agencies to treat carcinogens as though they all act by the same mechanisms, even as it has become apparent that they do not.

From a public health standpoint, regulatory agencies have generally regulated carcinogens at exposure levels that reflect a very low probability of tumor production (e.g., excess cancer risk of 1–100 per million exposed). However, for practical reasons, it is impossible to conduct animal studies of a size that would allow observation of effects following treatment at such low doses. The practice has therefore been to conduct animal studies at relatively high dose levels and then extrapolate the results from high to low dose and from animals to humans. Thus, the chronic animal bioassay results, extrapolation from high to low doses, and extrapolation across species are used to derive potency factors (i.e., indicators of carcinogenic potency) for carcinogens. These potency factors enable one to relate an estimated chemical dose in humans to an upper bound probability of tumor occurring as a result of that dose. Even with established human carcinogens, extrapolation procedures must still be used to extrapolate carcinogenic response from high to low dose (e.g., workplace to ambient) or from one type of exposure condition (e.g., intermittent, subchronic) to another (e.g., continuous, chronic).

This section on carcinogens first provides some basic information on mechanisms of carcinogenesis, then it describes some of the key issues that agencies address in the interpretation and application of scientific data on carcinogens. These issues fall into the categories of *hazard identification* and *dose–response assessment*.[32] Hazard identification for carcinogens addresses two questions: (1) What is the evidence that a particular chemical is an animal carcinogen? and (2) What is the likelihood that an animal carcinogen is a human carcinogen (and under what circumstances of exposure pathway and dose)? Dose–response assessment has traditionally attempted to determine the probability of tumor production given a particular exposure or dose level (i.e., assuming a low-dose, linear response).* The dose–response assessment section of this chapter discusses mathematical models used to extrapolate from high to low doses, physiologically based pharmacokinetic (PBPK) modeling to relate administered and effective doses in animals and humans, and issues concerning the relationship between effective dose and response.

Mechanisms of Carcinogenesis

Carcinogenesis is generally understood to be a multistage process that has, until recently, been described as a relatively linear process involving the initiation, promotion, and progression of normal cells into neoplastic cells, although, as discussed later in this section, this framework is likely over simplistic in a number of cases. In the initiation, promotion, and progression model, chemicals can act at one or more of

* As discussed in later sections of this chapter, for carcinogens that act through a threshold mechanism, such probabilistic low-dose models are not appropriate.

these stages; action can be through direct (e.g., mutagen) or indirect (e.g., immune suppression) mechanisms. Initiation is the first step in the process of carcinogenesis and is generally understood to be a permanent and irreversible event involving DNA mutation. Some genotoxic agents are considered to be capable of initiating activity and thus having the potential to begin the transition from normal to cancer cells. Thus, genotoxic (particularly mutagenic) agents have been considered to act via a nonthreshold mechanism; this belief has formed the basis for linear extrapolation of effects seen at high doses down to low doses. Inferences as to the absence of a threshold for initiating agents come from the study of mutations that result from these agents. In addition, some studies investigating the number of preneoplastic focal lesions induced by an initiating agent did not find a measurable threshold.[88] Certain chemicals (e.g., aflatoxin B_1, diethylnitrosamine, tobacco smoke) are considered to be complete carcinogens—in other words, capable of initiation, promotion, and progression. Potential factors modifying the efficiency of initiation include rates of cell division and DNA synthesis, rate of metabolism of a chemical to its active form, or rate of metabolic detoxification. (It should be noted that, due to the existence of repair mechanisms and other factors that reduce or eliminate responses at low exposure levels, even the no-threshold concept may not be applicable to all mutagenic carcinogens. This point is discussed subsequently.)

The second stage of carcinogenesis, promotion, has been characterized by clonal expansion of the initiated cells. Promoting agents can act by various mechanisms to increase rates of cell proliferation or decrease rates of cell death. For example, cell proliferation can be induced by cytotoxic agents or mitotic agents. Interference with intercellular communication may also be involved in clonal expansion of initiated cells.[89] An important feature of this stage is its reversibility and, in some cases, the existence of a threshold for the effect. In the standard tumor initiation/promotion model, withdrawal of the promoting agent halts the development of tumors. The promotion stage can also be modulated by environmental factors, including frequency of dosing, age of test animal, and diet.[88] Promoting agents are generally thought to exhibit a threshold (or inflection point) in the dose–response curve. Examples of promoting agents include hormones, alcohol, and dietary fat.

More recent studies indicate that the earlier paradigm is, as noted earlier, likely to be overly simplistic in a number of cases. There are situations where available data on certain tumors do not comport with the linear initiation–promotion–progression model. For example, as described by Cohen and Arnold,[90] evidence from cancer studies in animals and humans indicates that there are many malignancies that do not occur with an intermediate stage of benign proliferation. While some chemical carcinogens may be characterized as DNA reactive (i.e., initiators in the paradigm described earlier) and others as non-DNA reactive (i.e., promoters in the paradigm), in actuality, DNA-reactive chemicals can, at certain doses, induce cell proliferation. In some cases, as with the example of formaldehyde, it is this cell proliferation that is more relevant to carcinogenicity.[90] Other chemicals may act primarily through non-DNA-reactive mechanisms that, by virtue of increasing the actual number of cell replications in a relevant target cell population, result in increased mutational events simply by increasing the size of the cell population.[90] For example, the rat-specific bladder carcinogen, dimethylarsinic acid (DMA), induces cytotoxicity to the urothelial cells of the bladder followed by necrosis, cell regeneration, proliferation, and hyperplasia, leading to tumor production. In this case, genotoxicity occurs subsequent to cytotoxicity in both dose and time and appears to have a limited, if any, relationship to carcinogenicity. Thus, with respect to DMA, genotoxicity would not be indicative of a linear dose–response relationship.[91] In the case of hormonal carcinogens, tumors may arise as a consequence of prolonged stimulation of cell division in which genetic damage occurs as a secondary event.[92,93]

Hazard Identification

The question of how to decide whether a particular chemical is a potential human carcinogen is currently the subject of considerable scientific debate. It is an important question because the act of labeling some chemicals, but not others, *carcinogens*, can have important regulatory and societal implications.[94] The regulatory paradigm, whereby chemicals are regulated either as carcinogens or as noncarcinogens, requires that the question of whether a particular chemical is a carcinogen typically be answered with a *yes* or *no*. In the United States, most regulatory agencies have historically regulated all carcinogens as though they operate via the same no-threshold mechanism. However, the various mechanisms of tumor formation are not all consistent with the mechanistic assumptions that form the basis of the regulatory framework for carcinogens. A chemical may be carcinogenic via certain routes of exposure and not others or only above certain dose levels. More flexible classification approaches have been developed[95] that allow the incorporation of greater understanding of MoA into the classification process.

The next section describes current classification approaches, but the reader is reminded that current scientific debate on these schemes continues to fuel new approaches. Regulatory agencies generally classify potential carcinogens based on an evaluation of both human and animal studies, as well as supporting information from short-term tests for mutagenicity and structure–activity relationships. Because human evidence exists for relatively few chemicals, animal studies typically provide most of the available information about the potential of a chemical to be carcinogenic to humans.

Animal Studies

The evidence that a chemical is an animal carcinogen frequently derives from long-term animal bioassays. Such studies usually consist of exposing groups of about 50 animals (typically rats or mice) to two to three concentrations of a chemical over the lifetime of the animals. Sex- and

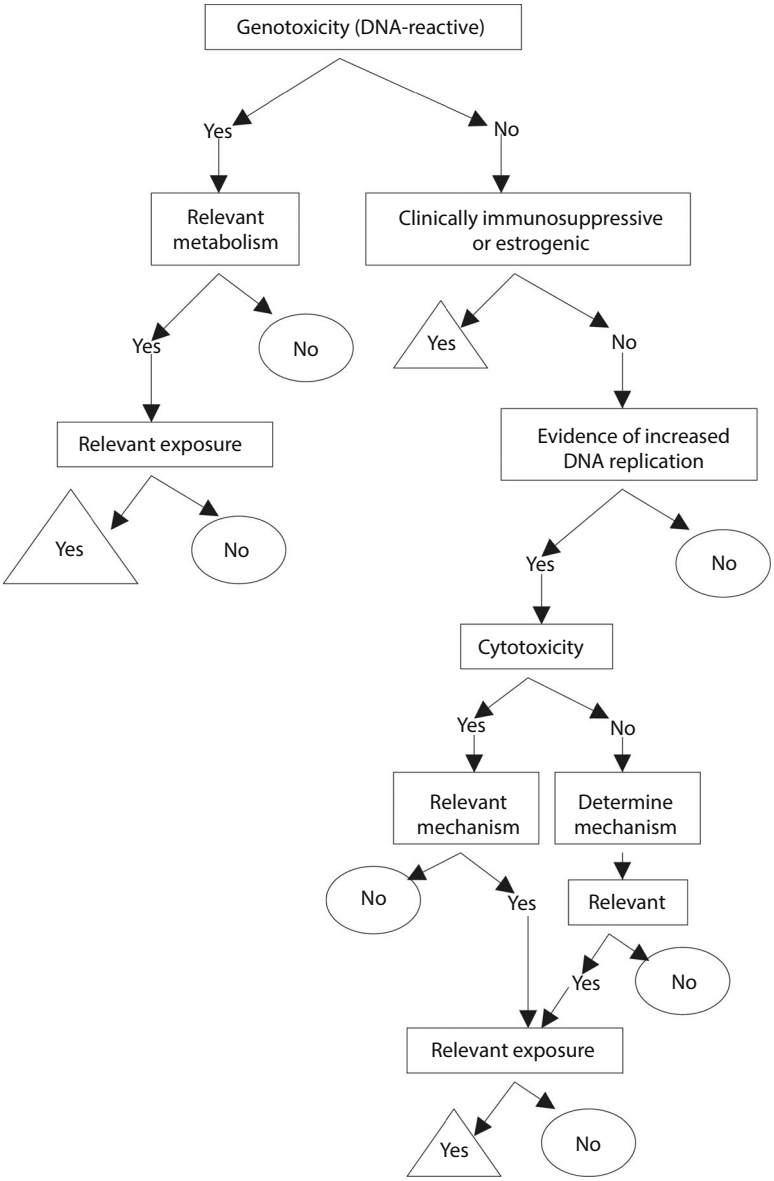

FIGURE 2.4 A proposed guide for evaluating the potential carcinogenicity of chemicals. Each box poses an evaluation to be performed. If the sequence results ultimately in a *no* that is in a circle, there is no (or negligible) carcinogenic risk in humans. If the sequence results ultimately in a *yes* that is in a triangle, it poses a presumptive human carcinogenic risk. (From Cohen, S.M., *Toxicol. Sci*., 80(2), 225, 2004. With permission of Society of Toxicology.)

age-matched unexposed animals constitute the control group. At the termination of the bioassay, the animals are killed and the number of tumor-bearing animals and the number and type of tumors per animal are quantified. All tumors are recorded, including those that are present as a consequence of spontaneous processes. Interim examinations may be performed, particularly on animals that appear moribund. Alternatives to the standard bioassay are being developed. For example, genetically engineered strains of mice in which tumor suppressor genes are inactivated (knockouts) or activated oncogenes are introduced (transgenics)[96] may allow detection of carcinogens in shorter periods of time than the standard bioassay; however, use of transgenics and knockouts remains limited for a number of reasons, including limited histopathological analysis. More recently, based on MoA considerations within the multistage model of carcinogenesis concept, Cohen has proposed a testing framework, described in Figure 2.4, that uses shorter-term exposure. This framework also evaluates key parameters for carcinogenesis, such as DNA reactivity and cell proliferation.[97] This and similar approaches, particularly when combined with tissue-specific markers, have the potential to act as an initial screen for carcinogenicity under much shorter time frames than the typical 2-year bioassay.

Maximum Tolerated Dose

Dose selection plays a key role in the design and interpretation of the animal bioassay. Animals are typically exposed

at two dose levels: the maximum tolerated dose (MTD) and one-half the MTD. In recent years, one-quarter of the MTD has also been used. The MTD is predicted from subchronic toxicity studies as the dose "that causes no more than a 10% weight decrement, as compared to the appropriate control groups, and does not produce mortality, clinical signs of toxicity or pathologic lesions (other than those related to a neoplastic response) that would be predicted [in the long-term bioassay] to shorten an animal's natural lifespan."[98] The MTD is not a nontoxic dose, but is expected to produce some level of acceptable toxicity to indicate that the animals were sufficiently challenged by the chemical. The MTD has been justified as a means of increasing the sensitivity of an animal bioassay involving limited numbers of animals so as to be able to predict risks in large numbers of humans.[99]

An objection to the use of MTDs has been that metabolic overloading may occur at high dose levels, leading to an abnormal handling of the test compound.[100] For example, toxic metabolites could be produced as a consequence of saturation of detoxification pathways. Organ toxicity could occur that might not happen at lower concentrations of the chemical,[101] particularly at those concentrations to which humans are typically exposed. Thus, it has been argued that nongenotoxic agents that are determined to be positive in rodent carcinogenicity bioassays may exert their carcinogenicity via target organ toxicity and subsequent cell proliferation and should not be assumed to be carcinogenic at low doses.[102]

Ames and coworkers[103,104] have suggested that target organ toxicity and subsequent mitogenesis is responsible for the fact that over half of all chemicals tested in chronic bioassays at the MTD are determined to be carcinogens in rodents. They observed that both genotoxic and nongenotoxic agents tested at the MTD cause increased rates of mitogenesis, thus increasing the rate of mutation. For several chemicals, induction of tumors was more strongly correlated with cell division than with DNA adducts or mutagenic activity. Others have reported that cancer potency and MTD are inversely correlated and, consequently, the potency estimate is simply an artifact of the experimental design.[105]

Gaylor[106] noted that, given sufficient animals (e.g., about 200 per group), it is estimated that about 92% of all chemicals tested at the MTD would yield a positive response at one or more tumor sites in rats or mice. Gaylor observes that "this MTD bioassay screen is not distinguishing between true carcinogens and non-carcinogens." The author further suggests a common mechanistic explanation for this result—that is, for nongenotoxic carcinogens in particular, the MoA involves cytotoxicity followed by regenerative hyperplasia. Thus, the relevant question is not so much whether a chemical causes cancer at the MTD (i.e., is a chemical a carcinogen) but at what dose does the chemical induce cancer.

The EPA[95] cancer guidelines note that bioassay results at doses that exceed the MTD can be rejected if toxic damage to target organs compromises study interpretation. The reason is that dosing above the MTD in a study may result in tumor production secondary to tissue damage, rather than a direct carcinogenic influence of the agent tested. Thus, use of information from testing at fractional doses of the MTD is expected to yield results that are more relevant to human risk. Importantly, the use of information on MoA, metabolism, and other biological processes is being used as a more scientifically grounded approach to dose selection.[107]

Other Issues in Hazard Identification

Another key issue in the evaluation of animal bioassays is the analysis of the tumors themselves. Considerations include the categorization of benign tumors and whether tumor analysis should be site-specific or based on all sites. The weight to be ascribed to benign tumors is based on a number of factors. For example, the IARC considers whether benign tumors have the same cellular origin as malignant tumors arising from the same organ, which may represent an earlier stage in progression to malignancy.[108] In this example, benign tumors would be given greater weight than in a situation where such tumors occur in the absence of any malignancy. It should be noted that findings of benign-only tumors may merit further investigation nonetheless.

It should be emphasized that chemical carcinogens produce specific types of tumors that are characteristic of that chemical, exposure route, and dose. There is no convincing evidence of a chemical agent that, in animal bioassays, increases overall tumor incidence, rather than increases at specific sites. Thus, the classification of 2,3,7,8-tetrachlorodibenzodioxin as a human carcinogen based on increase in all cancers as observed in some epidemiology studies[109–111] has been questioned on the basis of biological plausibility.[112]

Interestingly, reductions in tumor incidence are frequently observed in the same cancer bioassays in which tumor increases are observed. Linkov and coworkers[87] concluded that the anticarcinogenic effects observed in rodent bioassays are not explained by random effects. The basis for the reduction in tumors is not known and could be a consequent perturbation in the animal's physiology. These observations lend credence to the concept that animal bioassays must be interpreted with special attention as to whether biological phenomena are induced at high doses that may not occur (or occur with a relatively much lower frequency) at low doses. A similar observation is found in the evaluation of some human carcinogens, in particular those that act through hormonal processes. For example, oral contraceptives are associated with an increased risk of breast cancer but a decreased risk of ovarian and endometrial cancer (Table 2.5). Anticarcinogenic properties of carcinogens are typically not considered as part of the regulatory process for carcinogens.

Approaches to Interpretation of Carcinogenicity Findings

Agency Classification Schemes

The IARC, EU, EPA, NTP, German Commission for Investigation of Health Hazards, Health Canada, and ACGIH have developed classification schemes for carcinogens based on a weight-of-evidence or strength-of-evidence evaluation of available human and animal studies. These seven classification systems are shown in Table 2.6.

TABLE 2.5
Chemicals, Industrial Processes, and Environmental Factors Associated with Cancer Induction in Humans: Target Organs and Main Routes of Exposure in Humans and Degree of Supporting Evidence in Animals, According to IARC

	Humans		Animals
Chemical or Industrial Process	**Main Type of Exposure[a]**	**Target Organ(s)/Cancer Type[b]**	**Degree of Evidence for Carcinogenicity**
Acetaldehyde associated with the consumption of alcoholic beverages; and the consumption of alcoholic beverages[115]	Cultural	Esophagus, upper aerodigestive tract combined (acetaldehyde), oral cavity, pharynx, larynx, colorectum, liver, female breast; lack of carcinogenicity for kidney and non-Hodgkin's lymphoma	Sufficient for ethanol and acetaldehyde
Aflatoxins[116]	Environmental, occupational	Liver	Sufficient; limited evidence for alflatoxin B2; inadequate for alflatoxin G2
Aluminum production[116]	Occupational	Lung, bladder	Sufficient for the carcinogenicity of airborne particulate polynuclear organic matter
4-Aminobiphenyl[116]	Occupational	Bladder	Sufficient
Arsenic, arsenic compounds, and gallium arsenide[c,117]	Occupational, medicinal, and environmental	Bladder, skin, lung (liver, hematopoietic system, gastrointestinal tract, prostate, kidney)	Sufficient for DMA, calcium arsenite, and sodium arsenate; limited or inadequate for certain other forms of arsenic
Asbestos (all forms)[117]	Occupational	Lung, mesothelioma, larynx, ovary (pharynx, stomach, colorectum)	Sufficient
Auramine manufacture and auramine production[116]	Occupational	Bladder	Sufficient (auramine); no data for auramine production
Azathioprine[118]	Medicinal	Non-Hodgkin's lymphoma, skin	Sufficient
Benzene[116]	Occupational, environmental	Acute myeloid and acute nonlymphocytic leukemia (acute lymphocytic lymphoma, chronic lymphocytic lymphoma, multiple myeloma, non-Hodgkin's lymphoma)	Sufficient
Benzidine[116]	Occupational	Bladder	Sufficient
Benzidine, dyes metabolized to[116]	Occupational	(Bladder)[b,e]	Sufficient
Benzo[*a*]pyrene[116]	Occupational, environmental	(Lung)[d]	Sufficient
Beryllium and beryllium compounds[117]	Occupational	Lung	Sufficient
Betel quid (with and without tobacco), areca nut[115]	Cultural	Oral cavity, esophagus (with and without tobacco), pharynx (with tobacco)	Sufficient for betel quid with and without tobacco and areca nut; limited evidence for pan masala; evidence suggesting lack of carcinogenicity for betel leaf
Bis(chloromethyl) ether and chloromethyl methyl ether (technical grade)[116]	Occupational	Lung	Sufficient for bis(chloromethyl) ether; limited for chloromethyl methyl ether
Busulfan[118]	Medicinal	Acute myeloid leukemia	Limited
1,3-Butadiene[116]	Occupational	Hematolymphatic organs	Sufficient for 1,3-butadiene and diepoxybutane metabolite
Cadmium and cadmium compounds[117]	Occupational	Lung (kidney, prostate)	Sufficient for cadmium compounds; limited for cadmium metal
Chlorambucil[118]	Medicinal	Acute myeloid leukemia	Sufficient
Chlornaphazine (*N,N*-Bis(2-chloroethyl)-2-naphthylamine)[118]	Medicinal	Bladder	Limited
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (Methyl-CCNU; semustine)[118]	Medicinal	Acute myeloid leukemia	Limited
Chromium (VI) compounds[117]	Occupational	Lung	Sufficient
Ciclosporin[118]	Medicinal	Skin, non-Hodgkin's lymphoma, and cancer at multiple other sites	Limited
Clonorchis sinensis (infection with)[119]	Environmental	Cholangiocarcinoma	Limited

TABLE 2.5 (continued)
Chemicals, Industrial Processes, and Environmental Factors Associated with Cancer Induction in Humans: Target Organs and Main Routes of Exposure in Humans and Degree of Supporting Evidence in Animals, According to IARC

	Humans		Animals
Chemical or Industrial Process	**Main Type of Exposure[a]**	**Target Organ(s)/Cancer Type[b]**	**Degree of Evidence for Carcinogenicity**
Coal, indoor emissions from household combustion of[115]	Environmental, cultural	Lung	Sufficient for combustion of coal and coal-derived soot extract
Coal gasification[116]	Occupational	Lung	Sufficient
Coal-tar distillation[116]	Occupational	Skin, including cancer of scrotum (lung)[b,e]	Sufficient
Coal-tar pitch[116]	Occupational, environmental	Lung, bladder (limited)	Sufficient
Coke production[116]	Occupational	Lung	Sufficient
Cyclophosphamide[118]	Medicinal	Bladder, acute myeloid leukemia	Sufficient
Diethylstilboestrol[118]	Medicinal	Cervix/vagina, breast (testis, endometrium)	Sufficient
Epstein–Barr virus[119]	Environmental	Burkitt lymphoma, non-Hodgkin's lymphoma, Hodgkin's lymphoma, extranodal NK/T-cell lymphoma (nasal type), and cancer of the nasopharynx (lymphoepithelioma-like carcinoma, gastric cancer)	No data
Erionite[119]	Environmental	Mesothelioma	Sufficient
Estrogen-only menopausal therapy[118]	Medicinal	Endometrium, ovary (breast), colorectum (protective)	Sufficient
Estrogen–progestogen menopausal therapy (combined)[118]	Medicinal	Breast, endometrium	Limited for estradiol plus progesterone and for conjugated equine estrogens plus medroxyprogesterone acetate
Estrogens-progestogen oral contraceptives[118]	Medicinal	Endometrium (protective effect), breast, cervix, liver, ovary (protective), colorectum (protective)	Sufficient
Ethanol in alcoholic beverages[115]	Cultural	Esophagus, oral cavity, pharynx, larynx	Sufficient
Ethylene oxide[116]	Occupational	Lymphatic and hematopoietic systems (limited evidence)	Sufficient
Etoposide (with cisplatin and bleomycin)[118]	Medicinal	Acute myeloid leukemia	No data for combination; inadequate evidence for etopside alone
Formaldehyde[116]	Occupational, environmental	Nasopharyngeal, leukemia[f] (sinonasal—limited evidence)	Sufficient
Helicobacter pylori[119]	Environmental	Stomach (esophagus—protective effect)	Sufficient
Hematite mining (underground; exposure to radon; listed under internalized α-particle emitting radionuclides)[120]	Occupational	Lung	No data
Hepatitis B virus (HBV)[119]	Environmental	Liver (biliary tract, non-Hodgkin's lymphoma)	No data
Hepatitis C virus (HCV)[119]	Environmental	Liver, non-Hodgkin's lymphoma (biliary tract)	No data
Human immunodeficiency virus type 1[119]	Environmental	Cervix, anus, and conjunctiva; Kaposi sarcoma, non-Hodgkin's lymphoma, and Hodgkin's lymphoma (vulva, vagina, penis, liver, skin [nonmelanoma])	No data
Human papillomaviruses[c,119]	Environmental	Cervix, vulva, vagina, penis, anus, oral cavity, oropharynx, tonsil (larynx)	None
Human T-cell lymphotropic virus Type 1[119]	Environmental	Adult T-cell leukemia/lymphoma	Sufficient
Internally deposited α-particle emitting radionuclides (including individually listed Group 1: radium-224, radium-226, radium-228, radon-222, plutonium-239, thorium-232, and their decay products)[c,120]	Environmental, occupational	Lung, bone, liver, leukemia, bile ducts, gall bladder, paranasal sinuses and mastoid process (pancreas, prostate)	Sufficient

(*continued*)

TABLE 2.5 (continued)
Chemicals, Industrial Processes, and Environmental Factors Associated with Cancer Induction in Humans: Target Organs and Main Routes of Exposure in Humans and Degree of Supporting Evidence in Animals, According to IARC

	Humans		Animals
Chemical or Industrial Process	**Main Type of Exposure[a]**	**Target Organ(s)/Cancer Type[b]**	**Degree of Evidence for Carcinogenicity**
Internally deposited β-particle emitting radionuclides[c] (including individually listed fission products [including strontium-90] phosphorus-32 as phosphate, and iodine-131)[120]	Environmental, occupational	Thyroid, leukemia (digestive tract, salivary gland, bone and soft tissue sarcoma)	Sufficient for following β-emitting radionuclides: ^{3}H, ^{32}P, ^{90}Sr, ^{90}Y, ^{91}Y, ^{131}I, ^{137}Cs, ^{144}Ce, ^{147}Pm, ^{228}Ra; limited for calcium-45 and lutetium-177
Iron and steel founding[116]	Occupational	Lung	No data
Isopropyl alcohol manufacture (strong acid process)[116]	Occupational	Nasal cavity	No data
Kaposi sarcoma herpesvirus (KSHV)[119]	Environmental	Kaposi sarcoma, primary effusion lymphoma (multicentric Castleman disease), multiple myeloma (protective effect)	No data
Leather dust[117]	Occupational	Nasal cavity, paranasal sinuses	No data
Magenta and magenta production[116]	Occupational	Bladder	Sufficient for CI Basic Red 9
Melphalan[118]	Medicinal	Acute myeloid leukemia	Sufficient
8-Methoxypsoralen (methoxsalen) plus UVA radiation[118]	Medicinal	Skin	Sufficient; limited evidence for methoxsalen alone
4,4-Methylenebis(2-chloroaniline) (MOCA)[116]	Occupational	(Bladder)[e]	Sufficient
Mineral oils, untreated or mildly treated[116]	Occupational	Skin (observed in the scrotum)	Sufficient for untreated vacuum distillates, acid-treated oils, and aromatic oils; mildly hydrotreated oils [class 4]; and used gasoline-engine oil
MOPP and other combined chemotherapy including alkylating agents[118]	Medicinal	Lung, acute myeloid leukemia	No data
Mustard gas (sulfur mustard)[116]	Occupational	Lung (larynx—limited)	Limited
N′-nitrosonornicotine (NNN) and 4-(*N*-nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK)[117]	Environmental, cultural	(Lung)	Sufficient
2-Naphthylamine[116]	Occupational	Bladder	Sufficient
Neutron radiation[120]	Medicinal, Occupational, Environmental	Unclear[g]	Sufficient
Nickel and nickel compounds[c,117]	Occupational	Nasal sinus, nose, lung	Sufficient
Opisthorchis viverrini[119]	Environmental	Biliary tract	Limited
ortho-Toluidine[116]	Occupational, environmental	Bladder	Sufficient
Painters (occupational exposures as)[116]	Occupational	Lung, bladder, mesothelioma (childhood leukemia)	No data
Phenacetin (in analgesic mixtures)[118]	Medicinal	Renal pelvis, ureter (phenacetin and mixtures containing phenacetin)	Sufficient for phenacetin; limited for analgesic mixtures containing phenacetin
Plants containing aristolochic acid[118]	Medicinal	Renal pelvis, ureter	Sufficient
Radon and its decay products (listed in monograph for internally deposited α-particle emitting radionuclides)[120]	Environmental	Lung (leukemia)	Sufficient
Rubber industry[116]	Occupational	Bladder, leukemia, lymphoma, lung, stomach (prostate, esophagus, larynx)	No data
Salted fish (Chinese-style)[115]	Environmental	Nasopharynx (stomach)	Sufficient
Schistosoma haematobium[119]	Environmental	Bladder	Limited
Shale oils[116]	Occupational	Skin (observed in scrotum)	Sufficient
Silica dust, crystalline, in the form of quartz or cristobalite[117]	Occupational	Lung	Sufficient for quartz dust; limited for tridymite and cristobalite dust

TABLE 2.5 (continued)
Chemicals, Industrial Processes, and Environmental Factors Associated with Cancer Induction in Humans: Target Organs and Main Routes of Exposure in Humans and Degree of Supporting Evidence in Animals, According to IARC

	Humans		Animals
Chemical or Industrial Process	**Main Type of Exposure[a]**	**Target Organ(s)/Cancer Type[b]**	**Degree of Evidence for Carcinogenicity**
Solar radiation[h,120]	Environmental	Cutaneous malignant melanoma, squamous cell carcinoma of the skin, basal cell carcinoma of the skin (lip, conjunctival squamous cell carcinoma and ocular melanoma)	Sufficient
Soot, as found in occupational exposure of chimney sweeps[116]	Occupational	Skin (observed in scrotum), lung (bladder)	Inadequate evidence of soot alone; sufficient evidence of soot extracts
Strong inorganic acid mists[116]	Occupational	Larynx (lung—limited)	No data
Talc containing asbestos fibers[117]	Occupational	Lung, mesothelioma	Inadequate
Tamoxifen[118]	Medicinal	Endometrium (reduces risk for contralateral breast cancer in women with previous diagnosis of breast cancer)	Sufficient
2,3,7,8-Tetrachlorodibenzo-para-dioxin (TCDD), 2,3,4,7,8-pentachlorodibenzofuran, and 3,3,4,4,5-pentachlorobiphenyl (PCB 126)[116]	Occupational	Multisite with no site predominating (soft tissue sarcoma, non-Hodgkin's lymphoma, and lung for TCDD)	Sufficient for all three compounds
Thiotepa[118]	Medicinal	Leukemia	Sufficient
Tobacco products, smokeless[115]	Environmental, cultural	Oral cavity, esophagus, pancreas	Sufficient
Tobacco smoke, secondhand[115]	Environmental, cultural	Lung (larynx, pharynx)	Sufficient for mixtures of mainstream and sidestream tobacco smoke and sidestream tobacco smoke condensates
Tobacco smoking[115]	Environmental, cultural	Lung, oral cavity, naso-, oro-, and hypopharynx, nasal cavity and paranasal sinuses, larynx, esophagus, stomach, pancreas, colorectum, liver, kidney, ureter, bladder, cervix and ovary, myeloid leukemia, breast, childhood hepatoblastoma and acute lymphocytic leukemia; reduced risk for endometrium (postmenopausal) and thyroid	Sufficient
Treosulphan[118]	Medicinal	Acute myeloid leukemia	No data
Vinyl chloride[116]	Occupational	Liver (connective and soft tissue—contradictory)	Sufficient
Wood dust[117]	Occupational	Nasal cavity, paranasal sinus, nasopharynx	Inadequate
X- and γ-radiation[120]	Medicinal, occupational, environmental	Salivary gland, esophagus, stomach, colon, lung, bone, basal cell of the skin, female breast, urinary bladder, brain and CNS, thyroid, kidney, and leukemia (rectum, liver, pancreas, ovary, prostate, non-Hodgkin's lymphoma, multiple myeloma)	Sufficient

[a] The main types of exposure mentioned are those by which the association has been demonstrated; exposures other than those mentioned may also occur.
[b] Suspected target organs in parentheses.
[c] The evaluation of carcinogenicity to humans applies to the group of chemicals as a whole and not necessarily to all individual chemicals within the group.
[d] There are no epidemiological studies of exposure to B[*a*]P (only in mixtures of polycyclic aromatic hydrocarbons); classification is based on animal and mechanistic data in human lung tissue.
[e] No adequate epidemiological studies were available; classification based on animal carcinogenicity data and/or mechanistic data in animal and/or human cells.
[f] The working group was not in full agreement on the evaluation of formaldehyde causing leukemias in humans, with a small majority viewing the evidence as sufficient of carcinogenicity and the minority viewing the evidence as limited.
[g] The specific cancer types were not discussed for humans but likely mimic those seen for x- and γ-radiation.
[h] Solar radiation is *carcinogenic to humans (Group 1)*; use of UV-emitting tanning devices is *carcinogenic to humans (Group 1)*; ultraviolet radiation (bandwidth 100s nm^3, encompassing UVC, UVB, and UVA) is *carcinogenic to humans (Group 1).*

TABLE 2.6
Summary of the Classification Schemes for Carcinogens

Germany (DFG/MAK)[a]	1	Carcinogenic to humans.
	2	Carcinogenic in animal studies.
	3	Suspected carcinogenic potential.
	4	Nongenotoxic carcinogens.
	5	Weak potency genotoxic carcinogens.
EU[121]	1	Carcinogenic to humans.
	2	Should be regarded as if carcinogenic to humans.
	3	Cause for concern in humans.
		3A. Substances that are well investigated
		3B. Substances that are insufficiently investigated
IARC[108]	1	Carcinogenic to humans.
	2A	Probably carcinogenic in humans; limited human evidence; sufficient animal evidence.
	2B	Possibly carcinogenic in humans; limited human evidence; less than sufficient animal evidence.
	3	Not classifiable.
	4	Probably not carcinogenic to humans.
ACGIH[122]	A1	Confirmed human carcinogen.
	A2	Suspected human carcinogen, limited human evidence and sufficient relevant animal evidence.
	A3	Confirmed animal carcinogen with unknown relevance to human; epidemiological studies do not confirm risk to humans.
	A4	Not classifiable.
	A5	Not suspected as human carcinogen, based on properly conducted epidemiological studies or evidence in animal studies.
Health Canada[123]	Group I	Carcinogenic to humans.
	Group II	Probably carcinogenic to humans. Inadequate epidemiological evidence; sufficient evidence in animal species.
	Group III	Possibly carcinogenic to humans. Inadequate or flawed epidemiological studies. Limited animal evidence, or adequate animal evidence, but involves epigenetic mechanisms.
	Group IV	Unlikely to be carcinogenic in humans. No evidence in adequate epidemiological studies; positive animal studies of limited or unlikely relevance to humans.
	Group V	Probably not carcinogenic in humans. No evidence in adequate epidemiological studies. No evidence or inadequate evidence in animal studies.
U.S. EPA[95]		Carcinogenic to humans.
		Likely to be carcinogenic to humans.
		Suggestive evidence of carcinogenic potential.
		Inadequate information to assess carcinogenic potential.
		Not likely to be carcinogenic in humans.
NTP[124]	1	Known to be a carcinogen.
	2	Reasonably anticipated to be a carcinogen.
		A. Limited evidence in human studies indicating credible causal relationship evidence in human studies.
		B. Sufficient evidence in animal studies.

[a] DFG/MAK, Deutsche Forschungsgemeinschaft/maximale arbeitsplatz-Konzentration (German Commission for the Investigation of Health Hazards of Chemical compounds in the work area), as discussed in Seeley et al.[40]

Some agencies, including the IARC,[43] typically conclude that a chemical demonstrating *sufficient evidence of carcinogenicity* from animal experiments is a potential human carcinogen. To some degree, this conclusion is consistent with the evaluation of known human carcinogens in animal bioassays. About 2/3 of the 87 chemicals, processes, or environmental factors associated with cancer indication in humans by the IARC[113,114] have also been considered by that agency to be positive in animal bioassays (Table 2.5). More current understanding of carcinogenesis indicates that, based on MoA and other considerations, this assumption is not appropriate for all animal carcinogens.

A more sophisticated understanding of carcinogenicity with an emphasis on understanding the biology of carcinogenesis on MoA was presented in the groundbreaking 2005 EPA guidelines.[95] These guidelines, in their flexibility and incorporation of new science, represent a significant advance in carcinogen classification schemes. There are a number of

important features in the guidelines; in particular, the *MoA** forms the underpinning of other elements wherever possible.

The guidelines use five standard narrative descriptors to assess the carcinogenic hazard to humans: (1) carcinogenic to humans, (2) likely to be carcinogenic to humans, (3) suggestive evidence of carcinogenic potential, (4) inadequate information to assess carcinogenic potential, and (5) not likely to be carcinogenic to humans. The guidelines take a weight-of-evidence approach in which all human, animal, and other relevant toxicological information is evaluated. As part of this evaluation, the quality of individual studies and overall consistency across studies is considered. Confidence that a specific chemical is the cause of cancer in human studies is enhanced by positive findings at the same organ site in multiple studies with well-characterized exposures. In contrast to the 1986 EPA guidelines,[125] other evidence relevant to carcinogenicity—importantly, the MoA information in animals that attests to the relevance (or lack of relevance) of a particular tumor response—is considered explicitly. Data from human, animal, and other sources are combined to weigh the totality of evidence to classify the human carcinogenic potential of a particular chemical. Using this framework, some animal carcinogens such as DMA,[126] captan,[127] and chloroform[128] have been identified by the EPA as associated with a threshold MoA; that is, at exposures less than the threshold dose, the risk of the chemical's potential as a human carcinogen is expected to be negligible—if not zero.

The 2005 guidelines allow for multiple descriptors of carcinogenicity—that is, a chemical may be classified as *not likely to be carcinogenic* by one route of exposure but *likely to be carcinogenic* by another route. Dose may also be an element of the descriptor in which a chemical may be carcinogenic only above a specified dose (which is equivalent to assuming a threshold dose–response relationship).

In situations where there is not enough information to make a determination on a chemical's carcinogenic hazard to humans, the EPA has specified default assumptions; for example, positive findings in animals are assumed to be relevant to humans. However, as noted earlier, well-founded MoA information (such as findings that a kidney tumor response in rodents is a consequence of alpha-2-μ globulin accumulation) can be used to avoid use of such a default assumption.

Recent Approaches

There continues to be important developments in the evaluation of chemical carcinogens, providing for fuller incorporation of biological understanding into interpretation of carcinogenicity findings and bringing greater rigor to evaluations conducted by regulatory agencies. As a practical matter, such advances can influence the classification of chemical carcinogens and identify the most appropriate dose–response relationship for risk assessment purposes.

Building on earlier EPA and International Programme on Chemical Safety efforts, an expert panel organized by the International Life Sciences Institute Risk Science Institute (ILSI RSI) expanded upon the *human relevance framework* for chemical carcinogens. The framework addressed the sufficiency of evidence for a particular MoA in animals, the plausibility of key events in the MoA in humans (i.e., can the MoA occur in humans?), and, considering kinetic and dynamic factors, the plausibility of the animal MoA in humans (i.e., is it plausible that, under relevant exposure conditions, the animal MoA could actually occur in humans?). In this framework, an overall conclusion, along with a statement of confidence in the findings, is developed regarding likelihood of carcinogenicity in humans and under what circumstance(s). Key to the framework is the comparison of multiple plausible MoAs for an individual chemical to assess which MoA best fits the available data. The applicability of the framework was reflected in several case studies. For example, the MoA of melamine bladder cancer (accumulation of calculi) in rodents was considered plausible in humans under the framework, but such accumulation was considered unlikely to occur in humans under any realistic exposure conditions. This yielded the overall conclusion that melamine would not present a human cancer hazard.

The hypothesis-based weight-of-evidence (HBWoE) method provides a complementary approach to the ILSI RSI human relevance framework described earlier. With HBWoE, multiple hypotheses to explain a particular carcinogenic are identified. Findings in target and nontarget tissues and species are then presented, consistency with the proposed hypotheses is evaluated, and the need to invoke alternative assumptions is considered. Using this approach, Rhomberg and coworkers[129] concluded that the weight of evidence supporting a cytotoxic or dual cytotoxic/genotoxic MoA for naphthalene was stronger than that for an initiating genotoxic MoA.

Dose–Response Assessment

One of the most contentious aspects of the evaluation of animal carcinogens by regulatory agencies is characterizing the dose–response relationship at the exposure levels to which humans are likely to be exposed. Animals are typically exposed to carcinogens at levels orders of magnitude greater than those likely to be encountered in the environment by humans. It would be impossible to perform animal experiments with large enough numbers to directly estimate the level of risk at low exposure levels. Thus, to obtain a quantitative estimate of the risks humans are likely to encounter at ambient exposures requires the extrapolation of effects

* Mode of action is defined by EPA as a sequence of biochemical and cellular event resulting in tumor formation. It may be contrasted with a mechanism of action that implies a detailed understanding of the carcinogenic process, often at the molecular level.

observed at high doses to low doses and from effects observed in animals to humans. Even the use of carcinogenicity data from human studies (mostly occupational studies) frequently requires the use of extrapolation models to estimate risks to humans exposed at lower ambient levels.

Mechanistic models are being developed to assist in dose–response assessment. Pharmacokinetic models attempt to describe the relationship between exposure and biologically relevant dose to the target tissue. These models characterize absorption, distribution, metabolism, and excretion of chemicals. Pharmacodynamics models attempt to describe the relationship between the dose to target tissue and response. Both of these types of models can assist in extrapolation from high to low doses and across species.

Low-Dose Extrapolation

Extrapolation from high to low dose is done using models that are hypothesized to characterize the dose–response relationship of carcinogens at both the high dose and response levels observed in animal or human occupational studies and the low dose and response levels of interest for human exposures. The choice of mathematical model depends on two factors: (1) the hypothesis for the mechanism of carcinogenesis for a particular chemical and (2) the science policy decision to choose, in the absence of data firmly supporting one model or another, the more conservative model (of several biologically plausible models) or to present results from a range of plausible models.

Threshold versus Nonthreshold Mechanisms

The determination of whether carcinogenesis is a threshold or nonthreshold phenomenon is a key consideration in the choice of model to characterize the dose–response relationship. Chemical carcinogenesis has historically been considered as a nonthreshold phenomenon, particularly for certain types of genotoxic agents (i.e., those that interact directly with DNA to cause mutations). For example, trichloropropane was classified by the EPA as having a mutagenic MoA, supporting a linear no-threshold dose–response model.[130]

In the case of the linear no-threshold model, the measure of a chemical's carcinogenic potency is typically determined by fitting a model to the observed data and then linearly extrapolating to low doses, often from a POD (i.e., the highest dose associated with no tumors) or, in some cases, a precursor indicator such as stimulation of cell proliferation.[126] For chemicals that cause cell damage at high doses, or for chemicals for which detoxification pathways become saturated at high doses, it is likely that a different dose–response relationship will be observed at high and low doses, even for those chemicals where a nonzero slope is plausible at any dose. As discussed in "Maximum Tolerated Dose" section, work by scientists such as Cohen and Arnold[90] highlights the predominant role of cell proliferation in carcinogenicity of many chemicals that yield positive tumor responses at the MTD.

A striking example of different dose–response relationships for a single carcinogen is 2-acetyl-aminofluorene (2-AAF).[131] 2-AAF is a potent mutagenic carcinogen. The dose–response relationship for 2-AAF-induced liver cancer exhibits the expected (for a genotoxic carcinogen) linear dose–response relationship, whereas the dose–response relationship for bladder cancer is highly nonlinear—demonstrating an apparent threshold. The mechanistic basis for the different dose–response relationships appears to involve differences in the relative importance of genetic damage (the likely key event in liver cancer) versus genetic damage *and* hyperplasia of the bladder urothelium (the likely key events in bladder cancer). Thus, the selection of the appropriate shape of the dose–response relationship for *any* chemical requires understanding of the mechanism by which tumors are induced.

Models

The choice of the low-dose extrapolation model can have a major impact on the estimate of risk at low exposure levels, as presented by Bickis and Krewski.[132] The authors estimated risk from 2-AAF at low exposure levels using different models. The level of risk varied by many orders of magnitude at the same exposure level depending on the model chosen to characterize the dose–response curve in the unobservable region.

Because of the uncertainties in dose–response modeling for low-dose risk and an increased emphasis on MoA in cancer risk assessment, efforts are being made to incorporate greater biological understanding of tumorigenesis into cancer dose–response assessment. Some of the most comprehensive efforts in this area have been conducted by scientists at the Chemical Industry Institute of Toxicology (now the Hamner Institute) with respect to the development of a biologically motivated computational model for formaldehyde in the F344 rat. Investigators have developed a model that incorporates information on nasal dosimetry, cell replication, and DNA cross-links into a two-stage clonal growth model (see Figure 2.5).[133] This modeling yields a j-shaped dose–response relationship that reflects the highly nonlinear dose–response relationship for tumorigenicity. The biologically based modeling for nasal tumors from formaldehyde results in maximum likelihood estimates for cancer risk at 0.1 ppm formaldehyde in air that are, in some cases, as much as 1000-fold lower than the values used by the EPA in its Integrated Risk Information System. Analysis of formaldehyde-dG adduct data, an indicator of internal dose at the molecular target, has provided evidence that the EPA risk values may be overestimated, in some cases by several orders of magnitude.[134]

In the 2005 cancer risk assessment guidelines, the EPA revised its approach to dose–response assessment.[95] If sufficient data are available, a biologically based dose–response

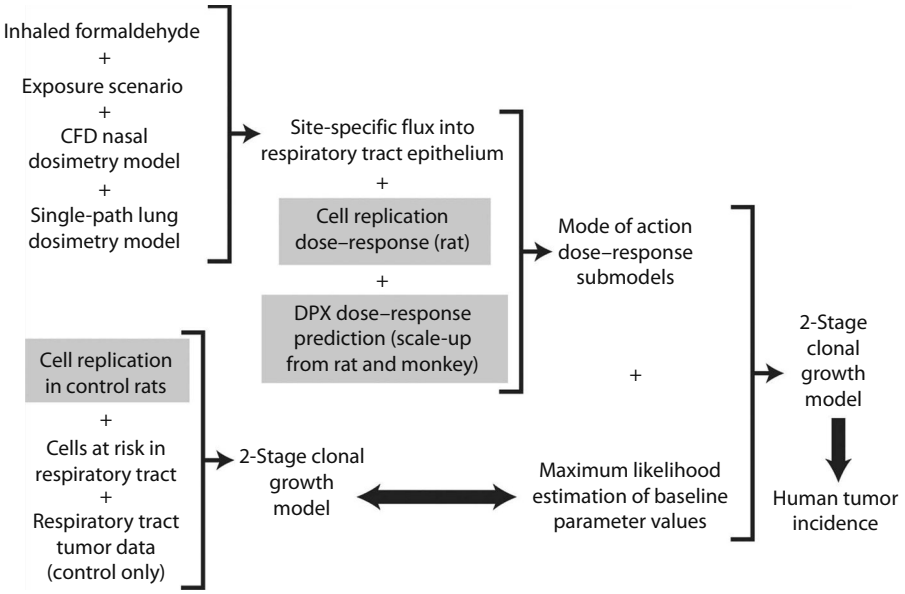

FIGURE 2.5 Interrelationships of the major components of the human dose–response model. (From Conolly, R.B. et al., *Toxicol. Sci*., 82(1), 279, 2004. With permission of Society of Toxicology.)

model (such as the one described earlier for formaldehyde) is chosen as the most appropriate method for evaluating the observed data and extrapolating to exposures below the observed dose range. However, the more likely case is that sufficient data are not available for development of biologically based models. In this situation, a *point-of-departure* approach is recommended. The POD represents a dose, within the range of observed data, associated with a specified extra tumor risk. The POD is developed using mathematical models, such as the linearized multistage model (although other models can be used), and it is typically expressed as the lower limit on effective dose (LED). The LED is the lower 95% confidence limit on the dose associated with specified extra risk (e.g., LED_{10} would be the lower 95% confidence limit on the dose associated with 10% extra risk above background). Risks below the LED_{10} are characterized either through linear extrapolation (for chemicals believed to act via a linear dose–response relationship [e.g., genotoxic carcinogens]) or through a margin-of-exposure analysis (for chemicals for which dose–response relationships are likely to be either threshold or nonlinear). For chemicals where data might support either linear extrapolation or a margin-of-exposure analysis, both analyses are presented.

EVALUATION OF NONCANCER EFFECTS

Noncancer effects are generally postulated to occur through a threshold mechanism. That is, there is a level of exposure below which there is minimal, if any, chance for an adverse effect. Noncancer effects can range from acute skin and eye irritation to subchronic or chronic damage to an organ system, such as pulmonary fibrosis. The underlying hypothesis for the threshold model for systemic toxicants is that multiple cells must be injured before an adverse effect occurs, and the injury must occur at a rate that exceeds the rate of repair. This is in contrast to the regulatory paradigm for carcinogens, in which a genotoxic insult involving direct DNA damage to a single cell is theoretically sufficient to allow that cell to grow to a malignant tumor.[135] (As discussed earlier in this chapter, it should be noted that this model for carcinogenesis is now viewed as too limiting.) Pulmonary fibrosis due to mineral dust exposure provides an example of a threshold-type injury. Fibrotic areas may be present and observed as radiographic or histopathological changes in the lungs of miners as a consequence of mineral dust exposure in the absence of any physiological impairment such as reduced lung function. Physiological impairment will occur as the fibrosis increases and the fibrotic areas begin to coalesce.[136]

For noncancer effects that may involve genotoxic mechanisms, such as developmental effects, a threshold model may still be the most appropriate choice of dose–response model. This is because multiple cells must be injured before an effect can be manifested. For example, the prenatal death of a single retinal cell, even through genetic damage, would not result in blindness because of the existence of many other retinal cells.

Acceptable Exposure Level

The general approach for setting exposure limits for noncancer effects is based on developing a reference value, or acceptable exposure level (AEL), which is associated with

minimal or no risk of adverse effects in humans. For ingestion and dermal exposures, the AEL is expressed in terms of mg/kg-day[137]; for inhalation exposure, the AEL is typically expressed as an air concentration (e.g., mg/m^3).

AELs are based on a POD from either an epidemiology or animal toxicology study, which could be a no observed adverse effect level (NOAEL) or lowest observed adverse effect level (LOAEL) or a benchmark exposure level. Uncertainty factors (UFs) are then applied to the POD to account for the uncertainty inherent in extrapolating from the adverse health effect observed in the human epidemiology or animal toxicology study to the likelihood of observing an adverse health effect in the general population.

The methodology for deriving an AEL is widely used or recommended by organizations such as the EPA, ATSDR, FDA, Joint Food and Agriculture Organization of the United Nations (FAO)/WHO Expert Committee on Food Additives (JECFA), Joint FAO/WHO Meeting on Pesticide Residues (JMPR), and NAS/NRC.[32,138] Table 2.7 lists AELs used by different governmental organizations.

Identifying a Point of Departure

The traditional approach for identifying a POD involves identifying a NOAEL or LOAEL for the most sensitive endpoint, in the most sensitive species. Ideally, AELs should be developed from studies in a susceptible population of humans. Because suitable human studies of sufficient quality are not available for most chemicals of concern, most AELs are based on animal studies. Although it is preferable to use a NOAEL from an animal study, NOAELs cannot be identified from all studies, in which case a LOAEL is used. Similarly, the study duration should correspond with the time frame for the AEL, although shorter durations can also be used.

There are several limitations in using a NOAEL or LOAEL as a POD, with the net result that chemicals with the same AEL are not necessarily associated with the same level of risk. This is because NOAELs/LOAELs do not represent a consistent response level across studies. Importantly, NOAELs do not always represent an exposure level at which there is no risk of an adverse effect; rather, these values correspond with an average response rate of 5%–20% above control. This is because NOAELs depend on both experimental exposure levels and sample size. Specifically, the choice of a NOAEL or a LOAEL does not take into consideration the greater experimental confidence associated with, for example, studies using more animals. An exposure level defined as a NOAEL in one experiment could turn out to be a LOAEL had more experimental animals been used (i.e., an effect may have been detected if more animals had been studied). As a result, poor-quality experiments may yield anticonservative AELs, since studies using fewer animals may result in a higher AEL than studies using larger numbers of animals.[144] In addition, the use of NOAEL or LOAEL as a POD does not account for the shape of the exposure–response relationship, which is a key determinant in assessing the likelihood of effects. That is, a chemical with a steep exposure–response curve would be associated with a greater likelihood of effects as exposure increased above the AEL (and a smaller likelihood of effects with exposures below the AEL) than would a chemical with a more shallow exposure–response curve.[145]

A preferred alternative to the NOAEL/LOAEL, when suitable studies are available, is the benchmark dose (BMD)/benchmark concentration (BMC). BMDs/BMCs are exposure levels (typically a dose or an air concentration) corresponding to a specific response near the low end of exposure–response curve. These values are derived using exposure–response modeling and statistics, thereby addressing issues such as experimental quality and shape of the exposure–response relationship in a manner similar to that used for developing cancer potency factors (as discussed in "Evaluation of Carcinogens" section of this chapter). Developing a BMD or BMC generally requires data showing a graded monotonic response at increasing exposure levels, with a significant exposure-related trend. If available, data should be modeled using a biologically based model; if not, the model that best fits the data is selected.[144]

For quantal data, the EPA recommends using a benchmark response (BMR) of 10%, which is close to the limit of sensitivity for most cancer bioassays and also for some noncancer bioassays. For continuous data, the EPA recommends identifying a BMR that corresponds to the level of change at which an effect is considered to be biologically significant. If individual-level data are available, continuous data can also be dichotomized for identifying a cutoff value associated with an adverse response. Alternatively, the response can be selected as a change equal to one standard deviation from the mean control response. For effects that are normally distributed, this response corresponds with an excess risk of approximately 10% for individuals either below the 1.4th percentile or above the 98.6th percentile. In the case of either quantal or continuous data, either higher or lower BMRs can be used, depending on statistical or biological considerations.[144] The BMD/BMC corresponding with a BMR provides a central estimate of an exposure level associated with a specific response. For the POD, the EPA recommends use of the 95% lower bound on a BMD/BMC (i.e., a BMDL/BMCL) to account for uncertainty associated with the study design, such as the number of animals per exposure group and the selection of exposure levels.[144]

Figure 2.6 illustrates derivation of a BMDL, in comparison to a NOAEL, as a function of number of animals per exposure group.

The benchmark approach overcomes many of the weaknesses of the AEL approach.[146,147] Because benchmark values are determined based on statistical modeling of exposure–response data, the approach accounts for the sample size and the slope of the exposure–response curve. Unlike NOAELs or LOAELs, benchmark values are not constrained to be one of the experimental exposure levels and are less dependent on the study design. Overall, the benchmark approach allows for greater consistency between values derived for different chemicals. Although BMDs/BMCs are preferred for identifying a POD, there are instances where a NOAEL/LOAEL would be used. This is because some chemicals

TABLE 2.7
Acceptable Exposure Levels Used by Different Agencies

Value	Description	Use	POD	UFs
RfD U.S. EPA[139]	"An estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime."	Support regulatory activities such as remediation	NOAEL, LOAEL or BMDL	Interspecies. Intraspecies. LOAEL/NOAEL. Subchronic/chronic. Database deficiencies.
RfC U.S. EPA[139]	"An estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime."	Support regulatory activities such as remediation	NOAEL, LOAEL or BMCL	Interspecies. Intraspecies. LOAEL/NOAEL. Subchronic/chronic. Database deficiencies.
MRL ATSDR[140,141]	"An MRL is an estimate of the daily human exposure to a hazardous substance that is likely to be without appreciable risk of adverse non-cancer health effects over a specified duration of exposure."	Screening levels for identifying contaminants associated with hazardous waste sites that may be a concern for the general population	NOAEL or LOAEL	Interspecies. Intraspecies. LOAEL/NOAEL. Subchronic/chronic. Database deficiencies (referred to by ATSDR as an MF).
Acceptable Daily Intake (ADI) U.S. FDA[142]	"A food additive generally is considered safe for its intended use if the estimated daily intake (EDI) of the additive is less than, or approximates, the ADI. Because the ADI is calculated to protect against the most sensitive adverse effect, it also protects against other adverse effects occurring at higher exposures to the ingredient."	Define safe levels for food additives	NOEL or NOAEL	U.S. FDA applies a safety factor of 100 for ADIs derived from animal studies. This safety factor may be modified to account for potentially sensitive subpopulations.
Acceptable Daily Intake (ADI) WHO[138,143]	"The ADI of a chemical is the estimate of the amount of a substance in food or drinking-water, expressed on a body-weight basis, that can be ingested daily over a lifetime without appreciable health risk to the consumer on the basis of all the known facts at the time of the evaluation. It is expressed in milligrams of the chemical per kilogram of body weight."	Established for food additives and pesticide residues	NOAEL, LOAEL or BMDL	Interspecies. Intraspecies. Adequacy of studies or database. Nature and severity of effect.
Tolerable Daily Intake (TDI) WHO[138]	"The TDI is an estimate of the amount of a substance in food and drinking-water, expressed on a body weight basis (milligram or microgram per kilogram of body weight), that can be ingested over a lifetime without appreciable health risk, and with a margin of safety."	Established for chemical contaminants	NOAEL, LOAEL or BMDL	Interspecies. Intraspecies. Adequacy of studies or database. Nature and severity of effect.

Notes: BMDL, lower 95% confidence limit on BMD; LOAEL, lowest observed adverse effect level; NOAEL, no observed adverse effect level; NOEL, no observed effect level.

may lack the minimum exposure–response data required to identify a BMD/BMC.[144]

Table 2.8 lists chemicals for which the EPA has derived noncancer toxicity criteria based on a BMR between 2000 and 2012. During this time, approximately 60% of reference doses (RfDs) and 50% of reference concentrations (RfCs) were derived using BMR rather than a NOAEL or LOAEL. A BMR of 10% is most common, although BMRs of 5% and 1%, those equal to one standard deviation from the mean or those equal to twofold greater than control response, have also been used. For example, a BMR of 5% was used for acrylamide. This response was considered to represent a

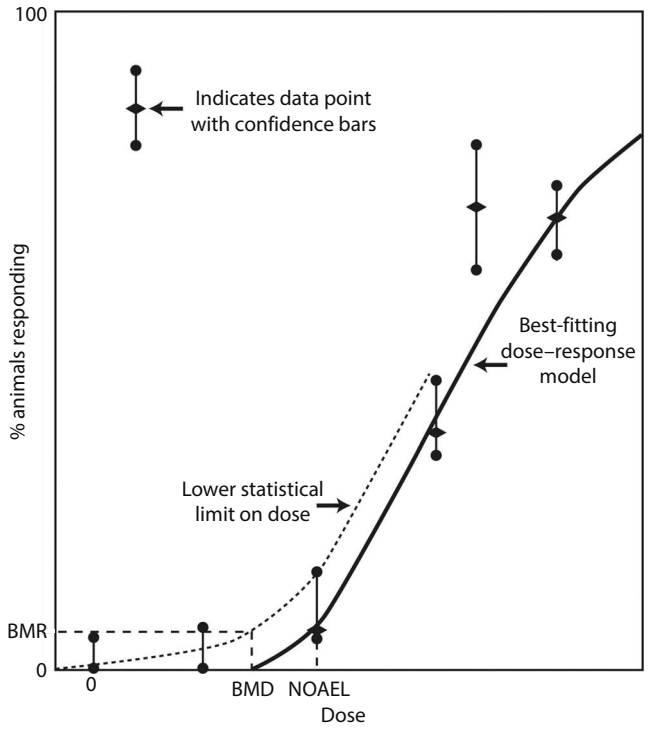

FIGURE 2.6 Relative magnitude of BMDL versus NOAEL as a function of number of animals per dose group (hypothetical data). (From U.S. Environmental Protection Agency, *The Use of the Benchmark Dose Approach in Health Risk Assessment*, Risk Assessment Forum, Office of Research and Development, Washington, DC, EPA/630/R-94/007, 1995.)

change that was of minimal biological significance, which was also near the range of observed responses, and it was further supported given that principal underlying studies used a relatively large number of animals.[148] A 5% response was also used for deriving the RfD for methylmercury, which was based on developmental neurological effects in humans. The response of 5% results in a doubling of the number of children responding below the 5th percentile of abilities for the normal population, which represents a significant level of compromise.[149] The EPA used a response of 1% for TCE due to the severity of the heart malformations considered as the critical effect.[150] Chemicals assessed prior to 2000 for which U.S. EPA also used a BMR as the POD include beryllium, tributyltin oxide, antimony trioxide, CrVI particulates, carbon disulfide, methylene diphenyl diisocyanate, methyl methacrylate, phosphoric acid, and 1,1,1,2-tetrafluoroethane. The EPA used a BMR of 10% for all of these chemicals.[151]

Selecting Uncertainty Factors

There are five possible UFs that can be applied to a POD, each with a default value of 10.[138,139,141] These are described in Table 2.9.

In the past, the EPA has also applied a modifying factor (MF); in practice, an MF is similar to the currently used database UF. This factor has been applied in deriving toxicity criteria for only a small number of chemicals, including RfDs for CrIII, CrVI, nitrite, 1,1-biphenyl, and manganese, as well as RfCs for methyl ethyl ketone and acetonitrile. In 2002, the EPA's RfD/RfC Technical Panel recommended against using an MF on the basis that the database UF should account for potential issues that the MF is intended to address.[139]

UFs are used multiplicatively. To derive an AEL, the POD is divided by the product of the individual UFs. Mathematically, this is represented as

$$\frac{\text{RfD}}{\text{RfC}} = \frac{\text{POD}}{\text{UF}_1 \times \text{UF}_2 \times \text{UF}_n} \tag{2.1}$$

The use of all five UFs (UF_H, UF_A, UF_S, UF_L, UF_D), each representing an order of magnitude, could in theory lead to a total UF of 100,000. This would occur if data were from a subchronic animal study that identified only a LOAEL and the database was limited. However, the EPA's RfD/RfC Technical Panel recommended against deriving a reference value using the full tenfold value for four or more UFs, as it is likely in such cases that the database is insufficient for deriving a reference value. The technical panel hence recommended using a maximum total UF of 3000.[139]

Although the basis for an initial choice of 10 as a default value for UFs was never defined, subsequent analyses provide experimental support that a value of 10 is adequate in most, but not all, cases.[154] Evaluation of data regarding toxicokinetics and toxicodynamics indicates that the tenfold factor for intraindividual variability is sufficient in most cases.[155] This evaluation, however, did not address children; thus, some scientist have contended that the tenfold interspecies UF may not account for potential increased susceptibility in that subpopulation.[139] Another instance for which a intraindividual UF of 10 may not be sufficient is in the case of genetic polymorphisms that may result in large variations in susceptibility.[139] Dorne and coworkers[156] observed an overall interindividual variability of 31% for compounds eliminated via glucuronidation. Walton and coworkers[157] evaluated interspecies toxicokinetic differences specifically for compounds eliminated by CYP1A2, including caffeine, theobromine, theophylline, and paraxanthine. They determined that that interspecies toxicokinetic UFs of 10.6, 5.4, 2.6, and 1.6 for mice, rats, rabbits, and dogs, respectively, would account for differences in the route of metabolism and metabolic enzymes. Because the variability observed for metabolism related to CYP1A2 and glucuronide does not account for differences in toxicodynamics, the default UF of 10 may not be adequately protective for all compounds metabolized by these enzymes; however, it would be necessary to assess the implications of such polymorphisms on dose to target tissue (considering factors such as absorption and distribution in addition to metabolism) before drawing confirmed conclusions as to the overall impact of polymorphisms on susceptibility.

There is also support for use of a tenfold factor to account for insufficient study duration. For example, the ratio between the subchronic and chronic NOAEL or LOAEL for 52

TABLE 2.8

TABLE 2.9
Basis for UF Use

Term	Information
Intraindividual—UF_H	To account for variations in susceptibility among humans; comprised of a component to account for variability in toxicokinetics (TK), which relates an external exposure to an internal dose, and a component to account for variability in toxicodynamics (TD), which relates an internal dose to a toxicological response. Whereas U.S. EPA equally apportions TK and TD components into default values of $10^{0.5}$ (3.16), which is sometimes rounded to 3; IPCS recommends values of $10^{0.6}$ (4) and $10^{0.4}$ (2.5).[139,152] • If a POD was identified from a long-term study in humans, this would be the only UF applied. In a later section of this chapter we discuss in detail the variability in human responsiveness to environmental pollutants and its relevance to the regulatory process. • A UF less than 10 can be used if the available data capture exposure–response relationships for susceptible subpopulations.
Interspecies—UF_A	To extrapolate from responses observed in animal data to expected responses in humans; comprised of a component to account for variability in toxicokinetics (TK), which relates an external exposure to an internal dose, and a component to account for variability in toxicodynamics (TD), which relates an internal dose to a toxicological response. Both U.S. EPA and IPCS equally apportion TK and TD components into equal values of $10^{0.5}$ (3.16), which sometimes rounded to 3.[139,152] • This factor is used when the POD is identified from an animal study, based on the assumption that humans may be more susceptible than experimental animals to a particular chemical. • U.S. EPA's RfC methodology applies a dosimetric adjustment factor (DAF) to the POD address interspecies toxicokinetic differences, for calculating a HEC. To account for interspecies differences in toxicodynamics, U.S. EPA uses a partial UF of $10^{0.5}$ (which is typically rounded to 3.0).[139] (Additional description of the RfC methodology is provided in the chapter by Rees and Hattis.)
Subchronic/chronic—UF_S	To extrapolate from a subchronic exposure to a chronic exposure. • This factor is used when the POD for a chronic AEL is identified from a study that involves less than lifetime exposure, and is based on the assumption that effects are proportional to both exposure level and exposure duration, with effects observed at lower exposure levels with increasing exposure durations.
LOAEL/NOAEL—UF_L	To extrapolate from a LOAEL to a NOAEL. • This factor is used for studies in which a NOAEL was not identified. The default assumption is that an exposure at 1/10 the LOAEL would result in a NOAEL.
Database—UF_D	To account for an incomplete database. • This factor is applied when the database is incomplete, based on the assumption that there is uncertainty as to whether the POD might be significantly lower if other studies were performed or if additional health endpoints (e.g., immunotoxicity, neurobehavioral toxicity, reproductive toxicity) had been evaluated.[153] A complete database is defined as having two chronic mammalian studies, one mammalian multigeneration study, and two mammalian developmental toxicity studies. If these five studies are available, and there is no reason to expect that the chemical would cause toxicity for other specific endpoints, such as immunotoxicity or neurobehavioral toxicity, then there is a high degree of confidence that one has approximated the lowest POD. • U.S. EPA uses a UF of 3 if RfD/RfC is based on animal data, in absence of data on prenatal toxicity or a two-generation reproductive study; UF of 10 may be applied if both prenatal and two-generation reproductive data are missing.[139]

chemicals was less than 10 in 96% of the cases, as described in the analysis by Dourson and Stara.[154] Thus, the UF of 10 would be an underestimate for only 4% of these chemicals. A similar analysis was performed by Lewis,[158] who observed that for 18 chemicals, the ratio of the subchronic to chronic NOAEL was 3.5 or less for 14 chemicals; only one had a ratio of greater than 10.[158] If the chemical with a ratio greater than 10 were excluded from the analysis, the mean subchronic to chronic NOAEL ratio was 3.3. Thus, the default UF of 10 for extrapolating from subchronic to chronic exposures would be very protective for most chemicals, and a UF of 3 may be more appropriate than the default value of 10 for many chemicals.

To account for interspecies toxicokinetic differences, as well as some aspects of toxicodynamic differences, the EPA now recommends allometric scaling, which involves scaling

physiological processes to growth and size. The EPA recommends using body weight to the ¾ power ($BW^{3/4}$), as follows:

$$\text{Dosimetric Adjustment Factor (DAF)} = \left(\frac{BW_a}{BW_h}\right)^{-1/4}$$

The EPA recommends applying this DAF along with an interspecies UF of 3, for both systemic and local effects.[159]

Use of allometric scaling to account for interspecies differences, which is consistent with the approach used for deriving cancer slope factors (CSFs), results in a human equivalent dose (HED). The HED is also analogous to the human equivalent concentration (HEC), which the EPA uses to derive an RfC (see Table 2.9).[159] As discussed by Rhomberg and Lewandowski, use of allometric scaling for physiological processes underlying toxicokinetics, such as metabolism, cardiac output, breathing rate, and glomerular filtration, is premised on similar anatomical features and biochemical processes operating at rates inversely proportional to size.[160] As such, allometric scaling is best applied to chemicals for which toxicity is related either to a parent compound or stable metabolite and which can be cleared by first-order processes.[159]

Table 2.10 shows DAFs for different species and the resulting interspecies UF, based on a partial UF of 3 to account for toxicodynamic differences. As this table shows, an interspecies UF of 10 may be insufficient for AELs based on studies in mice.

The process of identifying appropriate UFs is continually undergoing refinements, with increasing use of chemical-specific factors derived using PBPK models. Chemical-specific PBPK models are most often used to address the toxicokinetic component of the interspecies UF, although they can also be used to address the toxicokinetic component of the intraindividual UF. The next section of this chapter discusses the use of PBPK models for deriving chemical-specific UFs in more detail. Although much less common, chemical-specific factors can also be derived for the toxicodynamic component of the intraindividual and interspecies UFs, using in vivo, ex vivo, or in vitro data.[152] Table 2.11 lists chemicals assessed by the EPA for which PBPK models were used to address interspecies and/or intraindividual uncertainty and variability.

TABLE 2.10
Dosimetric Adjustment Factors and Interspecies Uncertainty Factors as a Function of Body Weight

Species	Weight (kg)	DAF	Interspecies UF
Mouse	0.03	7	21
Rat	0.25	4	12
Guinea pig	0.5	3	9
Rabbit	2.5	2	6

Notes: Values for weight and DAF are from U.S. EPA[139]; DAF calculated as $[BW_{animal}]^{-0.25}/[BW_{human}]^{-0.25}$.

TABLE 2.11
Subdivision of Uncertainty Factors for Inter- and Intraspecies Differences[162]

Species	UF_{AH}	UF_A / UF_H	Subdivision PK × PD
Mice	150	38	9.0 × 4.3
		4	2 × 2
Hamsters	100	25	7.0 × 3.6
Rabbits		4	2 × 2
Rabbits	40	10	4.0 × 2.5
Monkeys		4	2 × 2
Dogs

Notes: UF_{AH}, composite UF accounting for inter-individual variability and interspecies uncertainty; UF_A, UF for interspecies uncertainty; UF_H, UF for intraindividual variability; PK, pharmacokinetics; PD, pharmacodynamics.

The EPA used chemical-specific information to replace the default values for the toxicokinetic components of the intraindividual and interspecies UFs for developing an RfD for boron.[161] The endpoint of concern was the developmental effects in rodents; hence, the pregnant female was considered the sensitive population and the basis for the NOAEL. Data were available for differences in clearance rates of boron across species (the toxicokinetic component of the UF_A), allowing a UF_A for toxicokinetic of 3.3—only slightly higher than the default value of 3.16. For the toxicokinetic component of the UF_H, data on differences in glomerular filtration rate among women resulted in the use of value of 2.0 (vs. the default value of 3.16). Default values of 3.16 were used for the toxicodynamic component for the UF_A and for the UF_H. The total UFs in this analysis were 66, rather than the default of 100. Thus, the use of chemical-specific UFs for boron resulted in a more scientifically founded RfD that was somewhat lower than would have resulted from use of default values.

Another approach, to account for both intraindividual variability and interspecies uncertainty, has been proposed by Hasegawa and coworkers.[162] They identified distributions for both intraindividual variability and interspecies uncertainty and combined them using probabilistic methods to derive species-specific UFs, shown in Table 2.11, that account for both interindividual variability and interspecies uncertainty. Similar to the EPA's recommended approach of calculating an HED based on $BW^{3/4}$ scaling, these combined UFs are consistent with the use of the default UF of 10 for AELs based on studies in rats. The findings suggest that the default UFs may not be sufficient for AELS based on studies in mice.

Alternative Approaches to the Risk Reference Dose

For compounds that have been well studied, particularly in humans (both in terms of exposure and toxicity), distributional population approaches have been used to evaluate toxicity and provide input into the decision-making process. Such approaches have been applied mainly to evaluation of the NAAQS for criteria air pollutants (e.g., carbon monoxide [CO], lead, nitrogen dioxide [NO_2], ozone, PM, SO_2). Much of the basis for the selection of an NAAQS is based on data from human epidemiology and controlled exposure studies, although animal data are used in a supporting role.

An example of a distributional population approach can be seen in the evaluation of CO toxicity and exposure by the EPA.[163] As part of this assessment, the EPA reviewed several studies that evaluated the relationship between exposure to CO, using carboxyhemoglobin (COHb) in blood as an indicator, and percent decrease in time to angina or pain in the chest, as an indicator of effect. Most of the studies showed an impact of low COHb levels on angina. However, there was no consistent dose–response relationship when studies were analyzed in the aggregate. This may have been due to differences in study design, study populations, and other factors. Because of the lack of a clear dose relationship, the EPA evaluated the impact of different concentrations of CO in air upon various *cutoff* points of COHb—from 2.1% to 3.0%. These cutoff points are conceptually similar to the LOAEL used in RfD development. Levels of CO that result in COHb of 2.9%–3.0% or higher might constitute frank effect levels (FELs). This is because levels of COHb of 2.9%–3.0% or higher in persons with heart disease are considered as possibly increasing the risk of myocardial ischemia and diminishing blood flow to the heart.

The risk of CO exposure to people with heart disease in Denver (36,345 individuals at the time) was estimated under different CO levels.[163] The number of person-days where individuals might have at least one hourly COHb level greater than or equal to a defined percent COHb was estimated. Table 2.12 presents some of the results of this analysis. For example, under conditions at the time (considering both indoor and outdoor sources of CO), there were approximately 488 person-days in which the Denver population with preexisting heart disease would experience COHb levels greater than 2.1%. If only ambient air is considered, the person-days drop to 72. If the NAAQS for CO is attained, the person-days drop to 457 for all sources and 0 for ambient air only. This type of analysis is useful in showing the benefits of CO reduction, as well as identifying the significance of different sources.

Distributional population approaches to evaluating environmental chemicals provide a more comprehensive evaluation of risks than the RfD approach. Rather than focusing on point estimates (e.g., above or below the RfD), this method allows one to more fully characterize variability in responsiveness to chemicals and variability in exposure levels among defined populations. However, this approach is feasible only for a limited number of chemicals and is quite resource intensive.

TABLE 2.12
Heart Person-Days with at Least One Hourly COHb Estimate ≥ Value for Four Alternative Scenarios

	As Is Air Quality		*Just Attain* Air Quality	
Exposure Indicators	*Ambient Air* Plus Internal Sources	*Ambient Air* without Internal Sources	*Ambient Air* Plus Internal Sources	*Ambient Air* without Internal Sources
COHb ≥ 2.1%	488	72	457	0
COHb ≥ 3.0%	37	0	24	0

Incorporating Information on Severity of Effect

A critical difference in evaluating risks for carcinogenicity versus risks for noncancer effects is that, whereas from a regulatory perspective almost all types of cancer are considered equally severe, regulations based on noncancer effects can account for variations in severity. In general, regulatory agencies do not distinguish among carcinogens on the basis of malignancy of tumor type. Despite advances in earlier diagnosis and treatment, the fatality rate for cancer overall is still relatively high and, even when treatable, the treatment methods are not without adverse effects. For example, the relative 5-year survival rate for all cancers from 2001 to 2007, excluding nonmelanoma skin cancer, was 69% for whites and 59% for blacks,[164] meaning that 31% of whites and 41% of blacks did not survive 5 years past diagnosis. Nonmelanoma skin cancers such as squamous and basal cell carcinoma, which can be induced by agents such as ultraviolet (UV) light and arsenic, have relatively low (<10%) fatality rates, even when untreated.[165]

In contrast, target-organ effects range greatly in severity. For example, using the same target organ and susceptible population—namely, airways for individuals with asthma—responses may range from imperceptible mild bronchoconstriction induced by low levels of SO_2 to a fatal asthmatic response, as may have been due to acid sulfate pollution in the London smog episodes.[60,166] Table 2.13 lists effects, ranging from enzyme induction to severe organ function, and corresponding effect categories (e.g., NOAEL, LOAEL, FEL). Using these categories, the California EPA's Office of Environmental Health Hazard Assessment (CalEPA OEHHA) recommends using a LOAEL/NOAEL UF of 6 rather than 10 for mild effects (severity level grade 5 or less) for deriving acute AELs for inhalation exposure.[167]

TABLE 2.13
Relationship between Effect Categories and Severity

Severity Level	Effect Category	Effect
0	NOEL	No observed effects
1	NOAEL	Enzyme induction or other biochemical change (excluding signal transduction effects), consistent with possible mechanism of action, with no pathologic changes, no change in organ weights, and no downstream adverse developmental effects
2	NOAEL/LOAEL	Enzyme induction and subcellular proliferation or other changes in organelles, consistent with possible mechanism of action, but no other apparent effects
3	NOAEL/LOAEL	Hyperplasia, hypertrophy, or atrophy, but without changes in organ weight
4	NOAEL/LOAEL	Hyperplasia, hypertrophy, or atrophy, with changes in organ weight
5	LOAEL	Reversible cellular changes including cloudy swelling, hydropic change, or fatty changes
6	(LO)AEL	Degenerative or necrotic tissue changes with no apparent decrement in organ function
7	(LO)AEL/FEL	Reversible slight changes in organ function
8	FEL	Pathological changes with definite organ dysfunction, which are unlikely to be fully reversible
9	FEL	Pronounced pathological change with severe organ dysfunction and long-term sequelae; developmental dysfunction including biochemical changes affecting signal transduction that result in developmental defects or dysfunction
10	FEL	Life-shortening or death

Notes: AEL, adverse effect level; FEL, frank effect level; LOAEL, lowest observed adverse effect level; NOAEL, no observed adverse effect level; NOEL, no observed effect level.

Consideration of severity then becomes important for regulatory decision-making in several ways. For RfD development, is an effect such as a 2% decrease in weight a NOAEL or a LOAEL? Does an effect of sufficient severity warrant protection of 95% the population or 99% of the population? Several agencies and organizations have developed approaches to incorporate information on severity of effect into the risk assessment or risk management process for environmental chemicals.

Information on severity has been incorporated into the *reportable quantity* (RQ) definition under CERCLA. Under this statute, releases of chemicals in amounts greater than some predetermined level, defined as the RQ, require that the EPA be notified of the release.[168] The amount of release that triggers notification is based on an assessment of the potency of the chemical and severity of the effect at the dose level where the potency was quantified. The ranking of severity is shown in Table 2.13,[168] where it can be seen that effects range from slight biochemical changes through gross toxicity—including lethality. Unlike the RfD process, this scoring is not restricted to datasets containing information on mildly adverse effects from subchronic or chronic studies. The RQ process can result in development of scoring indicators from lower-quality datasets, involving shorter time periods of exposure and more severe toxicity. The RQ process demonstrates the use of severity information in both risk assessment (developing RQ indicators) and risk management (defining release levels requiring notification as associated with defined RQ values).

Efforts involving the use of categorical exposure–response modeling demonstrate additional approaches toward consideration of severity. Guth and coworkers[158] analyzed acute effects resulting from methyl isocyanate exposures of less than 8 h in duration (as seen in Figure 2.7). Effects were separated into three categories—NOAEL (circles), adverse effect level (triangles), and lethal (squares). Effect categories were then analyzed on the basis of concentration and time using logistic regression. The straight line in Figure 2.7 presents the level above which there is a 90% probability that the true NOAEL lies. This method allows the use of data from a range of severity endpoints and considers various combinations of exposure level and exposure duration. Conceivably, this type of approach could lead to the development of concentration-time nomograms for definition of NOAELs for different exposure durations.

PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELS

PBPK models, which can be used to refine derivation of AELs and cancer potency factors, thus have implications for regulations. Rather than provide a detailed discussion of the structure and development of PBPK models, this chapter will focus on their regulatory impact. PBPK models are discussed in detail in Chapter 6.

PBPK models are essentially mechanistic models that describe quantitatively the pharmacokinetic processes affecting the disposition and metabolism of a chemical from the time it is absorbed through its elimination from the body, including its interaction with various body tissues. By incorporating basic physiologic and metabolic parameters, PBPK models are designed to predict

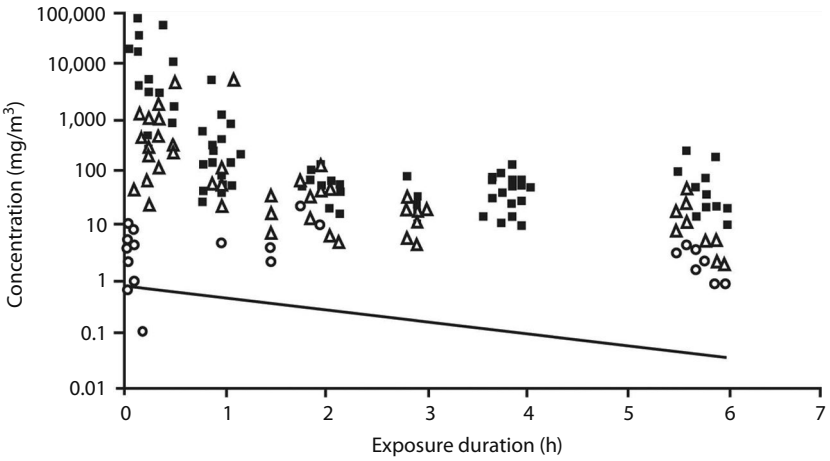

FIGURE 2.7 Categorical data from published results on methyl isocyanate.[158] Categorical data from published results on methyl isocyanate for exposures of less than 8 h in duration are shown as NOAEL (circles), AEL (triangles), or lethality (squares). The maximum likelihood model fit is shown by the line representing the model prediction of p = 0.1 that severity is greater than the NOAEL category at the corresponding exposure concentration and duration. (Reprinted from Beck, B.D. et al., *Fund. Appl. Toxicol*., 20/1, 1, Copyright 1993. With permission from Society of Toxicology.)

kinetic behavior over a wide range of doses and exposure conditions. PBPK models can also account for nonlinear processes, such as saturation of metabolic enzymes, enzyme induction or inactivation, and depletion of antioxidants.[169]

PBPK models involve multiple compartments defined by having similar physiology, with tissue weights and blood flow obtained from experimental data and compartmental rate constants based on physicochemical/biochemical properties of the modeled chemical.[170] Physiological processes such as absorption, metabolism, cardiac output, and clearance are described using a series of mathematical equations.[169] Tissues or compartments typically include target tissue and those involved in storage, metabolism, or clearance. PBPK models also consider transfer of chemical between blood and tissues, either via passive diffusion or active transport, and metabolism in liver or other tissues, either as linear (first-order) or saturable (Michaelis–Menten). PBPK models may consider other processes that can affect kinetics, such as protein binding in the blood or in tissues.[169,170]

PBPK models may be developed to quantify the magnitude and time course of exposure at the critical target site, for both the parent compound and metabolites. After the target tissue dose in the animal model has been estimated and validated, the information can be scaled to the human to obtain an estimate of target-organ dose in humans. This estimate may then be used to predict human cancer risk under different exposure conditions or develop more precise estimates of the AEL, enabling use of chemical-specific, rather than default, UFs. PBPK models can be used to extrapolate between and within species, between high and low exposure levels, and between exposure routes and durations.[169,170] The extent to which PBPK models are able to extrapolate toxicity data between or within species depends on the level of biological detail included in the model; the level of confidence in model predictions depends on the quality of data used for defining model parameters. Table 2.14 shows chemicals for which the EPA has used PBPK models to derive toxicity criteria. Figure 2.8 illustrates use of PBPK models for derivation of cancer potency factors for dichloromethane (methylene chloride). The EPA used a PBPK model to extrapolate target tissue doses from mice to humans and estimate toxicokinetic variability within humans.[171]

PBPK modeling can improve dose–response assessment by accounting for sources of change in the proportions of applied to delivered dose in animals versus humans and at high versus low doses. Although this approach does not account for the sensitivity of the target tissue to the delivered dose (which may differ in humans and animals or between high and low doses), it still addresses some major areas of uncertainty in risk assessment. In fact, many sources of potential nonlinearity in applied dose–response assessment involve saturation or induction of enzymatic processes at high doses or differences in toxification/detoxification pathways between humans and animals or across doses.

It is important to note that there are substantial uncertainties in PBPK modeling. For example, Hattis and coworkers[179] compared PBPK models for perchloroethylene developed by seven different authors and found appreciable differences among the model predictions. With respect to methylene chloride, Clewell[180] notes the importance of the tissue distribution of glutathione S-transferase (GST) enzyme activity across species, especially in humans, as a source of model uncertainty. Given identical exposure levels in humans, the range of values for metabolized perchloroethylene spans a 50-fold range, with six of the seven models having predictions with a 14-fold range. Studies to refine estimates of GST enzyme activity across species and within the human population will serve to provide more refined estimates of dose across humans and, hence, of potential differences in susceptibility.

It should be emphasized that although PBPK models can estimate dose at the target tissue, they do not provide information regarding the most appropriate dose–response relationship.[181,182] Furthermore, full validation of the model at

TABLE 2.14
Use of Physiologically Based Pharmacokinetic Models by U.S. EPA for Deriving Toxicity Criteria

Compound	PBPK Model Characteristics	Dose Metric	Critical Noncancer Endpoint	Application to Toxicity Criteria
Carbon tetrachloride[172]	*Rat/human model* • Four compartments: liver, fat muscle, viscera (richly perfused organs) • Saturable metabolism in liver • Estimates disposition of CCl_4 following inhalation	Mean rate of hepatic CCl_4 metabolism	Fatty liver changes in rats	• Estimate HEC for RfC and IUR • Replace PK component of interspecies UF for RfC
Dichloromethane[171]	*Mouse model* • Probabilistic • Five compartments: lung, fat, richly perfused organs, slowly perfused organs, liver • Saturable metabolism by P450 and first-order metabolism by GST in liver and lung • Estimates disposition of dichloromethane following inhalation *Human model* • Similar to mouse model, with addition of pathway modeling metabolism to carbon monoxide and formation of COHb	Amount of dichloromethane metabolized by GST pathway	Hepatocyte vacuolization in mice	• Estimate HED and HEC for RfD, CSF, RfC, and IUR • Replace PK component of interspecies UF for RfD and RfC • Estimate intraindividual PK variability • Replace PK component of interindividual UF for RfD and RfC
Ethylene glycol monobutyl ether (EGBE)[173]	*Human model* • Model for EGBE linked to model for EGBE metabolite 2-butoxyacetic acid • Eight compartments in EGBE model: lungs/arterial blood, rapidly and slowly perfused organs, fat, skin, muscle, liver, gastrointestinal tract • Model for 2-butoxyacetic acid includes kidney as additional compartment, to allow for saturable elimination pathway • First-order metabolism in liver: • EGBE to 2-butoxyacetic acid, as well as other metabolites and conjugates • 2-Butoxyacetic acid to carbon dioxide • Estimates disposition of EGBE, via metabolism to 2-butoxyacetic acid, following inhalation, dermal, and oral exposure.	AUC in blood of EGBE metabolite 2-butoxyacetic acid	Hemosiderin levels in rat liver	• Estimate HEC for RfC • Replace PK component of interspecies UF • Enable route-route extrapolation from HEC to HED, for deriving RfD • Replace PK component of interspecies UF

(*continued*)

TABLE 2.14 (continued)
Use of Physiologically Based Pharmacokinetic Models by U.S. EPA for Deriving Toxicity Criteria

Compound	PBPK Model Characteristics	Dose Metric	Critical Noncancer Endpoint	Application to Toxicity Criteria

Methanol[174]	*Rat model*
	• Six compartments: lung/blood, fat, liver, stomach, intestine, rest of the body
	• Saturable metabolism in liver via high affinity/low capacity and low affinity/high capacity pathways
	• Estimates disposition of methanol following inhalation or oral exposure
	Human model
	• Based on rat model, with exclusion of intestine, and inclusion of bladder
		AUC of methanol in blood	Decreased brain weight in neonatal rats	• Estimate HEC for RfC
				  • Replace PK component of interspecies UF
				• Enable route-to-route extrapolation from HEC to HED, for deriving RfD
				  • Replace PK component of interspecies UF
				• Provide support for value of 10 for interindividual UF

Tetrachloroethylene (PCE)[175]	*Rat/mouse/human model*
	• Comprised of main model for PCE, along with submodels for oxidative metabolism, conjugative metabolism (rat and human only), and trichloroacetic acid (TCA)
	  • Main PCE model includes nine compartments: respiratory tract, rapidly and slowly perfused tissues, fat, gut, liver, kidney, stomach, and duodenum
	  • Oxidative metabolism submodel estimates oxidation of PCE to TCA in liver, lung, and kidney
	  • Conjugative metabolism submodel estimates formation of conjugates in liver and kidney
	  • TCA submodel includes the liver and the rest of the body
	• Saturable and first-order metabolism
	  • Saturable oxidation and conjugation by mouse
	  • Saturable and first-order oxidation, first-order conjugation by human
	• Estimates disposition of PCE following inhalation, oral, or intravenous exposure
		AUC of PCE in blood	Neurological effects in humans	• Enable route-to-route extrapolation from inhalation to oral POD, for deriving RfD and CSF
				• Estimate HEC based on concentrations in mouse study for deriving IUR

1,1,1-trichloroethane[176]	*Human model* • Four compartments: liver, fat, rapidly and slowly perfused tissues • Saturable metabolism in liver • Estimates disposition of 1,1,1-trichloroethane following inhalation, intravenous, gavage, or drinking water exposure	Venous blood concentration	Neurobehavioral effects in humans	• Predict effect levels at 4, 8, 24 h, and 14 days, based on POD for a 1 h exposure

Trichloroethylene (TCE)[177]	*Rat/mouse/human model*
	• Comprised of main model for TCE, along with submodels for oxidative metabolism, conjugative metabolism (rat and human only), trichloroethanol (TCOH), trichloroethanol-glucuronide conjugate (TCOG), and trichloroacetic acid (TCA)
	  • Main TCE model includes nine compartments: respiratory tract, rapidly and slowly perfused tissues, fat, gut, liver, kidney, stomach, and duodenum
	  • Oxidative metabolism submodel estimates oxidation of TCE to TCOH, TCA, and other metabolites in lung and the rest of the body
	  • Conjugative metabolism submodel estimates formation of glutathione (GSH) conjugate in liver (humans only) and kidney (rats and humans), bioactivation of glutathione conjugate in kidney, and urinary excretion
	  • Submodels for TCOH, TCOG, and TCA include the liver and the rest of the body, with an additional bile compartment in the TCOG submodel
	• Saturable metabolism
	  • Oxidation of TCE to TCOH in liver and lung; GSH conjugation of TCE in liver and kidney
	  • Oxidation of TCOH to TCA and conjugation with glucuronide in liver
	• Estimates disposition of TCE following inhalation, oral or intravenous exposure
		Amount of TCE oxidized (per kg body weight)$^{3/4}$	Decreased thymus weight in mice
			Fetal heart malformations in rats
				• Estimate HED for RfD
				  • Replace PK component of intraindividual and interspecies UFs
				• Estimate HEC for RfC, based on route-to-route extrapolation
				  • Replace PK component of intraindividual and interspecies UFs
				• Enable route-to-route extrapolation from IUR to CSF

Vinyl chloride[178]	*Rat/human model*
	• Five compartments: lung, liver, fat, richly and slowly perfused tissues
	• Saturable metabolism in liver via high affinity/low capacity and low affinity/high capacity pathways
	• Estimates disposition of vinyl chloride following inhalation or oral exposure
		Amount of vinyl chloride metabolized per liver volume (for route–route extrapolation)	Liver cell polymorphisms and cysts in rats	• Estimate HED for RfD
				  • Replace PK component of interspecies UF
				• Estimate HEC for RfC, based on route-to-route extrapolation
				  • Replace PK component of interspecies UF
				• Estimate HED based on doses in rat study for deriving CSF
				• Estimate HEC based on concentrations in rat study for deriving IUR

Notes: AUC, area under the curve; CSF, cancer slope factor; COHb, carboxyhemoglobin; HEC, human equivalent concentration; GST, glutathione S-transferase; HED, human equivalent dose; IUR, inhalation unit risk; PK, pharmacokinetic; POD, point of departure; RfC, reference concentration; RfD, reference dose; UF, uncertainty factor.

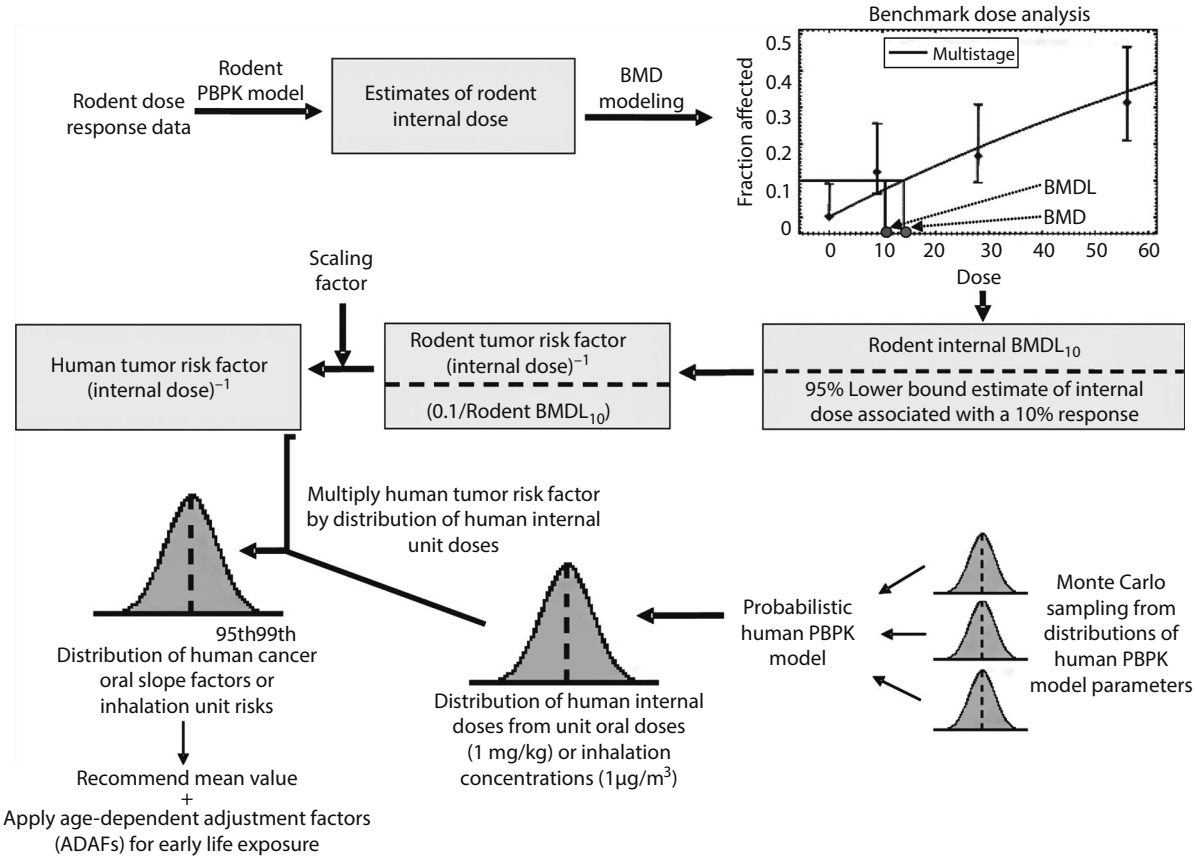

FIGURE 2.8 Use of PBPK models for derivation of CSF and IUR for dichloromethane. (From U.S. Environmental Protection Agency, Toxicological Review of Dichloromethane (Methylene Chloride) (CAS No. 75-09-2) in Support of Summary Information on the Integrated Risk Information System (IRIS) (Final), EPA/635/R-10/003F, 2011.)

the relatively low levels of environmental chemicals to which humans are typically exposed can be difficult. Another limitation of PBPK models is that, despite modeling processes that vary with life stages, such as metabolic clearance rates,[183,184] they are typically parameterized using adult values due to lack of availability of data for other life stages.[139]

ROLE OF HIGH-RISK GROUPS

The "Evaluation of Noncancer Effects" section described how AELs are used by regulatory agencies to estimate acceptable levels for noncancer effects. One of the UFs used for deriving AELs accounts for variations in population susceptibility. The purpose of this section is to expand upon that issue, describe the basis for variations in susceptibility and the magnitude of that variation, and demonstrate the relationship of this issue to the regulatory process. (For more detail, the reader is referred to references.[185–187])

There is a high degree of variability in the exposure level required to elicit a response in humans.[185,188] Knowing which groups of individuals are at high risk with respect to pollutants, for example, is very important, since these individuals will be the first to experience morbidity and mortality as pollutant levels increase. If the high-risk segments of a population are protected, the entire population is thus protected.

Consideration of Specific High-Risk Groups

A better approach than the use of generic UFs is to consider, when data are available, specific high-risk groups on a chemical-by-chemical basis. For certain chemicals, there are clear examples of groups more susceptible to adverse health effects (reviewed in Refs. [189–191]). These include the following:

- Individuals with genetic variations in metabolism. For example, a slow acetylator phenotype is associated with an increased risk of bladder cancer following exposure to aromatic amine dyes.[189]
- Individuals with inherited genetic defects. For example, individuals with xeroderma pigmentosum, a rare autosomal recessive disease, have defects in the nucleotide excision DNA repair pathway, which increases the risk of skin cancer by more than 1500-fold.[191,192]
- Individuals with preexisting illness. For example, individuals with asthma are more susceptible to air pollutants such as ozone and PM,[190,193] and those with hepatitis B are more susceptible to liver cancer.[189]

Other factors that can affect susceptibility to environmental chemicals include gender, age, lifestyle (e.g., cigarettes, alcohol, diet), and low socioeconomic status, which can be

associated with poor living conditions and inadequate health care.[27,194,195] The role of diet in the etiology of certain types of cancer is suggested in studies demonstrating an inverse relationship between the amount of vitamin A in the diet and susceptibility to hydrocarbon-induced epithelial cancers.[196] With respect to age, both young children and the elderly may be more susceptible to certain chemicals—children may be more susceptible due to reduced levels of xenobiotic-metabolizing enzymes, while the elderly may be more susceptible due to impaired cardiovascular and renal function.[184] Thus, it is likely that—even given the same exposure—individuals are not equally susceptible to the induction of cancer and other adverse health effects and, in many cases, the differential susceptibility could be large. In addition, certain subgroups may be at greater risk—not because of an inherent difference in toxicological susceptibility but because they are more likely to be exposed. For example, young children are at greater risk from soil contaminants because they tend to incidentally ingest more soil and dust than older children and adults due to significant hand-to-mouth activity.[197] Exposure to chemicals in the environment may also be higher in low-income communities, which are more likely to be located near one or more pollution sources.[194]

Regulatory agencies have focused in particular on the potential for children to be more susceptible to environmental chemicals. In 1996, the EPA emphasized its focus of protecting infants and children in a report titled *A National Agenda to Protect Children's Health from Environmental Threats*.[198] The 1996 FQPA requires use of an additional tenfold UF for pesticides to account for potential prenatal and postnatal developmental toxicity[199] for agents. The UF is not used if the agent has not been demonstrated to exhibit developmental toxicity in a reliable testing program. As noted by Roberts,[200] children may be more susceptible because many cells and organs are undergoing growth and development and have not yet matured. Metabolic capacity of the liver is also not fully developed when children are born, although most metabolic enzymes reach adult levels by 1 year of age.[183] A child's diet and physical environment, and therefore his or her exposure potential, may vary significantly from that of an adult. For many routes of exposure (air, food, water, and dermal exposures), chemical intake (on a per kilogram body weight basis) is generally greater for infants and children than adults.[201]

However, a subgroup at high risk for one chemical is not necessarily at high risk for other chemical exposures. For example, although children are often assumed to be more sensitive than adults, this is not always the case. Reactions to pharmaceuticals, since they are more widely studied than responses to environmental exposures, can be considered as examples. Acute overdoses of acetaminophen result in less hepatotoxicity in children than adults with comparable plasma concentrations, possibly due to differences in metabolism.[202]

There is currently debate about whether existing risk cancer assessment methods adequately account for more highly susceptible groups. Only recently has evaluation of carcinogen exposure addressed the role of population variability in susceptibility to carcinogens. As discussed in the following, the EPA now has guidelines to account for increased susceptibility of children to mutagenic carcinogens.[203] While differential susceptibility has generally not been addressed in cancer risk assessment, the conservatism of the process has been assumed to result in adequate protection of high-risk groups.

For noncancer effects, there is debate over the appropriate UFs to account for high-risk subgroups. At a conference organized by the ILSI and EPA,[204] it was suggested that "in many cases, genetic variation in human susceptibility may be greater than an order of magnitude when comparing differences between children and adults." A coalition of farm food, manufacturing, and pest management organizations concluded that it was not necessary to use an additional UF of 10 (as required by the FQPA) *across the board* to protect infants and children.[205] The coalition also concluded that the standard default UFs are adequate for a pesticide with a complete and reliable database, and an additional UF "should only be applied to an endpoint that is relevant to protection of fetuses, infants, and/or children."[205] The EPA is looking into establishing criteria for appropriate use of the tenfold additional FQPA UF.[199,206] In 2002, the EPA's RfD/RfC Technical Panel concluded that the intraspecies UF and, if necessary, the database UF should account for uncertainty regarding differences in susceptibility for perinatal exposures, such that for most chemicals an additional UF of 10 to protect infants children should not be necessary.[139] Overall, the best approach is to consider susceptible subgroups on a case-by-case basis when data are available, for both carcinogens and noncarcinogens.

Regulatory Implications

The role of population variability should be considered by regulatory agencies in risk assessments for both carcinogens and noncarcinogens. Identification and quantitative characterization of susceptible populations could provide decision-makers with a theoretical framework on which to base regulatory action. For example, Tamplin and Gofman[207] have employed knowledge of susceptible populations in predicting the incidence of cancer from radiation pollution in drinking water to help define acceptable levels of exposure. They assumed that the latency period is shorter for in utero exposure than for all radiation exposure beyond birth (i.e., 5 vs. 15 years). Consideration of the increased susceptibility of the fetus to radiation-induced cancer resulted in greater estimates of cancer risk.[208]

The EPA has specifically evaluated the increased sensitivity of high-risk groups in setting NAAQS for the criteria air pollutants (i.e., CO, lead, NO_2, ozone, particulates, and sulfur dioxide) and establishing drinking water standards for some environmental chemicals. Examples of the high-risk groups considered are shown in Table 2.15. For instance, the NAAQS for lead considers high-risk populations in a quantitative way by estimating the fraction of the susceptible subpopulation (children) that would be protected at different air levels of lead.[209] A detailed description of the EPA's consideration of high-risk groups in the derivation of drinking water standards for nitrates and cadmium (Cd) is presented in the following.

TABLE 2.15
High-Risk Groups in the Derivation of Standards by the EPA

A. Drinking Water Standards

Substance	High-Risk Condition Considered
Arsenic	None
Barium	No specific groups, but a safety factor of two incorporated to account for variation (or increased susceptibility) within the human population
Cadmium	None
Fluoride	Children—to prevent mottling of teeth
Lead	Children—to prevent neurological disorders
Nitrate	Infants—to protect against methemoglobinemia
Selenium	None
Sodium (no standard)	Individuals with heart and kidney disease
Chlorinated hydrocarbon insecticides (noncarcinogenic)	None
Chlorophenoxy herbicides (noncarcinogenic)	None

B. National Ambient Air Quality Standard

Substance	Original Group	Primary Groups Currently Considered
Carbon monoxide	Individuals with neurological or visual impairment	Adults with heart disease (angina, coronary artery disease)
Lead	Children—to protect against neurological and hematological impairment	Same
Nitrogen dioxide	Children—to protect against respiratory infections; also concern for changes in lung structure	Same
Ozone	Asthmatics	Exercisers, individuals with preexisting disease
Particulates	Elderly, individuals with cardiopulmonary disease	Same
Sulfur dioxide	Elderly, individuals with cardiopulmonary disease	Asthmatics

Nitrates in Drinking Water

The drinking water standard of 10 mg nitrate (NO_3^{-2}) as mg nitrogen per liter is designed to prevent the formation of elevated levels of methemoglobin (MetHb) in infants. In the presence of nitrite (NO_2^{-1}) formed from NO_3^{-2}, hemoglobin is oxidized to MetHb, which is not able to reversibly combine with oxygen. Levels of 1%–2% and 2%–5% MetHb are typical in the blood of adults and infants, respectively. When concentrations of MetHb are less than 5%, there are no obvious indications of toxicity. However, with levels of MetHb from 5% to 10%, clinical signs of toxicity (e.g., cyanosis) may appear.[185]

Compared to adults, infants are at considerable risk for nitrate-related toxicity. Factors that predispose infants to the development of MetHb formation include the following:

1. The incompletely developed ability to secrete gastric acid. This permits the gastric pH to be high enough (5–7 pH) to permit the growth of nitrate-reducing bacteria in the gastrointestinal tract, which facilitates conversion of NO_3^{-2} to NO_2^{-1} before absorption into the circulation.[210]
2. The higher levels of fetal hemoglobin in infants. This form of hemoglobin is more susceptible than adult hemoglobin to oxidation to MetHb.[211]
3. The diminished enzymatic capability of infants to reduce MetHb to hemoglobin.[212]

Research has revealed that levels of NO_3^{-2} beyond 20 mg/L result in a marked increase in the frequency of methemoglobinemia in infants but not adults.[185] Consequently, a drinking water standard of 10 mg/L is principally designed to prevent the occurrence of elevated levels of MetHb in infants, whereas a concentration of 20 mg/L would still protect adults.

Cadmium

Studies with rats show that renal damage is initiated at a kidney concentration of 200 ppm Cd. The EPA calculated that humans would need to ingest 50 g Cd/day for 50 years to reach this level of 200 ppm in their kidneys. In the derivation of the Cd drinking water standard, the EPA assumed a daily Cd exposure of 75 μg from the diet and 20 μg from water. This 20 μg Cd/day from drinking water would occur at a level

of 0.01 mg/L. The total daily Cd exposure is therefore approximately 95 µg Cd/day; thus, a safety factor of 4 was assumed.

In proposing its drinking water standard for Cd, the EPA requested feedback from the public as to whether the standard should include additional protection for cigarette smokers (smoking is a source of appreciable Cd exposure; approximately 1.5 µg Cd/cigarette).[185] Of the 52 comments received by the EPA on this issue, only three suggested the standard be modified to include protection for cigarette smokers. The EPA decided not to incorporate additional safety factors to protect smokers,[125] demonstrating a situation in which protection of a high-risk group was not taken into account in derivation of a standard.

Susceptible Groups and Early-Life-Stage Exposure to Carcinogens

Recent analyses by Ginsberg[213] and others (e.g., see Preston)[214] have evaluated whether children might represent a susceptible population with respect to carcinogen exposure. Answering this question is complicated by limitations in the available data. Relevant human data are derived primarily from epidemiological studies of radiation exposure and cancer development in atomic bomb survivors. Such studies provide evidence for increased risk of certain cancers from early-life exposure; however, it is difficult to extrapolate from studies of ionizing radiation, a direct-acting mutagen that can induce mutation at any stage of the life cycle, to chemical carcinogens, the majority of which are not direct-acting mutagens and require cell proliferation for indication of mutation (often via indirect mechanisms).[214]

Nonetheless, animal bioassays provide some insights on early-life-stage exposures to carcinogenic agents. For example, a greater tumorigenic response from early-life-stage than from later-life-stage exposures has been observed following acute exposure to mutagenic agents.[203,213] Mechanistic information also suggests a greater susceptibility to developing cancer for early-life-stage exposure from mutagenic agents. The high proliferation rate of cells early in life may increase the likelihood that a cell containing damaged DNA could replicate before the DNA is repaired. Studies of carcinogens with other MoAs (e.g., hormonally mediated) or genotoxic agents that are not direct acting but include genetic damage through other means (such as generation of reactive oxygen species) provide a more complicated picture, with evidence for and against early-life-stage susceptibility.

In response to concerns that children may be more susceptible to certain carcinogens than adults, the EPA developed guidance for early-life-stage exposures to carcinogens. Figure 2.9[203] provides a schematic for this approach. As with the 2005 EPA cancer guidelines (discussed in "Approaches to Interpretation of Carcinogenicity Findings" section), an understanding of the MoA is an important component of the approach. For agents with either a nonlinear or linear but nonmutagenic MoA, the dose–response approach is unchanged. However, for agents that the EPA concluded were likely to be linear due to a mutagenic MoA, the first approach recommended, where feasible, is chemical-specific adjustment. Where such an adjustment is not feasible, age-dependent adjustment factors are proposed—a tenfold increase in the potency factor for ages up to 2 years and a threefold increase in potency for ages 2 to <16 years of age.[203] The underlying premise is that direct-acting mutagens are likely to exhibit a linear, no-threshold dose–response; as discussed earlier in this chapter, this assumption considers neither repair mechanisms nor the potential for hormetic responses and, thus, may be especially conservative. The implications of these recommendations for regulatory decision-making remain to be seen.

Increased susceptibility of children to mutagenic carcinogens is directly incorporated in the EPA's CSF for vinyl chloride, for which there is evidence from studies in laboratory animals that early-life exposures differ both quantitatively and qualitatively from exposures occurring later in life.[178] To account for increased susceptibility of children, the EPA recommends a slope factor of 1.4 (per mg/kg-day) for lifetime exposure starting at birth, rather than the slope factor of 0.72 (per mg/kg-day) recommended for exposure during adulthood.[215]

IMPLICATIONS OF CHEMICAL INTERACTIONS FOR THE REGULATORY PROCESS

One of the major difficulties in current environmental public health practice is that the focus is on a limited number of environmental contaminants, with little consideration of interactive effects among pollutants. In fact, the number of environmental pollutants in different media is large, making it difficult to estimate the degree of public health protection afforded by the current regulatory paradigm (which largely focuses on single pollutants).

Recognition of the importance of considering potential interactions in the regulatory arena is not new. In 1996, the Safe Drinking Water Act Amendments required the EPA to address the potential for chemical interactions; efforts to date have focused primarily on disinfection by-products.[195] Also in 1996, the FQPA required the EPA to evaluate cumulative exposure to pesticides sharing a common mechanism of toxicity.[216] To date, cumulative risk assessments have been conducted for four groups of pesticides—organophosphates, N-methyl carbamates, triazines, and chloroacetanlides.[217]

Still, it is clear that, in many cases, the scientific and regulatory communities can do more to address the issue of multiple and/or interactive chemical exposures. In fact, animal models and human epidemiological studies show that interactions do occur among chemicals and that this can result, under certain circumstances, in greater-than-additive effects. For example, uranium miners who do not smoke have a fourfold greater risk of cancer than nonsmokers in the general population. However, uranium miners who smoke display a 40-fold greater cancer risk than the general population of nonsmokers.[218]

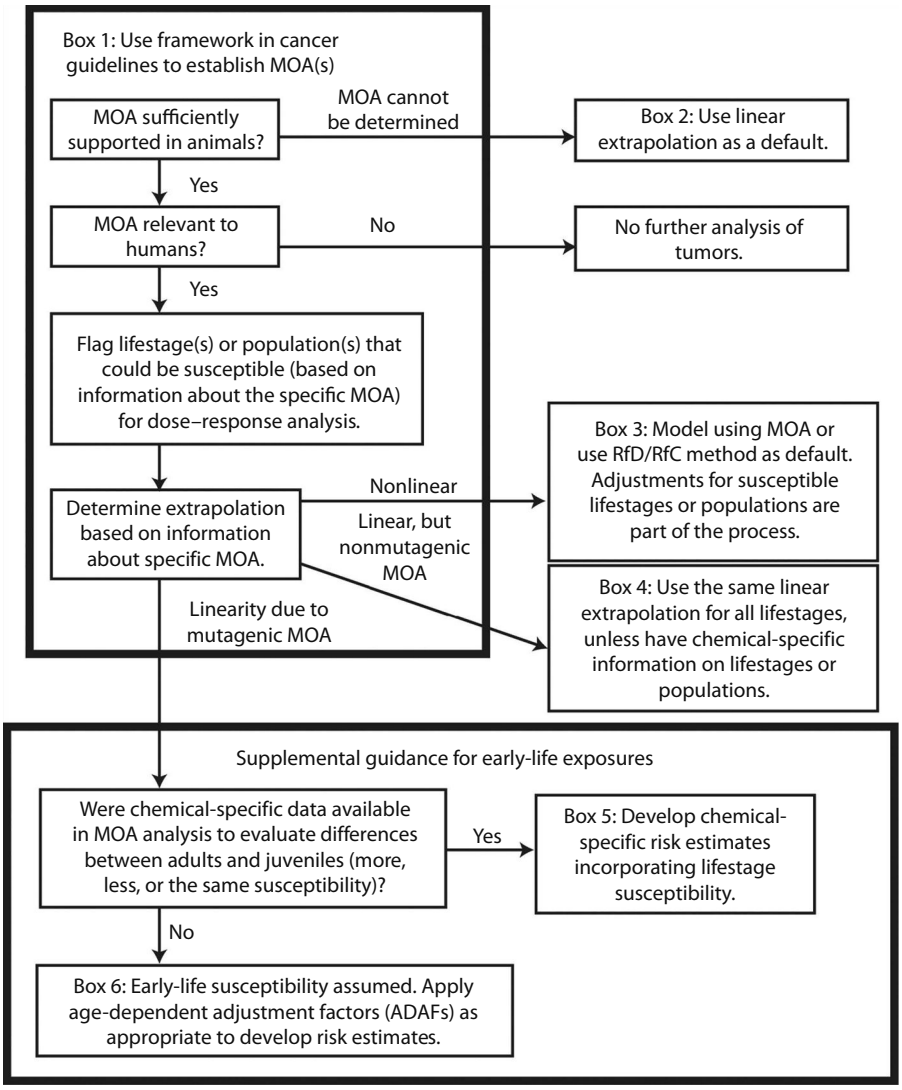

FIGURE 2.9 Flowchart for early-life risk assessment using MoA framework. (From U.S. Environmental Protection Agency, *Supplemental Guidance for Assessing Susceptibility from Early Life Stage Exposure to Carcinogens*, Risk Assessment Forum, Washington, DC, EPA/630/R-03/003F, 2005.)

Interactions have been studied for many years by the drug industry, insecticide manufacturers, and forensic/clinical toxicologists. Given the widespread use of multiple drug therapy, the need to anticipate possible adverse interactions has been essential. Thus, much of the basis of our current understanding of toxicological interactions is derived from the pharmaceutical industry. It should be recognized that there is uncertainty in extrapolating from drug exposures where doses are relatively high (i.e., by definition, at pharmacologically active doses) to environmental exposures, which are typically much lower than doses with established effects.

Chemical interactions have been broadly classified by three general terms: *addition* (additivity), when the toxic effect produced by two or more chemicals in combination is equivalent to that expected by simple summation of their individual effects; *antagonism*, when the effect of a combination is less than the sum of the individual effects; and *synergism*, when the effect of the combination is greater than would be predicted by summation of the individual effects. Other terms have been used, such as indifference and potentiation, which represent specialized aspects of antagonism and synergism, respectively.

Additive interactions for chemical mixtures can be characterized further as being either dose or response additive. The underlying assumption of dose additivity is that the individual chemicals in the mixture are toxicologically similar; therefore, the potency of the mixture is a function of the sum of the potencies of the individual chemicals. This approach is used for noncancer hazards, by way of the hazard index, which sums hazard quotients across chemicals and pathways.[219,220] An implication of this approach, as reflected in Figure 2.10, is that even though chemicals individually cause no toxicological response, they may result in toxicity when multiple chemicals (all below their NOAELs) are present in a mixture. In contrast, response additivity

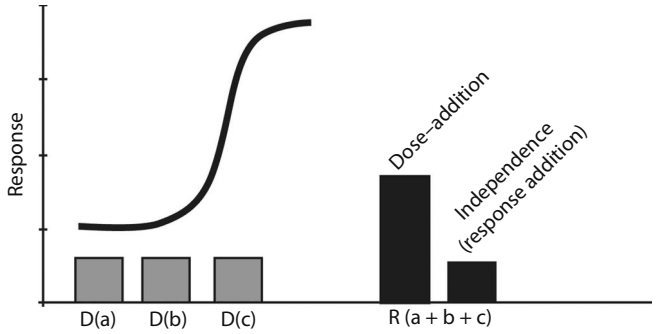

FIGURE 2.10 A model dose–response curve for an effect with a threshold.[222] Below the curve, bars indicate doses D(a), D(b), and D(c), each of which is one-half the toxic threshold for chemicals a, b, and c, respectively. The calculated combined response R (a + b+ c) would be greater or less than the threshold depending on whether a dose addition or independence model was used to predict the combined action of chemicals a, b, and c in a mixture. (Reprinted from *Toxicol. Appl. Pharmacol*., 201(2), Borgert, C.J., Quill, T.F., McCarty, L.S., and Mason, A.M., Can mode of action predict mixture toxicity for risk assessment?, 85–96, Copyright 2004, with permission from Elsevier.)

assumes that each chemical in a mixture acts independently to cause a similar health endpoint; thus, the toxicity of a mixture is a function of the toxic effects of the individual compounds.[220] In the example in Figure 2.10, response additivity would imply that no toxicity would ensue, since no individual chemical is associated with any toxicological responses (see also Monosson).[221] The EPA uses the response-addition approach for evaluating cancer risks, by first estimating cancer risk for each individual chemical in a mixture and then summing the individual cancer risks across chemicals.[220]

Implications of Chemical Interactions

Frequently, little information is available on toxic mechanisms. Nonetheless, regulatory agencies need to develop approaches in such situations when reasonable mechanistic predictions cannot be made. To this end, Finney[223] developed a theoretical mathematical approach for predicting the degree of toxicity derived from various types of chemical interactions. Of the 36 pairs of mixtures of industrial vapors tested for acute toxicity in rats, Pozzani and coworkers[224] found that only two deviated significantly from the calculations of Finney's theoretical approach for additive joint toxicity. According to Smyth et al.,[225] the study by Pozzani and coworkers[224] supported the hypothesis that the acute toxicity of randomly chosen chemical mixtures has a high likelihood of being accurately predicted by Finney's theoretical formula for additive joint toxicity. In an attempt "to evaluate the overall confidence that can be placed on the prediction of the joint toxicity of many chemical pairs," Smyth et al.[225] studied the toxicity of 27 industrial chemicals in all possible pairs to rats. Their results were consistent with Finney's[223] prediction that most interactions should be considered as additive until proven otherwise. Smyth et al.,[225] in agreement with the general findings of Pozzani and coworkers,[224] concluded that approximately 5% of the various combinations tested exhibited effects that were either less than or greater than additive.

However, it should be noted that recent studies of chemicals in mixtures at doses below the NOAEL provide evidence that dose additivity may overpredict the toxicity of a mixture (in which case, response additivity is a more appropriate characterization of the interaction). For example, Feron and coworkers[226] observed that exposure to a mixture of nephrotoxic chemicals, each below the NOAEL, did not result in a toxic response, suggesting that dose additivity may not appropriately describe interaction potential at low doses. A similar conclusion was reached by Borgert et al.[222] who postulated that the lack of additivity may reflect a different MoA at low doses.

Thus, it is possible that synergistic interactions—the type of interactions of greatest regulatory concern—may be less likely to occur at environmentally relevant exposure levels than at higher (e.g., pharmaceutical or some occupational) exposure levels.

Approaches Used by Regulatory Agencies to Assess Interactions

Despite the frequent lack of a clear mechanistic understanding of how chemicals may interact, regulatory agencies have developed interim approaches to facilitate the decision-making process. In this section, some of the typical approaches used by agencies are highlighted with illustrative examples.

Hazard Index Approach

Perhaps the simplest approach is the assumption of additivity of hazard. In this approach (applied to noncarcinogens), hazard indices (the ratio between the estimated dose and the AEL; see "Acceptable Exposure Level" section) are summed across chemicals and routes of exposure to obtain a total hazard index for a particular exposure setting.[227] If the decision criterion of a total hazard index of 1 is exceeded, further review is performed to determine which chemicals act at the same target organ. A subsequent summation is performed for chemicals grouped together by target organ. While this approach is useful as a screening approach, it has several limitations that must be considered when interpreting the results. These include (but are not limited to) the following:

- AELs (the denominator in the hazard index) for different chemicals contain different types and magnitudes of UFs. Thus, differences in the magnitude of a hazard index for a particular chemical or a pathway of exposure may reflect intrinsic differences in hazard as well as differences in the uncertainty of a particular toxicity value. This limitation can be addressed by use of the BMRs and PBPK models for deriving AELs.

- Different types of interactive effects are possible, even for chemicals that act at the same target organ. For example, organophosphates, which act via the inhibition of acetylcholinesterase at nerve endings, would generally be presumed to act in an additive manner.[228] In contrast, when consumed simultaneously, TCE and alcohol, both of which affect the central nervous system, can act synergistically (e.g., producing *degreaser's flush*); however, chronic alcohol consumption can, by induction of metabolizing enzymes, diminish the response to TCE.[80]

Both the EPA and ATSDR recommend using the hazard index approach as a default for most mixtures.[219,220] The hazard index approach, which assumes that greater-than-additive interactions are not likely at AELs, is likely appropriate in most situations. However, the possibility for greater-than-additive interaction effects due to cumulative, low-level chronic exposure cannot be completely ruled out.[229]

Toxicity Equivalency Factor Approach

The toxicity equivalency factor (TEF) approach has been applied to mixtures that contain structurally and toxicologically similar chemicals. Perhaps one of the best-known examples of the TEF approach was developed by the EPA for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and other dioxin-like compounds, including polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), and PCBs.[230] This approach is based on the assumption that PCDDs and PCDFs exert toxicity through binding to the aryl hydrocarbon receptor (AhR) with subsequent effects on transcription and translational events responsible for toxicity. The most potent PCDD, 2,3,7,8-TCDD, has the greatest affinity for the AhR; hence, it is assigned a TEF of 1.0. TEFs are developed for individual PCDDs and PCDFs and expressed as a fraction (typically in orders of magnitude) of that of TCDD. Thus, RfDs and CSFs for PCDDs/PCDFs are calculated as a ratio to the RfD and CSF for 2,3,7,8-TCDD. While there is experimental support for this approach based on mixtures of PCDDs and PCDFs, there are few, if any, data from long-term studies.[231] Other uncertainties in this approach include the choice of a particular TEF value, which can be influenced by selection of endpoint, exposure duration, and dose, as well as the assumption of additivity, where competitive interactions may occur at sufficiently high doses.[232]

Cumulative Risk Assessment

There is a growing recognition, both in the United States and Europe, regarding the potential for cumulative risks from combined exposure to chemical as well as nonchemical stressors, such as poverty, poor diet, living conditions, and inadequate health care.[27,195] Specifically, low-income communities, many of which have a high percentage of minority populations, are more likely to be located near multiple pollution sources. Furthermore, results from some studies indicate that individuals with low income and education levels may be more sensitive to pollutant exposures.[194] In a study regarding ways to improve how the EPA conducts risk assessment, the NRC recommended that the EPA expand its efforts at assessing cumulative risks from chemical and nonchemical stressors, with the short-term goals of developing default approaches and databases and long-term goals of sponsoring research, including epidemiology and PBPK modeling, to evaluate interactions.[27]

Several states have initiated efforts to evaluate cumulative risks from chemical and nonchemical stressors. The New Jersey Department of Environmental Protection (NJDEP) developed a screening tool to integrate measures of exposure to chemicals in the environment with demographic and socioeconomic factors. For evaluating chemical exposures, NJDEP uses a variety of data sources, including the EPA's cancer risk and diesel data from the National-Scale Air Toxics Assessments (NATA), state emissions inventories, traffic density, and density of contaminated sites, dry cleaners, and junk yards.[233] In 2010, the CalEPA OEHHA published a framework for assessing cumulative impacts of chemical and nonchemical stressors.[194]

Complex Mixture Approach

There are certain classes of chemicals for which toxicological data exist primarily for the complex mixture itself, with limited data for individual constituents. An example of this type of mixture is PCBs. Historically, in the United States, PCBs were manufactured under the trade name of Aroclors for use in electrical capacitors. Different Aroclor mixtures contained different percentages of chlorine. For example, Aroclor 1242 contained approximately 42% chlorine.[234] Much of the toxicity testing of PCBs consists of studies of different Aroclor mixtures.[234,235] As a result, toxicity criteria for PCBs are typically expressed as Aroclor-specific values, although there are also congener-specific toxicity criteria for certain dioxin-like PCB congeners.[236] For example, ATSDR developed a chronic minimal risk level (MRL, a value conceptually comparable to the RfD), for Aroclor 1254 based on immunological effects in monkeys exposed to Aroclor 1254 in feed for 23 months.[232] While this approach does not require assumptions on how individual constituents will interact, it does assume that the characteristics of the mixture in the environment are the same as in laboratory studies. Unfortunately, this assumption is not always correct; complex mixtures frequently undergo chemical transformations in the environment. Moreover, the individual constituents may partition differently in the environment. In the case of PCBs, for example, the more chlorinated forms bioaccumulate in fish more readily than the less chlorinated forms.[180] Table 2.16 lists chemical mixtures for which toxicity criteria have been developed.

TABLE 2.16
Toxicity Criteria Based on Chemical Mixtures

Chemical	Description of Mixture	Toxicity Criteria	Basis
Aroclor 1016[237]	Mixture of PCB congeners	RfD	Reduced birth weight (monkeys)
Coke oven emissions[238]	Complex mixture produced from carbonization of bituminous coal, contains gases and respirable particulate matter, including polycyclic organic matter, aromatic compounds (e.g., beta-naphthylamine, benzene), trace metals (e.g., arsenic, beryllium, cadmium, chromium, lead, nickel), and gases (e.g., nitric oxide, sulfur dioxide)[239]	IUR	Respiratory cancer (humans, occupational)
Diesel engine exhaust[240]	Complex mixture of hundreds of constituents in gas or particulate form. Key gaseous components of toxicological concern including formaldehyde, acetaldehyde, acrolein, benzene, 1,3-butadiene, and PAHs[241]	RfC	Pulmonary inflammation and histopathology (rats)
Fuel oils[242]	Mixtures of aliphatic and aromatic hydrocarbons	MRL (inhalation, acute)	Ataxia, disturbed gait (mice)
Jet fuels (JP-4/JP-7)[243]	Refined crude petroleum oil blended with other chemicals per specifications of the U.S. Air Force	MRL (inhalation, intermediate) MRL (inhalation, chronic)	Hepatic toxicity (mice) Hepatic toxicity (rats)
Polybrominated biphenyls[244]	Similar to PCBs, with bromine rather than chlorine substituted on phenyl rings	MRL (oral, acute)	Decreased serum thyroid T4 levels (rats)

Notes: RfC, reference concentration; RfD, reference dose; IUR, inhalation unit risk; MRL, minimal risk level.

Conclusions

Consideration of interactive effects in the regulatory arena is an evolving process. Because, in many cases, data are limited, simplifying assumptions are often used (e.g., the assumption of additivity for chemicals that act via the same target organ). As scientists acquire greater mechanistic understanding of interactive effects in complex mixtures, approaches that better reflect molecular events, such as the TEF approach, can be developed that can be used for chemicals that are structurally and toxicologically similar. It must be recognized, however, that uncertainty remains regarding the extent to which such effects occur at environmentally relevant exposure levels and under exposure conditions that do not mimic those tested in the laboratory (e.g., intermittent vs. chronic exposures).

CONCLUSIONS

This chapter has demonstrated the multiple applications of toxicology to the regulatory process. Applications include developing and evaluating chemical testing protocols, such as for endocrine disruptors, developing classification schemes (to date, mainly for carcinogens) aimed at characterizing the types of toxic effects that might be observed in humans, and developing health-based criteria for chemicals in various media (food, water, air, soil) or notification levels for release of chemicals under accidental circumstances.

In addition, toxicology is used in the regulatory process to help assess potential risk associated with defined exposure levels. The traditional paradigm is different for assessing risks related to carcinogens versus noncarcinogens: for carcinogens, potential risk is defined as an upper bound estimate of excess cancer risk based on cancer incidence at high dose levels; for noncarcinogens, potential risk is defined as the ratio of the estimated exposure to an exposure level associated with negligible, if any, risk. Advances in the understanding of toxicological mechanisms indicate that these methodologies are not appropriate in all circumstances. Some carcinogens, such as those that operate by receptor-mediated or cytotoxic mechanisms, may exhibit a threshold or nonlinear dose–response relationship; thus, exposure levels associated with virtually zero risk might be defined. Examples of chemicals with these types of dose–response relationships are saccharin and phenobarbital. The EPA's recent cancer risk assessment guidelines, which consider different dose–response relationships for different carcinogens, represent an important development in this area.

The use of BMRs and PBPK models for developing AELs is an example of recent advances in noncarcinogenic risk assessment. Our understanding of certain noncarcinogenic effects, such as angina associated with CO exposure, has been reasonably advanced; in this example, risks from CO are more fully described in terms of the number of individuals with heart disease who might be expected to exceed defined COHb levels under certain exposure conditions.

Toxicology is frequently applied in the regulatory context of developing permissible exposure levels in different exposure media, such as ambient air, drinking water, or food. As discussed in this chapter, defining a permissible health-based exposure level is only one part of developing a regulatory standard. Other important factors in the regulatory process include risk

management issues (such as the definition of acceptable risk), the weighing of the costs and technical feasibility of reducing risk, the availability of alternatives, and the consideration of potential new risks created by reducing the original risk (e.g., use of a less well-tested substitute chemical). Issues of equity and whether certain members of the population are unfairly burdened by chemical exposure represent other considerations.

In order to provide risk managers with the full information needed for making sound decisions, it is critical that toxicologists participating in the regulatory process effectively communicate not only the results of a risk assessment but the associated uncertainties as well. In addition, despite pressure to employ older methods for the sake of consistency, toxicologists must work to develop and encourage the use of new methodologies reflecting the advances in our understanding of toxicological mechanisms. May this chapter serve as a useful guide to the use of better science in the regulatory process.

QUESTIONS

2.1 How do different approaches used for noncancer risk assessment (e.g., BMD, RfD, and the distributional population approach) address susceptible populations?

2.2 What is MoA, and how is it used in carcinogen classification and in selecting dose–response models for cancer risk assessment?

ACKNOWLEDGMENTS

The authors wish to thank Ruthann Rudel and Tracey Slayton for their technical contributions to prior versions of this chapter, Ruth Lyddy and Heather Lynch for their technical assistance, and Bethany Allen, Ruth Buchman, and Adam Isbitsky for their editorial assistance.

3 Dose–Response
A Fundamental Concept in Toxicology

Edward J. Calabrese

CONTENTS

INTRODUCTION

What is the most fundamental concept in toxicology? Is there a most fundamental concept in toxicology? If there is, would it affect how toxicology is taught, how textbooks are written and organized, how toxicological research is conducted, and how hazard assessments are designed and executed?

Within this context, if one were to name some of the most significant discoveries in toxicology, what would they be? Would these discoveries assist in clarifying and defining the most fundamental concept in toxicology?

While there has been no published survey on this conjectural topic of the most important discoveries in toxicology, some possibilities might include xenobiotic metabolism, including cytochrome P450, phase 2 detoxification, the induction of mutations and cancer with ionizing radiation and chemicals, the linkage of mutation with cancer, DNA repair, biostatistical assessment of experimental data, receptor biology and cell signaling, epigenetics, intercellular communication, and apoptosis, among others. Each important toxicological discovery is expressed within a dose–response framework that affects critical dose-dependent transitions via physiological, pharmacological, and toxicological mechanisms that account for when, why, and how agents induce effects on biological systems.

The shape of the dose–response guides clinical medicine and therapeutics. It also affects the strategy and design of the hazard assessment, risk assessment processes, and regulatory decisions. The toxicology of the twenty-first-century report of the U.S. National Academy of Sciences [1] is set within a cellular and systems biology framework to derive reliable mechanistic understandings of the dose–response, especially in the low-dose zone. The long-stated euphemism that all roads lead to Rome has its toxicological equivalent. All toxicological discoveries and emerging concepts will lead to improved understandings of dose–response relationships.

Getting the dose–response right is at the core of toxicology. Failure to do so has profound implications for environmental risk assessment, regulatory decisions, as well as drug discovery and success in the clinical trial, therapeutics, and health care. Getting the dose right also affects environmental health with concerns over the effects of agents, such as pesticides on nontarget species, as well as their persistence and capacity to interact with other agents. The dose–response question is therefore an important one, dominating biomedical themes and social concerns.

The study of the dose–response is broad and complex. To understand the how's and why's of the dose–response requires the capacity to integrate findings from a wide range of highly specialized areas of research. It is very interdisciplinary by nature.

The dose–response is not simply a tool of toxicology; it is much more, being even more expansive than the concept of toxicity per se. Within this framework, knowledge of the dose–response is basic to the assessment of interspecies differences in response to xenobiotics and the survival strategies adopted within the plant and animal domains. Dose–response assessments are, therefore, at the core of not only toxic responses but also adaptive strategies.

The dose–response concept is of such fundamental importance to toxicology that it provides a framework by which toxicology may be defined. The concept of the dose–response implies the need to assess the entire dose–response continuum from very low doses that are seemingly without demonstrable effect to higher doses that cause frank toxic effects and mortality and the underlying mechanisms of these effects. Thus, contrary to what may be broadly believed and typically taught, toxicology is not a discipline that is exclusively concerned with adverse effects. It should be concerned with all processes that affect life, including adaptive responses. Ignoring adaptive responses in the study of toxicology impairs the capacity to develop accurate and more fundamental understandings of the dose–response.

Adaptive responses occur within a dose–response framework. What are adaptive responses? When are they induced? Are there molecular detection systems for the discernment of biological alterations/injuries that affect the upregulation of adaptive responses? How does the induction of the adaptive response, or the failure to do so, affect the dose–response for toxic endpoints? It is not, therefore, possible to separate the concept of adaptive response from that of the toxicological dose–response. These differential concepts are part of an integrated dose–response continuum.

Within this dose–response context, the risk assessment definition of EPA purposefully and explicitly excludes the concept of adaptation and repair. Yet, the concept of risk assessment is entirely dependent upon an understanding of the dose–response, its underlying mechanisms, and how they can be used to predict and estimate responses to toxic substances within the population [2].

This chapter therefore argues for a new and more expansive concept of toxicology, framed within a dose–response perspective that is at its core. The truncating of toxicology into those responses that occur at the so-called high doses, above the traditional threshold, and that deal only with induced pathologies has been its history. This history has suffered from a limited view of the dose–response, a perspective fueled by an incorrect understanding of the dose–response concept and its evolution. With the expansion of the dose–response concept into the area of the biological effects of low-dose exposures, including below-threshold effects, toxicology will interface in new and more integrative ways with related subdisciplines within the biological and biomedical sciences. This perspective offers a broader and more inclusive view while building upon past toxicological research achievements and understandings of dose–response relationships and mechanisms.

Toxicology is a fundamental component of systems biology as essentially all biological disciplines are inherently dependent on the dose–response. The dose–response is at the foundation of cellular messaging, biological regulation, plasticity, cellular and tissue repair, health, dysregulation, and disease. The notion that toxicology is a discipline that is only, or even principally, concerned with adverse health effects is

too limited. Toxicology needs to encompass the entire dose–response continuum.

The dose–response concept is therefore one that unifies and merges long-held conceptual differences between the disciplines of toxicology and its historical parents of pharmacology and physiology. These once distinct disciplines are being progressively seen differently in light of mechanistic advances and the tools by which they are studied. Toxicology is no longer simply a descriptive discipline; it has become transformed into a mechanistically focused discipline within a dose–response context setting where the lines of former disciplinary demarcations are blurring with striking rapidity.

All biological and biomedical disciplines have been built upon the dose–response concept. The dose–response concept emerged from and has been continuously used by researchers in many fields, including physiology, microbiology, pharmacology, ecology, entomology, biostatistics, radiation biology, radiation medical therapies, genetics, and botany [3–9]. Thus, researchers have historically developed toxicological concepts and frameworks based upon the issues in their own discipline. Such individuals have therefore entered the field of so-called modern toxicology from a broad range of scientific disciplines.

Despite the fact that all of the previous fields utilized the concept of dose–response, toxicology tends to see itself historically as an outgrowth of pharmacology during the middle decades of the twentieth century. Yet, the dose–response was emerging as quickly and often with a stronger dose–response basis in the areas of microbiology, plant biology, and entomology. These areas were important not only because of practical societal consequences, but they could also address dose–response issues more effectively (i.e., more doses, greater sample sizes, more replications) because of the ease and cost-effectiveness of more efficient experimental systems. Such areas were able to accommodate the possibility of developing and exploring broad dose–response relationships. This was not something that the area of whole-animal studies could readily accommodate.

Attempts to develop in vitro testing were initiated as early as the first decade of the twentieth century by Alexis Carrel (Figure 3.1) since he needed to avoid excessive variability in the responses of outbred animals in wound-healing studies [10]. Since there were no inbred rodent strains available at that time, Carrel opted to explore the novel yet imposing area of cell culture. While reliable findings were not easily obtained, these efforts were to play a determining historical role in the success of in vitro research today. These achievements also were important in the historic success of the Salk polio vaccine [11]. Carrel was initially interested in the search for agents that could significantly accelerate wound healing and then later applied these in vitro methods to assess ways in which life span could be increased within a dose–response context.

The challenging issues with whole-animal testing would continue to be the case throughout most of the twentieth century as whole-animal mammalian systems have been expensive, space demanding, and often yielding highly variable

FIGURE 3.1 French surgeon and biologist Alexis Carrel (1873–1944). (From Commons.wikimedia.org/wiki/File:Alexis_Carrel_02.jpg [PD-U.S.].)

results. So challenging has been the demands of whole-animal systems, it contributed significantly to the in vitro revolution of the 1980s and the incorporation of high-throughput chemical screenings, in an effort to more cost-effectively prioritize agents for further evaluation. These more recent efforts would have their origin with the extensive work of Carrel and his inspired followers such as Robert Parker and his remarkable work on the polio vaccine.

The dose–response therefore had detailed formulation and evaluation from other *nontoxicological* disciplines, well before the so-called transition of toxicology had been made from pharmacology. In fact, the development of early statistical assessment methods occurred in the first two decades of the twentieth century with the publication of William Gosset's (Figure 3.2) Student's T-test and Sir Ronald Fisher's the analysis of variance [12], both of which had an important role in the analysis of toxicological data in the second half of the twentieth century. Yet, their important advances were neither inspired by nor directly related to toxicology per se. The dose–response relationships for the use of disinfectants starting with the applications of Joseph Lister for the sterilizing of surgical activities in the 1860s–1870s were based on the discoveries of Louis Pasteur and expanded by the discoveries of Robert Koch that permitted the isolation and culturing of specific bacteria and other microbial species. Koch [13] was the first to assess the capacity of a range of chemical disinfectants in a concentration-dependent manner using pure cultures of bacteria. These findings accelerated developments in the areas of chemical assessment of disinfectants with their applications to public health practices from community drinking water disinfection starting in the first decade of the twentieth century. Detailed dose–response

FIGURE 3.2 William Sealy Gosset, British statistician. (From Commons.wikimedia.org/wiki/File:William_Sealy_Gosset.jpg [PD-U.S.-not renewed].)

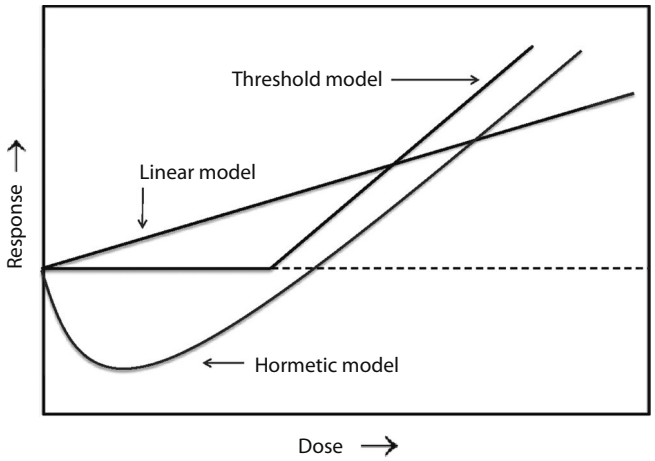

FIGURE 3.3 Most significant contemporary dose–response relationships.

modeling applying the law of mass action to the process of chemical disinfectants for bacteria was also undertaken in the first decade of the twentieth century [14–16]. Such modeling activities lead Chick and Martin [15] to derive concentration–response thresholds for the inhibitory actions of various disinfectants (e.g., mercuric chloride, silver nitrate, and phenol). Moreover, modeling-based threshold interpretations were based on experimental findings in the observable zone. Dose–response principles, practices, and applications were therefore developing in specific disciplines during the later decades of the nineteenth century.

The field of toxicology has tried to assert itself as a basic science just like physiology, pharmacology, genetics, microbiology, botany, and other biological disciplines have done. While toxicology has been largely successful in achieving this goal within the scientific and regulatory communities, its *basicness* is rooted not in a specific biological system (e.g., plant, microbe, animal), level of biological organization (e.g., in vitro, whole animal), or endpoint but in the dose–response concept, its mechanistic understandings, and applications. Ironically, the field of toxicology has inadequately grasped that its core is the dose–response and how this drives the hazard assessment, efficacy evaluation, and public health implications along with providing cellular mechanisms that account for its quantitative features. The dose–response concept not only provides the historical foundation of toxicology but also a fundamental context within which natural selection occurs at multiple levels of biological organization. When seen in a historical perspective, toxicology is a convergence of a broad range of biological disciplines in which dose–response evaluation and understandings are fundamental. That is, there are many differing biological disciplinary paths that require the use of the dose–response concept, modeling of dose–responses, and understanding of mechanisms that can account for the features of the dose–response and that lead to the discipline of toxicology. All are conducting toxicological assessments framed within a dose–response context.

This chapter will also explore the evolution of the dose–response concept for chemicals and radiation, underlying the development of the threshold and linear dose–response models, as well as additional models, such as the biphasic/hormetic (Figure 3.3) dose–response model and polyphasic (e.g., triphasic) models. Within this context, the dose–response concept in homogeneous experimental models will be compared with that of human epidemiology that is characterized by profoundly greater interindividual variation. The hazard assessment process will be assessed and how it was employed to validate the threshold dose–response concept that created it, resulting in a toxicological self-fulfilling yet failed prophecy.

The history of the dose–response is a rich one, with scientific, intellectual, and politicized disputes along with dynamic leaders that are far more than historical icons merely listed for completeness in historical assessments. This chapter will explore some of these key historical figures and describe how these intellectual leaders came to formulate the nature of what is called toxicology today, revealing their enormous contributions and perhaps their errors, conflicts, and successes, which have also come to mold and guide the evolution of this field.

DOSE–RESPONSE: HOW THE THRESHOLD DOSE–RESPONSE BECAME ACCEPTED

The widely acclaimed father of toxicology is Paracelsus. He is especially known for his insightful statement that "the dose determines not only the poison but also the remedy," a concept of dose and response that is extremely broad. This statement implies that the same agent could be both a toxicant

and one with therapeutic and/or health potential. According to Paracelsus, whether the agent was a toxicant or a tonic depended on the dose. While Paracelsus has long retained an esteemed status in the field of toxicology, his quote has often been truncated by recent generations of toxicologists to yield the following: "the dose determines the poison" [17]. This section explores the original Paracelsian insight into the realm of toxicology, addressing both toxicant and remedy as each is part of the dose–response continuum especially in light of the current experimental developments. It should be appreciated that the views of Paracelsus were not those of a toxicologist but one more closely tied to a philosophical perspective in which all things are interconnected and related. While there were many implications that emerged from this view, the previous idea of chemicals having both beneficial and harmful potential that was dependent on the dose was conceptual and intuitive. However, nearly four centuries would have to pass before these speculations could be experimentally tested.

While the concept of the dose–response may appear to be straightforward, it has had a highly controversial history. The first major debate of modern relevance over the dose–response was initiated by Samuel Hahnemann (Figure 3.4), the creator of the practice of homeopathy [18]. Hahnemann was a traditionally trained German physician who became strongly opposed to the medical treatment of his era, a period of the so-called heroic medicine. It was during this period when patients were treated by blood drawing and the administration of often intoxicating doses of heavy metals and other agents. He eventually came to the conclusion that such treatments were often worse than the disease. This led Hahnemann to seek alternative means of treatment that would be both healing and without toxicity. As a result of his intense moral conflict of harming patients while trying to cure them, Hahnemann quit his profession and began to support his family by becoming a professional translator of chemistry and related books. During the course of these translational activities, he developed an insight that was to change his life and lead him to create the medical practice of homeopathy. Based on information learned from reading of the medical literature, Hahnemann developed the belief that medicinal treatments could be obtained from plant extracts to relieve the symptoms of numerous diseases and to enhance healing and recovery from a broad spectrum of diseases and to do so without being toxic.

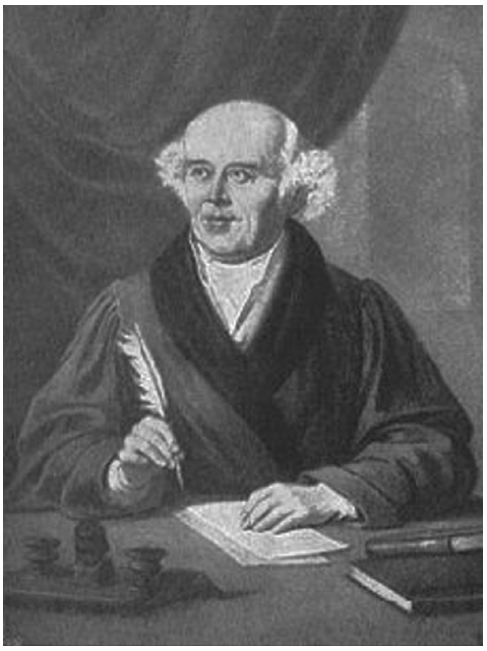

FIGURE 3.4 Samuel Hahnemann. (From commons.wikipedia.org/wiki/File:Hahnemann.jpg [PD-U.S.-not renewed].)

Hahnemann's drug discovery/medical treatment plan was based upon two principal components: The first was an effective drug needed to induce the same symptoms of the disease in healthy subjects that occurred in ill patients (i.e., the like cures like principle). Secondly, the medicinal treatment should be applied at a dose that was not toxic but sufficient to induce an adaptive response (i.e., called by Hahnemann a *vital force* that has been misrepresented to be an amorphous/undefined spiritual phenomenon). The general foundation of this dose–response concept is similar to that put forth centuries before by Paracelsus. However, over time, Hahnemann altered his dose–response concept, making it profoundly less acceptable to scientifically minded individuals by arguing that adaptive responses could be induced at infinitesimally lower doses. This high-dilution drug treatment position became untenable once Avogadro's number became quantifiably clarified in the early part of the twentieth century [19]. Using chemical molecule calculations based on Avogadro's number, it was shown that Hahnemann's extremism was indeed real, as many of his homeopathic preparations were estimated to have vanishing few, if any, molecules. Unease with this infinitesimal dosing/therapeutic practice had already been festering even during the life of Hahnemann who died in 1843. In fact, one of Hahnemann's former students was well known for challenging this infinitesimal dosing perspective [20]. Reflecting such disputes, it is clear that by the later decades of the nineteenth century, homeopathy, as a profession, had split into two main groups: the followers of Hahnemann (i.e., the high-dilution group) and those not accepting this view (i.e., the low-dilution group) but still accepting his first concept (i.e., law of similars). By the early 1880s, the high-dilution group represented only a small minority (<10%) of the homeopathy practitioners [18,21]. In practice however, many homeopaths actually tended to straddle the fence, being fiscally pragmatic, selling therapeutic preparations from both practitioner camps.

Despite this fracturing of the field of homeopathy, opponents of this practice, especially those within the field of traditional medicine, have invariably attempted to portray this entire profession as belonging to the Hahnemann *wing* of the movement. Why? Most likely, this was because the dose–response extremism of high-dilution homeopathy was an effective target. By lumping the entire practice

of homeopathy into the same dose extremism, it was easy to marginalize the entire field. The dose–response concept therefore that emerged from the work of homeopathy based on the early (i.e., prior to the adoption of infinitesimal dose scheme) writings of Hahnemann was that of a biphasic dose–response. The understanding of the dose–response during this time period was far more conceptual than experimentally based. In fact, this perspective was based on limited human exposure studies by Hahnemann and his school in a process called *proving*. Needless to say, by the time that Hahnemann died, the scientific basis of the dose–response was still fundamentally unexplored, lacking the technical capacity and resources for evaluation, especially on a reliably larger scale. However, this would change over the next 50 years with the onset of scientific advances in Europe, especially with the influence of the emerging fields of physiology, pharmacology, and toxicology.

While the well-known biologist Claude Bernard (Figure 3.5) introduced the concept of a threshold dose–response in the mid-1860s, relating to renal excretion [22], there was little serious scientific research concerning the nature of the dose–response until a report emerged from the laboratory of Hugo Schulz in the mid-1880s [23,24] (Figure 3.6). Schulz, a physician, as well as an expert in toxicology and pharmacology, became a highly polarizing figure when he reported that multiple chemical disinfectants not only inhibited yeast metabolism in a dose-dependent manner but also enhanced it at low concentrations, that is, below the toxicity threshold [25]. In his autobiography, Schulz ([26]; see Crump 2003 translation) noted that at first, he did not accept the low-dose stimulation response as real but probably the result of an experimental artifact. However, replication

FIGURE 3.5 Claude Bernard. (From commons.wikipedia.org/wiki/File:Claude_Bernard.jpg [PD-U.S.-not renewed].)

FIGURE 3.6 Hugo Schulz (1853–1932). (From http://dose-response.org/low-dose/scientists/schulz.htm.)

experiments revealed a reliable consistency of the biphasic dose–response:

> Since it could be foreseen that experiments on fermentation and putrescence in an institute of pathology would offer particularly good prospects for vigorous growth, I occupied myself as well as possible, in accordance with the state of our knowledge at the time, with this area. Sometimes, when working with substances that needed to be examined for their effectiveness in comparison to the inducers of yeast fermentation, initially working together with my assistant, Gottfried Hoffmann, I found in formic acid and also in other substances the marvelous occurrence that if I got below their indifference point, i.e., if, for example, I worked with less formic acid than was required in order to halt the appearance of its anti-fermentive property, that all at once the carbon dioxide production became distinctly higher than in the controls processed without the formic acid addition. I first thought, as is obvious, that there had been some kind of experimental or observation error. But the appearance of the overproduction continually repeated itself under the same conditions. First I did not know how to deal with it, and in any event at that time still did not realize that I had experimentally proved the first theorem of Arndt's fundamental law of biology [26].

While none of these observations should have been controversial, they became the object of intense scrutiny, debate, and ridicule. Why was this the case? Schulz made them so by claiming that he had discovered the underlying principle of homeopathy. Schulz set forth the premise that homeopathic remedies act by inducing adaptive responses that enhanced the capacity of biological systems to resist a broad range of environmental insults. The conclusion of Schulz was based on several lines of converging thoughts.

On the clinical side, there was a report in 1884 by Bloedau [27] that the homeopathic drug veratrine was successful in the treatment of gastroenteritis. Schulz [28] tried to verify that this botanically derived drug could actually kill the disease-causing agent. However, Schulz was unable to verify that this agent could kill the bacterial agent based upon considerable laboratory studies. Since the veratrine failed to kill the disease-causing agent in his laboratory but was apparently successful in the treatment of this disease in people, Schulz hypothesized that the drug acted not by killing the bacteria but by enhancing the adaptive capacity of the individual. While there could have been alternative explanatory possibilities proposed, Schulz then applied his biphasic dose–response observations with the yeast to account for the protective effect of the veratrine in people. It was by this linkage of the biphasic dose–response to homeopathy and its hostile relationship with traditional medicine that it (i.e., the biphasic dose–response) became the object of suspicion, hostility, and marginalization by the medical community starting in 1885 and continuing throughout the twentieth century [29–31].

Schulz [32] made this dose–response assertion in the midst of an intense rivalry between what is today called traditional medicine and the practice of homeopathy. In effect, he placed his newly observed biphasic dose–response into the homeopathic domain. His actions evoked a profound and prolonged series of professional criticisms and personal attacks as well as criticism of his dose–response model by leaders of traditional medicine as well as the medical faculty at his own institution [33,34]. This dispute about the nature of the dose–response could not have occurred at a worse time for the biological, biomedical, and toxicology communities. Experimental studies in these areas were just beginning, and various scientific concepts, including those related to the dose–response, were in the process of being formulated. The issue of the dose–response therefore was in its concept formation period. However, due to economic, philosophical, scientific, and personal conflicts with homeopathy, traditional medicine was *compelled* to attack all things homeopathic as if they were an enemy. Furthermore, the formation of the American Medical Association was explicitly based in part on the need to counter the growing societal influence of homeopathy. This is a generally underappreciated historical fact and one that had profound implications for the biphasic dose–response. As a result of being drawn into the homeopathy–medicine conflict, the biphasic dose–response concept would become collateral damage, leading to its marginalization and exclusion from medical, pharmacology, and toxicology textbooks, curricula, teachings, clinical practices, and government regulatory testing and evaluation procedures. The conflict with homeopathy and the involvement of the biphasic dose–response in the dispute would ironically play a significant role in the acceptance of the threshold dose–response model by the medical community. How could the rejection of Schluz's biphasic dose–response model have affected the acceptance of the threshold dose–response and, in fact, have even led to it?

FIGURE 3.7 Alfred J. Clark. (From Clark, D.H., *Alfred Joseph Clark (1885–1941): A Memoir*, C & J Clark Ltd., Glastonbury, England, 1985, 61pp.)

While Schulz had his many detractors, none were so visible and effective as Alfred J. Clark (Figure 3.7), a professor of pharmacology at the University of Edinburgh, a renowned researcher, scholar, an acclaimed textbook author, and a high-level government advisor. His influence upon the field was deep and pervasive and of long duration. One of Clark's goals was to discredit medical quackery. Unfortunately for Schulz, Clark labeled homeopathy as quackery and linked Schulz with the high-dilution wing of homeopathy, a charge that was demonstrably false [25]. Moreover, Clark vigorously attacked Schulz's biphasic dose–response hypothesis in his highly influential books [35,36] in an attempt to trivialize and marginalize Schulz and homeopathy. Clark also argued that research by Dannenberg [37] established that Schulz's findings could be explained by normal variation and that the low-dose stimulation findings were due to inadequate study design and chance and lack the capacity for replication. However, a reexamination of this critical paper by Dannenberg [37] revealed that it did not replicate the work of Schulz, using concentrations that were some 10–20-fold lower. In addition, the research did not collect data at multiple times, a necessary feature to evaluate Schulz's concentration–time response hypothesis. Thus, the paper was not relevant, yet the unfair criticism of Clark stuck because of his reputation and because Schulz, by temperament, would not usually defend himself and also that he was now several years into retirement. Furthermore, when Clark did have the opportunity to assess a paper that was specifically designed to replicate the experiments of Schulz, he never cited it. In this case, the research of Sarah Branham (Figure 3.8) [38] in the highly visible *Journal of Bacteriology* strongly confirmed the findings of Schulz.

FIGURE 3.8 Sara Branham (Matthews) (1888–1962). (Courtesy of Georgia Women of Achievement, Inc., LaGrange, GA, www.georgiawomen.org/_honorees/matthewss/index.html.)

FIGURE 3.9 Benjamin Minge Duggar. (From www.apsnet.org/about/history/pioneeringplantpathologists/Pages/DuggarBenjaminMinge.aspx [PD].)

Of further importance was that Clark's writings had a long reach, affecting several generations of pharmacologists and toxicologists. Such efforts were important in helping to ensure that the threshold model would be incorporated into research, teaching, and regulation, whereas the biphasic dose–response of Schulz would be excluded.

Over the ensuing next half century (~1885–1935), the so-called battle of the dose–responses was waged. However, it was a complex type of dispute. While many scientists were simply not part of the ideological battle between medicine and homeopathy, others, such as some very influential academic leaders of the British pharmacological community, were [29,39,40]. A review of the history of the dose–response reveals that traditional medicine was an organized, harsh, and powerful opponent for the biphasic dose–response. There is also little question that the lack of an *institutional* capacity for homeopathic activity resulted in researchers such as Schulz being isolated and without an institutional and professional support system.

A detailed accounting of the nonideological leading researchers documenting biphasic dose–responses revealed no tendency to organize around the biphasic dose–response concept or to promote it [8,9]. Most of these early leaders publishing in the area of biphasic dose–responses would transition professionally into other positions of leadership in science that, in effect, drew them away from this dose–response research domain [8,9]. In fact, many of these researchers who had demonstrated the occurrence of biphasic dose–responses were outstanding scientists with extensive reputations. For example, Benjamin Duggar (Figure 3.9) was involved in such research from the late 1890s throughout the first half of the twentieth century, becoming a major scientific feature in the United States and worldwide. Over time, he would become less involved with research and became more active with general academic scientific leadership. However, at the age of 72, following his retirement, he discovered the antibiotic Aureomycin in 1948 [41] and was nominated for the Nobel Prize. Yet he was not involved in the battle between homeopathy and traditional medicine.

The first biomathematical modeling of the hormetic–biphasic dose–response was published by the Cornell University microbiology professor Otto Rahn in 1932 [42]. The methods were based on the earlier modeling of the effects of disinfectants on bacterial survival by Chick [14] and others using the law of mass balance. Rahn [42] cited the extensive data supporting the findings of Schulz/Branham on the effects of metabolic poisons/chemical disinfectants on yeast metabolism. Rahn [42] also highlighted the earlier dissertation by Paul Hofmann [43] that paid very careful attention to the question of dosage and its optimization. In these experiments with 13 different agents, Hofmann reported not only that, at the lower concentrations, there were a larger number of colonies but that the colonies were enlarged.

Experimental proof for the biphasic dose–response was very demanding. First, a threshold response had to be estimated. Then both below- and above-threshold response areas need to be assessed when considering the possibility of a biphasic dose–response. While it may not have been appreciated in the early decades of the twentieth century, there was also a need for greater statistical power in the below-threshold doses. This added further difficulty in proving the reproducibility of the low-dose stimulation.

There was also the distinct possibility that there was a time component needed to demonstrate a biphasic dose–response. This was an initial finding of Schulz [23,24], Townsend, [44] and others, such as Branham [38] who carefully replicated the original findings of Schulz as noted previously. She clearly demonstrated that there was an initial dose-dependent toxicity/inhibition response, followed by a rebound or overcompensation response at low doses, resulting in the occurrence of the biphasic dose–response relationship (Figures 3.10 through 3.12). If the experiment included only one time measurement at the initial point of inhibition, then the stimulatory response would be missed but also the overcompensation response.

The low-dose stimulatory response was also invariably modest in magnitude, making it more difficult to observe and to replicate. Such a modest stimulatory response placed even more pressure on the need to replicate findings due to their greater inherent uncertainty as compared to high-dose toxicity effects. Thus, the dispute between followers of Schulz and those of traditional medicine about the dose–response was fully impacted by methodological and resource challenges that were needed in order to document the possible occurrence of biphasic dose–responses.

Despite these challenges to the study of biphasic dose–responses, there was a surprising and relatively copious

literature documenting the biphasic dose–response (called the Arndt–Schulz law [32]/or Hueppe's [45] rule [Figure 3.13]) published in leading journals during the early decades of the twentieth century. This research was based principally on work with microorganisms, plants, and insect models. There was also a copious literature in medical journals related to the effects of x-rays on numerous medical conditions such as gas gangrene, arthritis, sinusitis, and otitis media. The publications were typically case reports [46,47], often extensive and supportive of the biphasic dose–response. The biphasic dose–response concept also became formally integrated into leading textbooks of the first half of the twentieth century for both botany [48] and microbiology [49–52]. However, it was not until 2000 when this historical literature on hormetic–biphasic dose–responses was finally comprehensibly summarized with respect to chemicals [3–7]. Luckey [53,54] had comprehensively addressed the area of radiation hormesis first some 20 years earlier.

While the biphasic dose–response was often observed in the early decades of the twentieth century, it was never the object of an integrative assessment by any of the various researchers of that era. There was no demonstrable understanding or appreciation of the quantitative features of the low-dose stimulation; due to the fact that this stimulation could be both directly induced by a compensatory response, there was no broad discussion concerning the design of experiments to study biphasic dose–responses. This lack of integrative assessment probably resulted from the fact that most researchers with experience in this area, as noted previously, moved on to other professional endeavors. A few researchers, such as Herbert Maule Richards [55,56] at Bernard College, directed a relatively large number of undergraduate students in the study of biphasic dose–responses but never provided a broadly integrative assessment. This was also the case for Charles-Edward Winslow (Figure 3.14), an internationally recognized bacteriologist at Yale University, who directed multiple PhD students in the area of biphasic dose–responses [57–59]. In the case of Winslow, he was to be redirected from dose–response research with bacteria to broader health issues, becoming the editor of the *American Journal of Public Health* and holding that position for about 20 years starting in the mid-1930s.

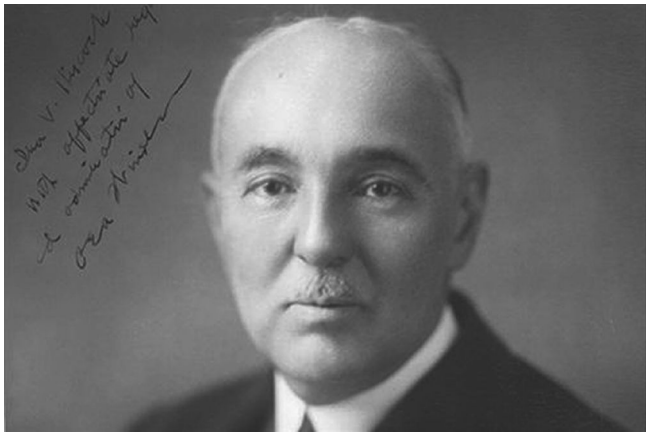

FIGURE 3.14 Charles-Edward Amory Winslow (1877–1957). (From http://www.google.com/imgres?imgurl=http://publichealth.yale.edu/Images/gallery202_74635History.)

The threshold dose–response model had a far easier time in this regard. It was markedly easier to evaluate, had profoundly less challenges with the replication of high-dose toxicity results, required far fewer doses, had smaller sample sizes, and had no complex time component. The threshold concept was also a model that resonated with personal experience. It also had leading researchers, including some in the area of biostatistics, which would advocate for its use and broad-scale applications. Thus, the road was much clearer for acceptance and understanding of the threshold dose–response than with the biphasic dose–response.

By the mid-1930s, the threshold dose–response model had made significant inroads of acceptance with the scientific [60–62] and regulatory communities, serving as the theoretical foundation for how hazard assessment would be conducted and the basis for the derivation of safety factors. While this concept would appear in the 1930s for chemical [63] and radiation safety factors [64], it was not until April 1953 that the safety factor concept became formally part of the FDA [65], the same month that Watson and Creek would publish their proposed structure of DNA. The recommendations of Lehman and Fitzhugh [65] would be broadly accepted affecting how environmental and food health exposure standards would be derived up to the present.

During this time period, the biphasic dose–response failed to become widely accepted, was poorly understood, and also continued to have a strong historical association with the practice of homeopathy, which itself had lost in the battle with traditional medicine in the treatment of patients. Furthermore, homeopathy also was the object of a blistering and profoundly influential attack by Abraham Flexner (Figure 3.15) [66] in 1910 that eventually lead to the closing of almost all the nearly two dozens of homeopathy medical schools in the United States by the early 1920s [67]. In effect, by the end of the 1930s, homeopathy was functionally decimated, and the biphasic dose–response of Schulz was fully marginalized, while the threshold dose–response model had become dominant along with traditional medicine. There were no other competitors.

FIGURE 3.15 Abraham Flexner. (From http://commons.wikimedia.org/wiki/File:Aflexner21.jpg [PD-U.S.-notrenewed].)

The threshold became the standard dose–response model for industrial chemicals, drugs, and radiation health effects evaluation. It received support from a variety of research perspectives including the occupational work experience for chemicals and ionizing radiation. Of particular importance was that the threshold dose–response model received mechanistic support based on the findings of researchers such as A.J. Clark who was able to demonstrate a relationship between receptor occupancy and the onset of biological effects [68]. He reported a threshold for acetylcholine that required approximately 20,000 molecules acting via receptors to produce an initial effect (i.e., isotonic contraction) on a heart cell. This was an impressive finding and one that Clark would exploit both in his extensive writings concerning the dose–response that would support a threshold model and in his criticism of the Arndt–Schulz law [35,36,69,70]. Therefore, the threshold dose–response appeared to have its foundation on secure scientific grounds. Clark also inspired an extensive series of statistical assessments of dose–response relationships that provided a solid foundation for application to wide-ranging subdisciplines within the biological sciences [71–80].

While the biphasic dose–response would come to have a scientific resurgence from the 1990s to the present, it simply appeared to be a dose–response concept in search of a cause or a proponent—which never seemed to materialize during the early 1900s, even when it was rediscovered and renamed as hormesis in the early 1940s by Chester Southam (Figure 3.16) and John Ehrlich [81] at the University of Idaho. Despite their rediscovery of the biphasic dose–response in research with fungi concerned with the rotting of wood, these two researchers, like so many other early researchers of the biphasic dose–response, soon redirected their focus from

FIGURE 3.16 Chester Southam. (From dose-response.org/low-dose/scientists/southam.htm.)

the dose–response. John Ehrlich moved to the University of Minnesota to work on methods to enhance the production of penicillin during World War II (WWII), later moving to the pharmaceutical company Parke-Davis in Detroit to participate in antibiotic/drug discovery activities (i.e., he became quite well known due to his role as a codiscoverer of chloramphenicol; in fact, one of the codiscoverers was nominated for a Nobel Prize). Chester Southam, on the other hand, moved to New York City, graduating medical school from Columbia University, later becoming an expert in the area of tumor antigenicity [8,9]. Thus, the early advocates of the biphasic dose–response model were to come and go, not having the focus and leadership of the medical community that A.J. Clark provided. Despite the dominance of the threshold dose–response and its generalizability, it nonetheless would be challenged during the twentieth century and into the twenty-first century.

HISTORY OF THE THRESHOLD DOSE–RESPONSE WITH PARTICULAR FOCUS ON OCCUPATIONAL RADIATION PROTECTION

In practical terms, the concept of a *threshold* dose had its origin in the domain of occupational health, with the focus on exposures to ionizing radiation from x-rays and gamma rays. In 1895, Roentgen discovered the x-ray and this ushered in a vast amount of research in a broad range of areas. It was soon learned that x-rays and gamma rays (which were discovered by Becquerel in 1898) could induce a wide range of harmful effects. Despite the early recognition of the hazard potential of ionizing radiation, it would take three decades for the regulatory community to begin to shape a response to this issue. That it might take considerable time to develop an organized response is not surprising given the nature of communications during that era as well as the occurrence of World War I (WWI) and its massive disruptions in Europe and the United States.

An organized assessment of the dose–response due to exposure to ionizing radiation was borne of the creation of the International Committee on X-Ray and Radium Protection by the Second International Congress of Radiology in 1928. The goal of this committee was to advise physicians on radiation safety measures, within a nonregulatory framework [9]. It had nothing to do with the issue of environmental contamination. In 1925, the first International Congress of Radiology met with the intention of renewing communication between opposing countries during the recently ended World War. The U.S. Bureau of Standards provided the liaison function for the United States, selecting Lauriston Taylor (Figure 3.17) as its representative. Taylor, an employee of the Bureau of Standards, would nonetheless act in a voluntary capacity to the international committee without an official U.S. government involvement in the activity. While the bureau would continue to provide the liaison function, the role of the bureau in this domain would become a political issue several decades later as President Eisenhower would create the Federal Radiation Council (FRC) to act as the official U.S. organization with direct accountability in the area.

In parallel to the actions of the international committee, Taylor created a U.S. national committee on radiation protection. This entity was initially called the American X-Ray and Radium Protection Committee. Almost two decades later (1946), after the conclusion of WWII, the name was changed to the National Committee for Radiation Protection

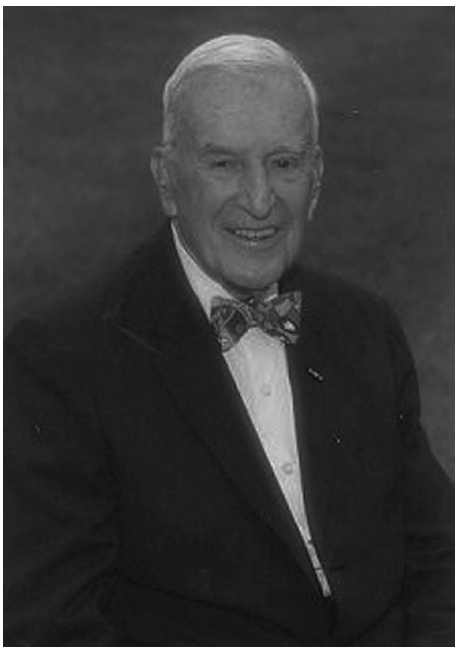

FIGURE 3.17 Lauriston Sale Taylor (1902–2004). (Courtesy of Health Physics Society, McLean, VA, http://hps.org/aboutthesociety/people/inmemoriam/LauristonTaylor.html.)

and Measurement (NCRPM). This committee was involved in the development of radiation protection standards and in related educational activities within the United States. The initial meeting of this organization was on September 18, 1929. This committee would come to publish documents about various safety procedures and exposure monitoring for workers involved with x-rays and gamma rays [64,82]. It was in the framework of evaluating radium that American X-Ray and Radium Protection Committee, as chaired by Taylor, concluded that the best indicators of ionizing radiation effects were skin changes seen with the fingertips. These areas displayed a reddening and shiny quality of the skin in the zone around the fingernails. An annual cumulative exposure of 600 R (i.e., 0.24 roentgens/day over 250 working days/year) was commonly viewed as the average erythema dose, that is, the exposure that affected a reddening of the skin. The value was obtained via a 1927 poll of radiotherapists. Their collective perspective yielded an average erythema dose of 550 R. The value was then rounded to 600 R in order to adjust for the presence of background scatter radiation [83].

The efforts of this committee of Taylor were preceded by the actions of Mutscheller who first proposed the concept of a tolerance dose for ionizing radiation in 1925, suggesting a value of 1/100 of the erythema dose averaged over 30 days. The approach of Mutscheller [84,85] was practically applied to estimate the quantity of lead shielding needed to protect workers. The concept of tolerance in this case was a type of equilibrium in which there would be a dose to which the workers could be exposed without noticeable harm. From this rather rudimentary start, the tolerance dose concept would proceed and provide the foundation for future radiation safety standards [64,82].

While the credit of first reporting on the concept of a radiation tolerance dose concept goes to Mutscheller, other radiation health experts were independently arriving at the same conclusion [86,87]. While each of these groups proposed a different time interval for the tolerance dose estimation, these values closely converged once similarly normalized. In these cases, the tolerance dose was dependent on the concept of a safety factor to reduce exposure using a fixed fraction of the estimated minimally affecting dose (erythema dose).

During the late 1920s, the International Committee for Radiation Protection (ICRP) offered their version of a tolerance dose for occupational radiation exposure, which was adopted in 1928. This ICRP standard was based on Mutscheller's safety factor of 1/100 of an erythema dose. In fact, it remained the principal basis for international and U.S. prewar radiation standards [83]. The ICRP standard was also principally employed for the calculating of the thickness of lead shielding in x-ray production.

This situation would change during the next decade as Professor Gioacchino Failla (Figure 3.18) of Columbia University Medical School would lead an effort to better understand effects of radium exposures on people and whether safety standards could be derived using skin and blood changes as biological markers. This research suggested that 0.6 R/month would be a safe dose, a value that

FIGURE 3.18 Gioacchino Failla. (From http://www.orcbs.msu.edu/radiation/resources_links/historical_figures/failla.htm.)

was 10-fold lower than the Mutscheller and ICRP recommendations. Despite the acceptance of the basic clinical findings of Failla and the safety factor concept, the committee agreed upon a higher tolerance dose using a lower safety factor. In this case, the tolerance dose was 0.1 R/day.

The tolerance dose and a threshold dose–response were not believed to be identical by the leaders of this era. The concept of tolerance assumed that there was probably some level of minor harm or damage. However, such assumed minor changes were not thought to be serious enough that they had to be avoided. Thus, the reddening of skin was clearly not a below-threshold response. The observation of reddening skin following radiation exposure was a definitive indication that a biological response threshold had been exceeded. The reddening of skin was used as a biomarker, as a type of warning signal for more serious concerns should the exposure exceed this level. Yet the issue of tolerance and threshold was often functionally confused. The use of a specific numerical limit was often interpreted to mean that there was a threshold of radiation exposure below which no harm would occur.

While the ICRP and other radiation advisory committees were debating the concept of a tolerance dose, thresholds, and skin and blood changes, their field would be turned upside down by a report from Hermann J. Muller (Figure 3.19) that x-rays could cause mutations in the male fruit fly sperm [88,89], which was extended to plants by Stadler [90] within a few months of the Muller report. Furthermore, the findings of mutations as induced by x-rays in fruit flies soon became widely reported by others working in the field [8].

These concept changes failed to be immediately implemented into regulatory guidance-based/exposure practices as committee activities were shut down during WWII. While

FIGURE 3.19 Hermann Joseph Muller (1890–1967). (From http://en.wikipedia.org/wiki/Hermann_Joseph_Muller [PD-U.S.-only].)

the genetic concerns were raised in the years leading up to WWII, such issues became dominant in the aftermath of the dropping of the atomic bombs on Japan and activities associated with aboveground testing of nuclear weapons. This set the stage for a long-term debate over the nature of the dose–response in the low-dose zone from ionizing radiation. This debate would be led by the genetics research community under the aegis of the NCRPM, ICRP, and National Academy of Sciences (NAS).

The debate over whether toxicologically based dose–response thresholds exist is a long one, approaching its hundredth year. It is difficult to think of other examples in the scientific literature where a major question still remains as broadly uncertain and contentious and as practically important as ever. On the surface, it would appear that this should not be a particularly difficult problem to resolve. However, this has not proven to be the case. As far as genotoxic carcinogens are concerned, regulatory agencies adopted a precautionary philosophy toward carcinogens based on fear of the cancer endpoint and the possibility that the process of carcinogenesis could be initiated by a single mutagen molecule or ionization in a single cell. This set of concerns gave the assessment and regulation of carcinogens a unique status within society and forced the regulatory agencies to deal with chemical carcinogens and ionizing radiation in a different manner than agents that were not classified as carcinogens. For noncarcinogens, there was believed to be a threshold below which no adverse effect(s) would occur. For genotoxic carcinogens, this was not the case. The regulatory agencies decided to treat them differently assuming there was no safe exposure. The next section will therefore address the theoretical foundations of why the scientific community has long adhered to a belief in a threshold dose–response model. These concepts have involved statistical, thermodynamic, and biological/toxicological domains. The subsequent section will provide a detailed assessment of scientific challenges to the threshold dose–response model, including that initiated by the radiation genetics community that ushered in the linearity at low-dose concept.

THRESHOLD DOSE–RESPONSE: THEORETICAL FOUNDATIONS

Introduction

While the threshold dose–response model was adopted without having been validated by the scientific, medical, or regulatory communities during the early decades of the twentieth century, this section of this chapter offers a perspective on what could be the toxicological foundations that would support a threshold dose–response. Five arguments are made with documentation that supports a threshold interpretation. These include the following: (1) there are observations that large numbers of atoms/molecules are needed to induce biological responses; (2) the second law of thermodynamics imposes an energy requirement for chemical reactions to occur, resulting in a threshold; (3) there are pharmacokinetic and pharmacodynamic processes; (4) the use of arithmetic/linear graphing can create a false impression of a linear dose–response, whereas logarithmic dose graphing using molecules/kg/day lead to the conclusion of a distinct threshold for chemical carcinogens; (5) since tumor latency is a function of dose, it is possible to obtain *practical* thresholds for carcinogens, even assuming a linear dose–response relationship.

Relationship between Biological Function and the Number of Atoms Inducing It

In 1943, George Evelyn Hutchinson [91] (1903–1991), Yale University professor and the father of limnology and modern ecology, explored the relationship of biological functions and the number of atoms required to induce such functions using the liver cell as his model. He provided a listing of various elements from the periodic table and estimated their presence in a human liver cell. Twenty-years later, he provided a considerably expanded view of the number of atoms needed to induce specific liver cell functions [92].

He concluded that it takes the presence of a relatively large number of atoms to affect a response even when there may be a highly evolved biochemical specificity for a reaction to take place. He hypothesized that even at its most sensitive level of activity, the liver cell, as well as probably most cell types, may require more than 10^4 atoms/molecules per cell to induce a response. Even in the case of nonnutritive agents, such as Cd and Pb, the number of atoms for each of these agents is 10^6–10^8/liver cell and was associated with no detectable effects.

Such findings were interpreted by Bertram Dinman [93], a prominent University of Michigan toxicologist, that the presence of specific atoms in a cell does not provide proof of biological activity nor does it offer any biological significance from a beneficial or harmful perspective. Using a complementary approach to Hutchinson [91,92], Dinman [93] concluded that nearly 400 in vitro studies of enzymatic inhibitors for 100 different enzymes [94] revealed that the lowest concentration at which most sulfhydryl enzyme inhibitors act was in the 10^4–10^5 molecules/cell range, a value similar to that proposed by Hutchinson [92]. Taken together, these different approaches lead Dinman [93] to suggest thresholds are the rule in biological systems. Dinman went on to conclude that

> To believe that such molecules cause an undesirable effect disregards the presence of multiplicity of interfering substances. Such thinking also does not take into account the fact that the dose of a foreign atom may be related to the probability of its interacting with an available active site, or that similar probability governs the answers to the question of whether interactions will occur at discrete topographical loci upon a structural or functional molecule (or on a possible precursor). While the construction of stochastically sound models is remote, the reasonableness of the hierarchy of cellular element concentrations as these relate to metabolic function suggests that a threshold for biological activity exists within a cell at 10^4 atoms.

A practical approach for assessing the threshold issue may be to consider the actual exposure that humans experience from environmental concentrations of well-known toxins. In the case of lead, the CDC has long used 10 μg/100 mL of whole blood as an action level (recently reduced to 5 μg/100 mL). At this concentration of Pb in blood (10 μg/100 mL), there are 3×10^{16} Pb atoms. If the exposure standard were to be reduced to 1 μg/100 mL, there would be 3×10^{15} Pb atoms per 100 mL, or 3×10^{13} Pb atoms/1 mL. It is difficult to consider that at 1 μg/100 mL, a value common today in apparently healthy humans, there are 30-trillion lead atoms for each of the 7500 mL of blood in the average U.S. adult. Such calculations support the existence of an individual and public health threshold for lead.

In a similar fashion, the U.S. EPA benzene drinking water standard of 5 μg/L has an estimated (1×10^{-5}) lifetime risk of developing leukemia based on linear nonthreshold (LNT) models. At the drinking water standard of 5 μg/L, there is an estimated 8×10^{15} benzene molecules/L. This cosmologically large number is further expanded when one considers that the EPA assumes that 2 L is consumed each day of a 70-year life. These two examples are not exceptions but illustrate the rule as far as the relationship between exposure to atoms/molecules and the onset of adverse health effects are seen in humans. In fact, regardless of whether the regulated agent is a carcinogen or not, the estimate of acceptable exposures is typically in the 10^{14}–10^{20} molecules/day for 70 years.

Second Law of Thermodynamics and Dose–Response Relationships

While individual thresholds are typically observed in toxicological and epidemiological studies, the issue of population-based thresholds has been less certain. This uncertainty is based on the fact that considerable variation exists between individuals with respect to their susceptibility to toxic/carcinogenic agents due to genetics, diet, developmental, and aging processes, among other factors. Thus, apparent thresholds can profoundly differ between individuals. The regulatory challenge therefore may not be that of an individual threshold estimation but a population threshold, thus transforming this question from a biological to a biostatistical one [95,96]. The question therefore is whether there is a population-based threshold for noncarcinogenic toxic substances and carcinogens.

A central fact that underlies the current debate over threshold or LNT for radiation-induced cancer is that each individual experiences cosmic numbers [97] of mutations/cell each day (e.g., depending on the cell type—millions to multiple billions) from normal metabolism and background radiation. If, in fact, a single hit were to be enough to cause cancer, as suggested by the LNT theory, it is difficult to explain why many, perhaps most individuals, would not quickly display various toxicities and/or cancer, unless reasonably efficient repair processes exist.

Despite the fact that vast numbers of mutations occur and are repaired on a daily basis, are there exposures that will not induce genetic damage? According to Schaeffer [96], the second law of thermodynamics provides a basis for such a threshold. This conclusion is founded on the premise that there is a minimum net free energy required for the reaction of an agent (in this case, a toxicant or carcinogen) with a target molecule [98–101]. If the threshold value is diminished, the net free energy that is related to the threshold value would also diminish. However, the net free energy cannot reach or become zero as this can only happen if both the activation energy and the net free energy are zero at all levels of exposure [99,102]. Since chemical bound energy is the "exclusive source of utilizable energy in biological systems, there is a minimum activation energy and a minimum net free energy above zero for all cellular reactions including the induction of cancer." Mutagen binding to DNA affects DNA alterations (i.e., mutagens) and can initiate the process of carcinogenesis. A thermodynamic analysis of this process has yielded a specific energy threshold that needs to be exceeded for the induction of chromosomal aberrations. Such an assessment provides a basis for why each interaction between molecules does not result in a chemical reaction and product formation that could lead to a biological effect. Each xenobiotic agent needs to provide the activation energy to react with the receptor molecule. Using the Maxwell–Boltzmann equation, Koch [103] estimates that the activation energy may vary between 16 and 42 kJ/mol for biochemical reactions in vivo. The minimum net energy required to induce a single strand break

was estimated to be at least 17 kJ/mol [101], supporting the existence of a threshold.

According to Schaeffer et al. [99], it may be appropriate to use the biological analogy of fertilization of an egg by a sperm when placing the process of chemical carcinogenesis in context. While there are billions of sperm that are present and actively attempting to fertilize the egg, only one does. Furthermore, the process of fertilization requires the presence of massive numbers of sperm. In a similar fashion, chemical reactions take place only where there are sufficient molecules, each displaying kinetic energy, eventually colliding with each other and eventually yielding a novel intermediate molecule that then transforms to the final product. The formation of the reactive intermediate represents a random event within an environment of many millions of molecules. The actions of a carcinogen must therefore be seen as a stochastic process involving massive numbers of targets and a cosmically large numbers of molecules.

Since chemical reactions are subject to entropy and free energy constraints, Schaeffer et al. [99] indicated that mutational effects and carcinogens likewise display activation and free energy requirements as well as entropic dependence. Since entropy represents a statistical estimate of system disorder, these reactions will show the mass requirements of chemical reactions. In fact, therefore, thermodynamic principles lead one to conclude that LNT is both chemical and biologically highly improbable. Pharmacokinetic reasons (absorption, tissue distribution, metabolism, storage, excretion) and the number of molecules that reach a target and thermodynamic parameters that affect molecule activation create the foundation for a physical/chemical/biological basis for biological/toxicological threshold.

This perspective reinforces the previous views of Dinman [93] that there is likely to be a minimal number of atoms/molecules needed to affect biological responses. In fact, the use of the number of Dinman [93] led Friedman [104] to estimate the minimally inducing number of molecules for various potent carcinogens (i.e., 8.6×10^{15} molecules/kg body weight or 10^8 molecules/kg). Using such analyses, Koch [103] estimated a *response threshold* level for various drinking water contaminants including chemical carcinogens. This modeling considered standard parameters such as average body weight, amount of water consumed/day, molecular conductivity as well as estimates of lipophilicity, and tissue distribution of biological activity. Koch [103] concluded that such outcomes provide not only a theoretical but also a practical means of translating toxicological findings into risk assessment practices. He also emphasized that this perspective illustrates that it is profoundly unrealistic to believe that a single molecule may affect the occurrence of cancer, thereby supporting a threshold dose–response perspective.

Despite their solid underlying foundations, the arguments of Hutchinson [92] and Dinman [93] and similar extensions by Claus [105] and Jukes [106] have not attracted significant formal attention in the literature. However, in 1980, Preussmann [107], a well-known experimental cancer researcher, attempted to apply such concepts to the issue of chemical carcinogen thresholds using the data of Mohr and Hilfrich [108]. In this study, kidney tumors were induced in rats via a subcutaneous (SC) injection of diethylnitrosamine (DENA) using eight different single-dose treatments ranging from 1.25 to 160 mg/kg. They reported 11/20 kidney tumors in the single dose of 100 mg/kg and 1/20 kidney tumors at 1.25 mg/kg. The 1.25 mg/kg dose was the equivalent of 0.3 mg/rat. The control group showed no kidney tumors. The 1.25 mg/kg level of exposure, which was presumably carcinogenic, corresponded to about 2×10^{18} molecules/rat or approximately 10^{16} molecules/kidney. Assuming the weight of the kidney was about 10^{-10} g, Preussmann [107] stated that there was about 10^6–10^7 molecules of DENA/kidney cell at this dose. The 10^6–10^7 molecule number range per cell was about 100–1000-fold greater than the postulated theoretical threshold of 10^4 molecules/cell.

DNA Adducts: A Method to Estimate Thresholds and/or Linearity?

As an alternative to the proposition of a theoretical molecule threshold that was postulated by Hutchinson [92], Dinman [93], Claus [105], and Preussmann [107] suggested a more mechanistic approach using DNA adduct biomarkers within susceptible tissue. This approach has demonstrated appeal in the subsequent decades with numerous researchers exploring the relationship of DNA adducts as biomarkers for chemically induced tumors. One of the most integrated of these attempts is seen in the publications of Williams et al. [109,110]. These authors have traced the biological processing of the chemical exposures from the portal of administration through the spectrum of pharmacokinetic processes to pharmacodynamic activity, inducing DNA adduct formation, location of the adducts, and efficacy of DNA repair, and to the route of neoplasmic cell transformations, including the number of mutations, development of tumor microvasculature, and tumor-suppressive elements. The documentation of this type of information was placed in a quantitative perspective, leading Williams et al. [111] to derive a new cell-based mechanism of action that could provide what they called a safe exposure level (SEL) for a DNA-reactive chemical carcinogen; the SEL was based on a DNA binding of less than 1 adduct/10^9 nucleotides for a single chemical agent. As suggested previously, the methodology used by Williams et al. [111] follows the administered agent(s) from the beginning to the end stage quantifying all changes that led to the final product and integrating the pharmacokinetic- and pharmacodynamic-mediated information along with tumor development activities.

Starting with an oral exposure to a stable procarcinogen, Williams et al. [111] noted that following ingestion, the agent will be subjected to the risk of degradation caused by chemical and biological processes including gut microflora. Following G.I. absorption, the agent will be transported via the portal blood flow to the liver and undergo the first-pass extraction. For that portion of the dose not taken up by the liver, it will enter systemic circulation, typically

in a highly diluted manner. For these *escaped* molecules, they become spread out to many organs and their cells, further diluting the dose.

As far as DNA-reactive carcinogens are concerned, the only cells at risk for initiation (and therefore cancer development) are reproducing stem (labile) cells. These cells typically represent <1% of the cell population in any tissue. Another factor affecting exposure to critical cellular sites is that cells display an active extrusion process via p-glycoprotein ATPase to pump hydrophobic cationic agents out of the cell and/or prevent their entry. Williams et al. then generalized that it may be reasonable to assume that perhaps 80% of the *carcinogenic* molecules may be detoxified in the liver. Of the remaining 20% of activated agent, a certain proportion would be *consumed* by encountering any of a wide range of macromolecular nucleophiles in the cytoplasm. In fact, the binding of bioactivated agents is typically much greater in the cytoplasm than nucleus, with a differential of about 100:1.

As each of the activated chemicals reaches the nucleus, it must still contend with the fact that the DNA is enshrouded with nucleophiles that further reduce the potential for mutagenicity. With respect to the cellular genome, it consists of about 3.2×10^9 base pairs. Within this framework, there are approximately 30,000 genes with an average size of 3,000 base pairs, with about 9×10^7 functional nucleotides. Up to about six genes would have to be mutated to effectively mediate the process of carcinogenesis [111].

In DNA adduct studies, at low levels of exposure, a relationship between dose and adducts has been shown as follows [111]: aflatoxin, 70 adducts/10^8 nucleotides; DMN, 360 or 5/10^9 for N^7 and O^6 methylguanine adducts; and 1/10^8 for meIQX. The question arises as to what level of DNA adduct displays biological/toxicological significance. Since spontaneous DNA damage based on labeling studies reveals about 1 lesion/10^6 nucleotides, it appears that background DNA adducts are about 10–100-fold greater than that reported in the previous experimental studies.

Based on such information, Williams et al. [111] hypothesized that an adduct formation rate of 1/10^{11} should be considered without biological significance. The occurrence of 1 adduct/10^9 nucleotides would represent about 3 adducts/cell, at most affecting only 3 of the 30,000 genes/cell. Even with 1 adduct/10^9 nucleotides, these authors concluded that there is little biological concern. Further, only a proportion of such adducts will be mutagenic, while others will have their mutagen damage repaired. In addition, not all mutations are of equal concern. Only mutations in certain locations of susceptible genes can alter gene function. Thus, many mutations can be without critical biological effect. For example, the vast majority of mutations of the p53 tumor suppressor gene did not significantly affect the amino acid structure of the protein [112]. Another consideration affecting the development of a tumor cellular mass is the need to circumvent host resistance and to form a neovasculature for expansion to a neoplasm. According to Williams et al. [111], the likelihood that a preneoplastic lesion will progress to a tumor is ≤1/1000. The capacity to progress is a function of dose, which can affect the replication potential of the affected cells and related promotional stimuli. At low doses, these promotional factors are far less evident.

Based on the previous mechanistic approach, Williams et al. [111] have addressed the issue of dose–response in general and the threshold concept in particular. Within this framework, these authors isolated specific stages of the process of carcinogenesis including cell proliferation and the induction of numerous preneoplastic and progressive hepatocellular lesions. For each of these steps, they report the occurrence of a threshold response. These collective factors led Williams et al. [111] to propose a change in the risk assessment of carcinogens—from that of an LNT model to the one that is both mechanism and threshold based using the frequency of DNA adducts as the key molecular endpoint to predict the risk of cancer.

The line of argument that has just been presented is the result of nearly 40 years of detailed toxicological investigations [113]. It confronts the long-held linearity perspective as stated in 1969 by Fahmy and Fahmy [114] that "there seems to be no such thing (i.e., thresholds) as far as mutations are concerned." Even more so, the toxicologist Bruce Ames [115] expanded on this area by stating

> It is worth emphasizing that one molecule of a mutagen is enough to cause a mutation and that if a large population is exposed to a 'weak' mutagen it may still be a hazard to the human germ line, since no repair system is completely effective, there may be no such thing as a completely safe dose of a mutagen.

While these historical cautionary statements of Fahmy and Ames still even now seem prudent, the cumulative findings as presented previously demonstrate that this type of conceptualization is fundamentally flawed stochastically, pharmacokinetically, pharmacodynamically, and thermodynamically.

Threshold Dose–Response: Dose-Dependent Transitions and Underlying Mechanisms

Within the past decade, there has been a strong consideration given to the topic of dose-dependent transitions in toxicity and how such descriptive changes in the dose–response could be mechanistically explained. The Health and Environmental Science Institute (HESI) conducted several workshops that addressed this issue [116,117]. These efforts were premised on the belief that a range of different mechanisms may occur for a toxic substance across a very broad dose–response range.

Such dose-dependent toxicities could also impact the risk assessment process and need greater clarification. The expert committee identified various processes that might contribute to the occurrence of dose-dependent toxicity transitions. These processes include gastrointestinal (G.I.) tract or respiratory absorption, tissue distribution as affected by protein binding and active transport systems, and chemical transformation, including bioactivation and detoxification,

TABLE 3.1
Mechanistic Basis for Dose-Dependent Transitions in Case Studies

Case Study	Mechanism
Acetaminophen	Metabolic activation and glutathione depletion
Butadiene	Metabolic activation
Ethylene glycol	Saturation of oxidation
Formaldehyde	Changes in cell kinetics
Manganese	Low-dose essentiality and high-dose toxicity
Methylene chloride	Metabolic activation
Peroxisome proliferator-activated receptor (PPAR)	Receptor activation
Progesterone/hydroxyflutamide	Receptor interaction
Propylene oxide	Altered homeostasis
Vinyl acetate	Altered homeostasis
Vinyl chloride	Adduct formation and DNA repair
VDC	Enzyme saturation and depletion
Zinc	Deficiency toxicity and high-dose toxicity

receptor interactions, tissue and DNA repair processes, as well as altered homeostasis. Thirteen distinct examples of dose-dependent transitions were identified (Table 3.1) and discussed (Table 3.2). These examples were selected since they affect a broad spectrum of mechanisms such as metabolic activation, altered homeostasis, enzyme saturation and depletion, alteration in cell kinetics, adduct formation and DNA repair, and glutathione depletion.

An instructive example of a dose-dependent transition involved the toxicological assessment of acetaminophen, an agent whose toxicity has been closely associated with a depletion of reduced glutathione (GSH). This depletion begins to occur upon saturation of glucuronidation and sulfation pathways. This saturation process results in more acetaminophen becoming converted to the toxic electrophilic metabolite of acetaminophen called NAPQ1. Once formed, the NAPQ1 becomes quickly detoxified by GSH in the affected tissue, resulting in GSH depletion. At high metabolite doses, the GSH depletion becomes more extreme, leading to occurrence of NAPQ1-induced damage. Thus, the central factor

TABLE 3.2
Factors Affecting Dose-Dependent Transitions

Dose-Dependent Changes in Excretion

Considerable research has been conducted concerning the quantitative renal saturation behavior of drugs.

Two types of saturable active transport processes affect the urinary elimination of xenobiotics (tubular secretion and tubular resorption).

Saturation of tubular secretion tends to lower renal clearance at high doses; this results in yielding a larger internal body concentration at higher rates of external dosing.

Saturation of tubular resorption processes displays the opposite effect.

Dose-Dependent Alterations in Metabolism

Michaelis–Menten enzyme kinetics.

As activating/detoxifying enzymes have limited capacity, they will become saturated at some elevated dose.

At progressively higher doses, a larger fraction of the xenobiotic is metabolized and may be routed to other pathways.

Dose-Dependent Changes in Repair, Cell Killing, and Rate of Cell Replication

Tissue repair.

DNA repair.

Saturation of repair systems at elevated levels of exposure tends to result in longer biological half-lives of the induced lesions and a greater likelihood for the lesion to be incorporated into the genome following DNA replication. This type of process would enhance the incidence of mutations per incident of exposure.

Induction of repair process can also influence the degree of damage retained. It is generally unknown how the dose of mutagens affects the magnitude of the repair induction process and how this may vary between individuals. These factors are likely to affect dose-dependent transitions.

in acetaminophen's induced hepatotoxicity involves both the formation of NAPQ1 and the tissue's ability to produce adequate amounts of GSH. The acetaminophen-induced hepatotoxicity will be affected by factors that influence that capacity for bioactivation as well as GSH production and regeneration. There is likely to be some degree of interindividual variation in the capacity of acetaminophen to transition into a toxicity mode. Another example of a saturable enzyme involves the metabolism of ethanol by alcohol dehydrogenase (ADH). Once this enzyme becomes saturated, the toxicity response becomes nonlinear. In contrast to the example with acetaminophen, the saturable enzyme is the one that led to detoxification.

Another example of an agent that is metabolized via cytochrome P450-dependent monooxygenases to a metabolite that binds to and depletes GSH is vinylidene chloride (VDC). According to Slikker et al. [116,117], the GSH depletion decreases in proportion to the concentration of the toxic metabolite generated. However, a dose-dependent toxic transition occurs when the GSH has been depleted by 60% that occurs at 50 mg/kg with no toxicity occurring at 25 mg/kg. It was speculated that the 60% GSH decrease may reflect the limits of reserve capacity below which the toxic mechanisms are able to alter plasma membranes leading to frank toxicities.

A particularly interesting example of a dose-dependent transition involved the mechanism by which propylene oxide induces nasal tumors in rats following exposure via the respiratory route [116,117]. Of particular interest was that the nasal tumor incidence reflected a clear threshold dose–response, whereas the occurrence of hemoglobin and DNA adducts followed a linear dose–response relationship and were thus not capable of accounting for the nasal tumor incidence. However, the cell proliferation induced in the nasal respiratory epithelium also followed a similar threshold pattern of the nasal tumors. These findings show a very strong association between cell proliferation and nasal tumor incidence (Figure 3.20).

The dose-dependent cell proliferation model has also been proposed in the assessment of formaldehyde-induced nasal squamous cell carcinoma in rodents. The doses associated with the cancerous responses were those that induced cell death while subsequently stimulating regenerative cellular proliferation (RCP). In a detailed cancer bioassay study with formaldehyde, Monticello et al. [118] employed five concentrations (0.7, 2.0, 6.0, 10.0, and 15.0 ppm) at which RCP was measured at multiple locations in the nasal tissue over days 1, 4, and 10 and at weeks 6, 13, 26, 52, and 78. Of particular interest was that the formaldehyde-induced dose-related changes in the rate of cell replication were J-shaped with below control responses seen with the two lowest concentrations. At low concentrations of formaldehyde exposure, the incidence of nasal tumors was less than in the control group. This finding was consistent with the hypothesis that the tumor incidence risk is well predicted by the cell replication rate as was the case with the propylene oxide. The decrease in the cell proliferation rate at low concentrations of formaldehyde was proposed to be caused by a reduction of DNA synthesis and cellular replication due to the occurrence of DNA cross-links that block cellular replication complex. The number of cross-links and their rate of removal were proposed to be rate limiting, therefore controlling the replicative synthesis. While this process was still ongoing at high concentrations, the capacity of formaldehyde to form the DNA cross-links was believed to be overwhelmed by its capacity for inducing cytotoxicity, leading to the increased tumor response at high concentrations of exposure.

Other examples of dose-dependent changes in the metabolism of xenobiotics as affected by enzyme saturations have been shown to affect dose-dependent toxicity transitions. For example, Belinsky et al. [119] assessed the implications of saturation of bioactivation of the carcinogen nicotine-derived nitrosamine ketone (NNK) on adduct formation. NNK forms O^6-methyl guanyl adducts eightfold more efficiently at low IP doses (0.3–1.0 mg/kg) than at 100 mg/kg. The difference in response between the high and low doses was hypothesized to be due to the saturation of a local enzyme that produced the methylating agent. A similar type of dose-dependent kinetic mediated response was reported for vinyl chloride. In this case, the tumor incidence response is linear at low dose but flattens out at high doses (1,000–10,000 ppm). Of interest is that testing at only high doses would have yielded an underestimation of tumor risks to the low-dose range with standard modeling procedures [116,117].

Plotting Data: A Key Element in the Threshold versus Linearity Debate

There has been considerable debate in the toxicological literature on the plotting/graphing of dose–response relationships. This debate has been led by William Waddell of the University of Louisville, who argues that dose–responses should be plotted via the use of logarithms rather than linear scales. Waddell has argued that current risk assessment methods typically assure that there is no safe exposure to carcinogens, only at a zero dose. He claims further that the selection of linear scales for plotting dose–response relationships has no scientific basis and, in effect, has concealed the existence of thresholds. The perspective of Waddell was stimulated by Rozman et al. [120], who argue that how one plots data can affect their perspective on the nature of the dose–response. These authors asserted that the case for low-dose linearity emerged from a conversion of the logarithm plotting of the dose–response as recommended by Gaddum in 1945 [121] to an arithmetic approach but a few years later. Based on data concerning the induction of CYP A1 by Tritscher et al. [122], who used nearly two dozens of doses of tetra-CCD, the data plots were compared with either an arithmetic or logarithmic approach. Arithmetic plotting created the distinct impression that the measurements were taken close to zero and that the Michaelis–Menten-based fit would be approaching zero. Rozman et al. [120] indicated that the arithmetic plotting creates a profound misrepresentation of the findings. They indicated that the dose–response

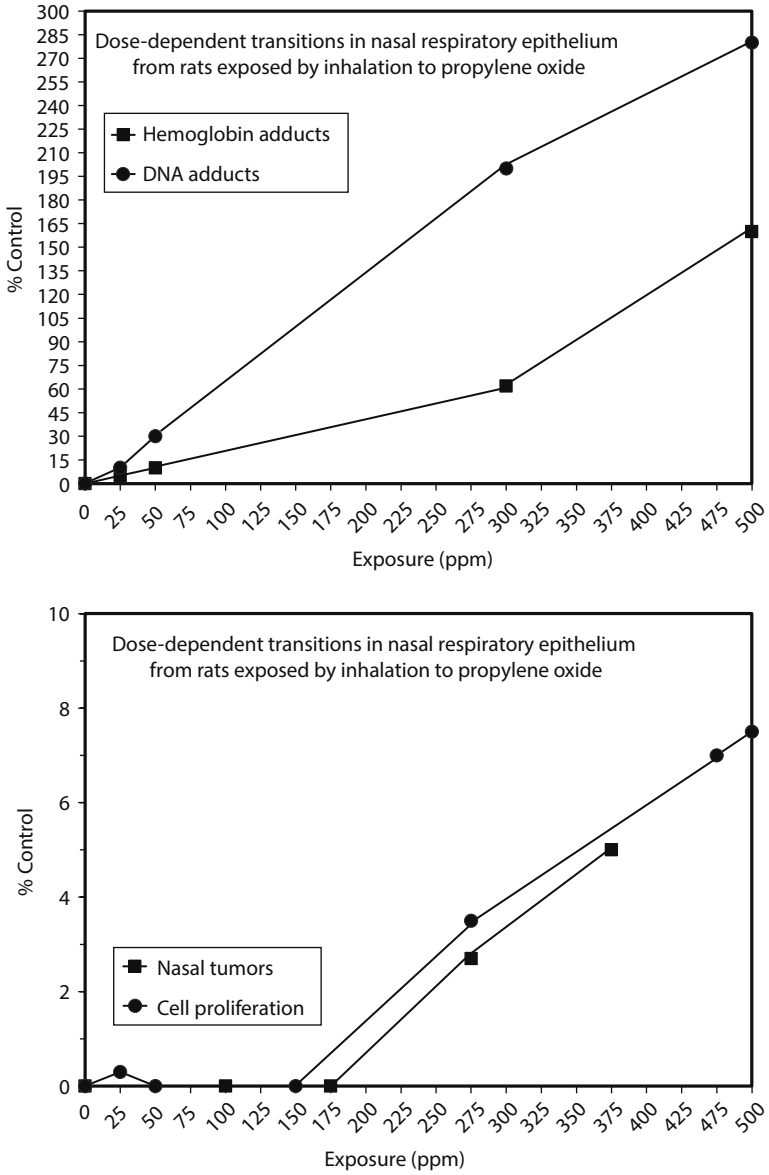

FIGURE 3.20 Dose-dependent transitions for nasal respiratory epithelium from rats exposed by inhalation to propylene oxide. (Based on Slikker, Jr. W. et al., *Toxicol. Appl. Pharmacol*., 201, 203, 2004; Slikker, Jr. W. et al., *Toxicol. Appl. Pharmacol*., 201, 226, 2004.)

should be represented logarithmically since one molecule is in close proximity to a zero point of reference. A limitation to using logarithmic is that the log of zero for the control is undefined. While this is an issue, it is commonly dealt with by giving the control group a very small positive value of no practical consequence.

It is generally accepted that quantitative risk assessment (QRA) for carcinogens was implemented to replace the apparent arbitrary judgment of extrapolating animal data to humans via the use of uncertainty factors. The underlying basis for this change was via the assumption that a single molecule can cause a mutation that can cause a molecular transformation with the result eventually leading to the development of cancer. Since there was an inadequate understanding of the process of carcinogenesis and great fear of this disease, it supported a precautionary perspective. Prior to the switch to QRA for carcinogens, there was the creation of the carcinogenicity bioassay. This assay had the simple goal of answering a qualitative question: was the agent to be tested a carcinogen or not? This being the case, a large number of doses were not deemed necessary. Typically there were only one or two doses that were administered. While this testing framework was adequate to answer the qualitative yes or no question, this design failed to address the quantitative demands for assessing the cancer dose–response [120]. A qualitative test system was used by the toxicology community for critical quantitative estimates of the dose–response in the low-dose range. To further distort the low-dose evaluation estimates, the qualitative design has incorporated the maximum tolerated dose (MTD) concept (see "Maximum Tolerated Dose/Dose–Response" section) and used it as a standard.

To illustrate the difference in plotting methodology, Waddell employed data from a 4000-rat cancer bioassay with nitrosodiethylamine. The dose–response data strongly fit a linear dose–response relationship when plotted on the linear scale. In contrast to the linear scale, Waddell introduced the logarithmic scale [120] that plots not via the mg/kg/day method but by using molecules/kg/day. On the abscissa, a logarithm represents dose as the number of molecules/kg/day from 1 to 10^{23}. The difference in the representation of the results is striking with the linear plotting giving the impression that the cancer risk approaches a background of zero exposure in a linear fashion. With the logarithm-scale molecule exposure model, the cancer incidence response does not approach zero molecules but approaches/collides with the abscissa at 10^{17} molecules/animal, thereby providing the distinct impression of a dose–response threshold.

Waddell demonstrated that this was the general pattern of dose–response relationships for numerous positive cancer bioassays [123]. The assessment of Waddell [123–134] attracted considerable attention of leading toxicologists and dose–response modelers, some of whom took issue with his methodology [135–140]. The interpretation of Waddell was disputed, dismissed as highly flawed by Crump and Clewell [135], and seen as a visual artifact based on the scale of the plot. Andersen et al. [136] stated there was no realistic representation of a threshold that could be demonstrated even in very large toxicity studies. Even though Andersen et al. were sympathetic to the likelihood of thresholds for chemical carcinogens, they argued that the only way to establish such a threshold was via a mechanistic understanding of the biological dose–response process. Lutz [137] offered further criticism of the Waddell perspective arguing that a major problem for this approach was that the logarithm transformation of the dose made it impossible to indicate a control group response since the log of 0 is undefined. He also criticized Waddell for creating this *problem* by simply subtracting the control group incidence from the treatment groups' incidence.

The series of papers of Waddell are important for a variety of reasons. The most substantial is that plotting of dose–response relationships using the number of molecules as the dose is highly instructive and provides an improved context for assessing toxicological data. Such plotting does not prevent the plotting of data via other approaches. In fact, such comparisons can lead to more insightful follow-up questions about the experimental findings. Waddell plotted tumor incidence dose–responses for 50 chemical carcinogens showing that the estimated zero response was in the 10^{17} molecule range/animal. This is an important observation that should not be dismissed.

An objective appraisal of this debate between Waddell and those who criticized his approach is that they came to the same practical conclusion. That is, the science reveals that there is no measureable enhanced risk at lifetime doses in which the number of molecules can reach 10^{17}/animal even at a de minimus level. The debate over whether there is linearity existing after an extrapolation over 17 orders of magnitude of dose is simply unresolvable in a technical/experimental manner. If advocates of an LNT position can retain a theoretical belief in LNT, then it should be accompanied with the recognition that there are, at the least, practical thresholds.

The Rozman plot has been widely publicized for the assessment of carcinogens. This concept is general and could readily be applied to noncarcinogens as well. As an exercise in this regard, the number of molecules in a liter of drinking water at U.S. EPA drinking water standards was estimated. These are exposure standards and are generally based on the reference dose (RfD)/no observed adverse effect level (NOAEL)/uncertainty factor process. That is, these exposure standards first select the most sensitive animal model, study, and endpoint, and then a threshold of toxicity is estimated. Uncertainty factors from 100 to 1000 are typically employed. At that point, a relative source contribution component is incorporated into the standard derivation process. Based on such a process, it may be expected that there should be a substantial level of confidence that an exposure of 2 L/day at the exposure standard should not be associated with any adverse health effects. That is, the exposure standards should therefore generally be considered as being of a highly precautionary nature. Yet, even with those *highly precautionary* daily exposures at the level of the drinking water standard, the number of molecules per liter is generally in the 10^{16}–10^{18} molecules/L. Once again at a rate of 2 L/day for 70 days, the number of *toxic* molecules that can be safely consumed in a lifetime from drinking water alone would be in the 10^{20}–10^{22} range. It should be noted that these exposure standards are based on the premise of protecting those at increased risk.

So what does this dose–response relationship based on molecules mean? The findings indicate that no demonstrable toxicological activity occurs until massive numbers of toxic molecules/day to noncarcinogens are administered. This is also the case for carcinogens as well.

CHALLENGES TO THE THRESHOLD MODEL

Introduction

The threshold dose–response has been the dominant dose–response model in pharmacology and toxicology throughout the twentieth century to the present. As discussed earlier, the biphasic dose–response model and the threshold dose–response models were advocated by homeopathy and traditional medicine, respectively, in the early decades of the twentieth century. By 1930, the biphasic dose–response, along with homeopathy, was significantly marginalized, whereas the threshold dose–response, along with traditional medicine, was transformingly dominant in the United States. In fact, the success of traditional medicine in the United States was due principally to major institutional, governmental, and performance reforms that were direct offshoots of the 1910 Flexner Report [66], transforming U.S. medicine education into a far more scientific and rigorous profession, with a strong research base [67]. This remaking of American medical education proved to be the key vehicle for

the transcendent dominance of American medicine in the twentieth century and as an offshoot, the dominance of the threshold model, and an offspring of traditional medicine. This critical association of the threshold model to the field of traditional medicine was the most significant factor affecting the acceptance and widespread use of this dose–response model in society. Despite its widespread acceptance and profound influence in the medical and scientific domains, the threshold dose–response model has also been the object of considerable criticism and challenged on multiple scientific and policy fronts. The following section presents and assesses the most significant challenges to the threshold dose–response model and their scientific foundations and places the threshold model and alternatives in a broad and integrative toxicological context.

Challenge #1: LNT and Ionizing Radiation

The radiation geneticist Hermann J. Muller [88], at the University of Texas at Austin, Texas, reported that high doses of x-rays induced mutations in the germ cells of male fruit flies. Based on limited experimental data, all of it at very high doses, and some of it contradictory to his hypothesis [9], Muller soon developed a strong belief that the mutation rate would be proportional to the dose of energy adsorbed. This implied that in the case of mutation, there would be no threshold. This issue would become progressively more contentious, especially with the expanding use of medical x-rays, the development of atomic weapons, dropping of the atomic bomb, and testing following their atmospheric explosions in the early cold war years.

During the 1920s to the early 1940s, the use of x-rays for therapeutic purposes for children and adults was extensive, treating arthritis, sinus infections, staphylococcal infections, otitis media, tuberculosis, pneumonia, and a myriad of other conditions besides cancers [46]. Seen within this perspective, one could sense the value of health concerns expressed by Muller, even if he might be incorrect with respect to the linearity hypothesis. It was only following the commercialization of penicillin after WWII and the rapid development of other antibiotics that the use of x-rays for such conditions was abandoned.

With respect to ionizing radiation, the idea of a threshold dose–response was first proposed in the mid-1920s based on occupational exposure concerns. The threshold concept was associated with the idea that workers could tolerate a certain amount of exposure without any significant health concern. That the threshold would need to be exceeded before harm would occur was generally accepted and especially accepted by the medical community. However, this view would become challenged by Muller following his discovery that x-rays induced mutations in fruit fly germ cells.

The first national impact of Muller's findings and advocacy occurred in 1935 within the American X-ray and Radium Protection Committee, later (1946) to be called the National Committee on Radiation Protection and Measurement (NCRPM). At this time, an unnamed committee member wrote to Taylor with the recommendation that the tolerance dose be reduced from 0.1 to 0.05 R/day based on the Muller findings that suggested a cumulative effect of x-rays on the genome over a prolonged period of time. Yet, the committee was at a loss as to how to extrapolate the findings in fruit flies to humans and to do so in a quantitative manner. Nonetheless, the data of Muller and others were kept at the forefront as the committee struggled with the issue of reproductive safety within the workplace and for patients. Over the next several years, the minutes of this committee reflect how the findings of Muller progressively came to challenge the view of a threshold. At the December 1938 meeting of the committee, a proposal was offered to amend the statement on the tolerance dose to the following: "The generally accepted tolerance dosage is taken as 10^{-5} r/sec for a 7 hr day. Geneticists on the committee pointed out that because of the cumulative effect of X-rays the tolerance dose should not exceed 10^{-6} r/sec ([82], see footnote 300)." By the December 1940 meeting, the committee explicitly stated that the rationale for lowering the tolerance dose was because of a concern with mutational effects ([82], see footnote 305). This recommendation did not sit well with the influential Failla who felt that a switch to a mutational endpoint would create considerable uncertainty since there may not be a threshold for a genetic effect. However, the data were still not viewed by the majority of committee members as adequate to prove that a threshold did not exist.

The committee tried to find a way through the confusing dilemma of the threshold versus linearity debate. While the committee believed that the term tolerance dose referred to a dose that could be tolerated or accommodated without any biologically significant damage, this was not the case with genetic damage that was thought to be irreversible, cumulative, and harmful. The dose–response change from threshold to linearity would lead to a new concept called *permissible exposure*. This was an important change because a permissible dose could still injure; it was not considered *safe*.

Permissible exposure was the means by which the *acceptable* risk concept became operational. Whether the general public understood or misunderstood the differences between a tolerance dose and a permissible dose is not known. Nonetheless, it would have important implications for the process of risk assessment and risk management. In offering a compromised position, the committee proposed not changing the exposure standard (i.e., a practical solution); this would placate the supporters of threshold; however, they would yield on the theory. The dose–response concept would change from a tolerance phenomenon based on the threshold concept to one without a threshold. The exposure would now be seen as a permissible dose, a concept built upon *acceptable risk*. The permissible dose terminology therefore represented a profound conceptual change, indicating that a threshold for x-ray-induced germ cell mutations was no longer assumed. However, despite the years of debate and the switch in terminology and concept, this critical policy change was never published (i.e., acted formally on); this failure to follow through on the agreed course of action would

lead to new controversy and debate in the years immediately following WWII.

The permissible dose concept was not lost during WWII despite the inactivity of the committee during that period, as committee members were reassigned to other activities for the duration of the war. However, following the end of the war and with the Nobel Prize recently received (i.e., December 1946), Muller was invited to join the NCRPM that was chaired by the more conservative Failla. In their 1947 draft report, the committee dropped the tolerance dose concept since ionizing radiation was now assumed to have no threshold and to display cumulative damage. Once again, organizational inertia and personal disputes hit and the 1948 recommended changes of the NCRPM would not be published for some 6 years! Based on these factors, it was hard to predict the behavior of the NCRPM committee. However, its actions were quickly overshadowed by a new NAS/NRC committee that was dominated by Muller and other radiation geneticists that were loyal to his perspective. The situation was also problematic since some scientists, such as Muller, with clear ideological perspectives, were serving on multiple national and international advisory committees, addressing the same dose–response policy topics [9].

In their groundbreaking publication of 1956, the NAS Biological Effects of Atomic Radiation (BEAR I) committee [141] formally asserted the concept of low-dose linearity for ionizing radiation-induced germ cell mutation. The geneticist community, as lead by Muller, saw the NAS committee as the vehicle to finally change the national risk assessment policy and to do so in a highly visible and far-reaching manner. That is, the 1956 report was widely distributed, was the subject of considerable media attention, and would have a profound impact on policy. The genetics section was intentionally written to be read by a general reader, further enhancing the spread of the linearity concept and fear of radiation in the media and general public.

The transition from threshold to linearity required about three decades, starting with Muller's seminal publication in 1927 [88]. During an oral history, the longtime chairman of the NCRPM Lauriston Taylor revealed that his committee was awaiting anxiously for the guidance of the prestigious NAS committee as they wanted to follow its lead. Within 1 year of the 1956 NAS report, the NCRPM generalized the concept of linearity for germ cell mutation to somatic cells, thereby affecting cancer risk assessment [9]. Soon other national and international committees would concur and a remarkable dose–response revolution had occurred, with significant long-term implications and consequences.

The generalization from the germ cell linearity response to somatic cell linearity was a key event, especially coming so soon after the NAS BEAR I report. It was also remarkable because even though the NAS BEAR I committee carried the greatest scientific credibility, the NCRPM committee, in effect, affected the major policy change. It is ironic that the NCRPM committee, which so intensely and anxiously awaited the guidance of the BEAR I committee, actually ignored guidance that emerged from the BEAR I committee activities on the question of somatic cell effects. More specifically, in a reading of the near-final draft report of the genetics panel of the BEAR I committee, Dr. Warren Weaver, chairman of that committee, stated on February 5, 1956 (see transcript of meeting), that "A little radiation, now and then, does not directly harm the person receiving it." Weaver then quoted from the next paragraph of the same report:

> From the above statements a very important conclusion results. Although there may be and probably is, a safe rate at which a person can receive radiation (say so much per week) if one is concerned only with direct damage to that person, the concept of safe rate of radiation simply does not make sense if one is concerned with genetic damage to future generations.

In the final report of the 1956 BEAR I committee, one can see a generally similar but slightly nuanced restatement of the earlier drafted statement as quoted by Chairman Weaver. The final report states:

> It has sometimes been thought that there may be a rate (say so much per week) at which a person can receive radiation with a reasonable safety as regards certain types of direct damage to his own person. But the concept of a safe rate of radiation simply does not make sense if one is concerned with genetic damage to future generations [141].

Both the near-final draft and final report statements are in agreement on the genetic effects to future generations. As for the somatic cell effects, the draft report is clear that a threshold effect is emphasized. The final report restates the somatic cell threshold interpretation but more subtly via a type of third-person comment rather than the more direct style of the draft report. Nonetheless, the NCRPM made the leap to linearity for somatic effects, not the genetics panel of the 1956 BEAR I NAS committee.

The generalizing of mutation linearity dose–response to somatic cells and its impact on cancer risk assessment was profoundly influenced by one of Muller's geneticist colleagues and future Nobel Prize winner, E.B. Lewis, and fueled by his widely acclaimed article in the journal *Science* [142] along with an accompanying and highly supportive editorial by the journal's editor in chief [143]. Muller likewise had obtained prepublication copy of the Lewis *Science* paper and distributed it to key groups such as the NAS BEAR genetics panel in December 1956, emphasizing the estimated cancer risk to the human population from radioactive fallout [82]. Thus, the first serious challenge to the threshold dose–response model was one of a developmental scientific perspective that was set within a highly charged international political context.

While the 1956 BEAR committee did not formally address the issue of somatic effects, the 1960 BEAR committee did. The conclusion of this committee on this issue is given in the following quote from its final report. The committee stated that it "does not consider it justifiable to predict human tumor incidence from small radiation doses based on extrapolation from the observed incidences following high dosage."

Furthermore, the 1960 BEAR committee acknowledged that the number of mutations in mouse sperm and oogonia was less when the x-rays were given at a lower dose rate than with an acute exposure in which the dose rate was greater but the total dose was identical under both approaches. This was a conclusion of the Caspari and Stern [144] study with *Drosophila* sperm that caused so much scientific confusion and subterfuge by Stern and Muller as they desperately tried to deflect the findings of the Caspari research [10,29,39,145]. Now some 12 years later, the findings were generalized to mice based on the work of William Russell at Oak Ridge. At his Nobel speech, Muller would argue that similar damage with the same cumulative dose, despite different dose rates, was de facto proof of the linearity model. Yet now, he would make no such statement in the context of the 1960 BEAR committee. Nor would the BEAR committee of 1960 and its genetic panel, still dominated by Muller, change their linearity recommendation for mutational effects in light of the challenging findings in mammalian cells to the linearity dose model.

These historical quotations are not simply the stuff of academic arguments but should be seen for how they came to impact major public policy in the dose–response and risk assessment domains [29]. The NCRPM gave the impression of deferring their position to that of the 1956 BEAR I committee; yet they developed a policy on somatic cells that was not formally addressed by this NAS/BEAR I committee in a direct policy sense but was actually in apparent conceptual disagreement with it. Furthermore, a position on somatic cell responses for cancer was explicitly addressed by the prestigious 1960 BEAR committee; it did not support the concept of extrapolating from high to low doses for cancer risk. This position was in direct conflict with the recommendations of the NCRPM. However, it was the 1956 report of the NAS BEAR I committee that received enormous publicity within the scientific community and the popular press, while the 1960 NAS BEAR committee's report was generally overlooked, lacking any notable impact. This point was explicitly addressed by a member of both committees, Dr. James Crow [146] and others (e.g., [147]), in a subsequent historical evaluation of the impact of such National Academy of Sciences efforts on radiation health policies in the United States.

While the 1956 NAS committee and other influential advisory committees were adopting the LNT perspective, an important independent action in the U.S. Congress was about to come to a similar conclusion, also with profound implications. That is, the Delaney *Amendment* to the Food Additives Amendment became law on April 26, 1958. It affirmed that no additive would be considered if it induced cancer in animal models or humans. The Delaney Clause was subsequently placed into the Color Additives Amendment of 1960 in response to the highly publicized cranberry crisis of 1959 [148].

The Delaney Amendment was premised on a belief in linearity at low dose for chemical carcinogens. Over time, the FDA would modify the Delaney Clause to address the issue of de minimus risks, that is, a risk that is both too low to be accurately measured and below practical concern. This modification enabled FDA to permit carcinogens to be added to food if the estimated risk had lower than a calculated risk (e.g., $\leq 10^6$/70 year lifetime) deemed to be de minimus, based on animal extrapolation and biostatistical modeling procedures. Despite their similarity in time, the development of the LNT cancer risk assessment model in the Delaney Clause developed independently of the NAS BEAR I-inspired LNT cancer risk assessment activities, although their implications converged [9].

The next serious challenge of the LNT model to the threshold dose–response model occurred two decades later in 1977 in the bursting forth of the environmental regulatory revolution in the United States when the NAS Safe Drinking Water Committee (SDWC) recommended that the EPA apply the guidance of the NAS BEIR II committee for ionizing radiation to the domain of chemical carcinogens [149]. From the late 1950s to the early 1970s, profound intellectual debate focused on the linearity versus threshold policy decision for ionizing radiation and cancer risk. As noted, the NCRPM first recommended the switch from threshold to linearity. In fact, the NCRPM orchestrated a very significant compromise between the opposing parties of this debate [8]. It got the linearity advocates to admit that the data supporting linearity at low dose were not convincing. Likewise, the same argument was used against the threshold perspective. As a result of this intellectual impasse/conundrum, the committee concluded that

> it was not possible to establish the exact character of the dose curve. Lacking sufficient unequivocal information, the committee believed it would be desirable to take a conservative position and to assume a non-threshold linearity dose response relationship [82].

While this position seemed to represent a compromise, it represented a major victory for the concept of the *precautionary principle*. This was similar to the type of compromise that was brokered in the 1940s over the issue of tolerable dose versus permissible dose. However, in that earlier case, the outcome was far different. The concept of permissible dose was accepted as scientifically more plausible, but the threshold concept would govern the regulation. Some 25 years later, the concept of linearity had lost scientific support, yet its underlying philosophical perspective (i.e., precautionary principle) was adopted by the NCRPM. Other leading advisory groups would also struggle with this problem with the NAS BEAR committee of 1960 rejecting linearity on scientific grounds, whereas the U.S. FRC (1960) accepted the linearity concept based on the precautionary principle. This type of back-and-forth struggle would continue between different committees and their varying compositions over the next decade. However, the precautionary perspective reemerged with the next NAS committee (now called BEIR I/II, 1972) [149], a perspective that would strongly affect the actions of the 1977 NAS SDWC [150]. This committee would also rely heavily upon a series of papers they claimed that supported the scientific foundations of low-dose linearity [151–154].

The EPA accepted this 1977 recommendation of the SDWC and, within 2 years, applied the LNT model to the risk assessment of trihalomethanes (THMs) and then soon to dozens of other chemical carcinogens up to the present. The theoretical foundation of this challenge to the threshold dose–response model for chemical carcinogens was built upon eight guiding principles as laid out in the NAS book *Drinking Water and Health* [150]. The eight principles are as follows:

1. Only one or two changes in a cell could transform it, and this could lead to cancer.
2. Human population heterogeneity was a factor, and some people may be at greater risk. Such heterogeneity leads to the conclusion that there was no population-based threshold.
3. A transformed cell will be irreversibly propagated.
4. If the mechanism involved mutation, there would be no threshold; in fact, if there were no information on mechanism and cancer occurred, mutation should be assumed.
5. It is necessary to assume that a single molecule or a few molecules can cause a mutation. Therefore, linearity at low dose can be assumed.
6. There is also the assumption that the response would be directly additive to background, if acting via the same mechanism. This would also support the linearity conclusion.
7. Available mutagenicity data with radiation indicated that it was linear at relatively *low* doses.
8. Since chemical carcinogens act like ionizing radiation, low-dose linearity should also be assumed to be the case for such chemicals.

It is also evident that the committee did not choose to document possible alternative opposing arguments to linearity at low dose or weaknesses in the so-called eight principles. Furthermore, it would have been of considerable value if the committee had ranked the principles in terms of the degree of scientific confidence that each had individually and its relativity to each other. The committee should have distinguished those principles that were guided by scientific data as compared to those more influenced by a protectionist philosophy rather than science. Furthermore, these key references used by the 1977 SDWC provided data and/or conclusions that directly contradicted the previous principles #1, #3, #4, and #5. For example, Nordling [154], Muller [152], and Iversen and Arley [153] argued that multiple successive mutations in the same cell (i.e., up to seven mutations) would be needed to cause human cancer, thereby challenging key principles of the 1977 committee that relied upon these papers.

While each of the eight guiding principles was important in order to provide the underlying support for the EPA to adopt low-dose linearity for carcinogen risk assessment, the intervening four decades have not provided confirmatory support for any of these *principles*. Rather, the findings that have emerged during this time period have, in fact, revealed that those views are now generally either scientifically untenable or practically impossible to study at a sufficient level of detection. For example, that a single alternation in DNA would be sufficient to lead to cancer or that the process of carcinogenesis, once initiated, is irreversible has been repeatedly demonstrated as not occurring [111]. Driver et al. [155] demonstrated a strong linear dose–response relationship from DMN-induced adducts and foci production in the kidney of male F344 rats. However, the linear dose–response pattern disappears displaying clear evidence of a threshold dose–response for this genotoxic carcinogen (Figure 3.21). Such a dose–time response strategy supported the concept of cancer being a multistage process and with repair-related processes occurring at lower doses, resulting in a regression or suppression of the carcinogenic process.

The idea that chemically induced cancer occurs via the same mechanism as similar as background cancer in the population has not been established. The level of mechanistic detail and biological complexity today reveals how superficial and implausible the *principle* was. In fact, in the domain of x-ray-induced germ cell mutation in fruit flies, it was shown that low dose of x-rays induced a DNA repair process that repairs background lesions while having no effect on those mutations induced by the x-rays [156]. The additivity to background concept would fail in this case as well. Thus, the concept of *reasonable* guiding principles became confused to mean something akin to scientific certainty. The confusion was not only passed on the general public but has affected the development of regulatory agencies' risk assessment actions for chemicals and ionizing radiation with widespread societal implications.

Challenge #2: Hormesis

Historical Foundations

The challenge to the threshold and LNT dose–response models from the hormesis dose–response is relatively recent, being little more than a quarter century old. While the concept of hormesis is about 130 years old, starting with the German physician and pharmacology/toxicology professor Hugo Schulz in the 1880s, that it might challenge current models or might inform the risk assessment process was probably first suggested by Donald Luckey et al. in 1975 [157] in the introduction of the book *Heavy Metal Toxicity, Safety and Hormology*:

> Agents which are found to cause stimulation when given in small quantities are colled [called] *hormetics* and the action is *hormesis*, taken from Southam et. al. [and Ehrlich] (1943). Unterstanding [Understanding] the extent of this phenomenon is essential before world wide committees and legislative bodies make recommendations which consider only toxic actions…

This publication was followed 5 years later by a detailed book by Luckey [53] on ionizing radiation and hormesis that raised the visibility of this concept within a new scientific regulatory context. While the issue of hormesis or biphasic

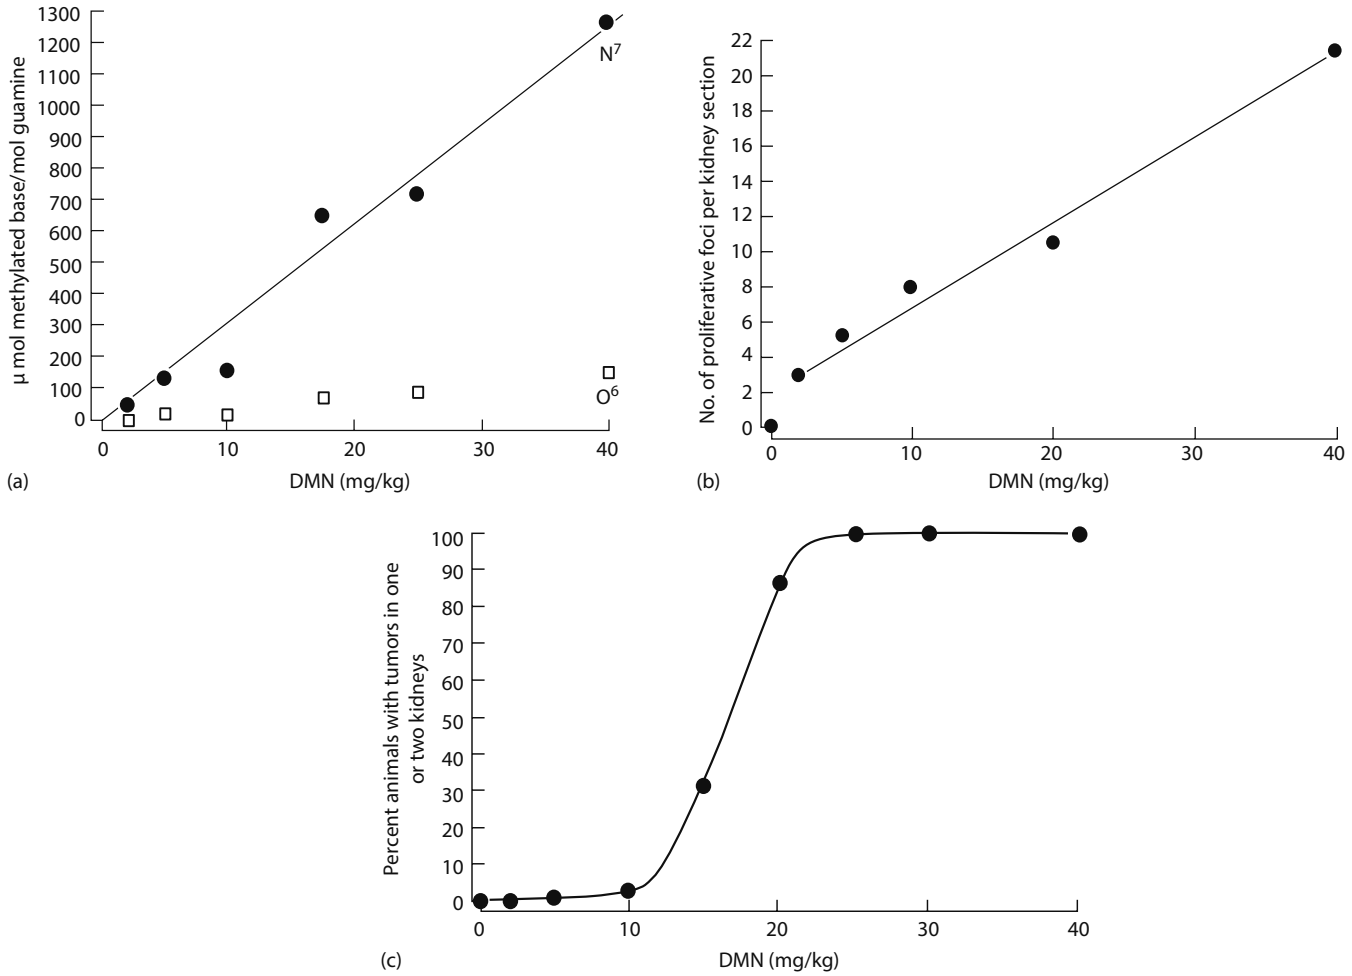

FIGURE 3.21 Dose–response for DMN: (a) renal adducts, (b) renal foci, (c) renal tumors. (From Driver, H.E. et al., *Br. J. Exp. Pathol.*, 68(2), 133, 1987.)

dose/responses seen in an earlier era in the confrontation between homeopathy and traditional medicine was in the attempted commercialization of treatments to enhance agricultural production [4], the goals of Luckey were different. He was far more academically based, with the ostensible goal to educate the regulatory community to the scientific foundations of the hormesis concept and its regulatory implications for setting exposure standards in all types of settings, be they occupational, environmental, food, consumer products, or within the home for concerns such as with radon gas. While these initial activities of Luckey created interest in the hormesis dose–response model, they were not persuasive to the regulatory communities and lead to frustration in dealing with agencies such as EPA in the regulation of carcinogens—especially for ionizing radiation as reflected in a number of his subsequent publications.

Despite the 1980 book by Luckey, the dose–response debate during the early 1980s was not focused upon hormesis versus LNT per se but threshold versus LNT. In fact, this still is the case, even today, all for practical reasons. The regulated industry in both the chemical and radiation areas supported the less conservative threshold dose–response model, whereas the EPA had established the LNT model for their estimates of risks from carcinogens. Using the LNT model in the risk assessment process and in guiding risk management decisions was proving to be very costly to the industry. A key goal of the regulated industry was to find a means to convince the EPA to switch back to the threshold dose–response model for risk assessment purposes. A practical problem for the industry was that the agency assessed each chemical in the chronic bioassay (i.e., the 2-year rodent bioassay) on its own merits, evaluating whether the data generated in the bioassay best fit a linear or threshold model. While this might seem to be an objective approach, there were too few doses to objectively differentiate which model best fit the data. The very few doses were also delivered at very high dose rates, that is, at the maximum tolerated dose (i.e., the highest dosage that would not cause frank toxicity and not reduce body weight by more than 10%) and one-half of that value. With so few doses and those that were used being delivered at such a high dose rate, there were high-dose toxicological concerns and biostatistical limitations that could not be overcome. For all the attempts to rationalize the adequacy of those standard types of bioassay studies, they were far from perfect and not adequate to provide the type of data needed for risk assessment purposes for low-level exposures.

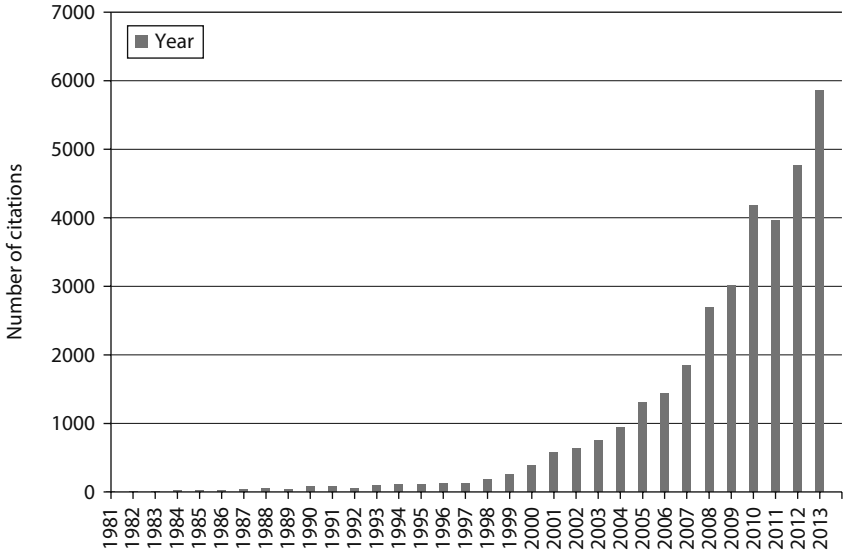

FIGURE 3.22 Citations of hormesis/hormetic in Web of Science database.

Typically both a linear model and a threshold model could similarly account for the observations that are produced in the chronic rodent bioassay. Since one biostatistical model is not particularly superior to the other for data generated in their experiments, the EPA, in such cases, invariably defaults to the most conservative or protective dose–response model. Thus, the linear model became the model selected, by default. There was no practical way around this risk assessment dilemma. The rules of the risk assessment process were very strongly biased toward using the LNT model. Thus, many in industry felt that the government's guidance rules were not scientific and were designed to always yield the same conclusion…. Thus, the *scientific* deck seemed to be stacked to yield a predetermined result.

Since the threshold model could not practically account for dose–response data better than the LNT model for the standard chronic bioassay data, some groups in the industrial sector became interested in the hormetic dose–response (HDR) as it might be easier to distinguish it (i.e., the HDR model) from the LNT than the threshold dose–response model. This might provide a better opportunity to avoid risk assessment estimates based on linearity. Secondly, the hormesis model had a threshold component and it was the establishment of a threshold that was the real goal. The fact that the hormesis model had the potential to estimate a possible public health benefit was politically problematic for industry since it would not be a wise strategy to claim that pollutants could induce beneficial effects at low doses, even if true. This can be readily seen in the range of policy concerns directed at the hormesis concept [158–161]. As stated previously, the goal of the industrial supporters of hormesis is for the threshold concept to gain regulatory traction, not for the concept of health benefit to be the focus.

The electrical power industry from the United States and Japan explored the area of hormesis by conducting a conference in August 1985 with the peer-reviewed proceedings published in the journal *Health Physics* in 1987. The proceedings were followed 2 years later by a debate on the issue of radiation hormesis in the journal *Science* by leaders of that initial conference [162,163]. While the issue of hormesis had resurfaced during the 1980s, it was a modest initial revival as reflected by citations in the Web of Science, which averaged only about 10–15/year (Figure 3.22).

Biphasic Dose–Responses: Multidisciplinary

Despite the rather slow unfolding of the scientific rediscovery of the hormesis concept during the 1980s, there were other developments that suggested an intellectual convergence on the topic of biphasic dose–responses. None of these newer developments were directly related to policies or specific actions of regulatory agencies. Reports from multiple scientific fields began to independently appear on the occurrence of hormetic-like biphasic dose–response relationships. For example, a significant development in the field of pharmacology occurred with the highly influential papers by Szabadi [164,165], which summarized the occurrence of biphasic dose–responses as far back as 1906, starting with research of the 1936 Noble Prize winner Henry Dale (1875–1968) [166] (see "Challenge #3: Pharmacology and the Biphasic Dose–Response" section). Of particular importance was that Szabadi [165] proposed a receptor-based mechanistic model by which such biphasic dose–responses could occur. The Szabadi [165] paper generated a spate of supportive commentaries and related papers [167–171], providing a strong foundation for further developments in this area. Likewise, the field of epidemiology published a number of studies showing U-shaped dose–responses for various types of medical and public health outcomes associated with environmental and occupational exposures [172]. A series of papers were published by Stebbing [173–175], providing a strong complement to the writings of Luckey concerning environmental toxicants and HDRs. During this period, researchers

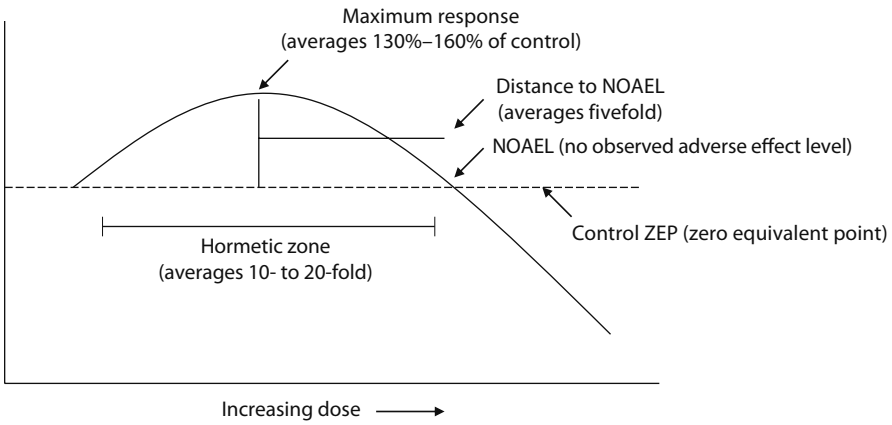

FIGURE 3.23 Dose–response curve depicting the quantitative feature of hormesis. (Based on Calabrese, E.J., *Am. J. Pharmacol. Toxicol*., 3(1), 56, 2008.)

in the area of genetic toxicology reported that low doses of chemical mutagens could induce DNA repair processes that would provide protection against subsequently more massive exposures to the same or different mutagenic agents [176]. By 1984, the concept of adaptive response to ionizing radiation had been reported by Shelly Wolff at the University of California at San Francisco [177]. In 1986, the concept of preconditioning in the biomedical sciences was published, which demonstrated that a short-term/low-dose prior hypoxic exposure would protect against a massive myocardial infarction-induced cardiac damage by about 70%–80% [178]. The findings from each of the previous cited areas of adaptive responses were soon replicated in extensive studies and then generalized to other cell types, organs, and biological models. The shape of the dose–response in each of these general areas was consistent with that of the HDR. In parallel with these emerging findings was the rapid development of in vitro methods and extensive economic and political pressure to employ fewer whole animals in biomedical and toxicological research. The switch to in vitro methods created the opportunity to assess more doses/concentrations per experiment. These changes have profoundly affected the conduct of toxicology, creating the opportunity to routinely evaluate from 8 to 10 doses per chemical screening. In fact, it was as a result of the newly acquired change to in vitro testing and its high-throughput dimension that profoundly expanded the number of reported cases of HDRs in the biomedical literature. The reliance upon test results with doses at the MTD and fractions of the MTD would not have the potential to explore the biological effects of low doses, including the hormesis hypothesis.

Hormesis Database

The 1980s therefore set the toxicological and biomedical stages for the evaluation of the HDR. The 1990s and the first decade of the new millennium witnessed a large increase in the reporting of HDRs in the toxicological and biomedical literature. This increase is especially evident in the second half of the 1990s. The hormetic response was found to be quite common, as well as very general, being independent of biological model, endpoint, and inducing agent. The HDR was also shown to display specific quantitative features, that is, the low-dose stimulatory response was generally quite modest with the maximum response being typically only about 30%–60% greater than a concurrent control group (Figure 3.23) [179–181]. This modest response would present challenges for the observation of hormetic responses, in attempts to distinguish it from normal background variation. Proving the occurrence of an HDR requires greater sample size/statistical power in the low-dose zone along with careful consideration of dose selection with more doses below the threshold along with a heightened need to replicate findings. Given the modest nature of the low-dose stimulation, it is essential that more detailed understanding of the historical variation in the control is known. Thus, false-positive low-dose stimulations could occur as a result of low-control group readings due to normal variation. This has also led to the need to conduct statistical simulations in order to estimate the frequency of false-positive responses. As a result of the recognition of such methodological challenges that are inherent in the assessment of HDRs, it has resulted in adding more dose–response insights, affecting the quality control, experimental design, and response criteria, thereby making conclusions concerning the likely presence or absence of HDRs more reliable. This is especially seen in the prospective testing of specific HDR hypotheses that are becoming more common in the biomedical and toxicological literature.

Defining Hormesis

As a result of the renewal of interest in the hormesis concept in the early 1980s, at least in part, via an industry initiative to avoid an LNT-driven regulatory-based cancer risk assessment, the low-dose stimulatory part of the HDR became viewed by some as beneficial. Without adequate evaluation, some in the environmental regulatory community became either suspicious or opposed to the HDR for philosophical/ideological reasons rather than scientific. However, the

low-dose stimulatory aspect of the HDR is neither inherently beneficial nor harmful [182–185]. One needs to assess not only the data from the experiment but also the biological context of the findings in order to make an informed judgment concerning whether the low-dose stimulation is potentially beneficial, harmful, or neither. When the low-dose stimulating results in enhancing longevity, greater disease resistance, improved memory, greater bone strength, and other comparable apparently desirable responses, it has generally been viewed as *beneficial*. When the responses reflect the enlargement of the prostate gland, the enhanced proliferation of tumor cells, or other undesirable responses, it has been viewed as potentially harmful [182]. In many cases, the clinical or public health implications of a low-dose stimulation may not be large enough to be practically significant. In such a case, the clinical or societal implications may be/are uncertain. Thus, the HDR is a scientific concept—not an ideological element.

Many in the endocrine disruption area describe such biphasic dose–responses as U-shaped nonmonotonic dose–response—not an HDR [184]. Yet, the quantitative features of the biphasic endocrine disruption dose–response follow similar quantitative features as that for the HDR. The underlying molecular mechanisms also follow similar receptor-based and signaling pathway-based processes. It is the opinion expressed here that the inverted U-shaped dose–responses reported within the context of endocrine disruptive agents are generally manifestations of the HDR model of hormetic response–endocrine disruption. The issue over terminology and language is important, especially in order to assist researchers, governmental officials, and others to better understand and apply the dose–response concept.

Hormesis Frequency

While the 1990s and early 2000s witnessed the publication of a large number of HDRs being reported in the biomedical and toxicological literature, there emerged the question of what was the frequency of hormesis in toxicology and pharmacology. Using rigorous entry and evaluative criteria, this question was assessed based on a review of approximately 21,000 papers from the toxicological, biomedical, and life sciences areas. It yielded a value approaching 40% for the frequency estimate of hormetic responses that satisfy rigorous a priori entry and evaluative criteria [186–190]. This observation was supported in follow-up large-scale evaluations [191–193].

Such results were striking since they represented a significant conceptual transition in the toxicological literature. That is, when the hormesis concept was beginning to be discussed in the 1980s, it was uncertain whether it was a real and reproducible phenomenon. If it was, then it was thought that it may be uncommon, rather infrequent, a type of paradoxical phenomenon. Yet, the deeper the investigations probed, the more general and frequent this dose–response was found to be.

Validation of Dose–Response Models

In the course of the previous evaluations of the HDR, the question was raised as to how the toxicology and pharmacology communities had validated the threshold dose–response model during the twentieth century. Since so many of environmental and occupational health regulations and FDA exposure standards were based on the use of the threshold dose–response model, it seemed logical to assume that these agencies as well as the scientific community must have validated the capacity of the threshold dose–response model to make accurate predications in the below-threshold zone. However, follow-up detailed searches of the literature did not yield any published attempts to test the validity of the threshold dose–response model predictions in the below-threshold zone. Likewise, interviews/discussions with senior toxicologists, both within and outside of government, also did not yield any published attempts that validated the low-dose prediction of the threshold dose–response. The below-threshold zone is critical since this is the area of the dose–response where humans principally live. While it is not possible to prove a negative, the results of multiple detailed searches of the literature to obtain articles that validated (or attempted to validate) the threshold dose–response model have been without success. This search failure has led to a tentative but confident conclusion that the toxicology, pharmacology, and regulatory communities failed to validate (or attempt to validate) the threshold dose–response model for accurate predictions in the below-threshold zone during the entire twentieth century.

When the concept of validation was then applied to the three most dominant dose–response models (i.e., threshold, LNT, and hormetic), using multiple, independent large data sets, the only one that was effective in accurately predicting responses in the low-dose zone was the HDR. The threshold model revealed that this model consistently failed to accurately predict responses across the entire spectrum of agents tested [193]. Inaccurate predictions were even more common for the LNT model. These observations were as challenging as they were surprising. These tests to validate the dose–response models upon which regulatory programs have been based were performed only long after these models had been adopted and applied by regulatory agencies in many countries. Thus, multiple decades after their establishment and acceptance, critical inadequacies were uncovered for key risk assessment dose–response models used for most risk-based regulations. Yet, enormous regulatory, administrative, and legal decisions have been made based on these dose–response models that were assumed by the public, elected officials, and probably the scientific community to have been vetted and validated by the scientific and regulatory communities.

The need to validate the capacity of dose–response models to make accurate response predictions, especially in the low-dose zone, is a surprisingly new development to the fields of toxicology, pharmacology, and risk assessment. It is a highly significant practical problem at present in these respective fields because the threshold dose–response model

was adopted nearly a century ago presumably on the assumption that it could make accurate estimates of responses below the threshold independent of biological model, endpoint, and chemical agent. The model estimates are supposed to be reliable and to provide confidence to the public that exposure standards are based on accurate dose–response estimates. The question must therefore be raised as to why the threshold dose–response model was accepted for regulatory use without having been evaluated. In fact, the model was accepted even in the absence of any documentation of what would be an acceptable model and how that decision would be made.

Beyond questions concerning what is an acceptable dose–response model for risk assessment purposes, the acceptance of a model has other important implications that may be overlooked. From a historical perspective, once the threshold dose–response model was adopted and integrated within governmental regulatory frameworks, a hazard assessment process was created based on the assumption that the threshold dose–response model provided accurate estimates of responses below the threshold. This hazard assessment testing protocol determined how chemicals would be tested and evaluated, including the animal models selected, the number and the spacing of doses, and the dose selection strategy. In fact, as a result of accepting the threshold dose–response as the model to be used in the estimation of responses in the low-dose zone, toxicology would become a discipline that would be characterized as using only a few very high doses in the chronic bioassay.

The hazard assessment concept was built upon several data requirements and goals: first, demonstrate toxicity at the highest dose while not exceeding the maximal tolerable dose; second, it is important that no statistically significant increase in toxicity occurs at the lowest dose so that a threshold dose might be more readily demonstrated. There was no interest in obtaining information on the entire dose–response continuum as it was assumed that only random bounce or noise would be observed for responses to doses below an estimated threshold. This type of hazard assessment methodology reinforced the assumption that the HDR did not exist. It was on this basis that past toxicological assessments were based.

There are multiple flaws in this hazard assessment process. If the high dose was too high, then the study would be dependent upon only a single dose. Since the second dose was still 50% of the high dose, this was also at risk for exceeding the MTD. Regardless of whether both doses provided valid data concern would still remain over what was the response at lower doses and whether the threshold was reasonably well characterized for the most sensitive endpoint. All the assumptions that were built into the bioassay and how the data that it produced would be interpreted were derived from assumptions about the threshold dose–response model. Nonetheless, the acceptance of the threshold dose–response model does not excuse the several decades of using only two doses before switching over to three. Even in the case of three doses, each separated by a factor of two is still far from satisfactory for estimating responses in the zone approaching a possible threshold as well as below the threshold.

The background tumor/disease incidence could affect the selection of the animal model. In the case of the HDR model, it would be necessary to test the predictive capacity of the model by ensuring that the control endpoint incidence for tumors and other disease endpoints would be such that one could detect a decrease in the incidence if hormesis were present. If the background incidence is negligible, then it would be impossible to detect the presence or absence of the HDR. The background disease incidence was not of theoretical concern in the selection of the threshold model.

The selection of the threshold model by the regulatory community therefore was never validated throughout the twentieth century in the United States and internationally as well. It was adopted for use by regulatory agencies such as EPA, OSHA, FDA, and all state regulatory agencies. It guided the testing of all chemicals and drugs for safety. The hazard assessment process also assures the testing of agents only at very high doses and with animal models that were given no consideration whether an alternative dose–response model might exist, such as the HDR model. In fact, it would have been a useful factor for this type of interpretational flexibility to have existed.

Attempt to Validate the LNT Model: The Megamouse Study

In contrast to the failure of governments to attempt to validate the threshold dose–response model, the U.S. FDA made an effort to validate the LNT dose–response model for chemical carcinogens. The strategy involved the selection of a well-studied chemical carcinogen (i.e., 2-acetylaminofluorene [2-AAF]) and evaluation of it in a massive experiment that used about 24,000 mice. The results of this massive study were extensively reported [194–196] and assessed in detail by a special expert panel of the U.S. Society of Toxicology (SOT) [197], highlighting the importance of the study. While the findings generated much discussion and debate, a major point of agreement was that the study was only able to assess tumor incidence to the level of 0.01. The report was therefore called the ED01 study. This was the most striking finding since it required about 24,000 mice and all that could be judged were risks to 10^{-2} when regulatory agencies need estimates to the 10^{-5} or 10^{-6} for de minimus risk estimates. It was not possible, therefore, to practically validate the LNT model for cancer risk assessment at the levels of risk that regulatory agencies need to estimate. As a result, no other rodent-based megamouse study estimate has been subsequently undertaken to validate risk in the low-dose range.

Despite these concerns and limitations, the SOT committee developed a dose-related time to tumor model evaluation. They found that the 2-AAF induced a J-shaped dose–response for bladder cancer, a finding that was consistent in all six rooms in which the large numbers of mice were maintained (Figure 3.24). The SOT expert committee unequivocally stated that there was both a threshold and a significant reduction in risks at doses below the threshold. Without using the term, the SOT panel concluded that the experimental findings demonstrated an HDR. This striking conclusion of

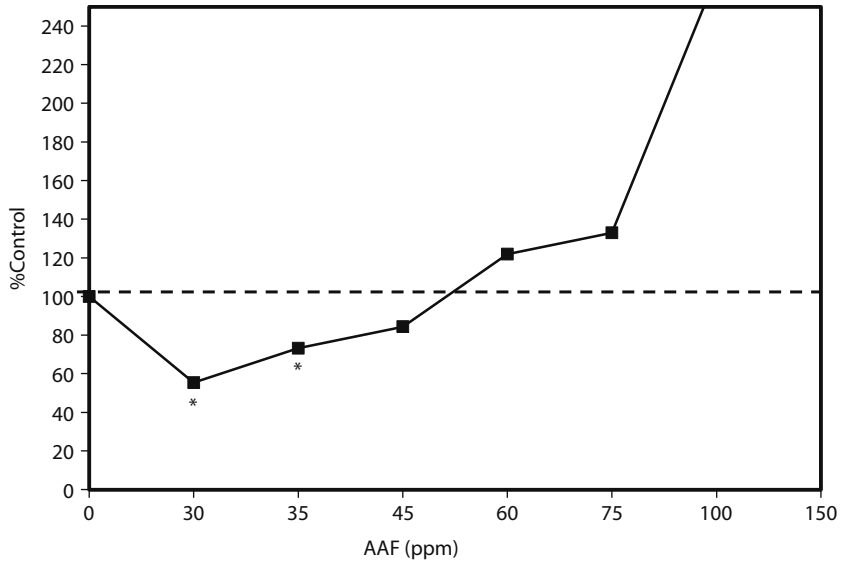

FIGURE 3.24 Bladder tumor incidence adjusted for time in ED01 megamouse study: HDR relationship. *Statistical significance. (Based on Bruce, R.D. et al., *Fundam. Appl. Toxicol*., 1, 67, 1981.)

the SOT panel was buried in the details of an analysis and was never widely cited. Yet, this is a principal finding of the largest rodent experiment, with a strong prospective study design to determine the nature of the dose–response in the low-dose zone. However, these results did not fit the preestablished regulatory agency LNT paradigm and were ignored by such agencies and the field of toxicology.

The validation of the LNT could have been undertaken by a far less expensive strategy and with the testing of more agents so that the issue of generalizability could be considered. For example, Japanese researchers assessed the dose–response for the liver carcinogen DDT using liver foci as the endpoint (Figure 3.25). The study was far less expensive and provided data using considerably less time; once again, the LNT model was not as supported as the hormetic model was.

Hormesis: Dose–Time Response (Overcompensation) Studies

Biphasic dose–responses are typically graphed as either an inverted U-shaped dose–response or J-shaped. The graphing of the inverted U- or the J-shaped seems to be a discipline-specific feature with those reporting disease incidence using J-shaped graphing and those disciplines reporting on growth or changes in longevity using the inverted U-shaped dose–response.

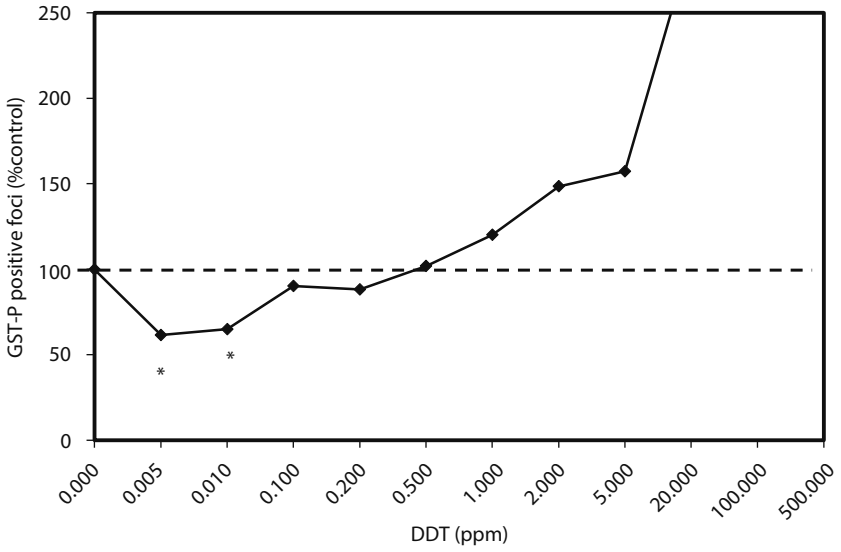

FIGURE 3.25 Effect of DDT on liver foci formation in male F344 rats: HDR relationship. *Statistical significance. (Based on Sukata, T. et al., *Int. J. Cancer*, 99, 112, 2002.)

The biphasic dose–response can also be not only dose-dependent but time-dependent as well. The biphasic dose–response can occur as a result of a direct stimulatory response at low dose followed by a high-dose inhibitory response (Figure 3.23). In contrast, the biphasic dose–response may also occur as a result of an initial dose-dependent decrease in response followed by an overcompensation response that over time yields the biphasic dose–response relationship [198,199]. At the lower doses, the compensatory response results in the response modestly exceeding that of the control group. However, at the higher doses, the compensatory response tends to fall short of a return to the control value. The resulting dose–response appears biphasic. Of particular interest is that the quantitative features for those dose–responses that are directly stimulatory and those that are compensatory are similar quantitatively, in fact, being distinguishable.

The compensatory stimulatory response has been widely observed in the pharmacological domain, with this type of response becoming very frequently cited since the early 1990s. The term *rebound effect* is widely used by researchers whose study designs typically include a dose and a time component. Dose–responses with the so-called rebound effect typically exhibit the same quantitative features of the HDR. In fact, in most cases, those dose–responses are examples of hormesis. For example, in the field of herbivory [200], it is commonly observed that following a low to modest removal of leaves, there is the occurrence of rebound effect in which there is an overcompensation of leaf growth. When excessive removal of leaves occurs, then the compensatory response is usually not adequate to return to control values. The quantitative features of the dose–response are strikingly similar to the hormetic–biphasic dose–response found in the toxicological literature. The term rebound effect is also commonly used in a wide range of biomedical disciplines as well. The use of multiple terms for similar phenomenon can make it difficult to gain a sense of the depth and breadth to which the HDR concept may have been studied.

Hormesis: Plasticity

Why would very large numbers of dose–responses using different biological models with different endpoints and inducing agents with or without a time component show biphasic doses with similar quantitative features, that is, similar magnitude and width of response? Such a highly diverse group of dose–response parameters showing similar quantitative dose–response patterns is not consistent with a random process. Given its general nature, it may have been highly conserved during the evolutionary process of natural selection. The consistency of this response across the plant and animal kingdoms is striking and indicative of an inherent adaptation consistent with providing an estimate of biological plasticity across biological systems, independent of endpoint and inducing agent and differential levels of biological organization.

The integration of the concept of biological plasticity into the interpretation of the dose–response is a novel one [201]. Plasticity has often been considered within several descriptive contexts. The adaptability of the brain with respect to repair following injury has been described as a manifestation of biological plasticity [202]. In a comparable manner, the variation in plant structure and form along a long and progressively steep mountain side would be another example of biological plasticity [203]. In the case of the plant example, plants experience numerous changes in the physical environment along the progressive mountain slopes. There would be changes in carbon dioxide and oxygen concentrations, temperature, soil types, access to nutrients, soil microbes, and many others. These changes along the slopes of the mountain affect the induction of the altered plant phenotypes displaying a range of plasticity changes within such a setting.

The examples of the plant alterations up a mountain side are changes that reflect the impact of numerous biological adaptations in response to alterations in environmental parameters (e.g., oxygen/CO_2), some of which conform to a dose–response gradient. While the changes in plant phenotype reflect biological plasticity, this example is one of the complexities with multiple variables. However, the field of toxicology can explore similar types of gradient changes with alterations in chemical or radiation dosage while keeping all other variables constant. In this manner, the change in treatment will affect the formation of new phenotypes that reflect biological plasticity [201]. The low-dose stimulation seen in the HDR is a manifestation of biological plasticity, a change in biological phenotype. It reveals how much gain or capacity there is for change. The HDR reveals that biological plasticity in response to a vast array of endogenous agents as well as exogenous chemicals is consistently very modest, being in the percentage range, that is, at maximum only about 30%–60% greater than background or control exposures (Figure 3.23). This observed biological plasticity capacity represents how the field of toxicology can interpret this concept within a dose–response context.

The limits of plasticity provide a biologically based resource management system. Large numbers of biological endpoints display HDRs. All have plasticity constrains in the low-dose region. Such responses are operational as part of normal living activities and under stressful conditions. In order to maintain stability in the management of limited biological resources, one strategy would be to regulate the allocation of such resources and to manage how they are handled. The low-dose stimulatory response displays how the *system* controls resources at multiple levels of biological organization and it does so by the use of the hormetic stimulation. The significance of this type of resource management strategy is seen across all types of life, from microorganisms to humans, representing a biological adaptation that is highly conserved. Thus, hormetic stimulation within the context of the dose–response plays a fundamental role in evolutionary biology. The HDR has the capacity to affect how evolutionary biologists consider dose–response processes.

The low-dose stimulation measures biological performance within the bounds of an overarching system of biological plasticity. The stimulation reflects an enhancement of integrated response endpoints, such as cell proliferation, wound healing, or memory. In each case of such integrated

endpoints, there is a limitation for its enhancement that is determined by the constraints of plasticity that is described by the quantitative features of the HDR.

At the time that the HDR was beginning its resurgence, another term was emerging in pharmacology called the *ceiling effect*. This term has generally been used to signify *the quantitative maxima* of a low-dose stimulatory response. The ceiling effect in pharmacology has been therefore used as another manifestation of the concept of biological performance within the framework of an HDR.

In 1907, Alexis Carrel stated that he hoped to find agents that would accelerate wound and other types of healing by 10–50-fold [204]. He hoped that broken bones could be healed in a few days rather than months. Yet, after more than a century, most reported attempts to accelerate healing show enhancements that are in the hormetic stimulatory range [205]. There is little doubt that rapid bone fracture healing (and other types of wound healing) would have important survival advantages. Thus, the degree of enhancement of repair is limited by the constraints of plasticity having a response *ceiling* in the percentage rather than fold zone, that is, being a manifestation of hormesis.

The concept of plasticity is also applied to biological regulation within the context of dose–response as these affect essentially all physiological systems and their control functions. Such low-dose regulatory-based responses represent a measure of biological performance, and such performance-related endpoints are in striking contrast to responses typically measured at the upper end of the dose–response spectrum.

The dose–response should not be interpreted as a simple continuum of agent-induced responses that increase or decrease in a monotonic manner. Substantial findings reveal a markedly different general dose–response pattern. That is, the effects that occur above the toxicological and pharmacological thresholds are often fundamentally different than those that occur below the threshold. The responses at high doses in the field of toxicology are typically, but not always, related to the induction of cellular and tissue damage, that is, true toxic responses. However, below the threshold, the response is not only adaptive but the means by which enhancements of responses occur and controlled and how these upregulated responses improve the chances of prolonged survival.

The dose–response therefore within a hormetic context is one of the low- and high-dose effects with very different biological response meanings. At the high end of exposure, one often encounters system toxicity; the high-end exposure can also reflect a system regulatory function in which the response may be slowed down via a receptor desensitization phenomenon or signaling pathway slow down, inactivation, or other alternative mechanisms. For example, low doses of anxiolytic drugs decrease anxiety in rodent models, while at higher doses, there is often an increase in anxiety. In rodent models, which prefer dark areas, low doses of anxiolytic drugs enhance the time spent in both open and lighted areas. This has been interpreted as a sign that the rodent overcomes some of its inherent anxiety of lighted zones. This suggests that there is an increase in traits such as curiosity and exploration. However, at higher doses, these behavioral patterns are reversed. From an evolutionary perspective, it would be an advantage to have the capacity to be curious and exploratory as well as cautious depending on the situation. Thus, the biphasic dose–response can be seen as displaying behavior patterns that are based in systems biology and of a regulatory nature.

Summary of Hormesis Challenges to the Threshold (and Linear) Dose–Responses

The HDR should assume a central role in the field of toxicology. Table 3.3 lists hormetic principles, while Table 3.4 summarizes scientific developments concerning HDRs. The amount of data indicating this biphasic dose–response is extensive and reproducible. There is also a substantial amount of mechanism understanding of HDRs that are based on receptor-mediated processes linked to signaling pathways. A key feature of the HDR model is that it is highly generalizable, being independent of biological model, endpoint, and inducing agents. The HDR model has illustrated biological and toxicological complexities that were either ignored or underappreciated for decades by the toxicological and pharmacological communities. For example, the low-dose

TABLE 3.3
Hormetic Principles

Low/modest stress induces prosurvival responses.
The quantitative features of the HDR are similar across species and individuals and independent of differential susceptibility and agent potency.
The magnitude of the stimulatory response is constrained by and defines the plasticity of the biological system.
Hormetic responses occur at multiple levels of biological organization, the cellular, organ, individual, and population.
Downstream processes integrate responses from multiple independent stressor agents/excitatory stimuli to yield an integrated dose–response (i.e., molecular vector) reflecting the HDR.
Hormetic responses reflect both a general response to environmentally induced stress/damage and some elements of chemical structure specificity for endpoint induction.

TABLE 3.4
Major HDR Observations

Most commonly observed dose–response relationship.
Distinctive quantitative features, making it a unique biphasic dose–response relationship.
Most unique feature is the modest magnitude of the stimulatory response, usually less than twice control values.
The low-dose stimulation can occur via a direct stimulation or via an overcompensation to a disruption of homeostasis.
HDRs may be seen as an adaptive response that ensures tissue repair in an efficient manner and protects against damage from subsequent and more massive exposures.
HDRs are highly generalizable, being independent of biological model, endpoint measured, and chemical class.
Numerous specific mechanisms have been reported to account for HDRs.

TABLE 3.5
Implication of Hormesis for Toxicology/Risk Assessment and Clinical Practices/ Pharmaceutical Companies

Toxicology/Risk Assessment

Changes strategy for hazard assessment, altering animal model and endpoint selection, study design including number of doses, and dose range and number of subjects per dose
Alters biostatistical modeling to predict estimates of response below control background disease incidence
Differentiates dose optima (i.e., benefits) for normal and high-risk segments of the population
Creates evaluative framework to assess benefits or harm below traditional toxicological threshold
Creates new framework for quantitatively altering the magnitude of uncertainty factors in the risk assessment process

Clinical Practices/Pharmaceutical Companies

Drug performance expectation will be constrained by the quantitative features of the HDR.
Drugs that are designed to act at high doses may have hormetic effects at low doses with possible undesirable effects (e.g., tumor cell proliferation).
Modification of biological set points will be constrained by the quantitative features of the HDR.
Clinical trials need to recognize interindividual variation in the HDR.
Clinical trials need to be designed to take into account the quantitative features of the HDR.

Source: Calabrese, E.J., *Am. J. Pharmacol. Toxicol*., 3(1), 56, 2008.

stimulatory effect can be a beneficial or harmful effect. The effects may also be time-dependent. These factors indicate that the hazard assessment as used by regulatory agencies would have to be modified in order to take into account of the possibility of HDRs (Table 3.5); such changes would include alterations in the hazard assessment protocol, in study design (i.e., number of doses, dose spacing), sample size, and statistical power strategies and the need for replication. It may also affect the choice of the biological model with special consideration given to control background values and the variability of key endpoints. Table 3.6 briefly summarizes historical factors that impeded or prevented the concept of hormesis from being accepted by the toxicological community and by regulatory agencies within the risk assessment process.

Challenge #3: Pharmacology and the Biphasic Dose–Response

The historical foundations of the dose–response relationship in pharmacology were largely based on the classic research of Alfred J. Clark [35,36,68] and his contemporary and successor John Henry Gaddum [80,206]. Based on extensive research on the quantitative actions of drugs such as acetylcholine and atropine, these authors showed that combining of drugs with specific receptor groups could be mathematically similar to the function used in the Langmuir (1918) adsorption isotherm. The responses of a tissue were assumed to be directly proportional to its specific receptor groups as occupied by the drug, the receptor occupation followed the law of mass action, and drug molecules would have equal access to all receptor groups. This perspective became the dominant pharmacological dose–response paradigm for the remainder of the twentieth century.

Despite its general intellectual dominance within the field of pharmacology, this dose–response model of Clark and Gaddum needed further development, refinement, and correction over the subsequent years. In fact, not long after the theoretical formulation by Clark [35,36], it was found that adsorption equations besides that of Langmuir's could fit the dose–response data just as well and that a maximal response

TABLE 3.6
Factors Contributing to the Historical Demise of Hormesis

- Powerful conflicts with traditional medicine and homeopathy.
- Toxicology directly emerges from traditional medicine.
- Influential opponents to the hormesis concept controlling the vehicles of communication.
- Influential opponents (radiation) accepting data that supports hormesis and denying that it is hormesis.
- Biostatistical modeling being constrained to deny hormesis.
- Rejection of hormesis occurring during the period of toxicological concept consolidation.
- No intellectual counterforce at the time of concept consolidation (not yet addressed).
- Early supporters of the hormesis concept lack understanding of its dose–time response features.
- Hormesis being difficult to prove experimentally without proper study designs.
- Powerful regulatory agencies adopting rival dose–response models.
- Governmental hazard assessment protocols making it highly unlikely to observe hormetic effects.
- Being shunned from standard texts, society meetings, and academic teaching.
- Being excluded from research funding possibilities in major governmental grant programs.
- Biological/societal implications not appreciated nor anticipated.

Source: Calabrese, E.J. et al., *Toxicol. Appl. Pharmacol.*, 222, 122, 2007.

may not require maximal receptor occupation. However, despite such limitations in this pharmacological model of the dose–response, it became adopted along with the belief that the maximal response required the complete occupation of receptors by the agent [207].

While the previous conceptual framework of the pharmacological dose–response has had a long history of qualitative predictive utility, it frequently offered less than satisfactory quantitative agreement with experimentally derived data [208]. It was often reported that the observed dose–response did not follow the predicted form (some drugs [i.e., partial agonists] often stimulated tissues but did not produce the expected normal maximum response), nor could the model of Clark and Gaddum account for the antagonism shown by partial agonists to more powerful agonists, tissue desensitization following exposure to highly specific stimulants (acetylcholine, histamine), as well as responses when a vigorous excitation is quickly replaced by competitive antagonism [165].

These and other limitations lead to modifications in the receptor-based dose–response concept during the mid-decades of the twentieth century. Ariens [209] proposed that the drug–receptor union may have varying effectiveness, which he called *intrinsic activity*, while Stephenson [208] referred to this concept as *efficacy*. This efficacy or intrinsic activity concept was expressed quantitatively as the rate constant of the second step of a drug–receptor process that yields the active form of the drug. This concept was based on the studies on motor-endplate depolarizing activity [210–212].

Biphasic dose–response curves, especially those with a single active chemical group, offered a further significant challenge to the occupation receptor theory, proposing that such curves may be observed if a drug interacted with two-receptor systems [213]. In this context, Dale in 1906 [166] noted that adrenaline can act at both excitatory and inhibitory receptors in the vasculature; this observation lead Furchgott [214] to suggest that these receptors may occur on the same smooth muscle cell. By the 1960s, numerous, yet isolated, biphasic dose–responses were reported for drugs of pharmacological importance. These responses were accounted for by the presence of two opposing receptor populations. In his subsequent assessment of this literature, Szabadi [165] reported that most of the sympathomimetic amines activate opposite receptors in smooth muscle preparations with α-type receptors being stimulating, while β-receptors were negative. Likewise, by the 1970s, several researchers reported that histamine can activate both excitatory and inhibitory receptors [215,216] with H_1-type excitatory receptors being stimulating and H_2 receptors being inhibitory.

It also became recognized that two opposing receptor populations to the same agonist were often present on the same neuron consistent with the early suggestion of Furchgott [214]. This was the case of invertebrates for acetylcholine [217], dopamine [218], 5-HT [219,220], and histamine [221] on sympathetic ganglion cells along with numerous other examples.

As a result of these cumulative findings, Szabadi [164,165] proposed a theoretical model to explain how agonists and antagonists act in pharmacological systems containing opposite acting receptors. This model was derived from the combination of *double agonists* and functional antagonism as proposed by Ariens et al. [222]. Double agonism was generally defined as a phenomenon when a compound induces an effect by interaction with two different specific receptors. The Szabadi [165] model was a special case of double agonism when two receptors, which are activated by the agonist, mediate opposite effects. If the two types of receptors are assumed to be functionally independent, the model for functional antagonism is employed; the quantitative features of the model are described by the algebraic sum of the induced effects produced by the activities of both receptors.

The model of Szabadi [165] is very generalized, with the potential to account for a wide range of dose–response

relationships depending on assumed affinities and intrinsic activities. This model may also account for hormetic-like biphasic dose–response relationships. Since the publication of the Szabadi [165] model, the number of examples of biphasic dose–responses has markedly increased, including nearly 40 receptor families affecting a range of biological endpoints that govern essential physiological and behavioral functions [186–188].

The biphasic dose–response model of Szabadi [165] has been supported and extended by other researchers [168,169,223–225]. For example, based on research on α-lactalbumin production by rat mammary gland explants, Quirk et al. [226,227] were able to account for biphasic dose–responses even for highly specific glucocorticoids with binding to a single receptor. This response was accounted for with a model of a single *turn-on* nuclear receptor site for glucocorticoid receptors and multiple glucocorticoid regulatory refinements. This finding was consistent with those of Jarv that agonistic and antagonistic effects of ligands may be related to their binding in two separate sites of the same receptor molecule [228,229]. Evidence supporting this model was reported by Jarv et al. [230] for the muscarinic acetylcholine receptor.

While pharmacological evaluation of biphasic dose–responses has dominated the literature from the 1970s to present, there is both a convergence of concept and a reformulation of such perspectives in the area of toxicology and more broadly in systems biology. In 2004, Leuchenko et al. [231] presented a framework for biphasic regulation that is conceptually similar to the model of Szabadi [165] and the considerable research on the concept of hormesis. Leuchenko et al. [231] proposed four types of biphasic regulatory schemes, with the first two being similar to the one-receptor model [223,232] and the one-agonist two-receptor model [165]. However, the paper added a further dimension of progressive complexity.

In the third model (i.e., type III), the biphasic response results from signal transduction activities that are removed from the response element (ligand–receptor complex). In this situation, the biphasic nature of the dose–response derives from the properties of the signal-transducing components. The authors proposed a variety of ways in which the biphasic dose–response could occur depending on the type of properties of the RE, molecular inputs, and complexity of the biochemical pathways. An example of the type III biphasic regulation is seen with mesoderm induction in *Xenopus laevis* via the TGFB homologue that activates the genes *Xbra* and *goosecoid*. The activated receptor starts the signaling process by phosphorylating a signal transduction of the SMAD family that leads to gene transcription. Approximately 100 and 300 activin molecules need to bind the receptor to activate Xbra and goosecoid expressions, respectively. However, the expression of Xbra is suppressed by high goosecoid concentrations. Consequently, when activin activates about 100 receptors, Xbra expression is positively regulated, but if the activin concentration is increased by about 30-fold, goosecoid expression is enhanced, resulting in turning off Xbra expression.

The fourth model of biphasic regulation requires two inputs to affect the response rather than one as in the previous cases. This is seen in combinatorial inhibition when a molecule binds with two or more interacting molecules to form a single functional complex as is the case with scaffold proteins. A second type IV receptor involves two or more interactions between an activator and the activated molecules for full activation. Examples of both biphasic regulation with scaffold protein concentrations and distributive activator are seen in the MAPK cascades. Leuchenko et al. [231] speculated on the adaptive significance of biphasic regulatory strategies. They provide tunable filtering of the magnitude of the incoming signal and determine the sensitivity and strength of the response. The composite of these strategies may be seen as a framework of broad biological significance at multiple levels including global and local domains.

Challenge #4: Population-Heterogeneity-Based LNT

While it is often stated that each individual of the population may display a threshold response, the population itself may display no threshold due to normal heterogeneity within the highly outbred and socially and culturally diverse human population. While this is a conceptually logical statement, it is principally a theoretical one. The reason for this statement being theoretical is because the power of epidemiological studies to estimate low risks in the population is usually weak, due to limitations in assessing exposure, genetic variability, and numerous other disease and performance-modifying variables.

The principal controversy associated with the population-heterogeneity-based LNT hypothesis is the generalization of its applications to agents and endpoints, including those of a noncancer nature. It is also not clear how this concept would translate into what is permissible population-based risk [1]. However, as noted earlier, the 1977 SDWC [148] used this concept as one of their eight guiding principles to support the LNT model for carcinogens. Thus, this concept is not a new one—but one now reformulated to challenge the threshold dose–response for noncarcinogens. Would each adverse effect be treated in a similar manner, that is, with the same level of permissible risk, or would the permissible risk be related to the medical implications and cost of therapeutic interventions? This concept would appear to offer a profound challenge to regulatory agencies and would affect a reevaluation of environmental, food, and occupational chemical health standards.

The scientific foundations of a heterogeneity-based LNT model assume that there are multiple risk factors affecting susceptibility to all toxic substances and that these risk factors are randomly distributed within the population. This would be predicted to result in a rather broad distribution of susceptibilities with multiple interactive risk factors affecting a progressively smaller proportion of the population who would display a progressively greater level of risk and/or susceptibility. When taken to its extreme, those individuals with the greater number of significant risk factors will be the first to experience adverse effect and premature death.

The heterogeneity-based LNT concept also assumes that there is an additive to background adverse effect relationship providing further support for a linearity interpretation.

The underlying evidence to support the heterogeneity-based LNT is difficult to obtain since epidemiological methods have generally been shown to be hard to establish causality unless the risks exceed the control or reference population by a factor from two- to threefold. In the area of toxic torts, formal judicial guidance reflects this perspective, with judges being guided not to accept a causal relationship unless the related risk for the alleged exposure equals or exceeds a factor of 2 [233]. If, therefore, the population heterogeneity-based LNT dose–response model were to be accepted, it would come into conflict with the current standard for epidemiological guidance for tort-risk causality [234].

Despite the long-standing two- to threefold epidemiological causality rule of thumb as just discussed, this perspective has been challenged, especially with the area of fine particulates and community-based air pollution [235]. Numerous large-scale epidemiological studies in the United States and elsewhere have generally reported relative risks that have ranged from the slightly below 1 to about 1.2. Some investigators and regulatory agencies, especially in the state of California, have concluded that causality in such studies can be affirmatively made, even with population-based risk, below the twofold increased risk historical perspective. This has been a highly contentious matter since it is difficult to accurately identify known causes of deaths as well as underlying biological predispositions. Factors such as family characteristics, age, gender, stress, diet, prior disease, access to medical treatments, social factors, epigenetics, and other influences are likely factors affecting health outcomes. Given all the possible confounding variables and the extreme difficulty of their quantification or the general inability to control for such differences with surrogate parameters such as socioeconomic and other standard parameters, the capacity to use epidemiological methods to estimate risks to the less than the doubling rate is generally beyond the present capacity of this discipline. Thus, the population-based heterogeneity-based LNT model is limited by the inherent limitations of epidemiological methods. Even with marginal improvements in the sensitivity of epidemiological methods in the future, its capacity to address low-dose risks is principally theoretical and model dependent and has no capacity for validation. While this is a powerful argument against the acceptance and use of the population heterogeneity-based LNT, it would be similar to an argument against a toxicologically based LNT model based on experiments in which only a few very high doses were used within the standard chronic bioassay.

ISSUES

Dose–Response versus Dose–Time Response Relationships

The effects of the dose on biological systems may be expected to change over time. Biological systems are dynamic; they can be stimulated, stressed, or injured, and in response, such changes may display a wide range of adaptive or maladaptive processes. These responses to toxic substances may also affect the availability and utilization of various biological resources and the capacity of the system to respond to subsequent similar or different exposures. There is therefore value if experiments can assess such biological responses over time. In practical terms, investigators are typically confronted with a decision over whether to use a range of doses or to follow the response of a single dose over a range of time points. Combining these dose and time features would be the ideal research strategy as much is lost by the ignoring the other.

The fact that biological systems are dynamic and adaptive has long been known, first being explored in the 1890s [44]. Of particular importance to the history of dose–response was the work of Sarah Branham in 1929 [38], which was designed to provide a detailed and updated replication of the seminal findings of Hugo Schulz [23,24] on the effects of numerous chemical disinfectants on the metabolism of yeasts. Of particular interest was that Branham [38] assessed the effects of multiple chemicals over multiple concentrations each over multiple time periods. What Branham [38] demonstrated was that these agents initially induced a concentration decrease in metabolism. However, this was subsequently followed by a compensatory or rebound-type response that eventually led to a stimulation within the lower concentration range. Compensatory responses were also noted at the higher concentrations, but the degree of compensation was usually not enough to overcome the toxicity that was initially induced. The degree of stimulation was modest, being at maximum in the 30%–60% zone greater than the control values. Similar dose–time responses have been widely reported confirming the general nature of the dose–time overcompensation responses [199]. Such findings indicate the significance of study designs that include a broad range of doses along with multiple measures over time. Failure to incorporate both adequate dose and time point evaluations will lead to inadequate understandings of the dose–response. Unfortunately, the use of many doses and their evaluations over multiple time controls is resource intense. However, the value of such consideration is clearly represented in the work of Branham and others [38]. These findings reveal the dynamic nature of the biological affected systems when it is stressed and/or injured. The dose–response, therefore, is not static and the dynamics of cellular/system response are necessary to discern as it provides critical information of not only dose-induced damage but critical repair and recovery processes. In fact, it was the use of the time variable that provided the capacity to discover the phenomenon of preconditioning and postconditioning in the biomedical sciences and the adaptive response to radiation and chemical mutagens as seen in the following section.

Adaptive Response/Pre(Post)-Conditioning/Auto Protection

Another factor affecting the dose–response is the physiological state of the biological system. Prior exposure to an

agent can affect how the biological system will respond to subsequent and more massive exposures of the same or different agents. This phenomenon has long been recognized by different terms in the toxicological and biomedical sciences. A low dose of CCl_4, which caused a negligible toxic response to the liver based on the change in serum levels of AST and ALT, prevents rats from dying when they receive a subsequent LD_{95} dose of the same agent [236]. This phenomenon was called autoprotection, that is, a prior low dose of the chemical prevented adverse health effects caused by a subsequent and more massive exposure of the same agent. It was later shown that a prior dose of a similar but not identical agent could protect against a massive exposure of the similar toxic agent (i.e., heteroprotection). The mechanism of protection was widely thought to result from the possibility that the low prior dose may have reduced the cytochrome P450 activity, preventing the bioactivation of the CCl_4, thereby reducing the toxic potential of the subsequent massive exposure. This interpretation was challenged by Mehendale [237,238] who associated the enhanced survival due to the prior low dose with an accelerated process of hepatic tissue repair.

The concept of an autoprotection and heteroprotection for heavy metals was also reported during the same general time period. Yoshikawa [239] found that a pretreatment with low doses of various heavy metals could markedly reduce the acute toxicity of similar and other heavy metals in a mouse model. These findings were further evaluated over a broad dose range of the preconditioning/priming agent. A biphasic dose–response was reported for lead and mercury fully consistent with the quantitative features of the HDR.

That a low dose could protect against the effects of a subsequent more massive exposure was subsequently generalized to the field of chemical mutagenesis by Samson and Cairns [176] and for radiation-induced mutagens by Olivieri et al. [177]. These investigators referred to the phenomenon as adaptive response. Two years later, it was shown that a prior hypoxic stress to the heart of dogs reduced the toxic effects of a subsequent massive myocardial infarction, a phenomenon referred to as preconditioning [178]. Thus, the fields of chemical toxicology, chemical/radiation mutagenesis, and biomedical/pharmacology converged on the same low-dose–high-dose protection phenomenon and referred to this with differing names. These observations in each case were replicated and generalized, covering significant areas of research. Furthermore, in the aftermath of the research on preconditioning, investigators reported the phenomenon of postconditioning. That is, if the low dose was given after the more massive exposure, it affected a similar decrease in toxicity as the preconditioning phenomenon dose [240].

The autoprotection, adaptive response, and pre-/postconditioning phenomenon act via the use of an adaptive dose that induces mechanisms that reduce the toxicity of a larger dose. Of particular significance is that the magnitude of the protective response depends not only on the timing of the adapting dose but also on its dose level as well. That is, all adapting doses are not equal in their capacity to affect a protective response. Subsequent research revealed that the adaptive dose could be optimized. Detailed dose–response studies using a broad range of adapting doses were found to follow the hormetic–biphasic dose–response. This was also the case for postconditioning responses as well [240].

High-Risk Groups: Dose–Responses

The dose–response may be affected by a wide range of biological factors, including developmental processes, age, gender, dietary and nutritional status, genetic factors, preexisting disease conditions, and prior exposure history, among other factors. These conditions can be seen as either enhancing or reducing one's susceptibility to toxic substances, thereby altering the shape/slope of the dose–response. Since all individuals experience developmental and aging processes, there will be periods during the normal life cycle in which all people will be at enhanced risk to certain agents. In general, it is thought the young will be at enhanced risk to most, if not all, toxic substances. While this concept has been generally borne out in a wide range of toxicological studies, there are instances where the young are not more susceptible than a middle-aged population subjects. In fact, there are well-known situations (e.g., renal toxicity for fluoride and mercury) for which their risks are significantly lower [241]. These observations illustrate challenges that regulatory agencies confront in the assessment of risk.

The enhanced susceptibility within the high heterogeneous population is thought to be captured with a range of 10-fold starting from the median response of the normal population response [65]. This is a practical guidance value that has not been systematically assessed. For example, the effect of oxidative stressors on normal red blood cells can be assessed in a dose–response context. These cells could be compared with the response of red blood cells from individuals with various types of antioxidant enzymatic deficiencies (e.g., glucose-6-phosphate dehydrogenase [G-6-PD]), proceeding from moderate to more extreme [242]. Such experiments could provide information on differences in the magnitude of the cell damage at the same concentration as well as the differential threshold concentrations for each experimental subgroup. These population-based subgroups could be made even more complex by superimposing factors such as lower or higher exposure to dietary antioxidants, further affecting the threshold and magnitude of response.

How Physiological Status Affects the Dose–Response: The Anti-Inflammatory Phenotype

Low-level exposures to ionizing radiation can enhance several immune parameters while being inhibitory at higher concentrations [243]. These findings are in striking contrast to a rather large body of experimental data that demonstrates that low doses of ionizing radiation can have a depressive effect on immune functions if the biological system is in an inflamed condition [47,244–246]. In fact, the dose–response in this situation is U- or J-shaped. That is, at the lower doses, the ionizing radiation suppresses the inflammatory

condition, while at higher doses, it inflames it further. This phenomenon has been documented in five arthritic animal models with strong consistency [47,247–256]. Much follow-up work has been conducted on the underlying mechanisms contributing to the radiation-induced suppression of inflammation [257–265]. The key conceptual insight offered is that the dose–response relationship is dependent on the physiological state of the organism. At the same doses, the response could be opposite depending on whether the biological system was inflamed or not. Low doses of ionizing radiation can therefore induced two types of HDRs: one that enhances immune function at low doses and one that suppresses the immune-mediated inflammatory state, thereby creating an anti-inflammatory phenotype.

Triphasic Dose–Responses

While the principal focus on the assessment of dose–response relationships has been directed toward threshold, linear, and hormetic/biphasic dose–responses, triphasic toxic responses have also been reported. However, the frequency of such reports is quite limited. Nonetheless, the occurrence of triphasic dose–responses is possible based on biological theory. There are significant challenges in the study of such possibilities starting with requiring more dose/concentrations. A particularly interesting example of a triphasic dose–response relationship was presented by Hooker et al. [266] in an assessment on x-ray-induced mutations in the spleen of pKZ1 mice. At the high end of the exposure spectrum, the x-rays, as expected, enhanced the incidence of mutations. However, as the doses were lowered, the incidence decreased below that of the control group, demonstrating support for an HDR. As the dose was further diminished, the mutation rate returned toward the control value again, consistent with a hormetic interpretation. However, further reduction in dosing revealed a surprising and novel finding. The mutation incidence flared up again, significantly beyond that of the control group. The dose–response was triphasic, with an increase in the frequency of mutations, followed by a marked reduction below the control and then the increase at higher doses.

Radiation-induced triphasic dose–responses were also reported by Choi et al. [267] in zebra fish embryos, either one or two embryonic cells, irradiated by microbeam protons over dose range from 20 to 2000 protons. This study not only confirmed the occurrence of the triphasic dose–response but showed biological responsiveness down to the level of 20 protons.

Much data exist that could explain both the low-dose protection and high-dose enhancement of mutation. However, what could account for the increase in mutation rate at the lowest doses? While this remains an area of research, it may be hypothesized that at the very lowest doses tested, the x-rays/protons induced a low level of damage. However, in order for repair processes to be induced and the damage to be repaired, the damage signal must be first detected, thereby initiating the repair process. The question that is posed is how sensitive is the detection system in this particular biological model and to what type of damage. Thus, it has been proposed that the damage at low doses may reflect a level and type of molecular alteration that goes undetected and thus unrepaired, at least within the time period of the study observations.

These types of investigations raise a broad range of novel scientific questions concerning damage, detection, repair, the generalizability of this phenomenon to other tissues and biological models, and the adequacy of routine hazard assessment protocols to detect such effects. The issue of triphasic dose–responses and their toxicological implications is an intriguing area of study but is generally ignored by the regulatory and research communities. If these findings, as assessed in the mouse and zebra fish models, could be broadly generalized, it would have significant biomedical and risk assessment implications.

Maximum Tolerated Dose/Dose–Response

The information provided from the chronic bioassay based on the use of MTD-related doses has had a controversial history. The MTD is the highest dose that a treatment group can be exposed to over the 2-year period of the rodent chronic bioassay without experiencing toxicity and/or a loss of more than 10% body weight. However, it was not uncommon for some chemicals, especially at the highest dose, to cause cell damage in areas such as the liver. Lower doses were typically believed not to cause such cell damage or to do so with lesser frequency and intensity. As a result of the cell damage at the MTD dose, cell proliferation responses might be initiated in order to repair this damage, providing a tumor promotional response resulting in an enhanced tumor incidence at the highest/MTD dose. It was often the case that there was a significant tumor response at the MTD but not at the lower dose(s) [268]. Nonetheless, regulatory agencies would make a carcinogen designation for such agents. Based on cancer risk assessment methods, these data would be modeled via an LNT process. This area has been highly controversial as the cancer risk assessment is significantly affected by a toxicity/promotional effect at the MTD [268–270].

Shallow/Steep Dose–Responses

Descriptive considerations of the dose–response have revealed that some dose–responses are very steep, with the toxic responses occurring over a very narrow dose range. An example of this type of dose–response is seen with cyanide and its induced mortality. In contrast, some dose–responses are very shallow with toxicity occurring over a very wide dose range. An example of this type of dose–response would be petroleum. In general, a very steep dose–response is due to the fact that the risk factor is highly specific and not subject to a high degree of interindividual variation. In the case of cyanide, the reason for the steep slope is that this agent is not subject to considerable metabolism and its target for toxicity, that is, the key cytochrome oxidase is essential for energy/ATP generation, varies little between individuals.

Thus, the toxic effects of cyanide would be quick in most, if not all, animal models and humans. In the case of petroleum, it is a complex mixture, comprised of thousands of chemicals with differing metabolic patterns and with differing targets and mechanisms of toxicity. As a result, there are likely a wide range of risk factors broadly distributed within a highly heterogeneous population, resulting in a far shallower dose–response.

Cumulative Dose–Response versus Dose Rate Response

In the mid-1940s, the question was raised as to whether exposure to the same cumulative dose to ionizing radiation would result in the same degree of toxicity independent of the dose rate. This was a question raised during the Manhattan Project by the radiation geneticist Curt Stern at the University of Rochester since it was considered as a test for the linearity dose–response hypothesis. Initial studies assessed the effect of a broad range of x-ray doses administered to fruit flies (i.e., over seconds to minutes). The response gave evidence of a linear dose–response relationship. However, when the same cumulative exposure was given at a rate of only 1/15,000 of the acute dose, a threshold was reported. This was a seminal observation as it challenged support for the linear dose–response interpretation [144,271]. This challenge to linearity was believed to be so significant that Hermann Muller and Curt Stern, two of the most influential radiation geneticists, tried to prevent the acceptance of the findings of the Caspari research [10,29,39]. As noted earlier, research at Oak Ridge by William Russell with mice would support the Caspari findings and the belief that the genetic toxicity response to exposure was cumulative.

Carcinogens: Latency and Dose–Response

The principal way in which dose is used to evaluate carcinogenic responses is via tumor incidence. However, in 1943, Hermann Druckrey [272] published the first of a series of papers [272–275] establishing a relationship between dose and the time required to detect tumors, that is, the tumor latency period. This introduced a new concept with the potential to affect significantly how carcinogen risk might be estimated in a manner that was more responsive to human risk than the more limited dose–tumor incidence methodology. The key observation was an inverse relationship between dose and tumor latency. That is, the lower the dose, the longer the time required for tumor appearance. It was hypothesized that if the dose were reduced low enough, the latency period could theoretically be longer than the normal life span of the experimental species. In an analytical sense, the treated groups in such low-dose zones would have a tumor incidence indistinguishable from controls. An attractive aspect of this concept was that one could accept the linear dose–response model and yet still arrive at a *practical threshold* for carcinogens. The proposal of Druckrey represented a type of toxicologically based compromise between the LNT and threshold dose–response models.

The Druckrey dose–latency tumor incidence concept generated considerable interest worldwide. Several researchers were quick to validate the findings of Druckrey [276]. In the former Soviet Union, the concept of dose–latency was accepted in risk assessment practices by the late 1970s following its experimental validation by Yanysheva and Antomonov [277] for carcinogen benzo(a)pyrene. The authors stated that any carcinogenic effect of the benzo(a) pyrene would be observed only considerably after the normal life span of the species had been exceeded.

This idea also resonated with some leading researchers in the United States, including Hardin Jones at the University of California at Berkeley, an expert in human aging, especially with respect to the effects of ionizing radiation. He and his colleague Alexander Grendon published several papers that integrated the findings of Druckrey and others as well as new understandings of the process of carcinogenesis, deriving a predictive biomathematical model. In practical terms, Jones and Grendon [278] reported that if the dose were decreased by a factor of 1000 in the linear zone, the latency period would increase by a factor of 10. The Druckrey concept was also applied to the field of occupational cancer by Philip Enterline [279] at the University of Pittsburgh based on a meta-analysis of 11 major epidemiological studies of asbestos exposure and respiratory cancer.

Even though the findings of Druckrey were striking, substantially replicated and extended to a range of compounds, using animal models and epidemiological meta-analyses, it was rejected by U.S. regulatory agencies, with the concept failing to be integrated into and/or affecting hazard assessment and risk assessment processes. Why would this be the case? On the historical side, Occupational Safety and Health Administration (OSHA) conducted massive carcinogen policy hearings during 1978 [280]. The dose–latency concept of Druckrey and Jones was considered. However, Druckrey did not testify nor did any other researcher who had published supportive findings of the dose–latency argument. Jones was expected to offer testimony but unexpectedly died less than 2 months prior to the hearings. His relevant papers were entered into the record and commented upon, especially by those opposed to having this concept affect carcinogen risk assessment policy. Without his presence to explain and defend his position on this topic, there was little likelihood that dose–latency tumor position would even partially prevail as several notable opponents (e.g., David Hoel, Umberto Saffiotti, Richard Peto, and Marvin Schniderman) would counter his written statements without any real opposition. The most impressive of the criticisms was that by Hoel (based upon a paper by Guess and Hoel [281]). This paper argued that the findings of Druckrey of an inverse relationship between dose and latency not only were not unexpected but would be readily predicted via stochastic modeling assumptions. Thus, there was nothing new in this concept. As a result, the concept of dose–latency for carcinogens was dropped from the cancer risk assessment process and the hazard assessment testing scheme.

A counter argument not presented was that dose and time to tumor is an important concept and there was no reason to

restrict the assessment to only tumor incidence in the animal bioassay. A similar argument was made earlier by Albert and Altshuler [282,283] who argued for a novel approach in the extrapolation of laboratory studies in the derivation of environmental health standards. This approach incorporated the concept of age at the time of the appearance of an adverse health effect as well as its incidence, a position similar to that of Jones. Albert and Altshuler [282,283] stated that the usual approach for assessing carcinogenic risks such as providing the dose to incidence relationship could be extremely misleading and give an inappropriate degree of importance in the risk assessment/risk management process. The typical dose–incidence methodology used by regulatory agencies today fails to consider the age at which new tumors occur or the likelihood that additional carcinogen exposures could affect people who would have developed tumors from different causes. Supporting this perspective was a National Academy of Sciences [284] report, commenting upon the work of Albert and Altshuler [282], that it may be possible to establish standards for carcinogens that would limit the possibility of environmentally induced tumors to only very advanced age, with less than a 10% increase in the chance of cancer at 95 years of age. While 95 years of age may not seem as old today in the second decade of the twenty-first century than it did some four decades ago, the basic concept of the National Academy of Sciences was in agreement with the perspectives offered by Jones and Grendon [278] as well. Again, this OSHA hearing failed to bring forward representation of the National Academy of Sciences. Likewise, Albert and Altshuler, both prominent toxicologists, did not render testimony on this issue.

In the intervening years, several lines of research have supported the Druckrey/Jones perspective, revealing that it takes a higher dose of carcinogen to enhance tumor promotion than initiation. At higher doses, it is possible to turn on promoting processes that can markedly decrease the latency period. The reverse would also be the case. That is, at lower doses and with less promotion, the tumor latency would be extended. While the initiation process may well be stochastic in nature, this was not likely the case for the induction of promotion, which has been typically seen as demonstrating a threshold dose–response. Thus, the concept of dose affecting latency has a solid foundation, does not have to be associated with a stochastic process, and can provide a means to derive a practical threshold for carcinogens as originally intended by Jones. This area is likely to warrant considerable toxicological research as it has the capacity to profoundly affect the risk assessment process for carcinogens.

Epidemiology and the Dose–Response

There can be considerable variation in the dose–response that subjects display toward the same agent. If there is a wide range in susceptibility (i.e., interindividual variation) and if hormesis does occur within the various subgroups of the population, how may this affect the overall population-based dose–response? This will depend on the nature of each subgroup's dose–response relationship and each subgroup's proportion of the overall population. Consider the following subgroup-specific dose–response relationship and their impact on the overall dose–response relationship for the population. We are assuming that there are five population subgroups (G1–G5) and each has a defined dose–response relationship. Subgroups 1 and 5 show no evidence of an HDR, but subgroups G2, G3, and G4 display unique HDR patterns. For simplicity, assume that each subgroup comprises 20% of the population. The population average, as represented by the bolded line (Figure 3.26), displays a threshold-like response. If the population proportions for each subgroup were changed, then the composite (i.e., average) response

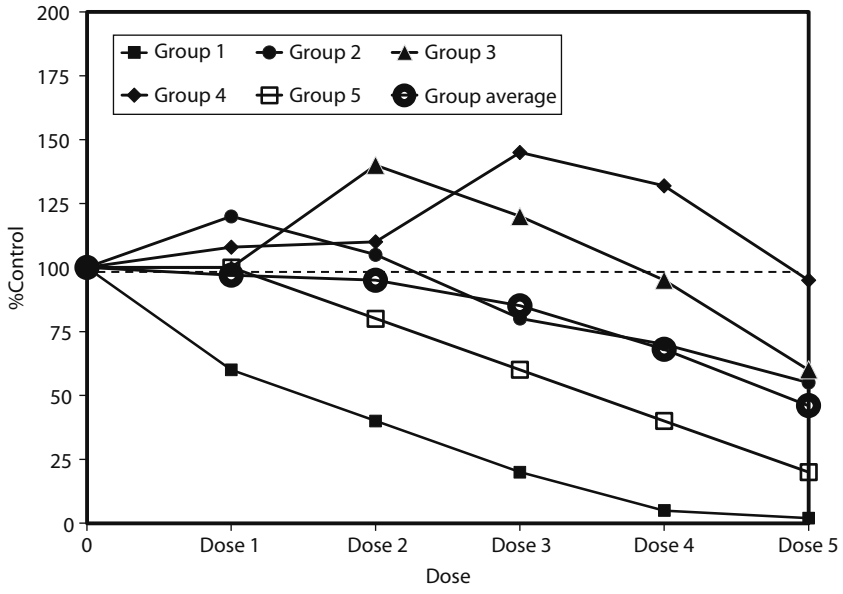

FIGURE 3.26 Population subgroup and population average dose–response relationship.

would also change. These findings demonstrate that a highly heterogeneous population has the potential to provide evidence that may or may not reveal a hormetic effect even when some of the subgroups display hormesis. This exercise demonstrates that the assessment of population-based data comparisons of substantial heterogeneity as may often be the case with humans may lead to findings that are not indicative of any underlying mechanism despite observed dose-dependent transitions. This is a situation that is not often appreciated, yet one with important biological and public health implications.

DOSE–RESPONSE IN PERSPECTIVE

One cannot underestimate the influence of biostatistical dose–response modeling in risk assessment since the mid-1970s when the EPA made the policy decision to apply linearity at low dose for carcinogen risk assessment. EPA selected what it believed to be a model with reasonable biological plausibility (i.e., the multistage model). The problem with this policy is that *assumed* plausibility does not equal validation. There was some toxicological support for a linear interpretation starting with the first systematic dose–response studies that were published during WWII, in Germany [272], and later extended by Druckrey and Küpfmüller [273] using butter yellow with five different daily doses ranging from 1 to 30 mg/rat. The administered total carcinogen doses were similar for all treated groups but that the median latency period (+) was inversely proportional to the daily dose. When plotted double logarithmically, the result was a linear dose–response relationship that followed a specific dose–time mathematical relationship in which the latency period for the time to the first appearance of a tumor was inversely related to dose. These findings were interpreted by Druckrey to mean that even very small daily doses of carcinogens could result in tumor development, that the doses were additive, and that the induction time is of considerable importance. Despite the fact that these findings clearly supported a linearity dose–rate relationship, they also indicated that latency was an important parameter that was affected by dose rate. Their data suggested that if the dose were decreased, low enough tumors would be predicted to occur long after the normal life span of the individual, in effect a practical population-based threshold. In a more statistical framework, the chemically induced tumor incidence would be indistinguishable from control group findings.

Another challenge to the linearity concept is that no LNT model, including the multistage model, could be validated in the low-dose zone. At the same time, numerous inconsistencies emerged that lead to an erosion of confidence in the estimated model predictions. For example, estimates of liver cancer in U.S. residents from aflatoxins, DDT, and chlordane were estimated via LNT modeling to be well over one million people/year [285]. Yet the number of liver cancers from all causes, including alcohol ingestion and virus infections, was orders of magnitude lower! These epidemiological validation challenges to LNT modeling predictions were complemented with the discoveries of a cascade of robust adaptive processes that further undercut the theoretical basis of the LNT model, while providing biological support for a threshold dose–response concept. Furthermore, during the late 1970s when the EPA was floating the idea for the LNT model, it also tried to support this position via two complementary approaches: one using the results of epidemiological studies in survivors of the atomic bomb blasts in Japan, while the second was via the use of mutagenicity data using the Ames data. In the case of the atomic bomb exposures, this support became quickly tentative given the nature of the exposures, the dose rates, and their relevance to low-dose exposures in society and the extreme difficulty in teasing out specific radiation exposures as its effects may have been affected by heat, shock, and other confounding factors and the apparent differential effects on different cancer types. The atomic bomb survivor study became more of a research vehicle rather than an environmental risk assessment instrument, forcing the agency to back away from using it as its central perspective to support a community-based linearity policy. A second policy probe put forward by the agency during this period was that of using evidence of linearity in dose–response with Ames mutagenicity strains. The EPA was linking the mechanism of genotoxicity to cancer with the Ames test data as the vehicle. This was also quickly withdrawn as the agency recognized the error of using DNA-deficient strains to support the LNT concept. Such tactics used by the EPA in the late 1970s were to be seen as scientifically amateurish, perhaps the action of a young agency. It was better to formulate a position based on a protectionist philosophy than to be embarrassed publicly on the science.

Much research and debate over the question of cancer risk assessment has focused on whether thresholds for mutagens might exist. Lost in this debate was the key paper of Caspari and Stern [144] that was marginalized by Stern and Muller (see Calabrese [10], Uphoff and Stern [286]). While the threshold debate initially focused on ionizing radiation [287–289], it was soon extended to chemicals [290–302]. During this period of the dose–response concept formulation for mutagens, the Environmental Mutagen Society proposed that mutagens be covered under the Delaney Clause and not be permitted to be added to food. They argued that there was no safe level of exposure since mutagens displayed a linear low-dose relationship. While this was a debate that the society lost, the debate over dose–response, especially for genotoxic agents and genotoxic carcinogens, has continued unabated to the present [112,303–321]. Regulatory agencies, such as EPA, have adhered to the LNT approach for carcinogen risk assessment for the next 40 years and continue to do so. Of interest in this regard was the striking statement of Kenny Crump, a key architect of the LNT multistage model used by the EPA in QRA in the mid-1970s to the present. In a major retrospective, Crump [322] tends to place this intellectual cacophony in the scientific world in perspective. He stated that "quantitative risk assessment, as currently practiced is broken. Despite a huge investment in 'risk research'

the effort has failed to resolve the shape of the dose response curve for any substance." Crump [322] further stated

> Science is not capable of determining the shape of the dose response at very low doses. Hypotheses regarding the existence or non-existence of thresholds are beyond the ability of science to resolve… Continuing to expend energy and time debating the irresoluble issue of thresholds, and base decision rules on it, are a detriment to fashioning a logical and workable comprehensive approach to risk assessment.

The argument of Crump is a statistical one. He notes that various research groups have reported on the occurrence of threshold and supported their conclusions by the use of a hockey stick dose–response model [316,323,324]. According to Crump [322], the best that can be said about the threshold dose–response in such cases is that it fits the data significantly better than a perfectly linear dose–response. Despite this factual conclusion, this assumption does not prove nor even imply that the true dose–response has a threshold. Crump [322] carried this argument further by assuming that the slope of the dose–response could, in fact, be quite shallow, yet still not a threshold. In this sense, he argued that this type of evaluation supports his conclusion that it is impossible to say which model is correct.

This statistical argument of Crump's has potential theoretical value when dealing with threshold dose–responses that also do not display a U-shaped or HDR. If an HDR were to be demonstrated, it would constitute proof that a threshold not only existed but had been reasonably demonstrated. This would be especially the case when the mechanism of the HDR was established.

OPEN LETTER

The concept of the dose–response has a long and controversial history in the field of toxicology and risk assessment. The controversy is not simply a modern one but one that emerged as soon as the first formal dose–response model was proposed in the 1880s. In fact, the controversies that swirl around the dose–response in the form of linearity, threshold, and hormesis can trace many of the issues back to the roots of the initial disputes. This chapter traced this history and its evolution. One of the further issues is that I have been at the center of the dose–response debate over the past two decades, leading the resurgence of the HDR in toxicology and the broader biomedical sciences. When one takes on both a leadership role and a scientific role in the development of a scientific concept, it can be challenging to be balanced in the assessment and in this case the writing of this chapter. The editor was quite clear to me that this chapter had to be about dose–response and not simply about hormesis. It was a challenge that I took seriously and looked forward to being successful with.

While I became very involved with the hormesis topic from 1990 to the present, I was first introduced to this concept as an undergraduate in a plant physiology class doing a laboratory exercise on the dose–response of a synthetic plant growth inhibitor with the peppermint plant. Unexpectedly, our research team observed that the growth inhibitor seemed to stimulate the plant growth. After the course ended, I followed up on this observation and worked with a professor to determine if the effects were reproducible. With multiple experiments and many hundreds of peppermint plants later, I was able to conclude that the findings were reproducible and showed an inverted U-shaped dose–response with a low-dose stimulation and a high-dose inhibition. The magnitude of the stimulation was always modest, being about 30%–60% greater than the controls. Since these initial findings were in soil, I did further work to see if the effects could be shown to occur in hydroponics. Similar reproducible findings occurred. The findings were published in the journal *Physiological Plantarum*. The dose–response was simply called a low-dose stimulation and high-dose inhibition as I had yet to hear of the term hormesis, even though I was to learn later that it had been created in the early 1940s.

I put aside the peppermint work and went to graduate school hoping to become an insecticide toxicologist. Over the next 20 years or so, I become very involved in the toxicology and risk assessment communities, serving on numerous major committees, including a series of NAS SDWCs, the Air Cabin Safety Committee that lead to the banding of smoking in airplanes, and an Institute of Medicine committee. I wrote nearly a dozen singly authored books, most of which dealt with the issue of dose–response. In rereading these books, my views were very much in line with the views of the federal agencies, supporting thresholds for noncarcinogens and linearity for carcinogens. In fact, this is the way that I taught my toxicology and risk assessment courses. My views on dose–response were completely *mainstream* and never challenging the status quo.

I was reintroduced to the topic of hormesis in 1985 when I received a brochure for a conference sponsored by the Electric Power Research Institute. I was invited to participate in the meeting by the late Leonard Sagan, with a paper addressing chemical examples of hormesis. While the paper was completed, it was presented by a graduate student, as I was unable to attend due to the birth of my second son. During the 1990s, my interest continued on the topic of hormesis, with an openness to discovering whether this phenomenon was very general and biologically significant. I was far from sure on this matter until the near to the end of the 1990s, when at last I had seen enough data within a sound evaluative framework that I finally concluded that there was something very significant going on with the hormesis concept. At that point, I threw myself fully into the study of hormesis, pretty much dropping all other previously funded areas. My scientific intuition told me that this could be very important to give it the highest priority. I have done this ever since and it was a good decision.

Despite this commitment to the study of hormesis, I did not give up my capacity to be objective, to see weaknesses in experiments, and to try to find ways to gain better scientific insights. Our work in this area is characterized by the publication of numerous articles in a broad range of high-level journals, with strong independent peer-reviewed activities. What I have learned is that it has been far harder to pass peer reviews on topics related to hormesis than all my previous areas of research. There is often an extra set of reviewers and a more skeptical associate editor that seem to raise the

publication bar far higher for things hormetic. While frustrating, this has been good in many ways as the finally accepted manuscripts are typically of higher quality. During the course of these years of hormesis focus, my work and I personally have been the object of much criticism and debate. Much of the criticism has been of excellent quality and has been helpful to improve future efforts. However, there are other criticisms that are clearly ideologically, based on a fear that hormesis may harm environmental regulations. Such criticisms often include personal attacks and unfounded accusations that hormesis is simply a ploy used by industry to weaken standards. We have shown from the early days of the hormesis revolution that the hormetic response could be beneficial, harmful, or neither. In fact, Baldwin and I were the first to publish this, a view that is now widely accepted. We have also reported cases in which the hormetic response was replaced by a triphasic dose–response, with damage occurring at the lowest levels of exposure. The point is that it is not hard to be objective, when one has been trained to be objective and where one has lived this way. This is the fun of science. The only way to gain solid insight is to follow the data. I have done this over 40 years since receiving my PhD, and I have tried to do this in this chapter on dose–response. Nonetheless, I have an informed perspective and I share it. It may not be fully correct and I suspect that my understandings and views will change with new data and assessments. Yet this chapter is my honest attempt to give the reader my best insight into the dose–response and how the toxicology community came to its understandings and whether they have been correct or wrong and why.

QUESTIONS

3.1 Could the inverted U-shaped dose–responses observed for some endocrine disrupting agents be examples of hormesis? Explain how and why you think that this might be the case or why not.

3.2 What are the risk assessment implications of the observation that latency of tumor development is inversely related to dose?

3.3 What are the toxicological advantages and disadvantages of having an animal model for the chronic bioassay to have a low or negligible background tumor incidence?

3.4 How does the concept of dose–response synergy differ depending upon whether the synergy occurs above the threshold or below the threshold in the hormetic zone?

3.5 In toxic tort litigation, epidemiological response less than twofold greater than the control group is not accepted as showing causality. Why is this the case and should there be exceptions to it, and what might they be and why?

3.6 Are their areas of toxicology and clinical medicine that do not show a dose–response? If so, what would they be? How would this phenomenon be explained?

KEYWORDS

4 Metabolism
A Determinant of Toxicity

Raymond A. Kemper, Mitchell E. Taub, and Matthew S. Bogdanffy

CONTENTS

INTRODUCTION

Understanding the metabolism, or biotransformation, of xenobiotics has come to be regarded as fundamental to appreciating the toxic mechanisms of chemicals, be they drugs, industrial chemicals, pesticides, or other molecule foreign to the body. This chapter discusses the major pathways of xenobiotic metabolism with an emphasis on the role that biotransformation plays as a determinant of toxicity. The material is organized in the traditional view of the functionalization of xenobiotics, that being biological oxidations, reductions, and hydrolytic conversions, frequently referred to as *phase I reactions*, and biochemical conjugation reactions, known as *phase II reactions.*

GENERAL FEATURES AND BASIC CONCEPTS OF XENOBIOTIC METABOLISM

The majority of organisms studied have biotransformation enzymes, although there is diversity in the occurrence, function, and rates of specific enzymes. Certain bacteria contain more primitive or less highly developed systems and may lack certain pathways altogether. Mammals demonstrate diversity in the activity or rates of specific systems, and as would be expected of genetically controlled functions, there are significant species and individual differences. This diversity extends to the organ level in multicellular organisms. Moreover, specific organs show different levels of activity, and specific cell types within organs demonstrate variation in biotransformation capability. There is even subcellular diversity, in that certain of these enzymes are compartmentalized whereas others are free in the cytoplasm.

The variety of chemicals to which organisms may be exposed requires that biotransformation enzymes have broad substrate specificity. This characteristic is not shared by the majority of enzymes involved in anabolic and catabolic metabolism. In addition, the types of reactions catalyzed are diverse, as shown in Table 4.1, including oxidation, reduction, epoxidation, deamination, hydroxylation, sulfoxidation, dehalogenation, and conjugation with endogenous compounds, to name a few. Although it is logical to initially focus on xenobiotic-metabolizing systems one at a time, in many cases, xenobiotic metabolism involves more than a single metabolic route. In addition, the eventual toxicity of a xenobiotic may be modified by a number of factors, including age, gender, physiological status, nutrition, diet, and the presence or absence of disease, among others.

Exposure of an animal to certain xenobiotics can result in the induction of specific enzymes associated with xenobiotic metabolism. When induced, their activity can dramatically increase, compared to their basal level. Induction is sometimes coordinated with more than one enzyme induced. Induction results in an increase in the ability of animals to metabolize xenobiotics, and in most cases, this reduces their susceptibility to its toxicity. Induction generally lasts only a few days. When exposure ceases, the enzymes return to their basal levels.

TABLE 4.1
Reaction Types and Enzymes That Participate in Xenobiotic Metabolism

Phase I Reactions

Oxidation
- Cytochromes P450
- FMOs
- Xanthine oxidase
- Amine oxidase
- MAO
- Semicarbazide-sensitive oxidases

Reduction
- Cytochromes P450
- NADP-quinone oxidoreductase
- Carbonyl reductases
- Glutathione peroxidases

Ester hydrolysis
- Carboxylesterases
- Amidases

Dehydrogenases
- ADHs
- ALDHs

Hydration
- Epoxide hydrolase

Miscellaneous
- Cysteine conjugate β-lyase
- Superoxide dismutase
- Catalase

Phase II Reactions

- UDPGTs
- SULTs
- GSTs
- Glucosyltransferase
- Thiotransferase
- Transacylases

Methylation
- O-methyltransferase
- N-methyltransferase
- S-methyltransferase

Acetylation
- NATs
- Acyltransferases

Miscellaneous
- Rhodanese

Because xenobiotic metabolism does not always result in detoxification, the term *biotransformation* has come into general use to denote the actions of xenobiotic-metabolizing enzymes, although it is still not semantically specific for xenobiotic metabolism. Biotransformation is divided into two distinct phases. Phase I reactions result in *functionalization*, the addition or the uncovering of specific functional groups that are required for subsequent metabolism by phase II enzymes. Phase II reactions are biosynthetic. These phase I and II reactions are often coordinated, with the product of phase I reactions becoming the substrate for phase II enzymes. A commonality of biotransformation reactions is the conversion of hydrophobic xenobiotics into more polar, more easily excreted compounds. Because the composition of cells is more lipophilic than their environment, nonpolar compounds tend to accumulate. This could lead to bioconcentration of chemicals within the cell to levels higher than that of the environment and increase the likelihood of a cytotoxic event; however, conversion of nonpolar chemicals to more polar metabolites allows them to be more easily excreted by the cell. Conjugation of a xenobiotic with an endogenous compound, a phase II reaction, increases water solubility, and in some cases, the added chemical group is recognized by specific carrier proteins or proteins involved in facilitated diffusion or active transport. This increases the ability of the cell to remove the xenobiotic.

Many diverse examples exist of xenobiotics whose toxicity is directly dependent on the activity of the biotransformation

enzymes. For most chemicals, increases in the activity of these enzymes result in decreases in toxicity, whereas decreases in activity result in increased toxicity; however, in some instances, the product of xenobiotic metabolism is more toxic than the parent compound. Conversion of a foreign compound to a more toxic metabolite is termed *metabolic activation*; for example, the majority of genotoxic and carcinogenic chemicals require metabolic activation to highly reactive species capable of interacting with DNA. The enzymes that protect the animal from the toxicity of certain compounds may be responsible for the toxicity of others. The susceptibility of an organism to the toxicity of a particular chemical is dependent, in many cases, on the delicate balance between detoxification and metabolic activation that exists during exposure to the xenobiotic. Due to the sensitivity of the enzymes of xenobiotic biotransformation to both endogenous and exogenous factors, this balance may differ among individuals and at different points in time.

BIOLOGICAL OXIDATION

Cytochrome P450-Dependent Monooxygenase System

The P450-dependent monooxygenase system is central to the metabolism of most xenobiotics. Not only is it the primary enzymatic system for metabolism of many xenobiotics, but it is also involved as the initial functionalization step in the further metabolism of many others. Consequently, P450 plays essential roles in several areas of research, including biochemistry, pharmacology, toxicology, physiology, and medicine. Several names for the P450 system exist in the literature. The names most commonly encountered include

- Mixed function oxidase
- P450 system
- P450-dependent monooxygenase system

Generally, these names either are related to a specific function or are descriptive of a biochemical mechanism. Currently, it generally is referred to in terms of a monooxygenase system to denote its ability to incorporate one atom of molecule oxygen into its substrates.

Components of the Cytochromes P450 System

The history of the discovery of P450 and elucidation of its functions and mechanisms of action is intriguing and has been reviewed by Estabrook.[1] P450 was first described independently in 1958 in microsomes isolated from rat and pig liver homogenates. The name P450 derived from the occurrence of a pigment that, when reduced and treated with carbon monoxide, yielded a spectrophotometric Soret band at 450 nm. The laboratory of Britton Chance at the Johnson Foundation was the first to observe the pigment. Six years later, Omura and Sato[2,3] published their pivotal papers describing P450 as a b-type hemocytochrome and demonstrated that the cytochrome was located in hepatic microsomes, which form from the endoplasmic reticulum upon cellular disruption. Upon isolation from the membrane, through the use of proteases, P450 is converted to an inactive form whose reduced carbon monoxide complex produces a spectrophotometric peak at 420 nm.

Before the discovery of P450, Julius Axelrod and his colleagues,[4] in the laboratory of Chemical Pharmacology at the National Heart Institute, were involved with studies on the metabolic disposition of drugs.[4] They found that the oxidative metabolism of amphetamine required the cofactor nicotinamide adenine dinucleotide phosphate (NADPH) (reduced form) and the presence of oxygen. Estabrook et al.[5] established that P450 was the terminal oxidase involved with the C-21 hydroxylation of steroids in adrenal cortical microsomes, giving P450 a role in endobiotic metabolism. Many individuals and laboratories have since played major roles in the development of the current knowledge concerning P450.

It soon became obvious that although P450 played a major role in the activity of the monooxygenase, it did not act alone. In 1950, Horecher[6] isolated a flavoprotein from the liver, but no function was identified. This flavoprotein used reducing equivalents from NADPH and was termed *NADPH–cytochrome c reductase*. In 1955, La Du et al.[7] showed that cytochrome *c* could inhibit dealkylation of aminopyrine. This was followed by the studies of Gillette et al.[8] in 1957, which presented additional evidence that cytochrome *c* reductase was involved in xenobiotic metabolism. In the 1960s, it was reported that NADPH–cytochrome *c* reductase occurred in the endoplasmic reticulum of liver cells, that antibodies to the reductase inhibited xenobiotic metabolism, and that the reductase is required for monooxygenase activity when reconstituted from isolated components.[9–12]

Although the major components of the P450-dependent monooxygenase system appear to be P450 and P450 reductase, other components may also be involved with the metabolism of specific xenobiotics. Cytochrome b_5 reductase has been proposed to participate in monooxygenase activity through electron transport to cytochrome b_5 and, subsequently, to P450; however, several systems of electron transport in the endoplasmic reticulum and isolated microsomes, as well as other activities such as peroxidation, have greatly complicated the elucidation of the role of cytochrome b_5. In many cases, cytochrome b_5 has been found to enhance NADPH-dependent substrate oxidation by P450, although the effect of cytochrome b_5 is dependent on both the specific P450 isoform and the substrate under investigation.[13] Cytochrome b_5 may enhance electron transfer to P450 by at least four different mechanisms. These include faster provision of the second electron to P450, the rate-limiting step in catalysis; enhanced coupling between NADPH consumption and substrate oxidation; formation of a complex with P450 that is capable of accepting two electrons from NADPH–P450 reductase; and allosteric activation of P450.[13] An elucidation of the role of cytochrome b_5 must await further understanding of the complex electron transfer pathways that exist in the endoplasmic reticulum.

Although the catalytic activity of the monooxygenase system appears to require only two proteins, NADPH–P450

$$\text{R-H} + \mathbf{O_2} + \text{NADPH} + \text{H}^+ \xrightarrow{\text{CYP}} \text{R-}\mathbf{O}\text{H} + \text{H}_2\mathbf{O} + \text{NAD}^+$$

FIGURE 4.1 Global reaction and stoichiometry of cytochrome P450.

reductase and P450, it is capable of carrying out a variety of different reactions on a large number of substrates. This ability is based on the occurrence of a variety of P450 isozymes, but it also is based on the basic reaction mechanism of the cytochromes and their overlapping substrate specificity. The nonspecificity of the monooxygenase provides important flexibility to xenobiotic metabolism, but this flexibility comes with a price. Generally, the enzymatic reactions of anabolism and catabolism are both extremely specific in substrate specificity and catalytically efficient, resulting in high activity and high substrate turnover number. The turnover number and efficiency of P450 are considerably lower than most enzymes. This is probably related to the inefficient electron transfer due to the presence of a water molecule at the active site. Some substrates are more efficiently oxidized because they exclude water from the active site.[14] Inefficiency of metabolism is more than made up for by the ability to metabolize a variety of chemical structures and the ability to catalyze a variety of reactions. An additional factor that compensates for the relatively low substrate turnover number is the high concentration of the system in organs important in xenobiotic metabolism.

Before discussing the various reactions catalyzed by P450, a discussion of the catalytic cycle is appropriate. Knowledge of the catalytic cycle will assist in understanding the various reactions catalyzed by the system and in predicting metabolic pathways for specific xenobiotics.

Catalytic Cycle of the P450-Dependent Monooxygenase System

The reaction catalyzed by the cytochrome P450-dependent monooxygenase system and its stoichiometry are illustrated in Figure 4.1. One molecule of substrate reacts with one molecule of molecular oxygen and NADPH to yield oxidized substrate containing one atom from molecular oxygen, water (containing the other oxygen atom), and $NADP^+$. The incorporation of one oxygen atom from molecular oxygen into the substrate is the source of the term *monooxygenase*. Oxidation of substrate and concomitant reduction of one atom of oxygen to water is the source of the name *mixed function oxidase*. Although the reaction stoichiometry appears simple, obtaining this stoichiometry in the laboratory is difficult.[15] The main difficulty is the number of oxidation–reduction reactions that occur simultaneously in the endoplasmic reticulum. These reactions use oxygen and NADPH and may yield water and $NADP^+$. When these diverse reactions have been accounted for, the predicted stoichiometry has been obtained.

It is recommended that the reader carefully follow the reaction sequence illustrated in Figure 4.2 during this discussion of the catalytic cycle. The initial step of the cycle is binding of the substrate (R–H) to P450 (Figure 4.2A).

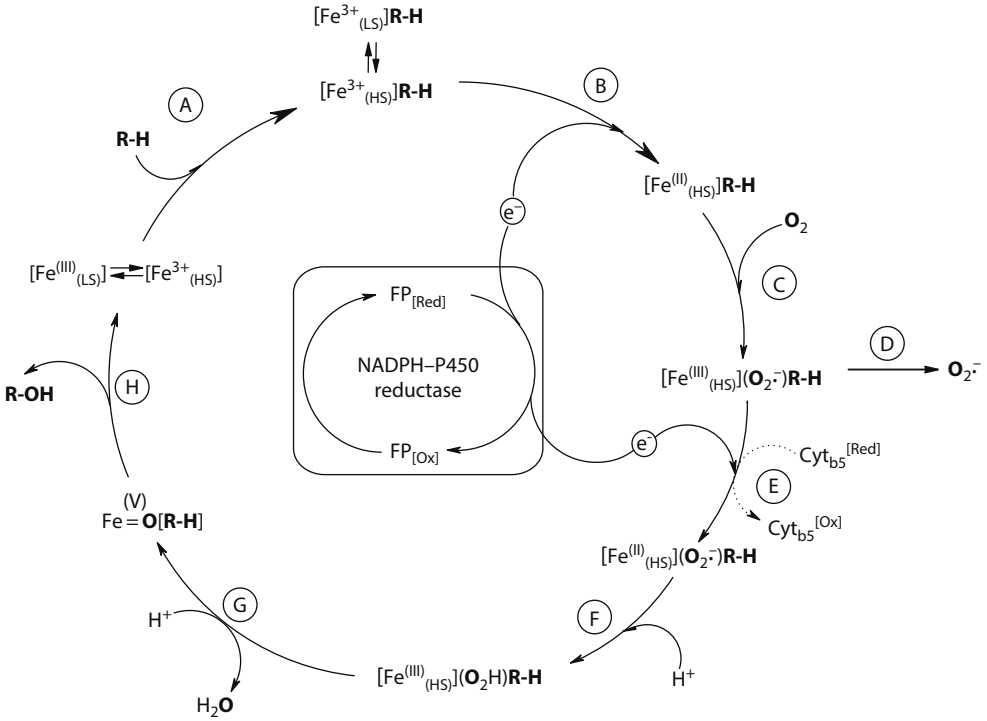

FIGURE 4.2 Catalytic cycle of cytochrome P450-dependent substrate oxidation. HS, high spin; LS, low spin; Cytb5, cytochrome B 5. See text for details. (Adapted from Testa, B., *The Metabolism of Drugs and Other Xenobiotics: Biochemistry of Redox Reactions*, Academic Press, London, U.K., 1995.)

As previously mentioned, P450 exists as a series of closely related isozymes, each of which demonstrates a degree of substrate specificity. This substrate specificity is not absolute, and overlapping is evident. At any one time, several isozymes of P450 exist in the endoplasmic reticulum. This is dependent on the specific genetic, environmental, and physiological conditions of the organism; therefore, binding of the substrate to the active site of P450 may represent binding to a single isozyme predominantly but not exclusively. The activity of the catalytic process (as well as the specific metabolites produced) is a function of the particular isozyme profile. Although our understanding of the structure of the active site of P450 is developing,[16,17] more remain to be learned. From the nature of the hemoprotein and its substrates, the active site contains the heme and a hydrophobic region. The substrate must have a specific orientation within the active site.

As occurs with many other enzymes, the binding of the substrate to the hemoprotein appears to produce conformational alterations in the enzyme that assist its catalytic activity; for example, substrate binding facilitates the reduction of P450 by NADPH–P450 reductase, in part, by lowering its redox potential. Binding of the substrate to the active site changes the absorption spectrum of the cytochrome. Because the oxidized heme iron is paramagnetic, electron paramagnetic resonance (EPR) can be applied to probe the environment of the iron in the heme. These studies have revealed alterations in the EPR signal that correlate with the blue shift in the Soret band from about 419 to 390 nm, observed when substrates bind the cytochrome. EPR and visible spectra changes result from the substrate binding in close proximity to the heme iron with a concomitant displacement of a water molecule from the iron. Substrate binding is energetically favorable and rapid, the heme is transformed from its low-spin form to the high-spin form, and the substrate is placed in close spatial proximity to the oxygen activation site on the heme. The relationships between the spin state of the cytochrome, interaction with the amino acids at the binding site, and substrate binding are more complex than described here. The reader is referred to discussions of changes in the spin state of P450 in Lewis,[16] Poulas and Raag,[14] Rein and Jung,[17] and Sligar and Murray.[18]

The next step in the catalytic cycle after substrate binding is the one-electron reduction of the substrate–P450 binary complex (Figure 4.2B). As mentioned, substrate binding and the concomitant alterations in P450 may facilitate this reduction step. The ferric (Fe^{3+}) hemocytochrome P450–substrate complex is reduced by a single electron to the ferrous (Fe^{2+}) hemocytochrome P450–substrate complex. This electron is provided by NADPH through NADPH–P450 reductase. This flavoprotein contains two flavins: flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). The flavoprotein appears to exist in its half-reduced (one-electron reduced) form and, upon reaction with NADPH, is fully reduced (two-electron reduction). The intramolecular electron flow appears to be from FAD to FMN. It is interesting that whereas the flavoprotein is a one-electron donor, its substrate, NADPH, provides two electrons. The mechanism for the two-electron shuttle by the one-electron donor flavoprotein is incompletely understood.[19]

NADPH–P450 reductase has at least two domains, one of which is imbedded in the endoplasmic reticulum membrane and the other above the plane of the membrane on the cytosolic side. The domain solubilized in the membrane consists mainly of hydrophobic amino acids. The actual interaction with NADPH and oxidation–reduction takes place outside the membrane. Another interesting aspect of P450 reductase is that the quantity of P450 is in large excess to the quantity of reductase (as much as 15- to 20-fold or more, depending on conditions). This means that each flavoprotein must reduce several P450 molecules, indicating that the interaction between the reductase and P450 is an important consideration, as discussed later.

Upon reduction of the ferric hemocytochrome P450–substrate binary complex to the ferrous state by the reductase, the enzyme binds oxygen (Figure 4.2C) to form a ternary complex. The oxygen binds at the free ligand of the heme iron and is believed to be oriented spatially with the substrate-binding portion of the active site. Uncoupling (interrupting the flow of electrons) the catalytic cycle at this point can produce the oxidized ferric P450 and a reduced form of oxygen, the superoxide radical (Figure 4.2D). Other reactive oxygen species can be generated by P450, including hydrogen peroxide and the hydroxyl radical. Generation of active oxygen species by P450 has been reviewed in Bernhardt.[19]

At this stage of the catalytic cycle, highly critical reactions take place that are still incompletely understood.[14] The major event is activation of the oxygen molecule. The ternary complex accepts a second electron required for the reaction (Figure 4.2E). The source of this electron can be either NADH or NADPH, depending on the mediator of electron transport. Because the purified, reconstituted system consisting of isolated P450, P450 reductase, and phospholipid requires only the presence of NADPH, NADPH–P450 reductase can mediate this step; however, as previously mentioned, in some systems, it appears that cytochrome b_5 can mediate the electron transfer employing reducing equivalents from NADH through NADH–cytochrome b_5 reductase. Whichever the source of the second electron, it results in the production of the peroxy P450–substrate complex, which has a net charge of −2 (Figure 4.2F). Of the variety of mechanisms proposed for oxygen activation and insertion into the substrate, two appear to be generally accepted. The first mechanism involves heterolytic cleavage of diatomic oxygen with the abstraction of hydrogen from the substrate and the insertion of oxygen into the substrate. The great majority of experimental evidence supports this mechanism,[20] particularly studies employing radical clock substrates.[21,22] Quite recently, direct spectroscopic evidence for the existence of the activated iron-oxo intermediate (compound I) has been obtained in CYP119 from *Sulfolobus acidocaldarius*, and its kinetic properties in oxygenating substrates have been defined.[23] The second more controversial mechanism involves homolytic cleavage, whereby two oxygen radicals are generated. Whatever the mechanism, one atom of this reactive oxygen is introduced into the substrate, whereas the other is reduced to water (Figure 4.2G). The oxidized substrate and water are released,

regenerating the oxidized ferric P450, which can again initiate the catalytic cycle (Figure 4.2H).

It must be emphasized that other pathways of electron transport in the endoplasmic reticulum can have significant impact on the catalytic activity of the monooxygenase by altering the availability of reducing equivalents. The interested reader is encouraged to consult other sources for a more comprehensive discussion of these pathways.[23,24]

This catalytic cycle is common to cytochrome P450-dependent monooxygenase activity associated with xenobiotic metabolism in a variety of organs and among different species; however, certain of these monooxygenases, especially the more specific forms associated with anabolic and catabolic metabolism, have different mediators of electron transport. For example, the adrenal cortex mitochondrial systems use a nonheme iron protein in addition to the P450 reductase in the electron transport chain, as does the monooxygenase system in certain microorganisms.[14,25]

The P450 system is not totally independent, and its activity is affected by a number of factors. One of these factors is the availability of reducing equivalents. The monooxygenase is primarily dependent on NADPH, as previously discussed, and possibly, to a lesser extent, on NADH. NADPH is generated from the pentose-phosphate shunt, isocitrate dehydrogenase, and the malic enzyme. Under most conditions, these pathways provide saturating levels of NADPH; however, certain conditions can compromise the ability of the cell to provide NADPH, and it may become rate limiting. Under conditions of high monooxygenase activity, starvation may reduce the activity toward certain substrates due to reduced levels of NADPH. It is generally believed that the decreased activity due to limiting NADH is an unlikely condition. A discussion of these and other factors that regulate monooxygenase activity can be found in Thurman.[26]

An additional factor that influences monooxygenase activity is the endoplasmic reticulum membrane. The asymmetric nature of the protein components of the system with respect to the membrane surface, coupled with the disproportionality of the concentrations of the components (i.e., a ratio of 1 to 15–20 between the flavoprotein and P450), indicates an interesting topology and interaction between the components. The membrane topology of the P450 system has been a topic of research for a number of years. The interaction between the protein components of the system and the interaction of these components with the lipid matrix of the membrane are important in the overall reactions of this system. P450 appears to be attached to the membrane of the endoplasmic reticulum by an anchor peptide at the NH_2-terminal end of the protein with the anchor peptide transversing the membrane. The active site, including the heme, is on the cytoplasmic side of the membrane. The active site portion is rich in alpha helix content, globular in nature, and not associated with membrane lipids. The area around the active site may be associated with the cytosolic surface of the membrane, providing a somewhat rigid character.

P450 appears to exist as multicomponent complexes of six P450 molecules clustered around a single P450 reductase. The NH_2-terminal regions on the opposite side of the membrane may interact to anchor this complex together. This allows for a catalytic advantage because of the close association of the components. This organization implies that each reductase would be capable of sequentially reducing several P450s. P450 may form a transient complex with the reductase that has an extremely short, non-rate-limiting half-life.[27,28]

Isozyme Heterogeneity and Substrate Specificity of Cytochrome P450

For many years, the apparent lack of substrate specificity of P450 intrigued investigators. It appeared that one of the major features of substrate specificity was lipid solubility. There appeared to be few other structural restraints for substrates. Intensive research on the nature of the hemoproteins has revealed that much of this apparent lack of substrate specificity results from the existence of multiple families and multiple subfamilies of P450 isozymes.

As the array of individual isozymes grew in number, nomenclature became increasingly problematic. It was sometimes difficult for investigators to know exactly which P450 they were working with because of inconsistencies in nomenclature. This led to attempts to develop a systematic nomenclature for the isozymes. P450 nomenclature has evolved from identifications based on spectral peaks to species-dependent nomenclature based on isolated and semipurified P450s to the current system, which is based on amino acid sequences that result from specific gene sequences.[29] P450 are now placed in families, which are further divided into subfamilies.

Names are based on the root CYP (derived from Cytochrome P450). The CYP is followed by a number identifying the gene family to which it belongs, such as CYP1, CYP2, and CYP3. The number for the gene family is followed by a letter denoting the subfamily to which the P450 belongs, such as CYP1A and CYP2A. The subfamilies are further defined by the addition of a number identifying the gene, such as CYP1A1 and CYP1A2; thus, P450 nomenclature is based on genetic relationships defined by protein and gene sequences. All P450s within a single family must exhibit a protein sequence similarity greater than 40%. P450s within the same subfamilies have sequence similarities greater than 55% within the same species. Subfamilies have sequence similarity that may be somewhat less than 55% when comparing species that are more distantly related. Members of subfamilies within a species appear to be located on a specific chromosome, and different subfamilies within a gene family may be clustered on the same chromosome.

As is generally found in biology, the classification system has exceptions resulting from P450s that do not fit the usual patterns. Although this nomenclature provides information on genetic and evolutionary relationships, it provides little information about substrate specificities and the reactions catalyzed by the different P450s. In fact, more is known

about the protein and gene sequences of many P450s than about their specific roles in metabolism. In the past decade, advances in molecular biology have driven an exponential increase in our ability to identify and sequence specific *CYP* genes, such that our knowledge of CYP primary structure has far outstripped our ability to define their specific roles in the metabolism of xenobiotics and endogenous compounds.

Different species may contain CYP genes or proteins that appear to be highly related; these are termed *orthologous genes* or *orthologs*. Orthologs are believed to have evolved from a single gene that existed before the two species diverged from a single species. Although these genes and their proteins may contain a high degree of sequence homology, it is not necessarily true that they share a catalytic similarity, or vice versa. A small change in an important amino acid sequence can result in a large change in the activity of a P450. Humans and rats have the CYP2 family and the CYP2D subfamily. The rat subfamily contains five genes, one of which is CYP2D1. This P450 has catalytic activity toward debrisoquine metabolism. The human P450 that has the highest catalytic activity toward debrisoquine is CYP2D6, which makes up less than 5% of the complement of P450 in the liver (Figure 4.3). Because these rat and human P450s have similar substrate specificity, it might be assumed that they have a high degree of sequence similarity, but this was found not to be the case. Therefore, even though these two isozymes have similar catalytic activity, they may have been derived from different ancestral genes. Sequence orthologs do not always predict similar catalytic activities. This is important for toxicologists who extrapolate toxicity from animal models to humans, as noted later.

The section that follows provides a brief description of the major P450 families involved in xenobiotic metabolism. Those families predominately involved in metabolism of endogenous substrates have been excluded. For a more complete discussion of the P450 families, the reader is referred to the excellent reviews in Ioannides,[30] Lewis,[31] and Smith et al.[32]

CYP1 Family

The CYP1 family contains two subfamilies of P450s: CYP1A and CYP1B. CYP1A has been much more extensively characterized than the CYP1B subfamily.

CYP1A Subfamily

The CYP1A subfamily contains CYP1A1 and CYP1A2, which appear to occur in all mammals. These two P450s may have been derived from a common ancestor approximately 120 million years ago. Both P450s are important in the metabolism of environmental xenobiotics. Historically, these two P450s were known collectively as cytochrome P448, due to their characteristic CO binding spectrum. Although these hemoproteins share a number of physiochemical characteristics, such as similar primary structures, they demonstrate different substrate specificities. For example, CY1A1 is highly active in the metabolism of planar polycyclic aromatic hydrocarbons (PAHs) such as benzo(*a*)pyrene (BP) (Figure 4.4), whereas CYP1A2 is active in the metabolism of acetanilide, caffeine, and other aromatic and heteroaromatic amines.[33,34]

Both CYP1A1 and CYP1A2 also play a role in catabolism of estrogens,[35,36] and CYP1A1 may be involved in heme catabolism.[31] Although low levels of CYP1A1 have been detected in liver, this isoform is constitutively expressed primarily in extrahepatic tissues, including lung, kidney, gastrointestinal tract, and breast. In contrast, expression of CYP1A2 is found primarily in liver, where it accounts for approximately 15% of total hepatic CYP (Figure 4.3). Both CYP1A isoforms are highly inducible by planar polycyclic aromatic compounds such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and 3-methylcholanthrene, and their induction is mediated by the aryl hydrocarbon (Ah) receptor. In addition, isosafrole

is a specific inducer of CYP1A2. The O-dealkylation of ethoxyresorufin has been used as a functional marker for CYP1A1 activity in vitro, while ^{3}N-demethylation has been used as an in vivo marker for CYP1A2 activity. A variety of CYP1A1 inhibitors have been characterized, including furocoumarins,[37] flavonoids,[38] and acetylenic aromatic hydrocarbons.[39] However, the specificity of these inhibitors for CYP1A1 remains to be demonstrated. Furafylline has been used as a selective inhibitor of CYP1A2.[40] For a number of years, there has been an interest in the role of CYP1A1 in the metabolic activation of polycyclic hydrocarbons, such as BP.

Although many of the investigations on the role of CYP1A1 in the activation of PAHs have been done in animals with induced CYP1A1, these compounds may be

metabolized by other CYPs in uninduced animals. Because its concentration in the liver is low, CYP1A1 may be more important in the metabolic activation of polycyclics in extrahepatic tissues, such as the lung. In humans, both CYP1A1 and CYP1A2 demonstrate genetic polymorphism (discussed later), with at least 15 variants of CYP1A2 reported to date.[34] CYP1A2 is active in the metabolism of a wide variety of drugs and environmental contaminants in humans. Good substrates for CYP1A2 tend to be relatively planar molecules containing one or more hydrogen bond donor/acceptors, which play a significant role in the regioselectivity of substrate oxidation.[31] CYP1A2 has been shown to be associated with the mutagenic activation of aromatic and heterocyclic amines, such as 4-aminobiphenyl, 2-aminonaphthalene, and 2-amino-3,5-dimethylimidazo[4,5-*f*]quinoline (MeIQ). It also O-dealkylates phenacetin and 4-hydroxylates acetanilide. Although CYP1A2 does play a major role in the bioactivation of aromatic and heteroaromatic amines, other CYP isoforms, notably CYP1A1, CYP1B1, and CYP3A4, can also contribute to the mutagenic activity of this chemical class.[32]

CYP1B Subfamily

CYP1B1 is the only known member of the CYP1B subfamily, which was identified and characterized in the mid-1990s.[41,42] CYP1B1 has been identified in mouse, rat, and human tissues. Expression of CYP1B1 mRNA has been detected in a number of normal human tissues including liver, kidney, gastrointestinal tract, endometrium, breast epithelium, and brain[43]; however, expression of the functional protein in normal human tissues has been much more difficult to demonstrate.[43] Interestingly, CYP1B1 has been shown to be highly expressed in a number of human tumors,[44] suggesting potential roles as a tumor biomarker or a chemotherapeutic target.[45] CYP1B1 is regulated by both Ah-dependent and Ah-independent mechanisms (addressed later) and thus is inducible by TCDD[46] and PAHs, as well as by estradiol.[47] Recombinantly expressed human CYP1B1 is capable of activating a variety of PAHs, aromatic amines, and heterocyclic amines to mutagenic metabolites, as demonstrated by the *Salmonella* (Ames) mutagenesis assay.[48] In addition, CYP1B1 is active in the metabolism of estrogens, particularly 4-hydroxylation of estradiol, which is the most specific functional assay for this isoform demonstrated to date. 4-Hydroxyestradiol is carcinogenic in male hamsters and may play a role in estrogen-induced tumorigenesis. The potential of CYP1B1 as a chemotherapeutic target has fueled interest in the discovery and development of specific inhibitors. Although a number of highly potent inhibitors have been identified, realization of sufficient selectivity for CYP1B1 remains a challenge.[49] Recently, 2,3′,4,5′-tetramethoxystilbene has been used as a specific inhibitor of CYP1B1 for elucidation of the role of this isoform in salt-sensitive hypertension.[50]

CYP2 Family

The CYP2 family contains a number of subfamilies important in xenobiotic metabolism, including CYP2A, CYP2B, CYP2C, CYP2D, and CYP2E.

CYP2A Subfamily

The CYP2A subfamily contains at least 12 members that differ in their substrate specificity, tissue distribution, and response to inducers and inhibitors. CYP2A1, CYP2A2, and CYP2A3 are rat P450s; Cyp2a4, Cyp2a5, and CYP2a12 are found in mice; humans express CYP2A6 and CYP2A7. Rat CYP2A1, along with CYP2A2, hydroxylates testosterone, progesterone, and androstenedione. CYP2A1 and CYP2A2 can also metabolize aminopyrine, benzphetamine, ethylmorphine, aniline, acetanilide, and *N*-nitrosodimethylamine. CYP2A1 has low activity toward 3-hydroxylation of BP and 7-ethoxycoumarin O-deethylation and does not metabolize 7-ethoxyresorufin. CYP2A1 occurs in liver and testis, but not kidney and lung. In adult rats, it predominates in females and appears to be under endocrine control. CYP2A3 appears to be lung specific, and its substrate specificity has not been well characterized. Human CYP2A6 demonstrates coumarin 7-hydroxylase activity but no activity toward testosterone, in contrast to rat CYP2A1 and CYP2A2. Moreover, it has no activity toward probe substrates such as 7-ethoxyresorufin, 7-benzyloxyresorufin, ethylmorphine, and testosterone.

Typical substrates for CYP2A6 include both planar and nonplanar molecules, and the preferred site of oxidation is generally within six topological steps of a hydrogen bond acceptor. In addition to coumarin, other substrates for CYP2A6 include nicotine, cotinine, acetaminophen, and methoxyflurane.[31] Coumarin 7-hydroxylation is commonly used as a functional marker for CYP2A6 activity, and inhibitors include pilocarpine and 8-methoxypsoralin. In primary human hepatocytes, CYP2A6 can be induced by phenobarbital (PB) and rifampicin, and 7-hydroxylation of coumarin was found to be accelerated in patients taking anticonvulsant drugs.[51] CYP2A6 accounts for approximately 4% of hepatic P450 (Figure 4.3) and is also expressed in skin[52] and respiratory tract,[53] where it may play a role in activation of tobacco-specific carcinogens. Initially thought to be monomorphic, recent data indicate that CYP2A6 is a polymorphic enzyme and that polymorphism of this enzyme may be a determinant of lung cancer risk in smokers,[54] although other authors have not observed this association.[55] Interest in this potential association continues to be fueled by links between CYP2A polymorphism and susceptibility to tobacco-related lung tumors observed in animal models.[56] As mentioned previously, studies in human microsomes have indicated that this P450 may play a role in the metabolic activation of a number of nitrosamines and possibly in the activation of aflatoxin B_1 (AFB_1) and 1,3-butadiene to carcinogenic epoxides.

CYP2B Subfamily

This subfamily contains P450s such as rat CYP2B1 and rat CYP2B2 that are highly induced by PB. Hydroxylation of testosterone at the 16β position is used as a specific substrate probe for these isoforms in rats. Other substrates for this subfamily include benzyloxyresorufin, ethoxycoumarin, and pentoxyresorufin. In rats, CYP2B1 has been detected in the lung, adrenal gland, testis, and brain, whereas CYP2B2 occurs in liver and brain. Although its role in xenobiotic

toxicity has not been thoroughly investigated, the CYP2B subfamily can metabolically activate xenobiotics, such as bromobenzene, carbon tetrachloride, BP, AFB_1, and some nitrosamines in the rat. Although the rat P450s in the CYP2B subfamily have been studied for a number of years, members of the CYP2B subfamily in humans have received far less attention.

Estimates of constitutive expression of CYP2B6 in human liver are variable, ranging from as low as 0.2% of total hepatic P450[57] up to 6% of total microsomal CYP protein.[58] In addition to liver, CYP2B6 has been detected in a variety of extrahepatic tissues, including various regions of the respiratory tract,[53] skin,[52] kidney, brain,[59] placenta, and endometrium.[57] CYP2B6 catalyzes oxidation of a variety of drugs and other xenobiotics, including several coumarin derivatives, methoxychlor, bupropion, benzyloxyresorufin, and benzphetamine.[31,60] Although debenzylation of 7-benzyloxyresorufin has been used as a marker for CYP2B6 activity, the selectivity of this appears to be questionable[57]; rather, N-demethylation of *S*-mephenytoin and ring hydroxylation of the phosphodiesterase inhibitor RP 73401 appear to be more selective probes for CYP2B6. Orphenadrine and 9-ethynylphenathrene have been used as inhibitors, although the former appears to lack selectivity for this isoform. CYP2B6 is inducible by PB, as well as classic CYP3A inducers such as dexamethasone and rifampicin, but a selective inducer of CYP2B6 has not been identified. Although CYP2B6 contributes to the metabolism of approximately 10% of marketed drugs, there is little evidence for significant drug–drug interactions (DDIs), reflecting the considerable overlap in substrate specificity of this isoform with other CYPs.[60]

CYP2C Subfamily

At least eight members of the CYP2C subfamily have been identified in rats, and P450s in this subfamily are expressed in both hepatic and extrahepatic tissues. Expression of rat CYP2C isoforms is gender specific, in contrast to humans. Four functional CYP2C subfamily members have been identified in humans: CYP2C8, CYP2C9, CYP2C18, and CYP2C19. Together, isoforms of the CYP2C subfamily are estimated to account for metabolism of approximately 20% of prescribed drugs in humans. All four genes are expressed in liver and small intestine, and CYP2C8, CYP2C9, and CYP2C18 mRNA have been detected in a variety of extrahepatic tissues. To date, CYP2C18 protein has not been detected in any tissue examined. Marker activities for CYP2C8 include paclitaxel 6α-hydroxylation and N-dealkylation of amiodarone, and both of these compounds have been used as probe substrates for these isoforms.[61] Relatively selective competitive inhibitors of CYP2C8 include gemfibrozil and montelukast. Moreover, gemfibrozil coadministration results in DDIs with a number of drugs metabolized by CYP2C8, including rosiglitazone, piogitazone, repaglinide, loperamide, and cerivastatin.[62] CYP2C8 is inducible by the prototypical enzyme inducers rifampicin, PB, and dexamethasone and is one of the most inducible members of the CYP2C subfamily.[63]

Polymorphism of CYP2C8 was first reported in 2001,[64] and since this time, a variety of variant alleles have been described. One of these variants, CYP2C8*5, has been associated with the development of rhabdomyolysis following administration of cerivastatin. Although several CYP2C8 polymorphisms result in pharmacokinetic changes for a number of clinically relevant drugs, evidence for adverse consequences is lacking. CYP2C9 is quantitatively the most important member of the human CYP2C subfamily in liver, second only to CYP3A4.[65] CYP2C9 oxidizes a wide variety of clinically important drugs, many of which contain weakly acidic groups. Among these, warfarin and tolbutamide have been used as probe substrates for this P450. CYP2C9 also catalyzes S-oxidation of tienilic acid, resulting in bioactivation of this compound to a reactive electrophile. Benzbromarone derivatives and sulfaphenazole are used as high-affinity selective inhibitors of CYP2C9.

In common with other members of this subfamily, CYP2C9 is polymorphic, and it has been estimated that up to 40% of Caucasians carry at least one variant CYP2C9 allele.[66] Because of its prominent role in the clearance of several low therapeutic index drugs such as warfarin and phenytoin, polymorphisms of CYP2C9 represent a significant challenge in the development of drugs metabolized by this isoform.[67] CYP2C19 catalyzes oxidation of a number of different drug classes, including proton pump inhibitors, antidepressants, and benzodiazepines. *S*-Mephenytoin is a prototypical substrate for CYP2C19, and 4′-hydroxylation of this compound is frequently used as a selective marker activity. Both omeprazole and ticlopidine have been used as inhibitors of CYP2C19, although the selectivity of these compounds has been questioned. Recently, *N*-benzylnirvanol has been shown to be a potent and selective inhibitor of CYP2C19 suitable for diagnostic purposes.[68] Induction of CYP2C8, CYP2C9, and CYP2C19 has been observed following treatment with rifampicin, and the former two isoforms are also induced by PB. Like other members of the human CYP2C subfamily, CYP2C19 is polymorphic, and at least eight allylic variants have been described. Although adverse drug reactions have been observed following coadministration of CYP2C19 substrates and inhibitors, a recent extensive review failed to find convincing evidence of adverse drug reactions related to CYP2C19 polymorphisms.[69]

CYP2D Subfamily

Rats have six members in the CYP2D subfamily, whereas three have been identified in humans: CYP2D6, CYP2D7, and CYP2D8. Mice have five CYP2D members, and this subfamily has been identified in other mammals. Human CYP2D6 is the most important member of the subfamily for xenobiotic metabolism in humans and was the first human P450 shown to be polymorphic. CYP2D6 is expressed in liver, lung, small intestine, and skin.[52,53] CYP2D6 accounts for less than 5% of total hepatic P450 in humans (Figure 4.3) but is estimated to participate in metabolism of approximately 20% of clinical drugs.[70] Substrates for CYP2D6 are relatively lipophilic and contain a basic amine group, and hydroxylation

generally occurs within 5–7 Å of the basic nitrogen.[71] Typical substrates include debrisoquine, dextromethorphan, and tricyclic antidepressants. The O-demethylation of dextromethorphan has been used as a functional marker for CYP2D6 activity. Numerous alkaloids are potent ligands for CYP2D6, and quinidine has been used as a selective inhibitor of this activity. Reactions catalyzed by CYP2D6 range from aryl hydroxylation to N- and O-dealkylation.

CYP2E Subfamily

The CYP2E subfamily is one of particular interest to toxicologists, due to its involvement in the metabolism and bioactivation of a wide variety of industrial and environmental chemicals. Currently, CYP2E1 is the only member of this subfamily in rats, mice, and humans. CYP2E1 appears restricted to mammals and may have evolved more recently than certain other gene families. It is expressed in liver and kidney and occurs at low levels in a number of other tissues including lung, skin, esophagus, and small intestine.[52,53] Although it normally represents less than 10% of the total P450 in human liver, it is induced by a broad array of its substrates. Its hepatic concentration can vary up to 50% between different humans. CYP2E1 is highly conserved across species, and rodent and human forms of CYP2E1 share many similarities, including similar substrate specificities. It is known to metabolize more than 70 different chemicals with diverse structures.

Structural requirements for CYP2E1 substrates appear limited to small molecules with hydrophobic character.[31] CYP2E1 does not appear to be active in the metabolism of many drugs but does metabolize a wide array of alcohols, aldehydes, alkanes, aromatic hydrocarbons, ethers, fatty acids, halogenated hydrocarbons (including anesthetics), heterocyclics, and ketones. Aniline hydroxylation and *p*-nitrophenol hydroxylation have been used as marker activities for CYP2E1, but both substrates are oxidized by other isoforms of P450. More recently, 6-hydroxylation of the muscle relaxant chlorzoxazone has been used as a diagnostic activity for CYP2E1. Although the selectivity of CYP2E1 for this substrate is not absolute, this reaction has become the marker of choice for CYP2E1 activity.[72] Carbon-tetrachloride-dependent lipid peroxidation has also been used to follow CYP2E1 activity in vitro. CYP2E1 can be competitively inhibited by many of its substrates, and a number of sulfur-containing compounds, including disulfiram and diallyl sulfate, have been shown to be mechanism-based inhibitors (metabolism dependent).[73] As noted previously, CYP2E1 is induced by many of its substrates, including ethanol, and it has been suggested that chronic alcoholics may be more sensitive to chemicals that undergo CYP2E1-mediated bioactivation than nonalcoholics.

Interest in the role of CYP2E1 as a mediator of toxicity comes from two of its actions. First, it is known to be important in the metabolic activation/detoxification of a number of carcinogens and heptatoxicants. Second, it may have an important role in free-radical production and oxidative stress.[74] For example, CYP2E1 is believed to be involved in the metabolic activation associated with the carcinogenicity of benzene, butadiene, nitrosamines, and azoxymethane, as well as the hepatotoxicity of nitrosamines, acetaminophen, halothane, and enflurane.

With respect to free-radical production, CYP2E1 is involved in the formation of a reactive hydroxyethyl radical produced during its metabolism of ethanol to acetaldehyde. This hydroxy radical is believed to play a role in ethanol-related liver damage. It also appears to be involved in the production of a trichloroethyl radical produced by chlorine removal during the metabolism of carbon tetrachloride. This radical may initiate membrane lipid peroxidation associated with carbon-tetrachloride-induced hepatotoxicity. An additional mechanism by which CYP2E1 could produce reactive radicals is associated with its potential for futile cycling in the absence of substrate. CYP2E1 appears more loosely coupled than some of the other P450s. Oxygen activation during the catalytic cycle in the absence of substrate results in the production of highly reactive hydroxyl radicals, superoxide anions, and hydrogen peroxide. Indeed, cells that constitutively overexpress CYP2E1 exhibited a 40%–50% increase in generation of reactive oxygen species compared to wild-type cells in the absence of substrate.[74] If these reach concentrations that overcome cellular protection mechanisms, they may initiate oxidative stress leading to tissue damage.

P450s are not evenly expressed in the liver but occur in specific zones; for example, oxygen tension varies significantly across the hepatic lobule, ranging from ~13% in the periportal region to ~4% in the centrilobular region, and this gradient is thought to be an important determinant of CYP expression.[75] The highest concentration of P450 is generally found in a layer surrounding the terminal hepatic venules. This is especially true for induced CYP2E1. Enhanced CYP2E1 activity in the centrilobular region appears related to the centrilobular necrosis produced by hepatotoxicants, such as ethanol, carbon tetrachloride, benzene, nitrosamines, and acetaminophen. It may appear that CYP2E1 is predominately involved with metabolic activation; however, this is not necessarily true. As noted before, P450-mediated xenobiotic metabolism is generally associated with the production of less toxic metabolites, but in some cases, more toxic metabolites are produced. CYP2E1 is no exception to this rule and participates not only in metabolic activation but also in detoxification.

CYP2F Subfamily

Isozymes of the CYP2F subfamily have been identified in humans, nonhuman primates, rodents, and ruminants.[76] Unlike other members of the CYP2 family, only a single isoform of CYP2F has been identified in each of these species. CYP2F is expressed almost exclusively in lung with very little expression in liver. The human form, CYP2F1, has been shown to be involved in bioactivation of a number of environmental toxicants, including 3-methylindole, naphthylene, styrene, dichloroethylene, and benzene, and the cellular localization of CYP2F1 correlates with the site of injury of these toxicants.[77] Thus, this isoform may play a

significant role in the pneumotoxicity of inhaled xenobiotics. To date, no selective substrates for CYP2F1 have been identified; however, the pneumotoxicant 3-methylindole has been found to be a selective mechanism-based inactivator of this P450. No data on the inducibility of CYP2F isoforms have been published.

CYP3 Family

The CYP3 family of P450s includes CYP3A1, CYP3A2, CYP3A9, CYP3A18, and CYP3A62 in rats; CYP3a11, CYP3a13, CYP3a16, CYP3a25, and CYP3a44 in mice; and CYP3A3, CYP3A4, CYP3A5, and CYP3A7 in humans, along with others from rabbits, dogs, and other species. The CYP3 family contains P450s that are important in the metabolism of many xenobiotics, especially drugs.

CYP3A Subfamily

This subfamily contains at least four genes in humans, CYP3A3, CYP3A4, CYP3A5, and CYP3A7. Together, these isoforms constitute approximately 30% of total hepatic P450 and are estimated to mediate metabolism of around 50% of prescribed drugs, as well as a variety of environmental chemicals and other xenobiotics. CYP3A4 is the major form of P450 expressed in human liver. It is also the major P450 expressed in the human gastrointestinal tract, and intestinal metabolism of CYP3A4 substrates can contribute significantly to first-pass elimination of orally ingested xenobiotics. For example, the immunsuppressive agents cyclosporine and tacrolimus undergo significant metabolism by human intestinal microsomes, and significant species differences in intestinal metabolism of the compounds have been observed.[78] Small amounts are found in several other organs, such as the kidney and skin. X-ray crystallography studies have demonstrated that CYP3A4 has a cavernous active site, allowing it to oxidize very large substrates such as erythromycin (MW = 734) and cyclosporin A (MW = 1203).[79] In addition, the large active site allows for simultaneous binding of multiple ligands and is thought to account for homotropic (same ligand) and heterotropic (different ligands) cooperativity in substrate oxidation.[80] This cooperativity is thought to be responsible for the non-Michaelis–Menten (sigmoid) enzyme kinetics observed for some CYP3A4 substrates such as nifedipine.[78] As such, CYP3A isozymes do not demonstrate a high degree of structural selectivity with respect to their substrates, and the substrate selectivity of CYP3A4 has been difficult to generalize.

Prototypical substrates include erythromycin and midazolam, both of which have been used as probes for CYP3A4 activity. Of significance to toxicologists, CYP3A isoforms are also capable of metabolically activating carcinogens, such as AFB_1 and BP. CYP3A4 is also responsible for bioactivation of naturally occurring toxins sometime found in herbal medicine. An example is epoxidation of the hepatotoxic diterpenoids teucrin A and teuchamaedryn found in germander.[81] Moreover, polymorphisms in CYP3A isoforms may play a role in interindividual differences in toxicity of drugs with narrow therapeutic indices, such as tacrolimus and other immunosuppressive agents.[82] A number of selective mechanism-based inhibitors for CYP3A4 have been identified, and ketoconazole is frequently used for this purpose. Ritonavir is another inhibitor of CYP3A4 and is used as a pharmacoenhancer with antiretroviral agents to boost plasma concentrations at lower administered doses. CYP3A4 and other members of the CYP3A subfamily are induced by a number of drugs, including rifampicin, PB, and phenytoin. Paradoxically, ritonavir is also an inducer of CYP3A4 and other drug-metabolizing enzymes.[83] Because of the large number of drugs metabolized by CYP3A4, it frequently plays a role in a number of DDIs that may result in adverse effects, and this has become an important factor in the development of therapeutic agents.

An example of how dietary constituents can affect specific isozymes is provided by the interaction between the consumption of grapefruit juice and CYP3A4. Consumption of grapefruit juice can cause an increase in the oral availability of a number of drugs that are CYP3A4 substrates. Increased bioavailability is produced by inhibition of intestinal CYP3A4 activity by 6′,7′-dihydroxybergamottin, which is a component of grapefruit juice. This dietary compound is a mechanism-based inhibitor of CYP3A4 that results in the rapid partial loss of CYP3A4 activity.[84] Inhibition of metabolism of the CYP3A4 substrates during their intestinal absorption accounts for the higher than anticipated plasma concentrations of the drugs.

Other CYP3A Isoforms

CYP3A5 is the most extensively studied of the minor isoforms in this subfamily. This P450 may be polymorphically expressed in humans (discussed in the following). It does not appear to have the broad substrate specificity of CYP3A4 and has lower activity. CYP3A5 phenotype did have any significant effect on in vivo metabolism of a variety of CYP3A4 substrates, including midazolam, nifedipine, cyclosporin A, and docetaxel.[85] However, clearance of tacrolimus was more rapid in individuals expressing CYP3A5, suggesting that this isoform may be active in drug metabolism in humans. CYP3A7 is active in the metabolism of steroids and retinoids, but a role in xenobiotic metabolism has not been demonstrated.

Other P450s

A large number of P450 families and subfamilies have not been discussed here. Most of these are involved with the metabolism of endogenous substrates or occur in species that are beyond the scope of the topic of this chapter; see Ioannides[30] and Lewis[31] for a more complete discussion.

Role of the Cytochrome P450-Dependent Monooxygenase in Toxicity

The toxicity of any agent is dependent on its concentration at its target site. This is a function of many factors, including the route of exposure, the pharmacokinetics of the xenobiotic, the excretion of both the parent compound and its

metabolites, and the sensitivity of the target site. The ability of the organism to clear the xenobiotic through excretion will have a profound influence on the concentration at the target site. Directly associated with the ability to clear many xenobiotics is the ability to metabolize the xenobiotic to more water-soluble metabolites.

Without doubt, the P450-dependent monooxygenase plays a pivotal role in the metabolism of xenobiotics. It is the prime metabolic route for the majority of xenobiotics, acting either directly in detoxification or indirectly by priming the xenobiotic for further metabolism through functionalization, as illustrated in other sections of this chapter.

The original interest in the P450 system was associated with its ability to metabolize drugs and decrease both their toxicity and duration of action. It soon became evident that in certain cases, this enzyme system converted certain drugs from pharmacologically inactive forms to active forms. Examples of the metabolic activation of toxicants, such as the in vivo conversion of the inactive insecticide parathion to its active form, paraoxon, were soon encountered. It was also discovered that this enzyme system could activate stable molecules such as BP to highly reactive metabolites capable of damaging cellular macromolecules, as shown in Figure 4.4. Further studies have indicated that metabolic activation plays an important role in the toxicity of a number of xenobiotics. Recently, an extensive review of bioactivation has been conducted, and a compendium of bioactivation reactions has been published.[86]

Studies undertaken to understand the biochemistry of P450 played a large role in the development of the modern fields of biochemical and molecular toxicology. Currently, much effort is being placed on the determination of the balance between metabolite activation and detoxification and the detoxification of activated metabolites. This is providing new insight for toxicologists seeking to understand the toxicity of xenobiotics. Studies on the active sites of P450 and other xenobiotic metabolism enzymes and the factors that influence their activity and their expression are bringing toxicologists closer to being able to predict potential toxicity with more accuracy. These efforts are also aiding toxicologists in the difficult task of predicting human toxicity from studies done with cellular and animal models.

Reactions Catalyzed by the Cytochrome P450-Dependent Monooxygenase System

On first inspection, it appears that P450 can catalyze a bewildering number of reactions (Table 4.2); however, on closer inspection, a degree of commonality exists among these reactions. The first area of commonality is that most of the reactions represent oxidations. Second, the reactions convert lipophilic substrates to more hydrophilic products. Third, many of the reactions can be understood as hydroxylations. For a detailed review of P450 reactions, see Testa[90] and Guengerich.[88] Representative examples of the various reactions catalyzed by P450s are illustrated in Figure 4.5.

Aliphatic Hydroxylation

Aliphatic hydroxylation may be thought of as a special case of the oxidation of an sp^3-hybridized carbon atom, and examination of aliphatic hydroxylation reactions is illustrative of several important aspects of monooxygenase activity. Hydroxylation of aliphatic carbon atoms represents one of the most common reactions in phase I metabolism of xenobiotics. The reaction mechanism, which may be common to several other types of monooxygenase metabolism, appears to occur by a hydrogen (or electron) abstraction mechanism (Figure 4.6). Oxygen activation produces a $[FeO]^{3+}$ at the heme of P450. Hydrogen abstraction from the substrate results in production of the carbon-centered radical. This radical interacts with activated oxygen (through

oxygen rebound) to yield hydroxylation. Other reactions, such as O-dealkylation of ethers and carboxylic acid esters, may proceed through this mechanism with decomposition of unstable hydroxylation products. Hydrogen abstraction is site selective, resulting in a nonrandom hydroxylation. The specific hydroxylation site is determined by structure and the specific spatial orientation of the substrate at the active site. Different isozymes of P450 show different degrees of site selectivity. For example, *n*-hexane hydroxylation can occur at C_1, C_2, C_3, or C_4. P450 isozymes induced by PB metabolized *n*-hexane to yield a four- to fivefold increase in the 2-, 3-, and 4-hydroxylated metabolites and only a slight increase

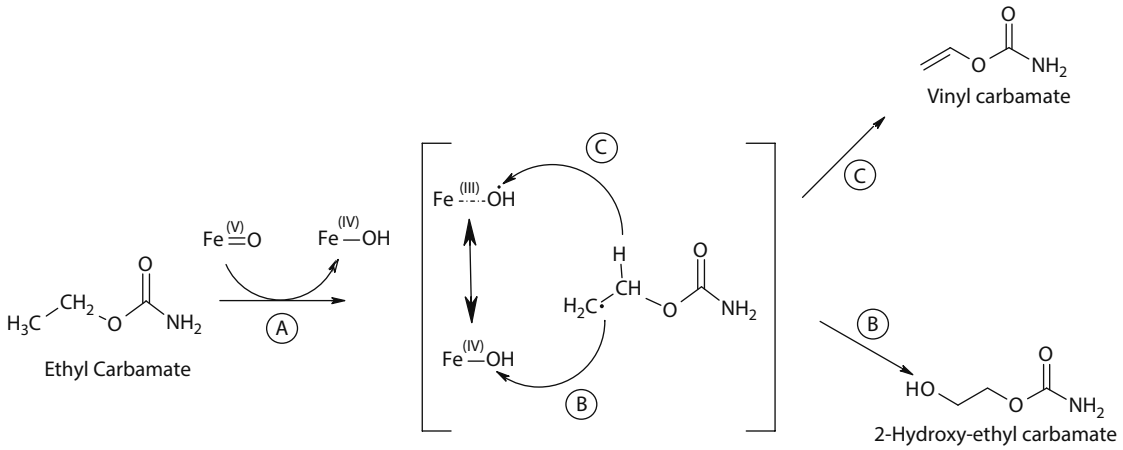

FIGURE 4.6 Mechanism of P450-mediated aliphatic hydroxylation and desaturation. Oxidation of aliphatic carbon begins with abstraction of a hydrogen atom by the electrophilic oxene form of P450 (A). The intermediate may collapse to the hydroxylated metabolite via the oxygen rebound mechanism (B) or may abstract a second hydrogen atom from the substrate resulting in desaturation (C). These two pathways compete kinetically.

at the 1 position. On the other hand, BP-induced isozymes result in decreased yields of the 1- and 2-hydroxylated products but increased yields of the 3- and 4-hydroxylated products.[89] Hydroxylation of aliphatic compounds is generally considered detoxification because of the greater water solubility of the products, but one must be cautioned against overgeneralization, as products that are more toxic could be produced by subsequent metabolism.

Aliphatic Desaturation

Aliphatic desaturation is another special case of the oxidation of an sp^3-hybridized carbon atom. Mechanistically, the first step of the reaction is abstraction of a hydrogen atom, similar to aliphatic hydroxylation; however, instead of oxygen rebound leading to insertion of oxygen, the second step in the mechanism results in abstraction of a second hydrogen atom and formation of a double bond. Compounds of toxicological significance that undergo CYP-mediated desaturation include the carcinogen ethyl carbamate and valproic acid.

Aromatic Oxidation

The mechanisms of aromatic hydroxylation are not completely understood but probably involve several alternative pathways. The exact mechanism for a given hydroxylation may be based on a number of factors, such as the steric features of the substrate and configuration of the active site of the specific P450. Potential mechanisms include direct oxygen insertion into the C–H bond to form an epoxide through radicaloid reactions or through intermediates bonded to $[FeO]^{3+}$. Evidence for intermediacy of an epoxide in the mechanism of aromatic hydroxylation comes from the so-called NIH shift, in which deuterium or halogen substituents are observed to migrate around the aromatic ring in a characteristic pattern during arene oxidation[90]; however, the necessity of an epoxide intermediate in the NIH shift has been challenged.[91] The production of arene oxides has been widely studied because of their importance in the formation of epoxide ultimate carcinogens.

Oxidation of Alkenes and Alkynes

In addition to aromatic compounds, both alkenes (aliphatic double bond) and alkynes (aliphatic triple bond) are subject to epoxidation by P450. The mechanism of these reactions involves abstraction of an electron to form the first C–O bond and a carbon-centered radical, followed by oxygen rebound giving rise to the epoxide. Epoxidation generally, though not always, occurs with retention of stereochemistry. With some terminal alkenes and alkynes, the carbon-centered radical may also react with one of the porphyrin nitrogens in the P450 heme, resulting in covalent binding and inactivation of the enzyme. In the case of polyhalogenated alkenes, migration of a halogen atom may occur with rearrangement of the product to the corresponding aldehyde, as seen in the metabolism of 1,1,2-trichloroethylene to 1,1,1-trichloroacetaldehyde. Other important examples of toxicological significance include oxidation of the industrial monomer 1,3-butadiene and the mycotoxin AFB_1. It is generally agreed that these reactive epoxides are the ultimate carcinogenic metabolites of the parent molecules.

Heteroatom Oxidation

P450 not only oxidizes carbon atoms but also nitrogen, sulfur, phosphorus, and halogen atoms. A number of nitrogen-containing compounds can be oxidized to stable N-oxides. Another hepatic enzyme, flavin-containing monooxygenase (FMO), can also catalyze this reaction, though the substrate specificities of these two enzymes are different (discussed later). P450 and FMO may form N-oxides from the same xenobiotic; however, FMO generally prefers substrates with an electron-deficient nitrogen, whereas P450 prefers an electron-rich nitrogen. P450-mediated N-oxidation is possible with primary and secondary aromatic amines to produce

hydroxylamines. This reaction is the first step in the bioactivation of this class of compounds to mutagens and is therefore thought to play a central role in the induction of cancer by many aromatic amines. S-Oxidation of secondary sulfides can also be catalyzed by P450 and FMO, leading to formation of sulfoxides, which can be further oxidized to sulfones. Free thiols can be oxidized to sulfinic and sulfenic acids, which may be electrophilic, reacting with protein thiol and glutathione (GSH) to produce mixed disulfides. The mechanism associated with all these reactions is believed to be electron abstraction from the heteroatom by $(FeO)^{3+}$, followed by oxygen rebound.

Heteroatom Dealkylation

P450-dependent heteroatom dealkylation begins like heteroatom oxidation with electron abstraction from N, S, O, or Si. This is followed by abstraction of H^+ from the carbon attached to the heteroatom (α-carbon). Alternatively, direct oxidation (hydrogen atom abstraction) of the α-carbon may also occur. In either case, the α-carbon is hydroxylated by oxygen rebound to form a carbinol intermediate. Carbinolamines and related intermediates are generally unstable and undergo carbon–heteroatom bond cleavage, followed by rearrangement to the corresponding aldehyde or ketone. Regardless of the identity of the heteroatom, the products of this reaction are the hydrogenated heteroatom compound and an aldehyde or ketone. Sulfur and silicon atoms generally are not as readily dealkylated as nitrogen and oxygen atoms. Dealkylations unmask more polar functional groups, facilitating conjugation and excretion; however, dealkylation can also facilitate bioactivation, as in the case of N-dealkylation of secondary aromatic amines.

Oxidative Deamination, Desulfuration, and Dehalogenation

Primary amines can be deaminated with the elimination of ammonia and the formation of an aldehyde or ketone. In a similar manner, P450 can catalyze desulfuration and dehalogenation, with the heteroatom being replaced with oxygen. Mechanistically, this reaction is identical to heteroatom dealkylation, discussed earlier.

Reduction Reactions

Reduction reactions are an interesting series of reactions in which P450 may participate under special conditions. These appear to involve transfer of electrons from Fe^{2+} to the substrate. Examples of such reactions are nitro reduction, azo reduction, arene oxide reduction, and reductive dehalogenation. These reactions generally are studied in vitro under anaerobic conditions in the presence of isolated microsomes and NADPH. Because these reactions require low oxygen tension to progress, their in vivo role (if any) is not well understood. Whether or not these reactions represent simply a curious phenomenon associated with P450 or a viable metabolic pathway is not known. It may be possible that under certain cellular conditions of low oxygen tension, these reactions could proceed in vivo.

Induction and Inhibition of Cytochromes P450

Induction

When animals are exposed to certain xenobiotics, their ability to metabolize a variety of xenobiotics is increased. This phenomenon is termed induction. Induction produces a transitory resistance to the toxicity of many compounds; however, this may not be the case with compounds that require metabolic activation because their toxicity may increase. The exact toxicological outcome of this increased metabolism will be dependent on the specific xenobiotic and its metabolic pathway. Because the toxicological outcome of a xenobiotic exposure can depend on the balance between those reactions that represent detoxification and those that represent activation, increases in metabolic capacity may, at times, produce unpredictable results. Induction of P450 has been reviewed in Bresnick,[92] Wang and LeCluyse,[78] and Waxman.[93] Approaches to understand induction potential of drug candidates in the discovery phase have recently been reviewed by Fahmi and Ripp.[94]

One of the initial reports of increased metabolic capacity associated with xenobiotic exposure suggests how induction may provide a survival advantage. In 1954, Brown et al.[95] were studying the metabolism of methylated aminoazo dyes and found that xenobiotics in the animal diets enhanced the P450-dependent demethylation of these compounds. Free-living animals consume a variety of feeds that may contain toxic constituents. If the animal can respond rapidly to these toxic compounds by developing resistance, it can continue to use the feed source and obtain a survival advantage. One mechanism of rapidly developing such resistance is through increased detoxification resulting from stimulation of xenobiotic-metabolizing enzyme activity. Conney[96] published a pivotal review in 1967 that indicated that more than 200 chemicals could induce P450-dependent metabolism, and most of these chemicals were monooxygenase substrates.

The classical definition of enzyme induction requires transcriptional activation at the level of DNA and increased production of mRNA, followed by an increase in the synthesis of the enzyme. The term has taken on a broader definition when used in respect to xenobiotic metabolism. This broader definition includes mechanisms such as mRNA and enzyme stabilization, all of which are associated with xenobiotic induction. The classes of P450 inducers are listed in Table 4.3; however, the concept of inducer classes has become less meaningful in light of recent advances in our understanding of CYP induction.

The PAH class of inducers includes 3-methylcholanthrene, BP, and TCDD, and their mechanism of induction in animals has been extensively investigated. These inducers induce CYP1A1, CYP1A2, and CYP2B1, which are expressed in the liver or extrahepatic tissues of rodents and humans. The low constitutive hepatic concentrations of CYP1A1 result from suppression of transcription by a nuclear repressor protein. Within the cytoplasm of the hepatocyte exists a receptor protein termed the Ah receptor (AhR), which is complexed with heat-shock protein (Hsp 90). When a

TABLE 4.3
Inducers of Cytochrome P450

Structural Class	Primary Examples	Other Examples	Receptor	CYPs Induced
Polycyclic hydrocarbon type	3-Methylcholanthrene	TCDD, BP, β-naphthoflavone, chlorpromazine, isosafrole, ketoconazole	AhR	1A1, 1A2, 1B1
PB type	PB	Phenytoin, griseofulvin, chlorpromazine, ketoconazole, dieldrin, BHT	CAR–RXR	2A1, 2B1, 2B2, 2B6, 2C6, 3A4
Glucocorticoid type	Rifampicin[a]	Dexamethasone, pregnenolone 16a-carbonitrile, spironolactone, prednisolone, methylprednisolone	PXR–RXR (GR)	3A
Ethanol type	Ethanol	Acetone, heptane, pyrazole	None	2E1
Clofibrate type	Clofibrate	Phorbol esters, WY-14,634	PPAR–RXR	4A

[a] Marked species differences exist in inducer selectivity. Rifampicin is the prototypical glucocorticoid-type inducer in humans; dexamethasone is a prototypical inducer in rodents.

polycyclic-hydrocarbon-type inducer enters the hepatocyte, it binds and activates the Ah receptor, resulting in the release of Hsp90. The Ah receptor is phosphorylated and subsequently binds to the AhR nuclear translocator (Arnt) protein, which is also activated by phosphorylation. This complex then moves to the nucleus of the hepatocyte. In the nucleus, this complex binds to a DNA regulatory sequence termed the xenobiotic response element (XRE). A DNA segment similar to rat XRE has been found in mouse and human cells. The XRE has also been found in genes of other xenobiotic metabolism enzymes, such as glutathione S-transferase (GST), aldehyde dehydrogenase (ALDH), and uridine diphosphate (UDP) glucuronosyltransferase (UGT), where it may be involved in regulation of their expression. Binding of the ligand-bound Ah–Arnt complex to XRE enhances transcription of the CYP1A1 gene, resulting in increased quantities of CYP1A1 mRNA followed by an increase in the hepatic concentration of CYP1A1.

CYP2A isoforms are induced by a structurally diverse array of xenobiotics from several different inducer classes[97]; for example, human CYP2A6 is induced by PB, dexamethasone, and rifampicin in primary hepatocyte cultures, and CYP2A3 was induced in rat lung by 3-methylcholanthrene. In addition, several metal salts induce CYP2A5 in mice. Induction of CYP2A is poorly understood and appears to occur by transcriptional activation, RNA stabilization, and protein stabilization. Further, the mechanisms of induction vary with the isoforms, species, and tissues examined. Roles in CYP2A induction have been proposed for several of the orphan nuclear receptors (discussed in the following), as well as for a variety of RNA binding proteins, which appear to bind in the 3′-untranslated region of CYP2A mRNA in response to pyrazole treatment.

PB and other compounds of diverse structure induce expression of CYP2B1 and CYP2B2, as well as, to a lesser extent, CYP2A1, CYP2C6, CYP3A1, and CYP3A2. PB also produces a general pleiotropic response in the liver, resulting in proliferation of the smooth endoplasmic reticulum in hepatocytes, increases in total microsomal protein, and increases in NADPH–cytochrome P450 reductase, as well as other xenobiotic-metabolizing enzymes, such as UDP-glucuronosyltransferase (UDPGT) and epoxide hydrolase. Induction of CYPs and other enzymes by PB occurs by transcriptional activation, but until relatively recently, no cytoplasmic receptor had been identified for the PB-type inducers. Over the last 10 years, however, significant gains have been made with respect to mechanisms of CYP induction by the PB-like inducers. Convincing evidence now suggests that PB-mediated CYP induction is associated with a cytoplasmic receptor known as the constitutively active receptor (CAR), so named because early studies in HepG2 cells indicated that this transcription factor was active even in the absence of ligand.[78] It has since been demonstrated that certain androgens, including androstanol and androstenol, bind to CAR and inhibit transcriptional activation of CYP2B and other genes[98]; hence, CAR is also known as the constitutive androstane receptor. CAR is one of the so-called orphan nuclear receptors, whose endogenous ligands are unknown. Other orphan receptors include the pregnane X receptor (PXR) (discussed in the following), the retinoid X receptor (RXR), and the peroxisome proliferator-activated receptor (PPAR) (discussed in the following).

The details of CAR-mediated induction of CYP are unclear. As is the case with several other orphan receptors, CAR forms a heterodimer with RXR, and the heterodimer forms a DNA-binding complex with the steroid receptor coactivator SRC-1. CYP induction in physiological systems is strictly dependent on the presence of PB or other PB-like inducers, but actual binding of the inducer does not appear to be required. It is thought that PB somehow causes dissociation of the androstanes from CAR, resulting in depression of transcriptional activation.[78] Compounds in the PB inducer class, such as terpenes, organochlorine pesticides, and polychlorinated biphenyls, may act through a common pathway of induction.[99]

CYP2E1 induction has been studied in detail in the rat and represents an interesting situation where induction is controlled at the transcription, mRNA stabilization, translation, and enzyme stabilization levels. CYP2E1 is induced by the ethanol-type inducers. Although not true for all P450s, the

CYP2E1 inducers generally are substrates for the isozyme. In many cases, the regulation of expression of CYP2E1 is controlled by stabilization of CYP2E1 mRNA and stabilization of the enzyme apoprotein, along with possible increased efficiency of translation. Cycloheximide, which blocks translation, blocked the increase in CYP2E1 apoprotein when mRNA was unchanged, indicating that the increase in apoprotein was related to increased translation. Actinomycin D, which blocks transcription, did not block the apoprotein increase, indicating that it was not transcription related. Many of the CYP2E1 inducers act by posttranslational stabilization, including acetone, low ethanol doses, pyridine, and pyrazole. With these inducers, CYP2E1 concentration increases, whereas no change in mRNA occurs. This indicates that CYP2E1 degradation decreases while synthesis remains constant, with the net result being increased CYP2E1.

Nutritional factors and disease conditions can also result in increased activity of CYP2E1. High-fat diets and starvation produce an induction of CYP2E1, as does insulin-dependent diabetes and obesity. One common factor in all of these conditions is increased plasma ketone body concentrations. Whether or not this induction is produced by increased ketone bodies, including acetone, or by other factors is currently under investigation.

The glucocorticoid-type inducers, such as dexamethasone and pregnenolone-16α-carbonitrile, induce CYP3A1 and CYP3A2 in rodents but not in human hepatocytes. In contrast, rifampicin is an effective inducer of CYP3A isoforms in humans and rabbits but not in rodents. Regulation of CYP3 induction is now known to be under the control of PXR, another of the orphan nuclear receptors. In humans, PXR is found primarily in the liver and gastrointestinal tract and in lower amounts in kidney and lung; thus, the tissue distribution of PXR tracks with the tissue distribution of CYP3A4 in humans. As with CAR and other orphan nuclear receptors, PXR consists of a DNA-binding domain, which is highly conserved across species, and a ligand-binding domain, with lower sequence homology across species. Differences in the selectivity of CYP3A inducers are due to structural differences in the ligand-binding domain of PXR, and site-directed mutagenesis has been used to convert the rodent PXR ligand-binding spectrum to a humanlike ligand selectivity that no longer responds to rodent CYP3A inducers.[100] Like other orphan receptors, PXR forms a functional heterodimer with RXR. Evidence suggests that the glucocorticoid receptor also mediates CYP3A induction, although the role played by this receptor is unclear. One hypothesis is that binding to the glucocorticoid receptor upregulates PXR, leading to induction of CYP3A and other PXR-dependent genes; however, some studies demonstrate glucocorticoid induction of CYP3A by a PXR-independent mechanism. Thus, the exact role of the glucocorticoid receptor in induction of CYP3A genes remains to be resolved. Because of the large number of drugs metabolized by CYP3A4 and the wide array of natural and synthetic PXR ligands, DDIs due to CYP3A4 induction are common, and PXR reporter assays have become popular in the pharmaceutical industry as a screen for CYP3A4 induction.

Clofibrate-type inducers induce the CYP4A subfamily that is, in the most part, associated with metabolism of endogenous compounds. The clofibrate-type inducers are structurally diverse but in general are highly lipophilic and possess a carboxylic acid functional group. They also cause hepatocyte peroxisome proliferation in rodents.

Induction of CYP4A and enzymes related to peroxisomal fatty acid β-oxidation is mediated by another member of the orphan nuclear receptor superfamily, PPAR. Three members of the PPAR family have been identified and designated as PPARα, PPARβ, and PPARγ. PPARα is responsible for induction of CYP4A in rodents and rabbits. Upon ligand binding, PPAR forms an activated heterodimer with RXR; the heterodimer binds to the peroxisome proliferator response element upstream from CYP4A and related genes, activating transcription. Many compounds that cause peroxisome proliferation in rodent liver are also hepatocarcinogens; however, no CYP4A induction has been observed in humans by PPARα ligands, and humans are resistant to peroxisome proliferation, suggesting that this phenomenon may have little relevance for humans. The low concentrations of CYP4A in human liver and its limited number of xenobiotic substrates reduce its role in DDIs in humans.

Although CAR and PXR were originally identified as mediators of CYP2B and CYP3A enzymes, respectively, there is significant overlap in the selectivity profiles of inducers of these two subfamilies. As such, many PB-type inducers are capable of inducing CYP3A genes, and several glucocorticoid-type inducers are effective inducers of CYP2B genes. This overlap may be related in part to the ability of CAR and PXR to recognize and bind to each other's response elements, a phenomenon referred to as cross talk. Another mechanism for cross talk may be the overlapping ligand-binding selectivity of CAR and PXR; for example, PB is a ligand for both CAR and PXR in humans.

Inhibition

Just as induction of xenobiotic metabolism can have important toxicological ramifications, inhibition of the ability to metabolize a xenobiotic can result in profound changes in its toxicity. Inhibition of the metabolism of a compound can result in a higher plasma concentration than predicted and unexpected toxicity. During treatment with multiple drugs, unexpected adverse effects can be produced through DDIs where one drug inhibits the metabolism of another, resulting in higher than expected plasma concentrations.

Four mechanisms are generally associated with inhibition of P450-mediated detoxification. First, two xenobiotics may be substrates for the same P450 isozyme and will compete for the active site of the enzyme, a phenomenon known as competitive inhibition. An example of this type of mechanism is the inhibition of bioactivation of the rodent carcinogen ethyl carbamate by ethanol, both of which are found in fermented beverages.[101] A second mechanism of competitive inhibition is the binding of a xenobiotic to the active site of a P450, although it is not a substrate for that P450. The presence of the nonsubstrate at the active site blocks the binding

of the true substrate, inhibiting its metabolism. Examples of this mechanism of CYP inhibition are rare. A third mechanism of inhibition involves the metabolism of a xenobiotic to a product that has a higher affinity for the active site than the parent compound, forming a so-called metabolite–inhibitor (MI) complex. The active site is then occupied and additional substrate cannot bind. This essentially makes the enzyme inactive and is an example of noncompetitive inhibition. Compounds such as erythromycin, nicardipine, and diltiazem reversibly inhibit human CYP3A4 by this mechanism.[102] The fourth mechanism is another example of noncompetitive inhibition resulting from the production of a highly reactive metabolite that binds (often covalently) to the heme or apoprotein of P450, destroying its activity. This type of inhibitor is termed a suicide substrate. As mentioned previously, inhibition of CYPs by trichloroethylene is an example of suicide inhibition. Both MI complex formation and suicide inhibition are examples of mechanism-based inhibition.

Other less common mechanisms can result in inhibition of P450-mediated xenobiotic metabolism, including compounds that may modify protein or heme synthesis or degradation, those that may uncouple electron transport to P450, those that may interfere with cofactor availability, and those that may directly inhibit NADPH–P450 reductase activity. Just as some substrates may demonstrate a higher affinity for specific P450s and others may not, inhibitors may show a narrow or broad range of affinity for a specific P450. Inhibitors have been useful tools in determining mechanisms associated with xenobiotic metabolism and in attempts to predict specific DDIs. Induction and inhibition of human cytochromes P450 have been recently reviewed in Pelkonen et al.[103]

Pharmacogenetics, Human Polymorphism of P450 Isozymes, and Their Toxicological Significance

Pharmacogenetics is the study of the hereditary basis of the observed differences in response (both therapeutic and adverse) to drugs by individuals and populations. The term can be expanded to include not only drugs but also dietary and environmental chemicals. This field has seen a large expansion over the last decade, as the understanding of the genetics, genetic regulation, and interindividual variations in P450 and other xenobiotic metabolism enzymes has increased. Maturation of methodologies from molecular biology and refinement of other methodologies to study genetic differences in individuals and populations have spurred interest in the pharmacogenetics of xenobiotic metabolism.

Many studies of the adverse effects of chemicals in animals and humans have indicated that highly significant differences exist between animal strains, among individual animals, and especially in individual humans and different human population groups. These genetic polymorphisms can result in unexpected drug and environmental toxicities and complicate safety assessments and the extrapolation of data from animal studies to humans. It has been estimated that almost 50% of drugs for which adverse reactions have been reported are metabolized by significantly polymorphic P450s.[104] As discussed later, this has led to recommendations that the specific family and subfamily of P450 that metabolizes a specific drug candidate be determined during early drug discovery efforts. This could avoid unexpected interactions and suggest potential adverse effects before additional developmental efforts with a drug or other chemical product are undertaken.

Several alleles in the CYP2D6 family, for example, are known to contain specific nucleotide deletions that result in inactive genes and a lack of production of the CYP2D6 protein.[105] Individuals homozygous for these gene variations will be *poor metabolizers* (PMs) of CYP2D6 substrates. In contrast, some individuals have multiple copies of the CYP2D6 gene, possibly due to gene duplication.[106] These individuals have enhanced capability to metabolize CYP2D6 substrates and are *ultrarapid metabolizers* (UMs).[107] A chemical whose detoxification depends on CYP2D6 would be more toxic than expected in PM, but less toxic than expected in UM individuals. In contrast, a chemical that is metabolically activated would be less toxic in PMs and more toxic in UMs. To predict toxicity, it is obvious that not only must the role of metabolism in the toxicity of a compound be known but also the potential genotype of exposed individuals.

Several human P450s have been shown to exhibit significant polymorphic expression, including CYP1A1, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP3A5, and CYP2E1. Many other CYP polymorphisms are known, encompassing most of the known human CYP-mediating xenobiotic metabolism, but the functional significance of many of these polymorphisms is unclear. The most up-to-date information on CYP polymorphisms can be found on the homepage of the Human Cytochrome P450 (CYP) Allele Nomenclature Committee (http://www.imm.ki.se/CYPalleles). The chromosomal locations of these P450 genes have been identified, and the genetic basis for the altered P450 activity is becoming understood. From a toxicological perspective, the most important P450 polymorphisms are those of the CYP2 and to a lesser degree the CYP3 subfamilies. These polymorphisms have been the subject of several recent reviews[103,108,109] and are summarized here.

CYP2A6

CYP2A6 is the major isoform responsible for C-oxidation of nicotine. Several significant allelic variants of this isoform have been identified, including CYP2A6*2, which is inactive due to a Leu–His substitution at position 160, and CYP2A6*4A, which is a complete deletion of the CYP2A6 gene. The former allele is found at a frequency of 1%–3% in Europeans, and the latter allele is more prevalent in Asians. Because of the role of CYP2A6 in nicotine metabolism, polymorphism of this isoform has been implicated in differences in smoking behavior and the incidence of lung cancer among smokers.

CYP2C9

CYP2C9 plays a major role in metabolism of the anticoagulant drug warfarin, and defects in this isoform can lead to excessive plasma concentrations and increased risk of

bleeding episodes in effected individuals. The major allelic variants of CYP2C9 are CYP2C9*2 and CYP2C9*3, both of which are due to missense mutations.[67,110] In Caucasians, the frequencies of these two alleles are approximately 11% and 7%, respectively, and the frequency of homozygotes, who express the PM phenotype, is around 3%–4%. For CYP2C9*2, decreases in activity between 8% and 94% have been reported, depending on the substrate used. Similarly, carriers of the CYP2C9*3 allele express significantly lower catalytic activity compared to the CYP2C9*1 genotype.[110] Polymorphisms in CYP2C9 can significantly effect therapeutic responses to a number of commonly prescribed pharmaceuticals, the most important of which may be warfarin, due to its narrow therapeutic window. Since 2007, warfarin has included pharmacogenetic information in its label, including a dosing table based on genotype, added in 2010.[111]

CYP2C19

CYP2C19 is responsible for metabolism of approximately 10% of marketed drugs.[67] Major polymorphisms of CYP2C19 are associated with deficient 4-hydroxylation of *S*-mephenytoin and the sensitivity of affected individuals to excessive sedation by this anticonvulsant agent. Deficient mephenytoin metabolism is found in 2%–5% of Caucasians but is much more prevalent in Asians, with a frequency of 18%–23%. Two major allelic variants were identified as CYP2C19*2 and CYP2C19*3.[112] CYP2C19*2 is a splice mutant that codes a truncated protein, and CYP2C19*3 contains a premature stop codon in exon 4. Both mutations lead to nonfunctional proteins. Gain of function alleles are also known. CYP2C19*17 results from mutations in the promoter region, which lead to increased gene transcription, and the CYP2C19*1/*17 and *17/*17 genotypes are considered UMs of effected substrates. In addition to mephenytoin, CYP2C19 is involved in bioactivation of clopidogrel, an antiplatelet agent used extensively in patients with cardiovascular disease. PMs are at higher risk for thrombosis and myocardial infarction during clopidogrel therapy, whereas UMs have an increased bleeding risk. CYP2C19 mediates metabolism of a variety of other drugs including proton pump inhibitors such as omeprazole and antiviral compounds such as nelfinavir, both of which show greater efficacy in PM phenotypes.

CYP2D6

High interindividual variability in the metabolism of the antihypertensive agent debrisoquine led to the discovery of one of the first CYP polymorphisms. Since its initial discovery, CYP2D6 polymorphism has been the subject of intensive research efforts and is probably the most thoroughly characterized CYP polymorphism. CYP2D6 plays a major role in the metabolism of tricyclic antidepressants and antipsychotics, and PM status has been associated with a higher incidence of extrapyramidal and other side effects, while UM status is associated with a lack of therapeutic effect of these agents. For example, the antipsychotic agent thioridazine is associated with higher risk of ventricular arrhythmia related to QT prolongation in CYP2D6 PM phenotypes.[113] One of the major defective CYP2D6 variants is CYP2D6*4, a splice mutation that is found in Caucasians at a frequency of almost 21%. Another common variant is CYP2D6*5, in which the entire gene is deleted. The frequency of this allele is 4%–6%. The UM phenotype is due to gene duplication, and frequencies for this phenotype range from 1% to 2% in Caucasians to almost 30% in Arabian and North African populations.[70]

CYP3A5

Functional CYP3A5 is expressed in approximately 20% of Caucasians and about 67% of African Americans. Although this isoform contributes to total CYP3A activity in these individuals, the clinical implications of CYP3A5 status are unclear in most cases. Recently, a specific role for CYP3A5 in the metabolism of tacrolimus has been described, suggesting that CYP3A5 expression status may play a role in the high interindividual variability seen with many CYP3A substrates.

Species, Strain, and Gender Differences in Monooxygenase Activity

The activities of cytochromes P450 play a central role in the expression of the toxicity of many xenobiotics. One factor that complicates extrapolation of toxicity between species is the quantitative and qualitative differences in how species metabolize xenobiotics. Generally, the basic reactions and major metabolites of a xenobiotic are similar between species; however, subtle differences in metabolism can lead to major differences in susceptibility to the toxicity of a xenobiotic. Mechanisms that may account for species differences include the following: (1) lack of a metabolic pathway or a genetic defect in a particular metabolic pathway; (2) differences in the K_m and V_{max} (i.e., level of expression) of specific enzymes; (3) the existence of different isozymes and differences in the ratios of specific isozymes of important enzymes, such as P450; and (4) differences in the ratio of activities of separate enzyme systems that act together to metabolize a specific xenobiotic.

When one metabolite represents a metabolically activated form and another a detoxified form, the ratio of these metabolites can dictate a species susceptibility to a xenobiotic. This type of species difference is most commonly encountered when the P450-dependent monooxygenase acts in coordination with another pathway. Species may differ in either the initial monooxygenase functionalization reaction or in the activity of the secondary pathway. This is illustrated by the metabolic activation of BP (see Figure 4.4) in rats and mice. The metabolic activation of BP requires initial epoxidation by the P450-dependent monooxygenase at the 7,8 position, followed by hydration of the epoxide by epoxide hydrolase to yield the 7,8-diol. This diol is then epoxidated by the monooxygenase to yield the ultimate carcinogen of BP, the 7,8-dihydrodiol 9,10-oxide. When mouse hepatic microsomes were used for metabolic activation in the Ames assay for mutagenicity, BP was highly mutagenic, indicating a high degree of

metabolic activation; however, when rat hepatic microsomes were employed in the same assay, only slight mutagenicity was evident. This indicates a significantly lower ability for the rats to metabolically activate BP in vitro.[114] Although mice do metabolize BP to a greater extent than rats, rats have six- to sevenfold more epoxide hydrolase activity. Further studies[114,115] indicated that both species have adequate monooxygenase to metabolically activate BP and that higher epoxide hydrolase activity in the rat may have been responsible for the lower mutagenicity; therefore, the species differences in the secondary pathway, epoxide hydrolase, may have controlled the mutagenicity, as opposed to differences in the monooxygenase activity.

Different strains of the same species may demonstrate differences in metabolism; for example, if a different strain of mouse had been used in the studies described earlier, the conclusions may have been different. It is important to recognize these strain differences when designing toxicological studies. The mechanisms associated with strain differences may be diverse. Without an understanding of these species and strain differences, it will be difficult to extrapolate toxicological studies performed with animals to humans.

Studies of species differences in animals are difficult to design and interpret, and those involving humans are even more complex. This complexity results from the large differences in xenobiotic biotransformation found in humans. Many factors contribute to these individual differences in metabolism, including the following: (1) humans are free-living and have few restraints to reproductive diversity, diminishing the development of small genetic pools that result in genetically less diverse, more homogeneous control of metabolism; (2) environmental factors, such as diet, nutrition, and xenobiotic exposure, are diverse among humans; and (3) humans generally have more control and probably more interest in consumption of varied nonnutritive materials, such as alcohol or drugs. These as well as other factors result in a large diversity in susceptibility to xenobiotic exposure. This is, in part, why such large safety factors are employed in risk or hazard assessments of xenobiotics to which humans may be exposed. These safety factors are used to attempt to protect the vast majority of individuals at risk. For further discussions of species differences, the reader is directed to several recent review articles.[116–118]

Gender differences in xenobiotic metabolism may be an important factor in gender-dependent differences in toxicity. The best example of gender differences in xenobiotic metabolism, especially cytochrome P450-mediated metabolism, is the rat. Because the rat is commonly used in toxicological safety assessments, it is important to realize the gender differences in this species and understand how they relate to the extrapolation of rat data to humans.

Generally, male rats have a higher capacity to metabolize xenobiotics than females. This difference is in large part related to the CYP content and its temporal pattern of growth hormone-regulated expression. Although females have 10%–30% less total P450 than males, this difference is not high enough to explain the 2- to 20-fold differences seen in metabolism. Much of the differential seen between males and females can be explained by differences in P450 isozymes between the sexes; for example, males express CYP2C11 but females do not. Isozymes that predominate in males are CYP2A1, CYP2A2, and CYP3A2. Adult females also have predominant P450s, such as CYP2C12, which occurs in juvenile and older males but not in young adult males. These differences are under hormonal control and can be altered by procedures such as castration and administration of sex hormones. They also are developmentally controlled, and the stage of life at which these procedures are done can influence their outcome. Neonatal castration of male rats results in different expression of P450 when they become adults. The adult expression of P450s can actually be imprinted during the neonatal period. Although sex hormones play an important role in the expression of P450 in rats, other hormones, including growth hormone, thyroxine, insulin, and somatostatin, may play important roles.

These differences between male and female rats also show an age dependency. As male rats age, their P450 isozyme profiles begin to appear more like females. Toxicologists using rats as a model in safety assessments need to be cognizant of these gender- and age-dependent changes. The toxicity data from young rats, generally used in toxicity studies, may not reflect the toxicity seen in old rats. During chronic toxicity and carcinogenicity studies, the response of rats to the toxicity of a test material may change as the study progresses. This is especially true of carcinogenicity studies that begin with in utero exposure. Early developmental changes in P450 in animals and humans may be important in responses to teratogens and embryotoxic compounds.[117]

If gender differences in xenobiotic metabolism in rats can complicate toxicity assessments, what about other species, including humans? Rats have been the most intensively investigated species in regard to gender differences; however, studies with other species suggest that they generally do not demonstrate such large gender differences. Mice, another species important in toxicology studies, generally do not show the exaggerated gender differences in xenobiotic metabolism seen in rats. Gender differences in mice seem to be dependent on the specific strain of mouse investigated. Where gender differences do exist in mice, it is generally the female that has the higher metabolic capacity, but the differences are not as great as that seen in rats.

Other species used in toxicological investigations, such as dogs, appear to demonstrate some gender differences in the expression of P450 isozymes, but, again, they are not as exaggerated as in rats. Although there are few reported studies, monkeys have not been reported to demonstrate significant gender differences in xenobiotic metabolism.

Humans have not been shown to demonstrate gender-dependent differences in the expression of P450 isozymes. Although there can be significant differences between human males and females in xenobiotic biodisposition, these appear to be more based on anatomical and physiological differences that affect absorption, distribution, and excretion. Individual humans can display large differences based

on lifestyle factors and exposure to environmental chemicals, foods, and drugs; however, inherent gender differences in the expression of P450 are not apparent.

This raises the question as to how species, such as rats, can be used to predict toxicity in humans. With care and knowledge of the differences between rats and humans, the rat can serve as a useful model for human toxicity. This has been shown through decades of use; for example, rats and humans share similarities between the CYP isozyme subfamilies CYP1A1, CYP1A2, and CYP2E1, and these subfamilies are not expressed in a highly gender-dependent manner in rats. Xenobiotics metabolized by CYP1A or CYP2E may reflect human metabolism because regulatory control over these isoforms has been highly conserved between rodents and humans; however, gender-dependent differences are generally not reflected when extrapolating from rats to humans.[68] Gender-dependent differences in xenobiotic metabolism are but one of the reasons toxicologists must use both sexes in the safety assessment of chemicals. Gender differences in xenobiotic metabolism have been reviewed.[68]

Microsomal Flavin-Containing Monooxygenase

Since 1960, it has been apparent that a microsomal monooxygenase other than P450 could catalyze the oxygenation of nucleophilic nitrogen, sulfur, and phosphorus compounds. Purification to homogeneity indicated that the enzyme was an NADPH-dependent, FMO distinct from P450. This monooxygenase has been referred to as amine oxidase, Ziegler enzyme, dimethylaniline monooxygenase, and FMO. This enzyme may be a good example of proteins involved in normal anabolic and catabolic metabolism being recruited for xenobiotic metabolism. The flavin prosthetic group that is characteristic of these enzymes is especially versatile at carrying out redox functions.

The catalytic cycle for the FMO is shown in Figure 4.7. NADPH reduces the FAD of the enzyme, and the oxidized $NADP^+$ remains bound (Figure 4.7A). Oxygen then binds to yield FAD peroxide (Figure 4.7B and C) followed by substrate binding (Figure 4.7F). Prior to substrate binding, the peroxide complex can decompose, releasing superoxide (Figure 4.7D). One oxygen atom from the peroxide is transferred to the substrate, leaving the hydroxyflavin (Figure 4.7G). The final and rate-limiting step of the cycle is the dehydration to regenerate FAD, yield water, and release the bound $NADP^+$ (Figure 4.7H and I). NADH can substitute for NADPH, but with lower affinity and activity.

The FMO has at least five isoforms (designated as FMO1–FMO5), whose genes are expressed across several species and tissues. These forms have different substrate specificities and are probably related to the species-dependent toxicity of certain substrates, such as the pyrrolizidine alkaloids. In addition to the five functional forms of FMO, at least six other FMO genes have been identified, all of which appear to be pseudogenes.[118] Humans, rats, and mice have relatively high activity of FMO1 in kidney. Humans and mice have low activity for this form in the liver, whereas the rat has high activity. This isoform is also expressed in human lung and brain. FMO2 is the primary isoform expressed in human

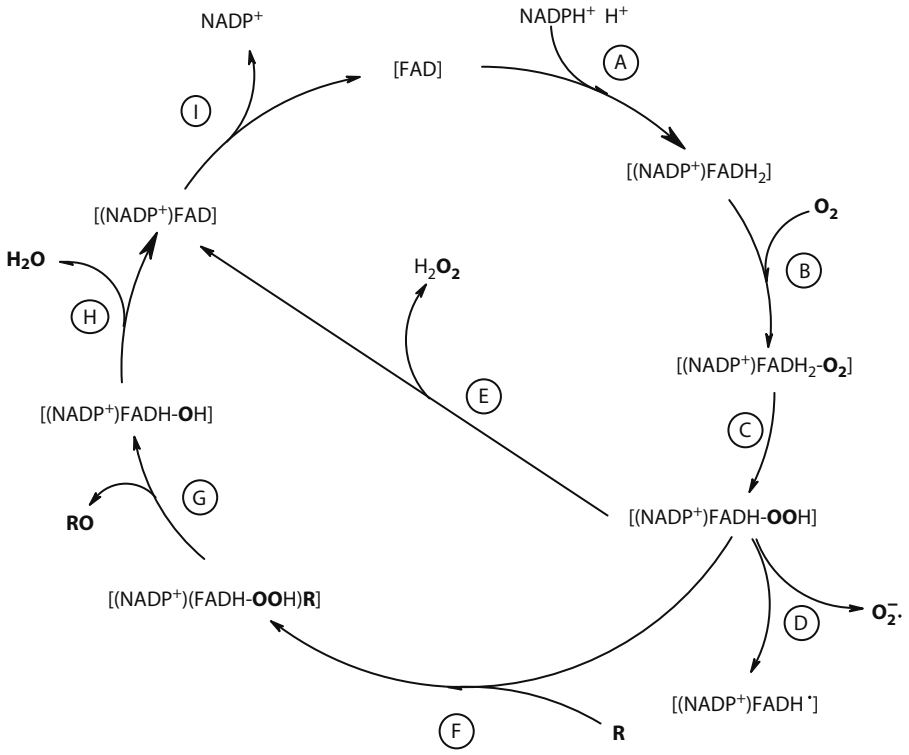

FIGURE 4.7 Catalytic cycle of the FMOs. See text for details. (Adapted from Masnil, M. and Testa, B., in *Advances in Drug Research*, Vol. 13, Testa, B., ed., Academic Press, London, U.K., 1984, pp. 95–207.)

lung, with lower amounts found in kidney, liver, small intestine, and brain. Humans and mice have high activity of FMO3 in the liver, whereas the rat has low activity. FMO3 activity has also been detected in human kidney, lung, and small intestine, and rat and mouse kidney both show high activity. In mice, only females express FMO3 and have two- to threefold higher activity of FMO1 compared to males. Human FMO4 expression levels are highest in liver and kidney, with lesser amounts in small intestine and lung and very low levels in brain. FMO5 is quantitatively the most important isoform in human liver and is also expressed in small intestine, kidney, and lung to a lesser, though significant, degree. FMO5 shows no gender differences. Male rats have higher total FMO than females and two- to threefold more FMO1 than females, but no differences are seen in FMO3.[119] Humans can show considerable individual differences, but no gender differences have been demonstrated. This information illustrates the species, gender, and tissue differences that can be encountered with this monooxygenase and emphasizes the importance of choosing an appropriate animal model for toxicological studies of compounds that are potential substrates for this enzyme.

FMOs catalyze the oxidative attack on the nucleophilic nitrogen and sulfur heteroatom of a variety of xenobiotics (Figure 4.8).[120] It was once believed that oxidations of basic aliphatic and tertiary aromatic amines were carried out by the FMO, primary aromatic amines and the acidic nitrogens of amides were catalyzed by P450, and secondary amines were oxidized by both enzyme systems. More recent studies with the purified enzymes have demonstrated no clear division between the types of substrates preferred by the two enzymes; therefore, the metabolism of each nitrogen-containing xenobiotic must be considered on an individual basis. The thermal instability of the FMO in the absence of NADPH (above 50°C) has provided a tool to separate the activity of this enzyme in vitro from that of P450; however, defining the relative contribution of the FMO and P450 to the metabolism of many xenobiotics is difficult because some inhibitors of P450, such as SKF-525A, are substrates for the FMO. More selective inhibitors of P450, such as *N*-benzylimidazole and aminobenzotriazole, are a better choice for distinguishing these two enzymes. Antibodies to specific P450 isozymes can also be used to inhibit P450 and determine the role of the FMO.

Many nitrogen- and sulfur-containing xenobiotics are metabolized by FMOs, as seen in Figure 4.8. N-Oxidation of nucleophilic tertiary amines yields N-oxides, and primary and secondary amines are oxidized to hydroxylamines. In addition, primary amines can be oxidized to oximes and secondary amines to nitrones. Thiols, thioethers, and other xenobiotic-containing sulfur can be oxidized to sulfur oxides. In addition to the functional groups shown in Figure 4.8, FMOs are also capable of oxidizing organic phosphines, boronides, selenides, and iodides. The flavin-containing monooxygenases have broad substrate specificity, but individual isozymes demonstrate some specificity. Broad substrate specificity and its occurrence in several tissues indicate that it can be a major determinant in oxidative xenobiotic metabolism.

Transcriptional regulation of FMOs has received much less attention than the regulation of P450s, and the mechanisms governing the expression of FMOs are unclear. Basal expression of FMOs is under hormonal control. To date, little evidence exists to suggest xenobiotic-mediated induction of FMOs. Few isoform-selective FMO substrates are known, although stereoselective N-oxidation of nicotine and S-oxidation of cimetidine have been used as marker activities for FMO3. Further, N-oxidation of trimethylamine is catalyzed by FMO3, and a genetic defect in this isoforms results in trimethylaminuria (fish odor syndrome). Few selective inhibitors of FMOs are known, although indole-3-carbinol and *N,N*-dimethylaminostilbene carboxylates have been used for this purpose. It has been suggested that targeting drugs for FMO-mediated metabolism may result in fewer adverse drug reactions, due to the lack of induction and selective inhibition of FMOs.[118] Numerous single nucleotide polymorphisms (SNPs) for FMOs have been identified, but because of the limited role of FMO in drug metabolism, the clinical significance of polymorphic FMO expression is uncertain.

Xanthine Oxidoreductase

Xanthine oxidase and xanthine dehydrogenase are members of the molybdenum hydroxylase flavoprotein family commonly referred to as the xanthine oxidoreductase (XOR) family.[121] Oxidation reactions carried out by xanthine oxidase and aldehyde oxidase are different from that of cytochrome P450-catalyzed oxidations in that hydroxylation of the substrate is derived from water rather than molecular oxygen.

Xanthine oxidase and xanthine dehydrogenase are actually different enzymes derived from the same gene product. Conversion of the dehydrogenase to the oxidase involves oxidation of critical protein thiol groups followed by the cleavage of a 20 kDa fragment from each of two subunits. Although both forms of the enzyme have been recognized for years, comparatively little information exists for this enzyme system, especially the dehydrogenase. XOR has been identified in tissues from all species studied to date, and among mammals, the highest activity is found in lactating mammary gland and cow's milk, liver, and intestine. The predominant form is the dehydrogenase, and both forms are localized in the cytoplasm. Human XOR is generally less active than that of other species.

XOR catalyzes oxidation of electron-deficient carbons, frequently adjacent to nitrogen in heterocyclic ring systems. XOR can also catalyze oxidation of aldehydes to carboxylic acids, though with much lower affinity than ALDHs. The XOR enzyme system is the rate-limiting enzyme in purine catabolism but is also well known to metabolize xenobiotics. XOR carries out the oxidation of hypoxanthine to xanthine and xanthine to uric acid (Figure 4.9). Anticancer drugs including substituted and unsubstituted purines, pyrimidines, pteridines, and azopurines and heterocyclic compounds such as doxorubicin and menadione are well-known substrates of xanthine oxidase. More recently, the generation of nitric oxide from *S*-nitrosothiols and nitrite by XOR has been demonstrated.

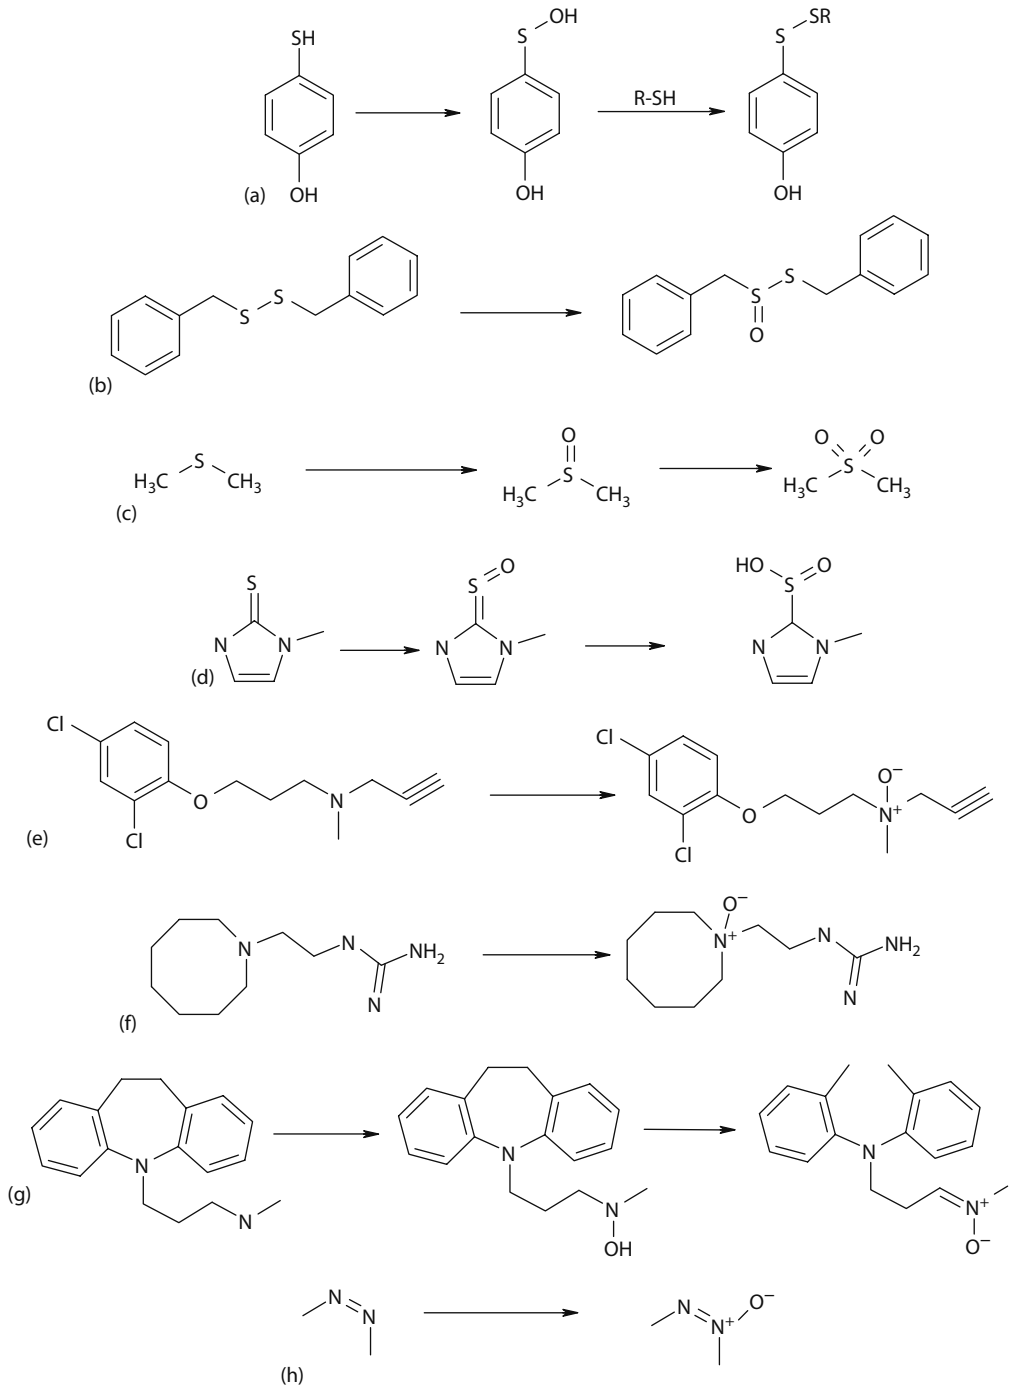

FIGURE 4.8 Examples of reaction types catalyzed by FMOs. Specific substrates are indicated in parentheses following the reaction type: (a) S-oxidation of thiols (thiophenol); the second step forming the disulfide is nonenzymatic. (b) S-oxidation of disulfides (benzyl disulfide). (c) S-oxidation of thioethers (dimethylsulfide). (d) S-oxidation of thiocarbamates, thiocarbamides, and thioureas (methimazole). (e) N-oxidation of aliphatic tertiary amines (clorgyline). (f) N-oxidation of alicyclic tertiary amines (guanethidine). (g) N-oxidation of aliphatic secondary amines (desipramine). (h) N-oxidation of azo compounds (azomethane).

Both the oxidase and reductase forms are capable of metabolizing xenobiotics with the preference determined by the specificity of each enzyme for a different electron acceptor.[121] The oxidase utilizes molecular oxygen as an electron acceptor with negligible reactivity toward NAD^+. Reoxidation of the oxidase enzyme takes place via two one-electron reductions of molecular oxygen to yield hydrogen peroxide. On the other hand, the dehydrogenase utilizes NAD^+ as an electron acceptor to produce NADH through a two-electron reduction. Thus, the xanthine dehydrogenase enzyme has been shown to participate in the redox cycling of doxorubicin and menadione, resulting in the formation of their hydroquinones, which are generally unstable and generate oxygen radicals. The efficient utilization of oxygen and

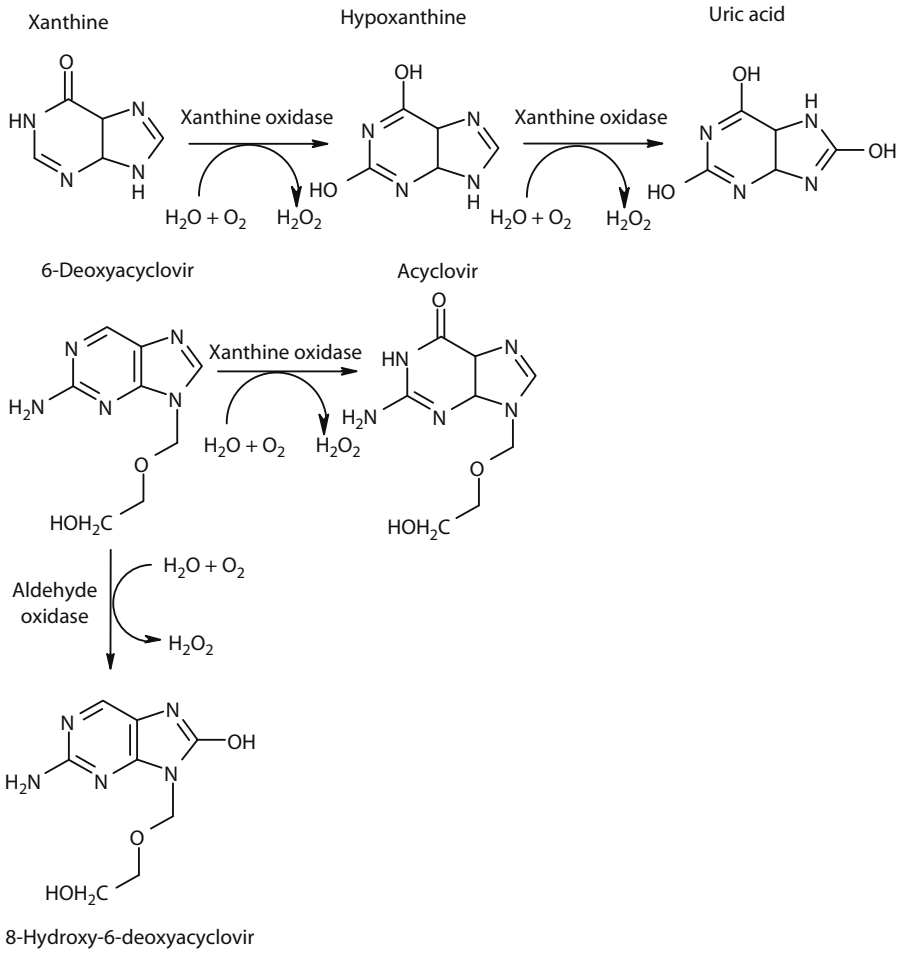

FIGURE 4.9 Oxidation of xanthine, hypoxanthine, and 6-deoxyacyclovir by xanthine oxidase or aldehyde oxidase using molecular oxygen as the electron acceptor.

the production of oxygen radicals have been proposed to contribute to the cytotoxic action of these drugs.[122]

Amine Oxidases

Amine oxidases can play a significant role in the metabolism of specific xenobiotics.[126] Monoamine oxidase (MAO) and related amine oxidases catalyze the oxidative deamination of endogenous amines. They can also be involved in the metabolism of primary, secondary, and tertiary xenobiotic amines. Two of the amine oxidases (MAO and semicarbazide-sensitive amine oxidase [SSAO]) will be used as examples of amine oxidases.

Most tissues express two forms of the mitochondrial enzyme MAO (termed MAO-A and MAO-B), each being expressed by a separate gene. Although MAOs are expressed in most tissues, expression in various tissues is isoform specific. The highest concentrations of both isoforms are found in the liver and gastrointestinal tract. Only MAO-B is expressed in human platelets. MAO is a flavoprotein capable of oxidative deamination of primary, secondary, and tertiary amines. Metabolism of primary amines yields an aldehyde and ammonia, whereas secondary amines yield an aldehyde and a primary amine. The aldehyde products may be further metabolized by other enzymes to carboxylic acids or alcohols. Unlike the monooxygenases, the oxygen used in the reaction is derived from water. During the oxidation, the FAD prosthetic group is reduced (FADγFADH2) then reoxidized by oxygen with the production of hydrogen peroxide. A number of amine drugs have been shown to be substrates for MAO. Some of these act as prodrugs and require MAO metabolism to produce the active form; others have their activities limited by MAO metabolism. MAO-A and MAO-B have different substrate specificities, but there can be overlap in specificity.

Induction of MAO by drugs or other xenobiotics has not been observed. Basal expression of MAOs is under hormonal control and can be perturbed by steroid analogs such as prednisone. Nonselective inhibitors of MAO include iproniazid and phenelzine, and selective inhibition of MAO-A and MAO-B can be achieved with clorgyline and pargyline, respectively. Although these inhibitors are useful for in vitro diagnostic studies of drug metabolism, they also inactivate some CYP isoforms, diminishing their usefulness as in vivo probes of MAO involvement. Polymorphisms of both MAO isoforms are known, although the consequences for drug metabolism and toxicity are not well understood. MAOs play a role in the metabolism of a variety of compounds, including

β-adrenergic agonists/antagonists and phenylethylamine derivatives such as mescaline. The quantitative contribution of MAOs to xenobiotic clearance is unknown but is likely to be low compared to P450s.

A well-publicized example of an MAO-related toxicity was initiated by individuals attempting to synthesize a narcotic related to demerol. Instead of the intended product, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) resulted from the synthesis. Individuals who self-administered MPTP demonstrated Parkinson's disease-like symptoms. This was related to neurocytotoxicity in dopaminergic neurons produced by brain MAO-B metabolism of MPTP to 1-methyl-4-phenyl-2, 3-dihydropyridine ($MPDP^+$), which oxidizes to the neurotoxic 1-methyl-4-phenylpyridine (MPP^+). The cytotoxicity of MPP^+ results from its inhibition of mitochondrial respiration.

SSAOs, like MAO, catalyze the oxidative deamination of endogenous amines but can also metabolize xenobiotic amines.[123,124] The SSAOs do not contain a flavin but do contain copper. They demonstrate a more limited activity than MAO by only catalyzing deamination of primary aliphatic and aromatic monoamines. They are sensitive to inhibition by semicarbazide but insensitive to the classic MAO inhibitors. The products of their reaction are an aldehyde, ammonia, and hydrogen peroxide. They occur in most species, including bacteria, fungi, plants, and animals. In animals, they occur in plasma and may be bound to tissues. Although they can metabolize several endogenous substrates,[125] their exact physiological role is currently unknown.

Considerable species differences exist for SSAO; for example, rats have relatively low concentrations of plasma SSAO compared to humans. SSAO can metabolize certain xenobiotics to more toxic metabolites. 3-Aminopropene has been used in the manufacture of pharmaceuticals and in rubber vulcanization; chronic exposure to this compound can produce lesions similar to acute myocardial necrosis and atherosclerosis. SSAO appears to metabolize 3-aminopropene to 2-propenal (acrolein), which alkylates and inactivates GST and allows excessive peroxidative damage.[126] Damage occurs in the heart and aortic tissue, which have high SSAO activity.[127] The tissue specificity of this effect is related to relatively high expression levels of SSAO in heart. This is in contrast to acrolein produced from allyl alcohol by alcohol dehydrogenase (ADH), which results in liver toxicity.

Aldehyde Oxidase

Aldehyde oxidase is similarly a cytosolic, sulfur-containing molybdenum hydroxylase, is closely related structurally and catalytically to xanthine oxidase, and is present in highest quantities in liver, particularly of the rabbit. Despite its ability to oxidize aldehydes in vitro, especially aromatic aldehydes (e.g., vanillin to vanillic acid), this misnamed enzyme preferentially catalyzes the oxidation of purines and other heterocyclic amines. Unlike xanthine oxidase, aldehyde oxidase is able to catalyze hydroxylations at the C-8 position of purines (Figure 4.9); thus, the prodrug 6-deoxyacyclovir undergoes hydroxylation at the C-8 position by aldehyde oxidase to yield active acyclovir.[128] The most efficient substrates for aldehyde oxidase are aromatic heterocycles with two fused six-membered rings.[129] There is also evidence that iminium ions can be metabolized to lactams by aldehyde oxidase.[130]

Cooxidation of Xenobiotics by Prostaglandin H Synthase and Other Peroxidases

Pathways other than the monooxygenases may be involved in xenobiotic oxidation. These include myeloperoxidases (MPOs), eosinophil peroxidase (EPO), uterine peroxidase, lactoperoxidase (LPO), thyroid peroxidase (TPO), and the prostaglandin synthases. Prostaglandin synthase, also known as cyclooxygenase, is the initial enzyme in arachidonate metabolism and the formation of prostanoids such as prostaglandins, prostacyclins, and thromboxanes. Marnett and Reed[131] demonstrated that prostaglandin H synthetase, an enzyme system responsible for prostaglandin biosynthesis, was capable of oxidizing BP to quinines (Figure 4.4). The following cycle of reactions is involved in the oxidation of xenobiotics[132]:

$$\text{Peroxidase} + \text{ROOH} \rightarrow \text{Compound I} + \text{ROH}$$

$$\text{Compound I} + \text{ROH} \rightarrow \text{Compound II} + \text{RO}-$$

$$\text{Compound II} + \text{ROH} \rightarrow \text{Peroxidase} + \text{RO}- + H_2O$$

The cyclooxygenase activity of prostaglandin synthase catalyzes the oxygenation of arachidonic acid to form the hydroperoxy endoperoxide prostaglandin G_2 (PGG_2). With a xenobiotic acting as an electron donor, PGG_2 is reduced to the hydroxyl endoperoxide PGH_2, with the coordinate oxidation of the hydroxyl group of the xenobiotic as illustrated in Figure 4.7, for acetaminophen cooxidation.

Two prostaglandin H synthase (PHS) enzymes, PGHS-1 and PGHS-2, have been characterized, and both are homodimeric integral membrane proteins. PGHS-1 and PGHS-2 are localized to the luminal surface of the endoplasmic reticulum, and PGHS-2 is also found in the inner and outer membranes of the nuclear envelope. Both enzymes share about 60% primary sequence identity but are encoded by separate genes on separate chromosomes. They are under regulatory control of cytokines and growth factors.[133] Two catalytic activities copurify with the synthase: fatty acid cyclooxygenase and prostaglandin hydroperoxidase. The cyclooxygenase catalyzes arachidonic acid oxidation to (PGG_2), and the hydroperoxidase reduces the hydroperoxide (–OOH) to the corresponding alcohol in prostaglandin H_2, as shown in Figure 4.10. Oxidation of xenobiotics results from a one-electron pathway involving an oxidizing agent produced during the hydroperoxidase-catalyzed reduction of PGG_2 to the hydroxyl endoperoxide PGH_2. Prostaglandin synthetase is a major source of alkyl hydroperoxides produced during normal metabolism. Most tissues possess prostaglandin synthetase activity and are capable of oxidizing certain xenobiotics, even if the tissue is low in P450 content. In fact,

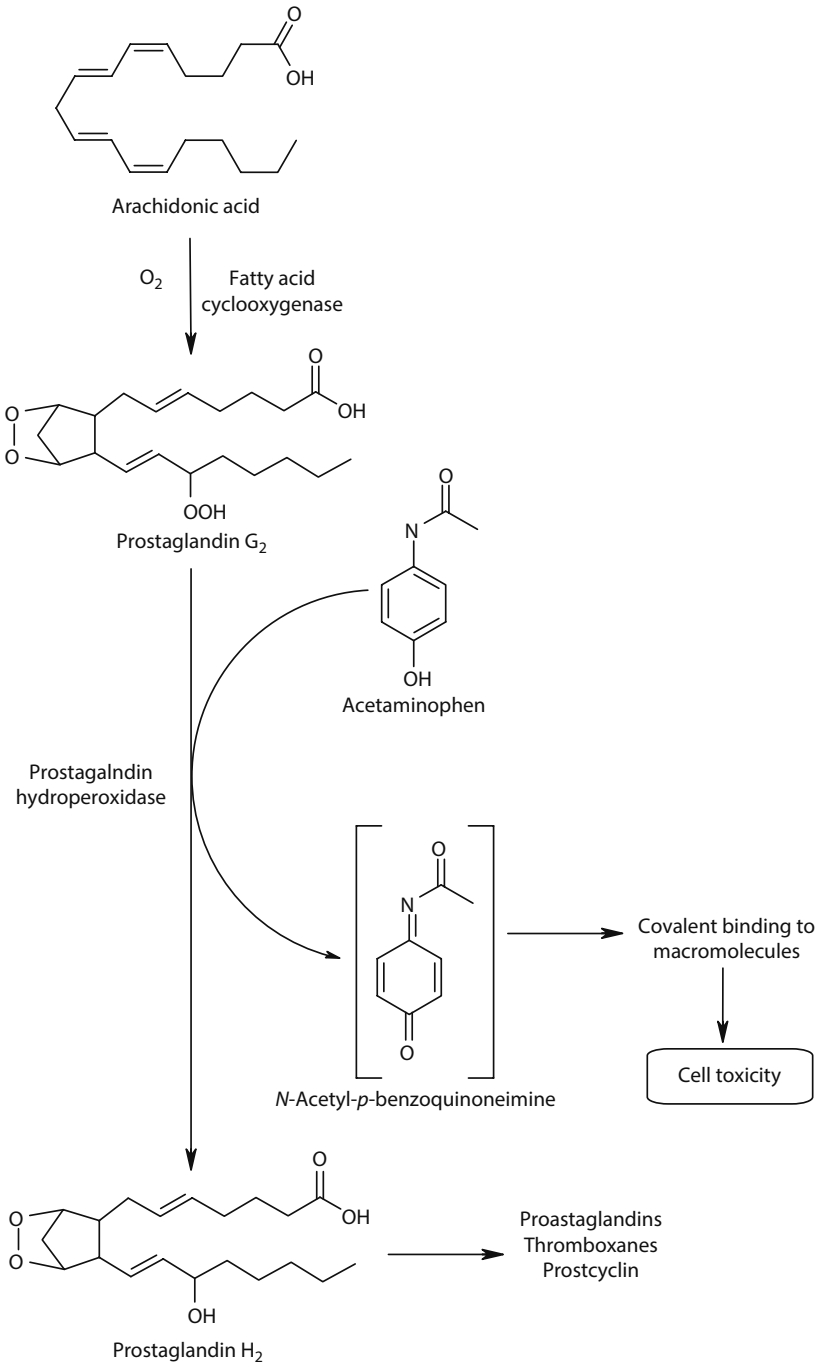

FIGURE 4.10 Cooxidation of acetaminophen by prostaglandin endoperoxide synthase.

acetaminophen, which is activated to a reactive intermediate by P450, can also be activated by prostaglandin synthetase in the medulla of the kidney. This tissue is low in P450 activity, but in the presence of arachidonic acid, the medulla activates acetaminophen to a reactive intermediate that covalently binds to tissue macromolecules.[133] The localization of prostaglandin synthetase in the inner medulla and papilla may be a contributing factor to the toxicity produced by other chemicals in this region of the nephron.[134] Other compounds that undergo cooxidation include aminopyrine, benzphetamine, oxyphenbutazone, benzidine, and BP.

In addition to kidney, other extrahepatic tissues including bladder, intestinal mucosa, spleen, and blood cells, such as peripheral blood mononuclear cells, and macrophages possess prostaglandin synthase activity. The bladder also possesses high prostaglandin synthetase activity. Mattammal et al.[135] proposed that several structurally diverse renal and bladder carcinogens are metabolically activated by prostaglandin synthetase; for example, the bladder carcinogen 2-amino-4-(5-nitro-2-furyl)thiazole is believed to be activated by prostaglandin synthetase cooxidation in bladder transitional epithelium to metabolites capable of covalently

modifying RNA and DNA. Feeding aspirin to rats can inhibit the bladder lesion induced by 5-nitrofuran, the ultimate carcinogen. This suggests that prostaglandin synthetase is involved in the metabolic activation, as aspirin is a specific inhibitor of prostaglandin synthetase.

Use of the analgesic *p*-phenetidine has declined because of reports of kidney damage in humans following prolonged use of the drug. Andersson et al.[136] proposed a mechanism by which phenetidine is activated by prostaglandin synthetase in the kidney. The primary amine nitrogen of phenetidine undergoes a one-electron oxidation similar to that shown in Figure 4.10 for acetaminophen. This leads to hydrogen abstraction, yielding a reactive nitrenium radical. A radical intermediate is postulated based on its rate of reaction phenacetin with reduced GSH in the presence of arachidonic acid and microsomes from sheep seminal vesicles. Benzene can be hydroxylated to phenol in the liver by P450, and the phenol can be further oxidized to hydroquinone. The phenol and hydroquinone can enter the blood stream and be distributed to other tissues. In the bone marrow, the phenol stimulates prostaglandin synthetase peroxidative activation of hydroquinone to reactive metabolites that form adducts with nucleophiles, such as protein and DNA. This is believed to result in the bone marrow suppression seen with chronic exposure to benzene. Phenolic compounds may be converted to reactive phenoxyl radicals by the one-electron oxidative process.

Another example of a PGHS-2-mediated metabolic activation reaction is the biotransformation of procainamide. Drugs such as procainamide undergo an N-acetylation reaction as a primary means of elimination; however, as discussed in another section, individuals with the slow acetylator phenotype do not readily eliminate procainamide via the N-acetylation pathway, leaving more drug to reach extrahepatic tissues. It is in tissues such as monocytes and macrophages that PGHS-2 can oxidize procainamide to the hydroxylamine and nitroso derivatives. These reactive molecules are proposed to form haptens and subsequently sensitize T-cells. The enhanced neoantigen formation and T-cell sensitization seen in slow acetylators might be explained by the higher concentration of procainamide that is available for extrahepatic N-oxidation in antigen-presenting cells.[137]

In the developing embryo and other conceptal tissues, levels of cytochrome P450 expression are very low, especially in the first trimester. Oxidative metabolism, however, can proceed through peroxidative mechanisms dependent on prostaglandin synthase as well as lipoxygenase, peroxidase, and lipid peroxidation-coupled cooxidation.[132] Metabolic activation of xenobiotics to toxic intermediates through these mechanisms may be responsible for certain terata. Phenytoin, an antiepileptic drug and known teratogen, was shown in vitro to be less effective when mouse embryos were cultured in the presence of inhibitors of the prostaglandin synthase and lipoxygenase pathways.

MPO, EPO, and LPO are unique among the peroxidases in that they are primarily found in lysosomes of neutrophils, eosinophils, and secretory cells of the exocrine glands, respectively (Table 4.4).[132] Neutrophil MPO catalyzes the oxidation of halides by hydrogen peroxide to produce hypohalous acid. Leukemias induced by benzene exposure have been attributed to DNA prooxidant phenoxyl radicals formed by the MPO/H_2O_2-mediated oxidation of the benzene CYP2E1 product phenol. TPO is a membrane-bound enzyme localized to the thyroid follicular cells and is under regulatory control of thyroid-stimulating hormone. TPO catalyzes the iodination of thyroglobulin tyrosine residues.

Alcohol and Aldehyde Dehydrogenases

Alcohol Dehydrogenase

ADHs catalyze the NAD^+-dependent oxidation of primary and secondary alcohols to aldehydes and ketones, respectively.[139] ADHs are dimeric cytosolic proteins with a molecular weight of approximately 40,000 and contain one structural and one catalytic zinc atom. Mammalian ADHs are encoded by six different genes (ADH1–ADH6), each of which codes for an individual subunit (designated α, β, γ, π, χ, and σ). Only five genes (ADH1–ADH5) are found in primates, including humans.[71] The α, β, and γ subunits have >90% sequence

homology and can thus form both homodimers and heterodimers. The π and χ subunits have lower homology and can only form homodimers. ADHs are divided into four classes (I–IV) based on their subunit composition. Class I ADHs, composed of α, β, and γ hetero- and homodimers, are the most important isoforms involved in ethanol metabolism. Class I ADHs are expressed at high levels in liver and adrenal gland and at lower levels in a variety of other tissues. Class IV ADH, composed of σ homodimers, is expressed primarily in the gastrointestinal tract in adult humans and is responsible for first-pass ethanol metabolism as well as extrahepatic oxidation of retinoids.[139] Because of its localization and activity in ethanol metabolism, this isoform is thought to be involved in the induction of gastrointestinal cancer following chronic alcohol abuse.[140]

The catalytic mechanism involves initial deproteination of the hydroxyl group, followed by hydride transfer to the NAD^+ cofactor (Figure 4.11). Enzyme activity can be followed by monitoring formation of NADH spectrophotometrically, and this has been used as a convenient nonspecific assay for ADH activity. ADHs have wide substrate specificity and can catalyze the dehydrogenation of a variety of primary and secondary aliphatic alcohols and aromatic alcohols, as well as diols and aminoalcohols.[141–143] Primary alcohols are more readily dehydrogenated compared to secondary alcohols, and within a series, catalytic efficiency appears to be correlated with lipophilicity. Pyrazole and 4-methylpyrazole have been used as selective inhibitors of ADH, although some isoforms such as ADH2 are resistant to these inhibitors[71] and at higher concentrations, these compounds can inhibit P450 activity as well.

ADHs are active in the metabolism of a variety of drugs and other xenobiotics. The most obvious example is conversion of ethanol to acetaldehyde, which is detoxified by ALDHs (discussed in the following). ADH mediates toxicity of a number of alcohol-containing toxicants; for example, ADHs oxidize methanol to formaldehyde, which is converted to formic acid, resulting in metabolic acidosis. Interestingly, formaldehyde can be scavenged by reduced GSH, and the resulting conjugate, *S*-hydroxymethylglutathione, is a major substrate for ADH3.[144] Similarly, ADH-mediated oxidation of ethylene glycol to glyoxal, which is ultimately converted to oxalic acid, results in kidney toxicity.[145,146] The ADH inhibitor 4-methylpyrazole is used to treat accidental and intentional ingestion of methanol and ethylene glycol. A third example is the ADH-mediated dehydrogenation of allyl alcohol to the hepatotoxin acrolein.[147]

Expression of ADH is polymorphic, with allelic variants occurring at the ADH2 and ADH3 loci (β and γ subunits). Humans express 3 isoforms of ADH1 (ADH1A–ADH1C), with broad and overlapping substrate specificity. Bile acids are exclusively metabolized by ADH1C.[71] ADH2*2 isoforms, containing at least 1 β_2 allele and collectively known as atypical ADH, occur at a frequency of approximately 90% in Pacific rim Asian populations and are responsible for the rapid oxidation of ethanol to acetaldehyde in these

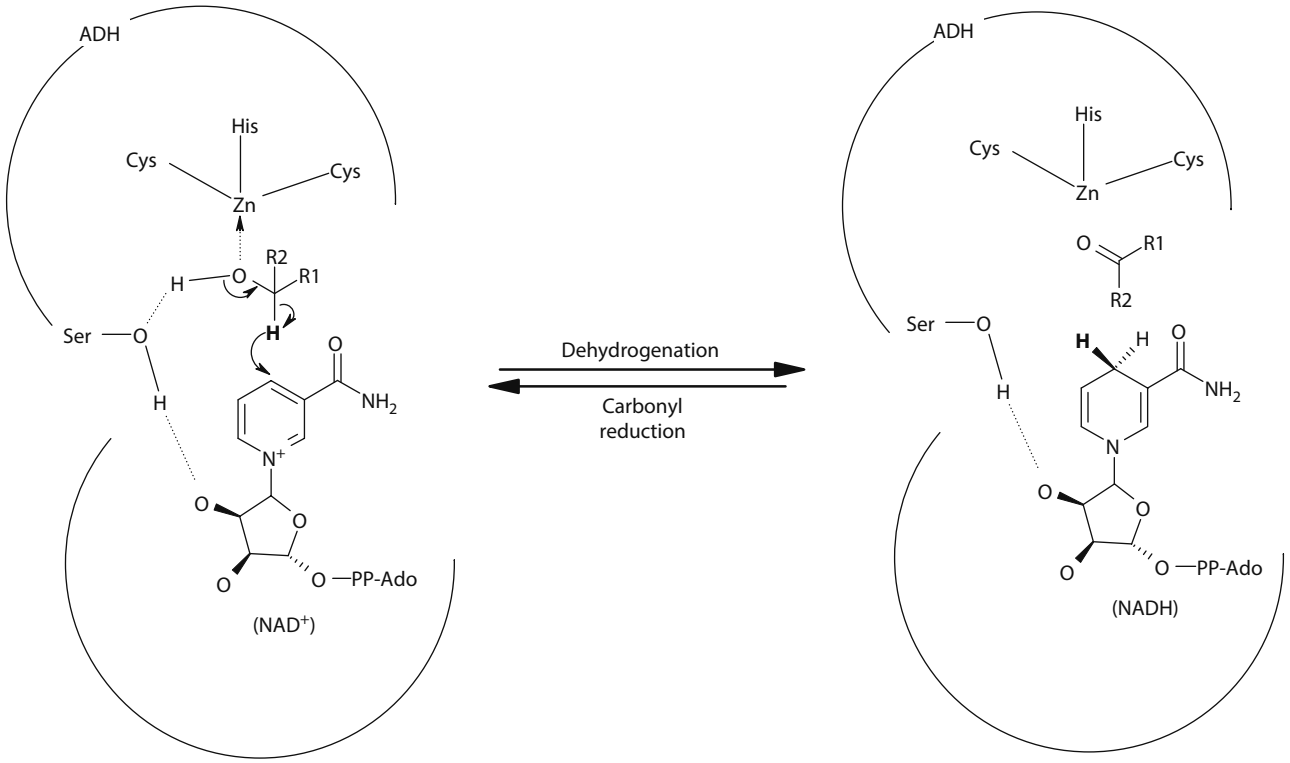

FIGURE 4.11 Catalytic mechanism of cytosolic ADH. Initial deproteination of the alcohol group is accomplished by a proton shuttle involving an active site serine, the ribosyl group of the cofactor, and an active site histidine residue (not shown). As shown, the reaction is reversible so ADH can also function as a carbonyl reductase.

individuals.[148] These isoforms are found at a much lower frequency in Caucasians and African Americans. ADH3*1 and ADH3*2 variants also occur at a high frequency in Pacific rim Asians, but these variants have little impact on ethanol metabolism.

Aldehyde Dehydrogenase

ALDHs are the major enzymes responsible for oxidation of aldehydes to carboxylic acids. ALDHs are found in the cytosol, mitochondria, and endoplasmic reticulum, and both constitutive and inducible forms are expressed in numerous tissues.[139] ALDHs exist as tetramers with an approximate molecular weight of 200,000–250,000 Da. ALDHs can use either NAD^+ or $NADP^+$ as a cofactor, and cofactor preference is isoform specific. ALDH genes are classified into families and subfamilies based on sequence homology. Isoforms with >40% homology are assigned to the same family (designated by an Arabic number), while enzymes with >60% similarity are assigned to the same subfamily (designated by a letter). Individual subfamily members are designated by an Arabic number. At least 17 ALDH genes have been identified in humans. These are arranged into 10 families and 13 subfamilies.[149]

The mechanism of ALDH catalysis is illustrated in Figure 4.12. In the initial step, the NAD(P) cofactor binds with the enzyme, followed by binding of the aldehyde substrate, which forms a covalent bond with an active site cysteine sulfhydryl group. The second step is the transfer of a hydride ion from the substrate to the pyridine moiety of NAD(P), which effectively oxidizes the substrate to an acyl compound. In the final step, the acyl compound is hydrolyzed, giving rise to a carboxylic acid.

Similar to ADH, ALDH can oxidize a broad array of substrates, including aliphatic and aromatic aldehydes and dialdehydes. ALDHs are involved in a number of endogenous biosynthetic pathways, such as the synthesis of retinoids, amino acids, and neurotransmitters; metabolism of folate and fatty aldehydes; and detoxification of aldehydes generated by lipid peroxidation. Xenobiotic substrates include acetaldehyde (from metabolism of ethanol), *p*-nitrobenzaldehyde, acrolein, and aldophosphamide (from metabolism of cyclophosphamide). Metabolism of acetaldehyde is mediated by ALDH1A1, ALDH1B1, and ALDH2 in humans, with the latter isoform taking the predominant role. ALDH1A1 also catalyzes oxidation of retinal, and competition between this substrate and acetaldehyde may be involved in the deficiencies in vitamin A metabolism observed in alcoholics.[150] The dithiol compound disulfiram is a potent inhibitor of ALDHs and has been used as a deterrent in the treatment of alcoholism; however, disulfiram has limited value as a probe inhibitor of ALDH in vivo, as its metabolite diethyldithiocarbamate also irreversibly inhibits CYP2E1. ALDHs are induced by PAHs and TCDD by an Ah-receptor-mediated mechanism. PB also induces some ALDHs, although the specific mechanism underlying this effect has not been investigated.

Many allelic variants of ALDH have been identified, although only a few are thought to play a role in polymorphic xenobiotic metabolism. The most thoroughly studied ALDH polymorphism involves a deficiency in ALDH2. The ALDH2*2 variant is caused by a point mutation in exon 12,

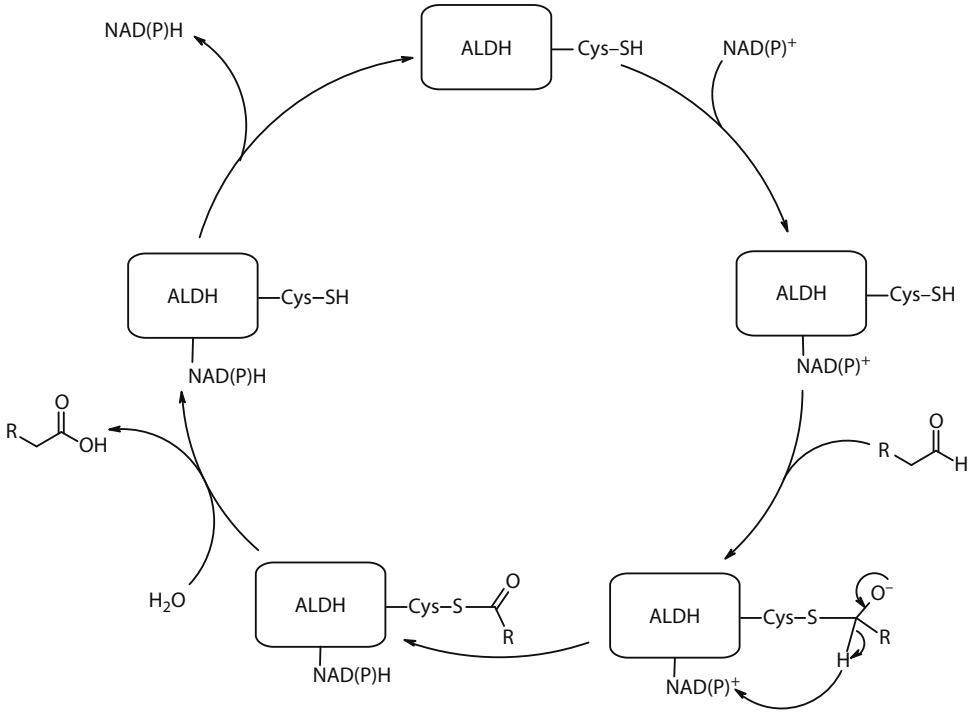

FIGURE 4.12 Catalytic mechanism of cytosolic ALDH. The oxidation of aldehydes to carboxylic acids occurs in two steps: dehydrogenation and thioester hydrolysis. By virtue of the second activity, ALDH can also function as an esterase.

resulting in synthesis of an inactive enzyme. This allele is common in Asian populations, and individuals carrying this variant have a compromised ability to detoxify acetaldehyde following consumption of ethanol. This deficiency is manifested as the so-called flushing syndrome common in Asians following ethanol consumption. ALDH1A1 polymorphism may also play a role in ethanol tolerance, although to a lesser degree.

Quinone Oxidoreductases

NAD(P)H:Quinone Oxidoreductase 1

NAD(P)H:quinone oxidoreductase 1 (NQO1; also known as DT diaphorase) catalyzes the two-electron reduction of quinones to the corresponding hydroquinones.[151,152] Functional NQO1 is a cytosolic homodimer containing two FAD prosthetic groups. High levels of NQO1 are found in liver of rodents and other common laboratory species. In contrast, human NQO1 was detected in lung, breast, and gastrointestinal epithelium; vascular endothelium; adipocytes; bone marrow; and several areas of the eye but not in liver. Thus, this enzyme does not appear to play a role in hepatic metabolism of xenobiotics. In addition to quinones, NQO1 can catalyze two-electron reductions of a wide variety of functional groups including quinone imines, GSH conjugates of naphthoquinones, azo compounds, and aromatic nitro compounds. NQO1 can also catalyze four-electron reductions of aromatic azo and nitro compounds. Dicumerol is a potent inhibitor of NQO1.

Quinone reduction by NQO1 can result in either detoxification or bioactivation, depending on the stability of the resulting hydroquinone; thus, NQO1 detoxifies redox-active quinones such as menadione by converting them to stable hydroquinones that are substrates for phase II conjugation reactions. Less stable hydroquinones can undergo autooxidation to semiquinone radicals or rearrange to alkylating species.

NQO1 can be induced by PAHs, azo compounds, and phenolic antioxidants, as well as by oxidative stress. The 5′ flanking region of the NQO1 gene contains both an antioxidant response element (ARE) and an XRE. Induction controlled by the XRE is mediated by the Ah receptor as described for P450 induction. Induction of NQ1 by the ARE may be mediated by a variety of transcription factors, including Jun, Fos, and Nrf, among others.[116]

Several polymorphisms of NQO1 have been identified. The most striking of these is NQO1*2*2, in which no active protein is produced. The frequency of this genotype varies from about 4% in Caucasians to over 20% in East Asian populations. The presence of this genotype has been shown to be a risk factor for the development of hematotoxicity of benzene.

NAD(P)H:Quinone Oxidoreductase 2

NAD(P)H:quinone oxidoreductase 2 (NQO2) has approximately 82% sequence similarity to NQO1, although it is 43 amino acids shorter at the carboxy terminal of the protein. In humans, NQO2 is expressed in a variety of tissues, including liver, kidney, and lung, although the highest expression levels were found in skeletal muscle. NQO2 is also similar to NQO1 in many respects, such as substrate specificity and response to inducers; however, these enzymes are different in a number of important ways. For example, NQO2 uses dihydronicotinamide riboside as a cofactor instead of NAD(P)H. Inhibitor selectivity is also different; NQO2 is inhibited by quercetin and BP but not by dicoumarol. Despite gains in understanding the expression and functional activity of this enzyme, the significance of NQO2 for endobiotic and xenobiotic metabolism remains to be demonstrated.[151,153]

BIOCHEMICAL CONJUGATIONS

Mammals can synthesize xenobiotic conjugates that are more polar and readily excreted compared with the parent compound. Two major reactants are required for conjugate synthesis: a xenobiotic with the appropriate functional group and a cosubstrate that can be conjugated with the xenobiotic. If the xenobiotic does not have a functional group amenable to conjugation, such as a hydroxyl group, it may be oxidized (functionalized) by cytochromes P450. The oxidized product and the cosubstrate must be simultaneously available for conjugation. Both functions must be tightly integrated for rapid excretion of the xenobiotic. Although the forthcoming sections will discuss each conjugation system as a separate entity, it must be emphasized that in vivo metabolism is integrated. Examples showing the integration of the conjugation systems with related pathways will be presented.

Glucuronidation: Uridine Diphosphoglucuronosyltransferases

P450s are the principle phase I oxidative enzymes. Similarly, uridine diphosphoglucuronosyltransferases (also known as UDP-glycosyltransferases [UGTs]) are the principal phase II enzymes. Glucuronosyltransferases can use monooxygenase products to form glucuronides; however, it is not a necessity for substrates of the glucuronosyltransferase to be monooxygenase products. Significant numbers of xenobiotics and certain endobiotics possess the necessary functional groups for glucuronidation and do not require functionalization. This pathway has been estimated to account for 35% of all drugs metabolized by phase II drug-metabolizing enzymes.[154] UDPGTs occur in several tissues, but their highest activity is found in the liver. Most isoforms have a distinct hepatic and/or extrahepatic expression resulting in significant expression in kidney, intestine, and steroid target tissues.[155] As such, glucuronosyltransferase is a significant metabolic pathway contributing to the elimination of xenobiotics and affecting poor bioavailability of orally administered drug substrates.[156]

Whereas the multienzyme complex of the P450 monooxygenase is termed a system because the enzymes are closely linked, the multiple enzymes of glucuronidation are not linked but are interdependent. The general reaction mechanism of the conjugating enzymes involves the activation of

an endogenous molecule. Subsequent reaction of this activated form of the endogenous molecule with the xenobiotic produces the conjugate. Activation may occur in a different cellular compartment than conjugation, as is the case with glucuronidation. Activation of glucose occurs in the cytosol, whereas conjugation occurs in the lumen of the endoplasmic reticulum.

Although the products of P450 are more water soluble than their parent compounds, some still possess considerable lipophilicity. Subsequent conjugation produces metabolites with higher water solubility. These metabolites can generally be readily excreted in the bile or urine. Transport proteins recognize the glucuronic acid moiety of the glucuronide and aid in excretion from the liver and kidney. An additional method by which glucuronidation produces less toxic metabolites is via the addition of a bulky moiety to the xenobiotic. This can result in both the shielding of reactive portions of the xenobiotic and in the blocking of reactions between the xenobiotic and the site responsible for the toxicological sequelae. In some cases, the product of glucuronidation has more toxicological activity than the parent compound, and conjugation can be considered metabolic activation, although examples are far fewer than with P450 oxidation. Similarly, conjugation with glucuronic acid results in significant structural change so pharmacologic activity is generally abolished, although in a few cases, glucuronidation will result in a molecule with similar or even greater pharmacologic activity.[157]

Recent findings on regulation of P450, UDPGTs, and transporters suggest that although nuclear receptor signaling induces different cytochromes P450, regulation may converge on single UGTs and transporters.[158] The nuclear receptors CAR, PXR, and AhR coordinate the induction of several CYP, UGT, and drug transporters (Table 4.5) and thus lead to differential expression of various UGT forms. As an example, rifampicin induction of CYP3A4 is PXR mediated and is responsible for the conversion in the liver of lithocholic acid to the less toxic form hyodeoxycholic acid. Hyodeoxycholic acid is in turn conjugated by several UGTs, and transport out of the hepatocyte is mediated by the rifampicin-inducible transporter multidrug resistance protein 2 (MRP2). Similarly, comedication with rifampicin leads to reduced effects of ezetimibe, an inhibitor of the cholesterol uptake transporter, by faster elimination via glucuronidation and subsequent intestinal or hepatic secretion via the efflux transporter P-glycoprotein (P-gp) and MRP2.[159]

Glucuronides are secreted either by the liver into the bile and consequently found in the feces or by the kidney into the urine. The excretion route is generally dependent on the molecular weight of the xenobiotic. In both cases, secretion is via specific organic anion transporters, members of the adenosine triphosphate (ATP)-binding cassette superfamily such as MRP2, at the apical plasma membrane, and MRP3, at the basolateral membrane of hepatocytes and enterocytes. The rat excretes glucuronides of xenobiotics with molecular weights greater than about 250–300 into the bile and those with lower molecular weights in the urine. Higher molecular weight xenobiotics, such as morphine, chloramphenicol, and endogenous steroids, are excreted in bile and enter the intestine. Biliary excretion can result in enterohepatic circulation, which can cause prolonged plasma half-lives for some compounds. Intestinal microflora express the enzyme β-glucuronidase, which catalyzes the hydrolysis of glucuronide conjugates. This releases the xenobiotic (referred to as the *aglycone*) in the intestine, where it can be absorbed into the blood. The xenobiotic can then be taken up by the liver, where it is reconjugated and excreted into the bile, where the cycle is again initiated. This can cause prolonged exposure to target organs, such as the liver, and result in unanticipated toxicity.

Nomenclature for UDP-Glucuronosyltransferase Gene Superfamily

Nomenclature for the UDPGTs has progressed similarly to that for the P450 superfamily.[160,161] It has been proposed that each gene be identified by the root symbol UGT for UDPGT. The gene family is identified by a number, and a letter is added to designate the subfamily (e.g., UGT2B) followed by a number to identify the gene (e.g., UGT2B1). This system, as with the P450 nomenclature, is an attempt to provide isoforms with a name that is not only specific but also reflects the evolutionary divergence of the genes.

There are four main gene families denoted UGT1, UGT2, UGT3, and UGT8.[162] Unlike UGT1 and UGT2, neither UGT3 nor UGT8 use UDP-glucuronic acid. UGT1 and UGT2

Note: Inducible rodent enzymes are listed in parentheses.

families are solely responsible for drug glucuronidation and therefore the discussion here is restricted to those enzymes. These two families are further divided into UGT1A, UGT2A, and UGT2B. The entire UGT1A family is derived from a single-gene locus and encodes eight different proteins via alternative splicing of the UDPGA-binding domain with different substrate-binding domains. Most of the UGT1A isoforms have been isolated from human liver whereas three isoforms have been isolated from extrahepatic sources such as bile ducts, tissues of the entire gastrointestinal tract, olfactory epithelium, brain, and fetal lung. UGT2 genes encode seven proteins and have also been isolated from liver, gastrointestinal tract, mammary gland, prostate, and adrenal tissues.

Biochemistry of Glucuronidation

Glucuronidation (illustrated in Figure 4.13) requires the availability of three reactants:

- UDP-α-D-glucuronic acid (UDPGA), generated in the cytoplasm
- UDPGT, bound to the endoplasmic reticulum
- Substrate with the requisite functional group and some hydrophobic character

Maximal enzyme activity is dependent on optimal concentrations of these reactants at the membrane site of catalysis.

As seen in Figure 4.13, D-glucose is the original precursor of UDPGA. During anabolic metabolism, D-glucose is converted to β-D-glucose-1-phosphate. This compound serves as substrate for UDP-glucose pyrophosphorylase, which catalyzes its reaction with uridine triphosphate to yield the high-energy phosphate-containing UDP-D-glucose and pyrophosphate. UDP-D-glucose then reacts with nicotinamide adenine dinucleotide (NAD) catalyzed by UDP-glucose dehydrogenase to yield UDP-D-glucuronic acid, which completes glucose activation. This compound is termed the glycone, indicating its source. The xenobiotic that is conjugated is termed the aglycone. Glucose activation occurs within the cytoplasm, whereas glucuronidation of the aglycone occurs at the endoplasmic reticulum. Because UDP-D-glucose is also used in glycogen synthesis, it generally is available in the cell. This is not true for all conjugation reactions and may be one of the reasons why glucuronidation is a major conjugation pathway.

UDPGTs are oriented in the endoplasmic reticulum in such a way that the majority of the protein protrudes into the lumen of the endoplasmic reticulum. The intraluminal portion of the protein possesses the UDP-glucuronic acid-binding domain as well as the xenobiotic- or endobiotic (endogenous substrates)-binding domain. This means that UDP-glucuronic acid must pass through the membrane, possibly by carrier mediation, and that the substrate must also pass through the membrane.[163] Molecular biology studies indicate that the C-terminal half of the protein is highly conserved among different UDPGTs, whereas the N-terminal region is highly variable. The C-terminal half of the protein contains the transmembrane sequences that anchor the enzyme within

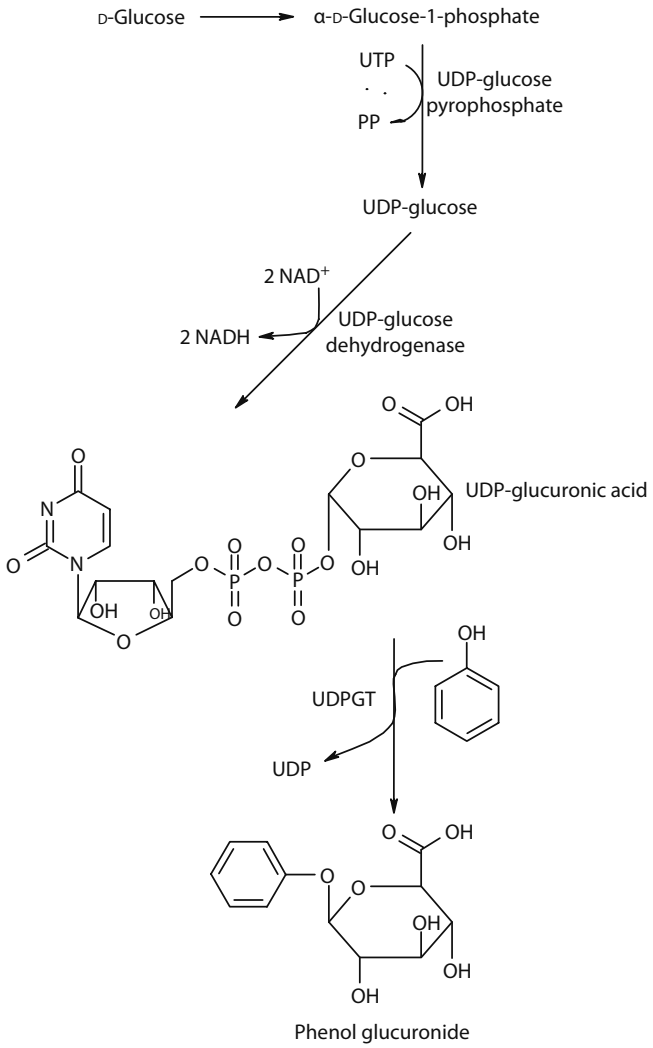

FIGURE 4.13 Glucuronidation of phenol; an example of the pathway leading to the production of glucuronic acid conjugates.

the membrane and the short portion of the C-terminus that protrudes from the outside surface of the endoplasmic reticulum into the cytoplasm. The C-terminal half of the enzyme may contain a UDP-glucuronic-acid-binding site. The broad substrate specificity is believed to come from variation in the primary sequence of the N-terminal region where the substrate-binding domain resides.[164]

UDP-glucuronic acid and the aglycone (xenobiotic or endobiotic) must be present for the conjugation reaction to be initiated. The number of xenobiotics that have been shown to be substrates for UDPGTs is large and continues to grow.[165] The major functional groups forming glucuronides are (1) hydroxyl, (2) carboxyl, (3) amino, and (4) sulfhydryl. The substituents to which these functional groups are attached can be quite variable (see Table 4.6). Similar to the substrate requirements for monooxygenases of the endoplasmic reticulum, the aglycone must be somewhat lipid soluble to be a substrate for the UDPGTs. This requirement reflects the need for the xenobiotic to penetrate the endoplasmic reticulum to gain access to the active site. All of the endobiotics

TABLE 4.6
Xenobiotic Substrates Glucuronidated by Expressed Human UDP-Glucuronosyltransferases

Human Glucuronides	Substrates
Linkage through –O–	
Aryl hydroxyl (ether)	Simple and complex phenols, anthraquinones and flavones, opioids and steroids, hydroxylated coumarins
Aryl or alkyl enolic	Coumarins, steroid-dione structures
Alkyl hydroxyl	Primary, secondary, tertiary alcohols
Acyl hydroxyl (carboxylic esters)	Bilirubin, carboxylic acids
Linkage through –S–	
Aryl and alkyl thiols	No examples reported
Linkage through –C–	No examples reported
Linkage through –O–	
Sulfonamides	No examples reported
Nonquaternary	Primary and secondary amines, arylamines, arylamine N–OH, tetrazoles
Quaternary	Cyclic tertiary, alicyclic tertiary, imidazoles, pyridines, triazoles

associated with normal metabolism and homeostasis that are substrates for the UDPGTs are lipid soluble and include bilirubin, catechols such as 3-*O*-methyladrenaline, serotonin, and 17-hydroxy-containing steroids.

Reactions Catalyzed by the UDP-Glucuronosyltransferases

As with many of the enzymes of detoxification, the glucuronosyltransferases have a low order of substrate specificity. This lack of substrate specificity makes them ideally suitable as detoxification enzymes. Whether or not they evolved as detoxification enzymes or represent enzymes of normal metabolism whose lack of specificity makes them suitable for detoxification is open to debate. Of interest in this respect is that they occur only in higher organisms. Glucuronosyltransferases have been found in all mammals, birds, and reptiles that have been investigated, although their specific activities toward specific substrates may vary among different species and strains. Unlike the monooxygenase, they have not been found in bacteria and other lower species. This fact suggests that these transferases evolved to metabolize endogenous compounds, such as bilirubin, catecholamines, and steroids, and not as detoxification enzymes.[166]

Table 4.6 illustrates the functional groups, generally nucleophilic heteroatoms, that form glucuronides and examples of the reactions. The glucuronides formed from these functional groups have different properties. Stability is among the most important with respect to detoxification. Breakdown of the glucuronide can lead to reformation of the parent compound and in certain cases the production of highly reactive electrophilic species. These reactive species may be responsible for the production of acute and chronic toxicity by covalent binding to nucleophilic sites on tissue macromolecules.

Among the most commonly encountered glucuronides are those involving linkage of glucuronic acid and the xenobiotic through an oxygen atom. These O-glucuronides may form with a number of chemical classes, including aryl, alkyl, and acyl compounds, as illustrated in Table 4.6.

The alkyl-O-glucuronides are ether-linked glucuronides that can form from a variety of primary, secondary, and tertiary alcohols. Although generally stable at physiological conditions, they can be hydrolyzed under acidic conditions.

The enolic glucuronides are formed from aglycones without a free hydroxyl group. Glucuronides are formed from the enolized keto group. These conjugates lack the stability of the ether glucuronides and are susceptible to both acid and alkaline hydrolysis. They are more stable at neutral and alkaline pH than in acid conditions. Ester glucuronides can be produced from a variety of carboxylic acids, including primary, secondary, and tertiary aliphatic acids and both aryl and heterocyclic compounds. They generally are stable in acidic conditions but are susceptible to alkaline hydrolysis.

The chemical properties of N-glucuronides are different from those of O-glucuronides. One of the most important of these is their lack of stability. They are especially unstable at pH below neutrality. The instability of these compounds may have important biological consequences; examples are discussed in more detail later. Quaternary ammonium N-glucuronides are formed by N-glucuronidation of cyclic and acyclic tertiary amines. These charged metabolites may be formed in higher primates while not being found in other animal models, such as the rat.

The S-glucuronides are not as commonly encountered as the O-glucuronides, but they represent important detoxification pathways for thiolic compounds. Their stability is similar to that of the O-glucuronides.

The C-glucuronides represent recently recognized conjugates, and only a few examples are known, such as phenylbutazone. Generally, they appear to be formed by the transferase, but other possible mechanisms of formation have been suggested.

Role of UDP-Glucuronosyltransferases in Detoxification and Metabolic Activation

The foregoing discussion indicates that the UDPGTs play a critical role in the metabolism and detoxification of xenobiotics. Some substrates require functionalization by the monooxygenase before metabolism by the transferase, whereas others can be directly conjugated. The conjugates are more water soluble than the parent xenobiotic, and some readily form salts. Addition of the glycone may enable some of the conjugates to be more readily excreted through carrier-mediated mechanisms. Mechanisms other than increased excretion rates may also be important. The addition of the relatively bulky glycone may hide or hinder the biological

reactivity of particular functional groups on the xenobiotic. In addition, binding of the toxicant to particular receptors responsible for toxicity may be blocked. Overall, these mechanisms represent an efficient system for detoxification. On the other hand, glucuronidation of certain compounds represents a metabolic activation where the product is more toxic than the parent compound.

Aromatic amines are among the most studied examples of the role glucuronidation plays in metabolic activation of carcinogens. These glucuronides transport the proximate carcinogen to the target site, where it decomposes to the species that react with cellular macromolecules producing the biochemical lesion responsible for generating the pathological lesion.

Several of the arylamines are potent bladder carcinogens, including 4-aminobiphenyl, 1-naphthylamine, and benzidine. Metabolic activation of these carcinogens to the ultimate carcinogen appears similar and requires the action of UDPGT. Metabolic activation begins with P450-dependent activation of the arylamine to the proximate carcinogen, an *N*-hydroxyarylamine. Other specific ring-hydroxylated forms may be produced and may represent more stable products. The unstable *N*-hydroxyarylamines are then converted to stable N-glucuronides. These N-glucuronides are transported to the bladder. In the bladder, the N-glucuronides are subject to β-glucuronidase activity, which splits off the aglycone. They are also subject to hydrolysis in acidic urine producing the *N*-hydroxyarylamine. The *N*-hydroxyarylamine spontaneously converts to the electrophilic arylnitrenium ion. A similar mechanism involving sulfonation-mediated formation of this reactive species is illustrated later in the chapter. The electrophilic arylnitrenium ion can then react with nucleophilic centers on macromolecules of the bladder epithelium, especially DNA, to initiate tumor formation. The concentration of the glucuronide in the bladder, in combination with the time the glucuronide remains in the bladder, can modify the potential for tumor formation. Glucuronides may function in this manner with a number of carcinogens and be important in explaining why certain target organs are susceptible to a specific carcinogen and others are not susceptible. In the earlier example, glucuronidation may protect the liver but makes the bladder, the target organ, susceptible.

Glucuronidation has also been implicated in adverse drug reactions of certain carboxylic drugs that have resulted in a toxic immunological response. It is believed that a reactive glucuronide covalently binds to cellular proteins that act as haptens, producing an anaphylactic reaction. Glucuronidation of the carboxylic acid moiety of drugs such as diclofenac, a nonsteroidal anti-inflammatory drug, leads to an unstable and reactive acyl glucuronide metabolite. The conjugate then undergoes transacylation of protein nucleophiles by the 1-*O*-acylglucuronide or glycation of proteins via mechanisms that involve open-chain aldehyde reactions with protein amino groups. These drug–protein adducts are believed to be recognized as foreign by the immune system, resulting in an immune response and thereby leading to the associated idiosyncratic hepatoxicity.[167]

Species, Gender, and Genetic Differences in UDP-Glucuronosyltransferase Activity

Studies of species, strain, and gender differences in glucuronidation are complicated by a number of factors. Activity may be affected by age, hormonal status, environmental exposure to xenobiotics in the diet and other sources, and nutritional status. Factors associated with the methodology to determine differences in glucuronidation also play a role, including substrate, assay method, method of freeing latent activity, and the method of isolating the preparation employed to measure activity. This has led to a number of reports of differences in activity that could be artifactual; however, the large number of reports concerning differences in glucuronidation among species, strains, and the sexes indicate that certain of these differences are real and may have a genetic basis.

As mentioned previously, lower animals, including prokaryotes and invertebrates, do not produce glucuronides. Fish and reptiles do demonstrate glucuronidation of xenobiotics but vary dramatically in activity, which is generally at least 10-fold lower than mammalian activity. Birds have glucuronidation ability similar to that of mammals.

Differences among mammalian species in their ability to glucuronidate a xenobiotic may be quite large, as is the case for the human immunodeficiency virus (HIV) drug zidovudine. This drug is eliminated in the rat and dog primarily unchanged, whereas the glucuronide represents the majority of metabolites in monkeys and humans.[168] The guinea pig generally has higher activity than most other laboratory species. This higher activity may be associated with less latent enzyme activity, as its UDPGTs can be activated by much gentler methods than other species. Cats are well known for their extremely low transferase activity. Although capable of forming glucuronides with endogenous compounds, they form only low levels of or no glucuronides with xenobiotics.

Glucuronidation of amines is divided into two groups: nonquaternary N-conjugates and quaternary N-conjugates. Major qualitative species differences do not appear to exist in the conjugation of the primary and secondary amines, sulfonamides, arylamines, and cyclic and heterocyclic amines to form nonquaternary N-conjugates, although quantitative differences do exist. Quaternary glucuronidation occurs in primates, including humans, but not in other species. In humans, quaternary-ammonium-linked glucuronides of aliphatic amines appear to be produced by UGT1A3 and UGT1A4.[170,171]

A well-known example of a strain difference is the almost complete lack of bilirubin glucuronidation in the Gunn rat. This rat strain also has low activity toward a number of xenobiotic substrates but normal activity toward others. There is a genetic component to this, with the low activity being autosomally recessive. The mutation in the Gunn rat responsible for its lack of bilirubin conjugation occurs in the UGT1 family and affects this entire group of isozymes. A frameshift mutation occurs because of a deleted guanine that results in a TGA stop codon occurring sooner than normal. This mutation results in a protein missing 115 amino acids that

constitute a hydrophobic region associated with insertion of the protein into the membrane. Lack of insertion negates the activity of this enzyme form and results in degradation of the incomplete protein. The genes in the UGT2 family are normally expressed in the Gunn rat.

Similar defects occur in humans and result in unconjugated hyperbilirubinemias. Gilbert's syndrome is a milder form of the disease that occurs in 2%–5% of the population. This large prevalence in the population makes it an important human genetic deficiency when considering interindividual variation in xenobiotic metabolism. These patients are characterized by mild, chronic, unconjugated hyperbilirubinemia that produces jaundice and an impaired ability to metabolize menthol. Decreased clearance of several drugs, including tolbutamide, rifamycin, josamycin, and paracetamol, has been observed. Crigler–Najjar syndrome is a familial form of severe unconjugated hyperbilirubinemia. Infants often develop severe neurological damage from bilirubin encephalopathy (kernicterus). Patients are divided into two types. Type I is more severe (unconjugated bilirubin, >20 mg/dL) and not responsive to barbiturate or glutethimide therapy. Type II patients respond to induction by PB, which suggests a fundamental difference from type I in the molecular basis of the genetic defect. Type I results from mutations in the UGT1 family that produces a loss of bilirubin conjugation,[172] whereas less severe mutations occur in type II that produce a decrease, but not a loss, of activity.

Gender differences appear hormonally related[173] and can be substrate dependent. Although it is sometimes stated that males have higher glucuronidation activity than females, this is substrate dependent, and no general classification should be made. Like monooxygenase activity, activity may be sensitive to imprinting or programming during the neonatal period. As with species and strain differences, care must be taken when extrapolating data obtained with one substrate to other substrates. Glucuronidation of estradiol and estrone is higher in female rats than male rats.[174] Paracetamol, oxazepam, and diflunisal are cleared 30%–50% faster in males, due primarily to enhanced glucuronidation.

Induction of the Glucuronosyltransferases

UDP-glucuronosyltransferases are inducible enzymes, much like cytochrome P450, and are inducible by some of the same chemicals. Evidence of a true induction process involving de novo protein synthesis and increases in mRNA has been observed for induction of the UDPGTs by PB. Most inducers of CYP1A, CYP2B, CYP3A, and CYP4A can induce these transferases. Rat UGT1A6 and UGT1A7 and human UGT1A6 and UGT1A9 are polycyclic-hydrocarbon-inducible transferases. Induction appears mediated by the Ah receptor. Rat UGT1A7 and human UGT1A9 have high activity toward the phenolic and diphenolic metabolites of polycyclics, such as BP.[175] Few specific inducers of the transferases that do not also induce the monooxygenase are known. For example, trans-stilbene oxide and ethoxyquin appear to only induce the transferases, but more studies are needed to determine if this is a true induction. Induction of the transferases modifies the toxicity of xenobiotics in a manner similar to induction of P450, as previously discussed.

Sulfonation: Sulfotransferases

Sulfonation of xenobiotics and endobiotics is catalyzed by a set of enzymes called *sulfotransferases* (SULTs). These enzymes belong to a multigene family and occur in prokaryotes, plants, and animals. Some of the enzymes are membrane bound and others occur in the cytosol. The membrane-bound SULTs are found in the Golgi membranes and are involved in the sulfonation of endogenous compounds, such as glycosaminoglycans, glycoproteins, and proteins, and peptides secreted by the Golgi apparatus; they are not involved in xenobiotic metabolism. The soluble or cytosolic SULTs catalyze the sulfate conjugation of a variety of substrates, including steroid hormones such as 17β-estradiol and dehydroepiandrosterone; thyroid hormones; catecholamines and xenobiotics, such as *N*-hydroxy-2-acetylaminofluorene; isoflavones; and many drugs, including acetaminophen and minoxidil. For the most part, sulfonation of xenobiotics results in metabolites that are less toxic than the parent compound; however, the SULTs, like many xenobiotic metabolism enzymes, can produce metabolically activated products that have mutagenic and carcinogenic potential.

Until recently, the SULTs have not been as intensely investigated as some of the other xenobiotic metabolism enzymes. Lately, interest has been renewed in these enzymes, particularly their description at the gene level. Utilization of the tools of molecular biology has provided new insight into their roles in metabolism, has revealed the complexity of their gene family, and has enabled development of a nomenclature system.[176–178] The ability to sequence the SULTs, identify new isoforms of these enzymes, and measure their activity with increased sensitivity has progressed faster than our understanding of their individual roles in xenobiotic metabolism.

Biochemistry of Sulfonation

A limiting factor in the sulfonation of xenobiotics by the SULTs is the availability of 3-phosphoadenosine-5′-phosphosulfate (PAPS).[179,180] As illustrated in Figure 4.14, PAPS is synthesized in a two-step process. The first step is formation of adenosine-5′-phosphosulfate (APS) catalyzed by ATP-sulfurylase. Although the synthesis of APS from sulfate and ATP is not energetically favored, the rapid hydrolysis of pyrophosphate and the rapid utilization of APS as a substrate for APS-kinase drive the reaction toward APS synthesis. APS-kinase catalyzes synthesis of PAPS from APS and ATP. This enzyme is tightly coupled with the ATP-sulfurylase, which results in the rapid utilization of APS.

Tissue concentrations of PAPS are relatively low compared to UDPGA, the active form of glucuronic acid used in glucuronidation. During active sulfonation, PAPS becomes rapidly depleted; for example, the SULT has a high affinity for acetaminophen, which forms a sulfate conjugate. At low doses, rats excrete the sulfated acetaminophen as a major urinary metabolite. As the dose of acetaminophen is increased,

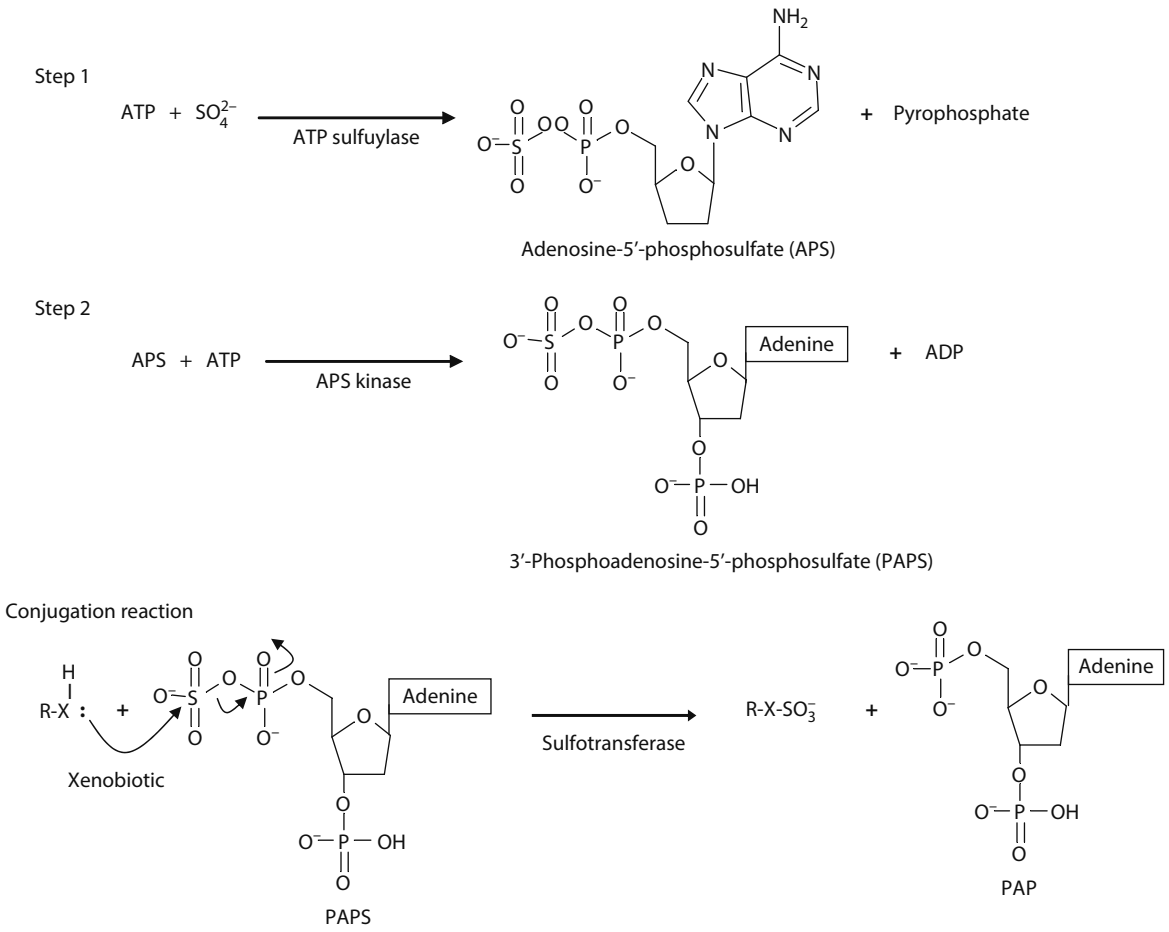

FIGURE 4.14 Reactions catalyzing the formation of PAPS and the xenobiotic–sulfate conjugate. X in the conjugation reaction represents a nucleophilic atom in a functional group such as oxygen in a hydroxyl group or nitrogen in an amine group.

the sulfate metabolite does not increase, whereas the glucuronide of acetaminophen increases dramatically; this is believed to be due to the limited availability of PAPS. The limitation in the synthesis of PAPS is sulfate. The major sources of sulfate include diet and degradation of sulfur amino acids (methionine and cysteine). These sources are inadequate to maintain sulfate concentrations for PAPS synthesis during rapid SULT activity. In the mouse, sulfonation appears more limited by SULT activity than by PAPS and sulfate.

Reactions Catalyzed by Sulfotransferases

As mentioned, SULTs esterify a variety of endogenous substrates, including steroids, carbohydrates, and proteins. Sulfonation also plays a role in the disposition of hormones. Sulfonation directs lipophilic compounds, such as the steroidal hormones, to more polar environments, including the active sites of enzymes, and to body fluids; for example, sulfonation enhances the elimination of steroids from the adrenal gland.[181] Sulfonation also facilitates deiodination of thyroid hormone and is a rate-limiting step in one of the elimination pathways of thyroid hormone.[182]

Xenobiotic conjugation with sulfate is an important route for the conversion of lipophilic xenobiotics to more readily excreted polar metabolites.[183,184] Sulfonation of xenobiotics with an aliphatic or aromatic hydroxyl group readily occurs; for example, phenol is excreted as its sulfate conjugate (Figure 4.15). Often, it is necessary for phase I metabolism to functionalize a xenobiotic with a hydroxyl group before it can be sulfated; for example, toluene is oxidized to benzyl alcohol before conjugation with sulfate (Figure 4.15).

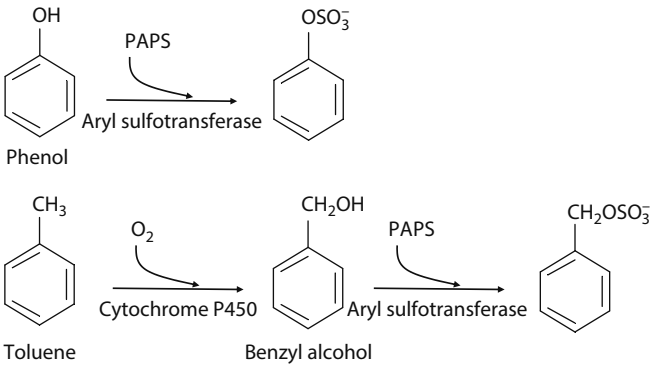

FIGURE 4.15 SULT-catalyzed sulfonation of phenol and toluene.

Role of Sulfotransferases in Detoxification and Metabolic Activation

Alcohols, phenols, aliphatic and aromatic amines, and aromatic hydroxylamines and hydroxylamides can be sulfated. These same groups can form glucuronides. At low doses, sulfonation may play an important role in detoxification of xenobiotics; however, as acetaminophen demonstrates, at high doses, glucuronidation becomes more important because of sulfate limitations. Secondary effects may be produced by the sulfonation lowering sulfate availability for the sulfonation of endogenous substrates. Depletion of sulfate pools as a result of the metabolism of high doses of drugs has been proposed to interfere with the normal biosynthesis of glycosaminoglycans during development, resulting in teratogenic effects in animals.[185] SULTs can be involved in the conversion of prodrugs to their active forms; for example, minoxidil is sulfoconjugated to its active form, which is more active as an antihypertensive and hair-growth stimulant than the parent drug.

SULTs can be involved in the metabolic activation of a number of mutagens and carcinogens. One of the best known examples is the metabolic activation of the carcinogen 2-acetylaminofluorene (2-AAF) (illustrated in Figure 4.16). N-Hydroxylation of the amide nitrogen by monooxygenases is followed by sulfonation of the N-hydroxy group. The sulfate ester is unstable and decomposes to an electrophilic nitrenium–carbonium ion, resonance ion that can form covalent adducts at nucleophilic sites on macromolecules. The support for the hypothesis that the sulfate conjugate of 2-AAF is the reactive metabolite comes from studies indicating that factors that modulate SULT activity also modulate 2-AAF carcinogenicity. Male rats have higher SULT activity and develop more 2-AAF-induced tumors than females. Reduction of SULT activity in male rats by castration, hypophysectomy, thyroidectomy, or steroid hormones reduces 2-AAF covalent adducts. These results are consistent with the hypothesis that sulfonation of 2-AAF is required for covalent modification of DNA. This mechanism is at least partially responsible for the activation of several other xenobiotics, including aromatic amines, mono- and dinitrotoluene, *N*-hydroxyphenacetin, 1′-hydroxysafrole, N^3-hydroxyxanthine, and other *N*-hydroxyarylamides.[186] Secondary nitroalkanes, such as 2-nitrobutane and 3-nitropentane, can be metabolically activated to mutagens by aryl SULT and hepatocarcinogens. Primary nitroalkanes, such as 1-butane and 1-nitropentane, are not activated by aryl

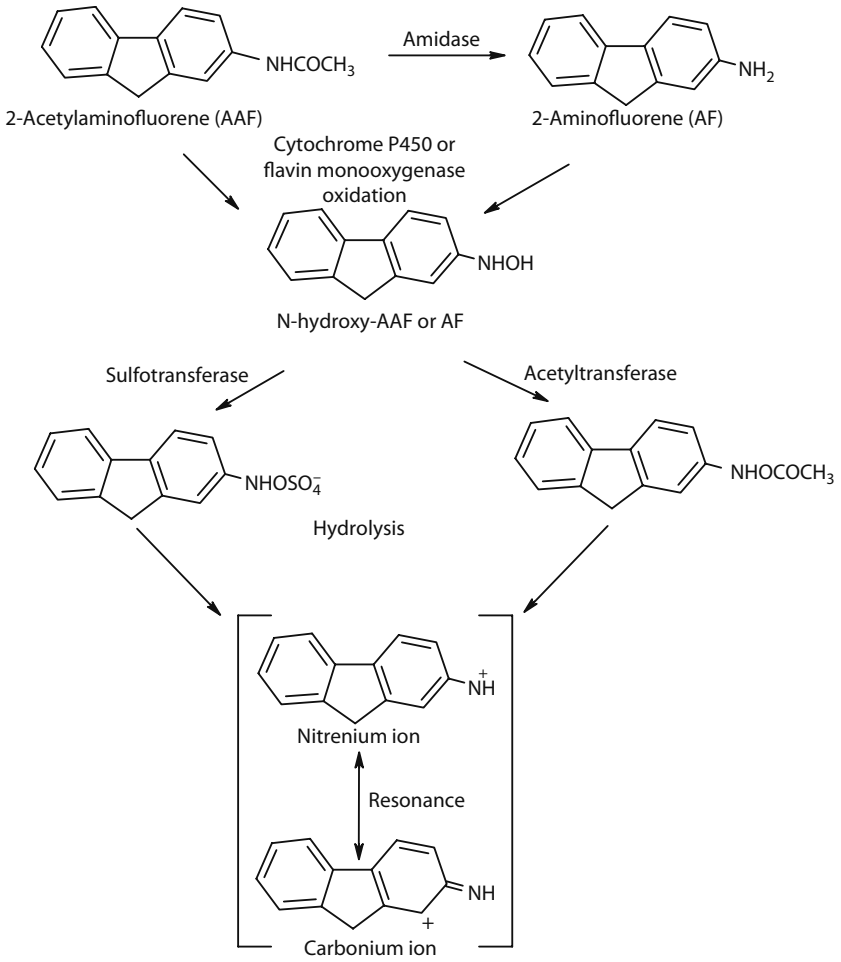

FIGURE 4.16 Metabolic activation of 2-acetylaminofluorene to a reactive metabolite capable of covalent modification of macromolecules.

SULT.[187] Mutagenicity testing is frequently hampered by the fact that phase II metabolic activation systems are typically not present in standard Ames bacterial mutagenesis assays, which do simulate phase I activation. New systems are being developed in which SULT genes are expressed in Salmonella strains and Chinese hamster V79 cells and are yielding a diverse set of structures capable of being activated by SULTs to mutagenic metabolites.[188]

SULTs can metabolically activate certain products of CYP1A1 metabolism of polycyclic hydrocarbons; for example, 9-hydroxymethylbenzo(*a*)pyrene can be sulfated to yield a highly reactive sulfate ester that is heterolytically cleaved to produce an electrophilic cation that damages DNA, RNA, and protein. In addition, 6-hydroxymethylbenzo(*a*)pyrene can be activated to the carcinogenic 6-sulfooxymethylbenzo(*a*) pyrene by rat and mouse SULT.[189] Other examples include 5-hydroxymethylchrysene and 7,12-dihydroxymethyl benz(a) anthracene.[190]

Sulfotransferase Isoforms, Genetics, and Species Differences

SULTs belong to a multigene family that produces a number of distinct enzymes that have different, but overlapping, substrate specificities. Some of these enzymes demonstrate species and tissue specificity in their expression. The nomenclature used to describe these enzymes is still evolving, but recently a system for classifying the cytosolic SULT superfamily has been proposed.[191] Membrane-bound SULTs that are localized to the Golgi apparatus exhibit a low degree of amino acid sequence identity with the cytosolic SULTs, and although they exhibit some structural similarity to cytosolic isoforms, they are generally considered a separate superfamily. The cytosolic SULTs are typically involved in xenobiotic metabolism; thus, their genetics and nomenclature is discussed here. The cytosolic form is identified by the abbreviation SULT.

More than 56 distinct eukaryotic SULT isoforms have been identified and functionally characterized.[191] SULT families are identified by the Arabic numeral immediately following the name and subfamilies identified by alphabetical categories (Figure 4.17). Unique subforms are further identified by an additional Arabic numeral; however, in some cases, such as SULT2A1, the standard nomenclature has been relaxed to accommodate more historic identifiers.

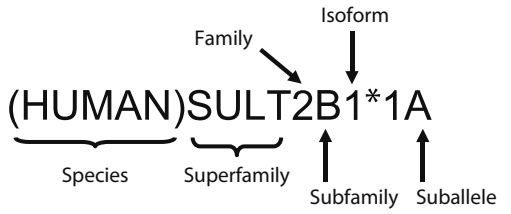

FIGURE 4.17 Naming convention illustrated for a representative cytosolic SULT allele name. A complete SULT allele name contains species, superfamily, family, isoform, allele, and suballele designations as shown. (Adapted from Blanchard, R. et al., *Pharmacogenetics*, 14, 199, 2004.)

Human genes are capitalized, while rat and mouse genes are in lowercase letters. To further facilitate the identification of orthologous SULT isoforms in different species, a three- to five-letter species code is placed in front of the SULT.

Many of the SULTs commonly encountered in xenobiotic metabolism are listed in Table 4.6. The SULT1 family, also known as the phenol SULTs, is comprised of at least 11 isoforms and is one of the most commonly encountered forms of SULT. The 1A isoforms are frequently referred to as phenol SULTs because of their high substrate specificity for phenolic xenobiotic molecules such as 17α-ethinyl estradiol, acetaminophen, minoxidil, and isoflavones but also for endogenous substrates such as 17β-estradiol, triiodothyronine, and thyroxine. The 1A isoform is highly expressed in liver and in brain, breast, intestinal epithelium, endometrium, kidney, lung, and platelets. The 1B forms also catalyze sulfate conjugation of typical phenolic substrates but are the major SULTs for thyroid hormones because of their high affinity for these substrates. The 1B form has been found in tissues such as liver, colon, small intestine, and white blood cells. The SULT1C family is involved in the sulfonation of *N*-hydroxyacetylaminofluorene, phenol, and other prototypical phenolic substrates. The SULT1E subfamily also catalyzes the sulfonation of phenolic substrates but has a much lower affinity than that of the 1A subfamily. The SULT1E isoforms are typically found in liver and small intestine.

The SULT2 family, also known as the hydroxysteroid SULTs, consists of two subfamilies, 2A and 2B, and typically catalyzes sulfate conjugation of 3β-hydroxy groups of steroids. The 2A family catalyzes the sulfonation of a range of xenobiotics, including benzylic alcohols of PAHs, and is expressed in adrenal gland, liver, brain, and intestine. 2B isoforms have only been identified in human prostate, placenta, and trachea and in mouse intestine, epididymis, and uterus.

Additional information on the SULT gene family, their nomenclature, and substrate specificities can be found in Blanchard et al.[191]

Humans demonstrate SULT genetic polymorphisms, which help explain some of the differences between individuals in response to specific xenobiotics.[192] SNPs have been identified in most isoforms but are more common in some isoforms than others. Allele frequency has been associated with certain ethnic groups and may contribute to differential drug responses in these individuals. For example, evidence is emerging that women carrying the SULT1A1*2 allele, which is associated with diminished capacity to sulfate SULT1A1 substrates such as the active antiestrogen 4-hydroxytamoxifen, show increased survival, perhaps as a result of improved drug exposure.[193] Because SULTs do not appear to be as sensitive to induction, exposure to xenobiotics may not be as important as with some of the other xenobiotic-metabolizing enzymes in producing individual variations in metabolism.

Sulfonation occurs in most species, including mammals, birds, reptiles, amphibians, fish, and invertebrates. The most notable exception to this is the low SULT activity in the pig. Members of the cat family are deficient in

glucuronyltransferase activity but have high SULT activity. This balance of glucuronyltransferase and SULT must always be kept in mind when evaluating the activity of either enzyme system. A deficiency in one pathway can shift metabolism, as similar functional groups are conjugated by the two enzyme systems. In addition, sulfonation appears to have high affinity but low capacity for phenols, whereas glucuronidation has low affinity and high capacity for these substrates.

Sulfonation of acetaminophen is limited by PAPS availability in rats. In mice, acetaminophen sulfonation is limited by lower SULT activity. Although mice have lower PAPS synthetic capability than rats, lower SULT activity is the major limiting factor in mice.[145] When the activities of acetaminophen SULT and 17α-ethinylestradiol SULT in hepatic preparations from monkeys, dogs, and humans were compared, rhesus and cynomolgus monkeys and dogs had higher acetaminophen SULT activity than humans.[194]

Factors Modifying Metabolism

SULTs are not induced by the classical inducers, PB and 3-methylcholanthrene, and these compounds may actually suppress their expression.[195] Several inhibitors of SULT have been discovered and exploited experimentally to study these enzymes. Pentachlorophenol and 2,6-dichloro-4-nitrophenol are potent SULT inhibitors. Only 0.2 μM pentachlorophenol is required for 50% inhibition of 2-dichloro-4-nitrophenol sulfonation by purified arylsulfotransferase.[196] Pentachlorophenol and 2,6-dichloro-4-nitrophenol are effective inhibitors because the ortho- and para-aromatic ring positions are substituted with electron-withdrawing groups. This effect is consistent with the mechanism whereby the SULTs facilitate electrophilic attack of the hydroxyl oxygen by the sulfur.

Gender Differences

Major gender differences have been observed in the sulfate conjugation of steroid hormones; for example, compared to female rats, male rats have a 10-fold higher expression level of SULT1C1, the isoform implicated in *N*-hydroxyacetylaminofluorene metabolism.[197] This male dominant pattern emerges at 40–50 days of age and is under gender-specific patterns of growth hormone control. Three steroid SULTs have been isolated from rat liver, and it is the relative amounts of these isozymes that account for the large gender difference. Aryl SULT concentrations in the livers of male rats were higher than in females; in contrast, hydroxysteroid SULT concentration was higher in the liver of female rats compared to males.[197,198]

Lower SULT activity observed in neonatal rats has been attributed to sexual immaturity because as gonads develop, SULT activity increases. Newborn infants, who characteristically exhibit pronounced immaturity in glucuronidation, have a fully developed phenol SULT activity; for example, newborns excrete acetaminophen as a sulfate conjugate, whereas adults primarily excrete it as a glucuronide conjugate. Chloramphenicol is extremely toxic in neonates because it is a poor substrate for SULT and is primarily cleared by glucuronidation in adults. Gender differences in clinical pharmacokinetics related to SULT activity are not widely reported.

GLUTATHIONE S-TRANSFERASES

A family of enzymes known as glutathione S-transferases (GST) is capable of conjugating relatively hydrophobic electrophilic molecules with the reduced form of the intracellular nucleophile GSH (Figure 4.18).[199] These enzymes are ubiquitously expressed in mammals, but are found in highest concentrations in the liver, kidney, intestines, and lung, but they occur in most tissues. GSH conjugates have higher molecular weights and are more water soluble and therefore more readily excreted than are the parent compounds. Further, GSH conjugates are substrates for several transporters involved in biliary and renal excretion, which facilitates their clearance from the body. In general, though not invariably, conjugation with GSH decreases the likelihood that a xenobiotic will react with toxicological targets.

Synthesis and Regulation of Glutathione

GSH, the essential cofactor for GSTs, is a tripeptide composed of glutamate, cysteine, and glycine. In contrast to the α-linkage normally found in most peptides, the glutamate and cysteine of GSH are joined by a γ-linkage, which confers resistance to hydrolysis by peptidases (Figure 4.18). Synthesis of GSH is carried out in two sequential steps (Figure 4.19). The first of these is catalysis by γ-glutamylcysteine ligase (GCL), which results in formation of the γ-linkage between glutamate and cysteine. The reaction requires ATP and is the rate-limiting step in GSH synthesis. GCL is a dimeric protein composed of a catalytic subunit that provides ligase activity and ATP hydrolysis and a regulatory subunit that lowers the K_m for glutamate.[200] The second step of GSH synthesis, addition of the glycine residue, is catalysis by GSH synthetase, another ATP-dependent enzyme. Regulation of GSH synthesis is mediated by GCL, which is sensitive to cellular redox status and GSH concentration. GCL is also regulated at the transcriptional level in conjunction with GSTs. Buthionine *S*-sulfoxime is a potent inhibitor of GCL that has been used extensively to study the biological and toxicological roles of GSH. Cysteine, which is the rate-limiting substrate for GSH synthesis, may come from several sources, including cystine, methionine, and the recycling of GSH itself, as depicted in Figure 4.19.[201]

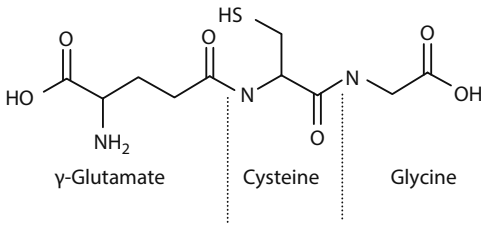

FIGURE 4.18 Structure of glutathione. Note the unusual γ configuration of the linkage between glutamate and cysteine.

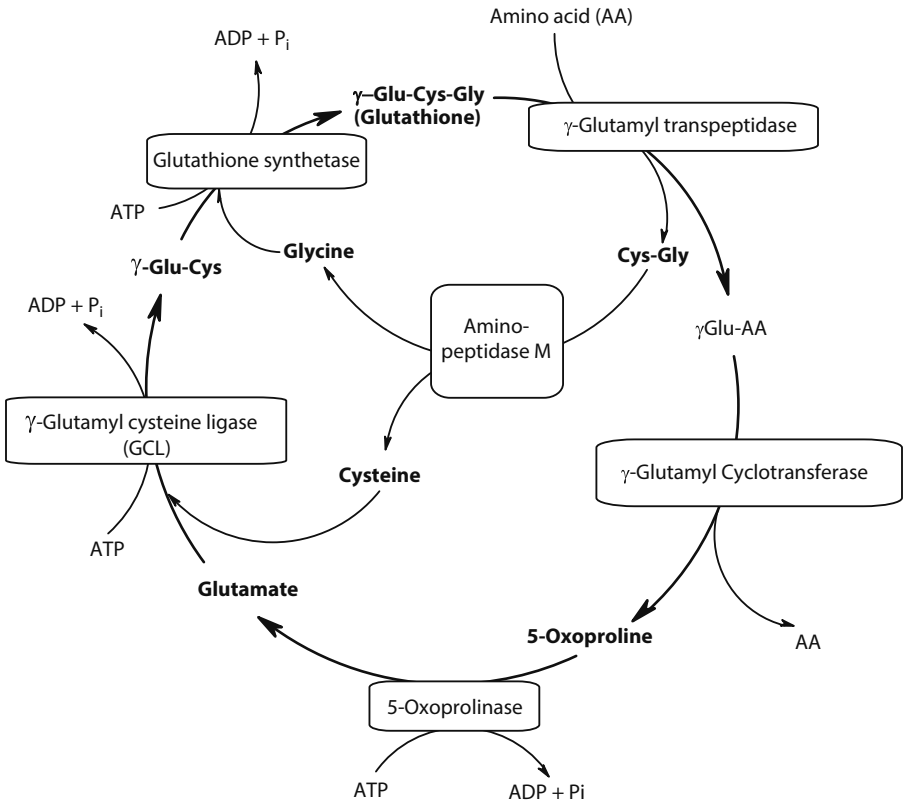

FIGURE 4.19 The γ-glutamyl cycle: biosynthesis of glutathione. Cysteine for glutathione synthesis may come from other sources, including cystine and methionine.

Organization, Structure, and Localization of GSTs

The mammalian GST superfamily is composed of three major families of proteins, which are expressed in the cytosol, mitochondria, and endoplasmic reticulum.[202] The cytosolic and mitochondrial proteins are dimeric, while the microsomal forms may exist as monomers, trimers, or higher-order aggregates.[202,203] The current nomenclature is based on amino acid sequence similarity and subunit composition. Enzymes within a class share >40% sequence similarity (generally, ~70%), while different classes have <25% sequence similarity. In humans, 11 major classes of GSTs have been identified. The cytosolic GSTs make up the largest family and include the alpha (α), mu (μ), pi (π), sigma (σ), theta (θ), zeta (ζ), and omega (ω) classes. The mitochondrial isoform, only a single member of which has been identified, is designated as the kappa (κ) class. The microsomal GSTs are designated as the membrane-associated proteins in eicosanoid and glutathione metabolism (MAPEGs), to reflect their predominant role in eicosanoid synthesis.

Cytosolic GSTs

The cytosolic GSTs are the major isoforms involved in xenobiotic metabolism, comprising over 95% of total cellular GSTs. Cytosolic GSTs are dimeric proteins with subunit molecular weights of approximately 22–26 kDa. Seven classes of cytosolic GSTs have been identified in humans, with varying numbers of distinct subunits in each class, each of which is encoded by a separate gene. The α and μ classes each have five subunits, the θ and ω classes each have two subunits, and only a single subunit has been identified for each of the π, σ, and ζ classes. Subunits from the α and μ classes can form heterodimers with other members of their class, but other classes of cytosolic GSTs exist only as homodimers. Cytosolic GSTs are named using an uppercase letter to designate class (A, M, P, S, T, Z, or O), followed by Arabic numerals to designate subunit composition[206]; for example, GSTA1-1 is an α-class homodimer of subunit 1. Previous GST nomenclature systems were based on either apparent substrate selectivity or elution order from chromatography columns,[204] and these designations are found in the older GST literature.

Like the cytochromes P450, the cytosolic GSTs exhibit broad and overlapping substrate specificities. The substrates for all isoforms are hydrophobic compounds possessing an electrophilic center. In addition to conjugation of xenobiotics, cytosolic GSTs play a role in metabolism of endogenous compounds, including amino acids, steroid hormones, and eicosanoids.[202,203,205] Cytosolic GSTs are also capable of binding chemicals on the enzyme surface. This binding may or may not inhibit the catalytic activity of the enzyme, but it prevents the xenobiotic from interacting with other critical cellular sites, such as proteins and nucleic acids. Some GSTs had previously been termed ligandins because of this property.[206,207]

Mitochondrial GSTs

Mitochondrial GSH constitutes approximately 10%–15% of the total cellular GSH pool, and several isoforms of GST have been identified in mitochondria. In rodents and humans, GST kappa (GSTK1-1) is a homodimeric mitochondrial GST containing a putative N-terminal mitochondrial targeting sequence that is responsible for its specific localization in mitochondria.[208] Structurally, mitochondrial GST is more similar to bacterial GSH-dependent isomerases and disulfide-forming oxidoreductases than it is to the mammalian cytosolic GSTs.[203] In rodents, GSTK is expressed at high concentrations in liver, kidney, stomach, and heart, but in humans, the tissue expression of this enzyme is ubiquitous. GSTK has high activity for 1-chloro-2,4-dinitrobenzene (CDNB) and cumene hydroperoxide, as well as eicosanoid peroxides such as (S)-15-hydroperoxy-5,8,11,13-eicosatetraenoic acid. Several other isoforms of GST are also found in mitochondria, including GSTA4-4, for which 4-hydroxynonenol is a preferred substrate.[209] Mitochondrial GSTs are thought to mediate diverse biological activity including signal transduction, and response to oxidative stress and dysfunction of mitochondrial GSTs has been associated with ageing and with various disease states such as diabetes and ischemia–reperfusion injury.[208] In addition to mitochondria, GSTK has also been found associated with peroxisomes, where it may play a role in fatty acid β-oxidation.[211] Its role in the metabolism of environmental chemicals and drugs remains to be elucidated.

Microsomal GSTs

Microsomal GSTs, currently referred to as MAPEGS, are membrane-bound enzymes involved primarily in eicosanoid synthesis. MAPEGs are divided into four subgroups, of which three (I, II, and IV) are expressed in mammals. MAPEGS exist as homotrimers, in which each monomer binds one molecule of GSH.[212] Interestingly, only one of the three GSH molecules is present as the catalytically active thiolate form.[210] MGST1, MGST2, and MGST3 are all capable of conjugating a variety of xenobiotic electrophiles, and the latter two isoforms also function as leukotriene C4 synthetases. For example, MGST1 has been shown to catalyze regioselective and stereoselective conjugation of fluoroalkenes,[211] though no specific xenobiotic substrates have been identified to date. MAPEGS also play a role in protection against oxidative stress and are upregulated following oxidative insult or covalent modification by electrophiles.[212,213] Recently, MGST1 has been shown to be highly expressed in a variety of different tumor cell types and, in some cases, correlates with poor response to chemotherapy, suggesting a potential role for this isoform in drug resistance.[214] Although MAPEGS are clearly capable of detoxication of xenobiotics, their quantitative contribution to xenobiotic metabolism is unclear.

Biochemistry of Glutathione S-Transferases

GSTs involved in xenobiotic metabolism catalyze the conjugation of GSH with substrates bearing an electrophilic atom.[215] The catalytic mechanism of GSTs involves stabilization of the S-deproteinated form of GSH (GS–). In the cytosolic classes of GST, this is accomplished by donation of a hydrogen bond to the glutathione cysteine sulfur, which effectively lowers the pK_a of the thiol to between 6 and 7.5. Thus, in the enzyme-bound state, the thiolate ion is the predominant form of GSH at physiological pH. The hydrogen bond may be provided by either tyrosine or serine, depending on the GST class. In the α-class enzymes, the thiolate receives additional stabilization from electrostatic interactions with an active site arginine residue, and similar stabilization by arginine is observed with MAPEGs.[213]

The substrate specificities of GSTs are broad and overlapping. The general structural characteristics of substrates for the cytosolic enzymes are that (1) they are relatively hydrophobic, (2) they possess an electrophilic center, and (3) they will react nonenzymatically with GSH at some measurable rate. The substrate selectivity of these enzymes is sensitive to small changes in the primary structure of the enzymes; for example, a GST of the π-class contains a tyrosine at a site important for selectivity (Tyr108), whereas a transferase of the α-class contains a valine. When the tyrosine of the π-class enzyme is replaced with a valine, its substrate selectively is changed toward that of the α-class. Similarly, by engineering minor modifications in GSTT1-substrate selectivity of this isoform can induce significant changes in the substrate-activity profile.[216,217]

Selective inhibitors of GST have been sought both as research tools and as potential therapeutic agents. Some commonly used inhibitors include ethacrynic acid, triphenyltinchloride, bromosulfophthalein, cibacron blue, and hematin.[218] Considering the broad substrate specificity of GSTs, it should not be surprising that the development of isoform-selective GST inhibitors has been challenging. A variety of chemotypes has been evaluated as selective GST inhibitors. These include GS–R conjugates (e.g., *S*-octylglutathione), GSH peptide analogs (e.g., substitution of SO_2NH for CONH in the γ-glu–cys linkage), nonpeptide GSH analogs, bivalent inhibitors that interact with both subunits of the dimeric protein simultaneously, and ligandin-type inhibitors.[219] These efforts have met with varying degrees of success, although truly isoform-selective inhibitors remain elusive.

Although not highly efficient in its reactions (relatively high K_m for the xenobiotic), GSTs are capable of catalyzing or reacting with a number of reactive chemical functional groups. Any lack of efficiency is made up for by the high cellular concentration of GSH and GST. Liver GSH concentrations are high (up to 10 mM), and GSTs can represent as much as 10% of the total hepatocellular proteins[220]; however, it is possible for GSH conjugation to become capacity limited at high doses of xenobiotics. GSH utilization can outstrip its synthesis, resulting in depletion, decreased conjugation, and increased toxicity.

Reactions of Glutathione S-Transferases

Some xenobiotics contain sufficiently electrophilic groups to react directly with GSH, whereas others must first undergo

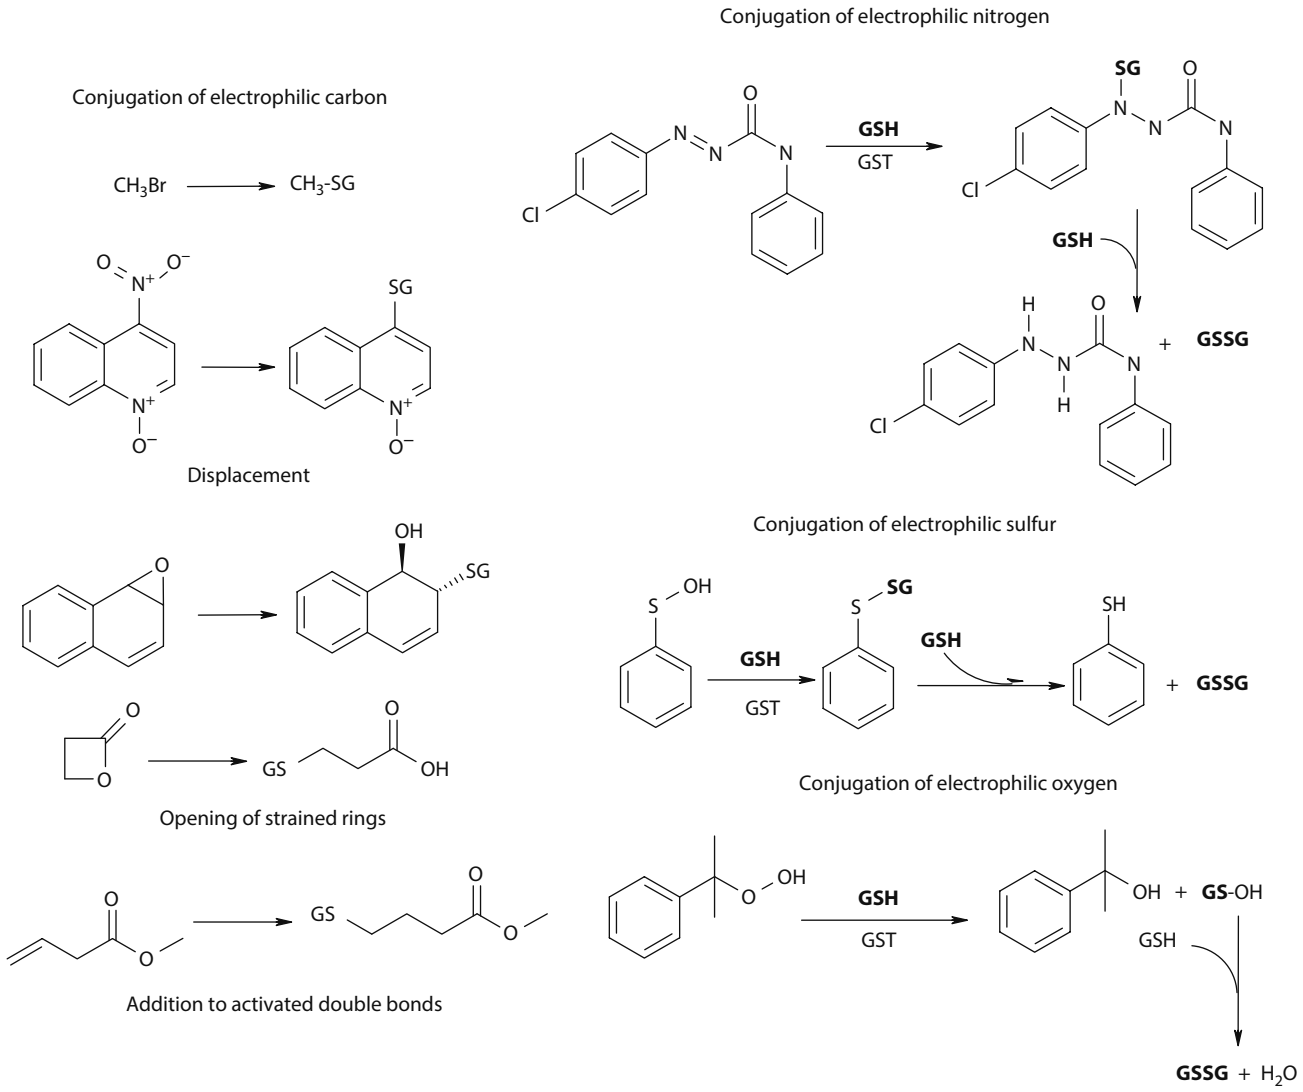

FIGURE 4.20 Examples of the reaction types catalyzed by GSTs.

phase I metabolism. Most xenobiotics react with GSH through the catalytic activity of the GSTs. GST reactions fall into four broad categories, as depicted in Figure 4.20: reaction with (1) electrophilic carbon, (2) nitrogen, (3) sulfur, or (4) oxygen.[221–223] For electrophilic heteroatoms, reaction with GSH results in formal reduction of the heteroatom with concomitant oxidation of GSH to its disulfide form (GSSG). The reactions types catalyzed by GST have been reviewed recently by Zimniak.[224]

Reaction with Electrophilic Carbon

The reactions of GSH with electrophilic carbon can be divided into three types: (1) displacement reactions, (2) opening of strained rings, and (3) addition to activated double bonds:

- Displacement of functional groups such as halides, sulfates, sulfonates, phosphates, and nitro groups from saturated or unsaturated carbon atoms. When carbon is bonded to an electronegative atom or group of atoms, electron density is drawn away from the carbon nucleus, creating an electrophilic center. Many electron-withdrawing groups make good leaving groups for nucleophilic substitution reactions. Such reactions occur for alkyl (sp^3-hybridized), olefinic, and aromatic (sp^2-hybridized) carbons. Displacement of the leaving group is facilitated if the saturated carbon atom bearing the leaving group is allylic or benzylic. Displacement of halide or nitro groups on aromatic rings can occur via an addition–elimination mechanism if the aromatic ring contains additional electron-withdrawing groups of sufficient strength (Figure 4.21). In this case, the rate of formation of a carbanion intermediate of the aromatic ring governs the overall rate of the reaction. Functional groups that withdraw electrons from the ring system stabilize the carbanion and are considered good leaving groups. On the other hand, electron-donating substituents

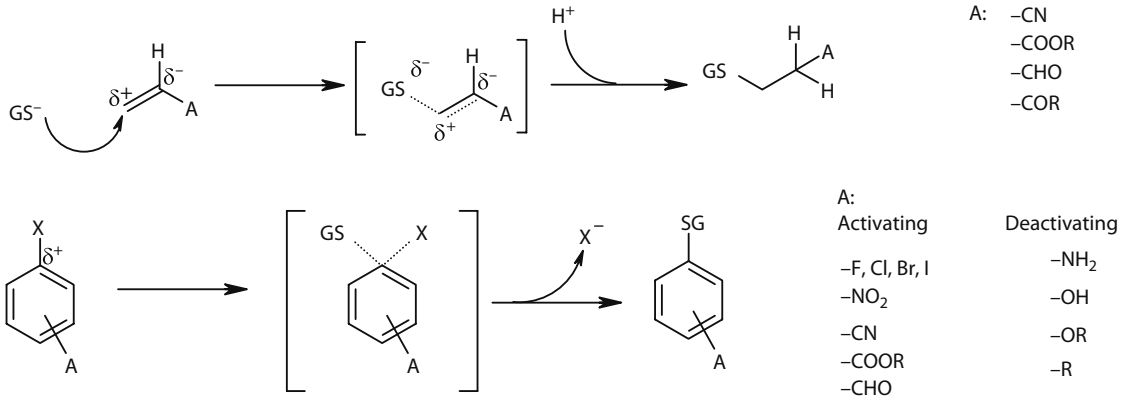

FIGURE 4.21 Putative reaction mechanisms for the GST-catalyzed Michael addition and aromatic substitution reactions. X represents a halogen atom, A represents the substituents listed to the right of each reaction, and R represents an alkyl group.

destabilize the anionic intermediate, deactivating the aromatic ring and making displacement of the leaving group by GSH less likely. A novel subclass of this reaction type that has received recent attention is transacylation with acylglucuronides and acyl-SCoA thioesters, which has been observed with a number of acidic drugs of toxicological interest.[225] Although this reaction is only weakly catalyzed by GSTs, the resulting conjugates may have significantly higher reactivity than the substrates, potentially contributing to toxicity of carboxylate-containing drugs.

- Opening of strained rings, such as epoxides and four-membered lactones. Ring systems with three or four members are highly strained, as the bond angles are forced from their minimum energy configuration (normally ~109° for sp^3-hybridized carbon). The presence of a heteroatom in such ring systems decreases electron density at the adjacent carbon and predisposes it to nucleophilic attack and ring opening. An example, shown in Figure 4.20, is conjugation of the 1,2-epoxide of naphthalene, resulting in a 1-naphthol conjugate of GSH. These reactions can be stereoselective; for example, phenanthrene-9,10-epoxide is converted exclusively to the 9S,10S-diasteromeric conjugate by rat GSTM1-1, while GSTM2-2 produces approximately equal amounts of each diastereomer.[226] Epoxide products of P450 are detoxified by this reaction and are an example of a phase II conjugation of a phase I-activated metabolite.
- Addition to activated double bonds via Michael addition. The presence of a carbonyl or cyano group adjacent to an olefinic group polarizes the electrons in the olefin double bond, creating an electron-deficient center on the β-carbon. The GSH thiolate anion will attack β-unsaturated xenobiotics due to this partial positive charge on the β-carbon, leading to 1,2-addition of GSH across the double bond, as shown in Figure 4.21.

Reaction with Electrophilic Nitrogen

GSH can react with electrophilic nitrogen atoms, such as diazenes.[227] The reaction is exemplified by the GSH-dependent reduction of the diazenecarboxamide JK-914.[228] As seen in Figure 4.20, the first step of the reaction is analogous to the Michael addition of GSH to polarized olefins. In the second step, the initial addition product reacts nonenzymatically with a second molecule of reduced GSH, resulting in the reduction of the diazenecarboxamide to a hydrazide with concomitant formation of oxidized GSH.

Reaction with Electrophilic Sulfur

Alkyl and aryl thiocyanates are substrates for GST-catalyzed conjugations, as shown in Figure 4.20. Products of this nucleophilic attack of the thiolate ion on the sulfur of the xenobiotic result in a mixed disulfide and hydrogen cyanide. The mixed disulfide can react nonenzymatically with another molecule of GSH to yield a thiol of the xenobiotic (RSH) and oxidized GSH (GSSG).

Reaction with Electrophilic Oxygen

Figure 4.20 illustrates how GSH reacts with organic hydroperoxides in a two-step sequence. The first step is catalysis by GST, which forms an alcohol or phenol and a glutathione sulfenic acid intermediate (G-SOH). Another GSH reacts nonenzymatically with the sulfenic acid to form oxidized GSH and water. An example of this reaction with endogenous hydroperoxides is the conversion of hydroperoxy-prostaglandin F_{2c} to prostaglandin F_{α}. Cumene hydroperoxide is metabolized as rapidly by purified GSTs as the classical transferase substrate probe CDNB. Denitrosation of trinitroglycerol is another example of a reaction with electrophilic oxygen.

Metabolic Fate of Glutathione Conjugates: Mercapturic Acid Formation

Mercapturic acids are N-acetylated, S-substituted, cysteine conjugates that arise from conjugation of a xenobiotic with GSH.[229] The GSH conjugates formed in the liver and other

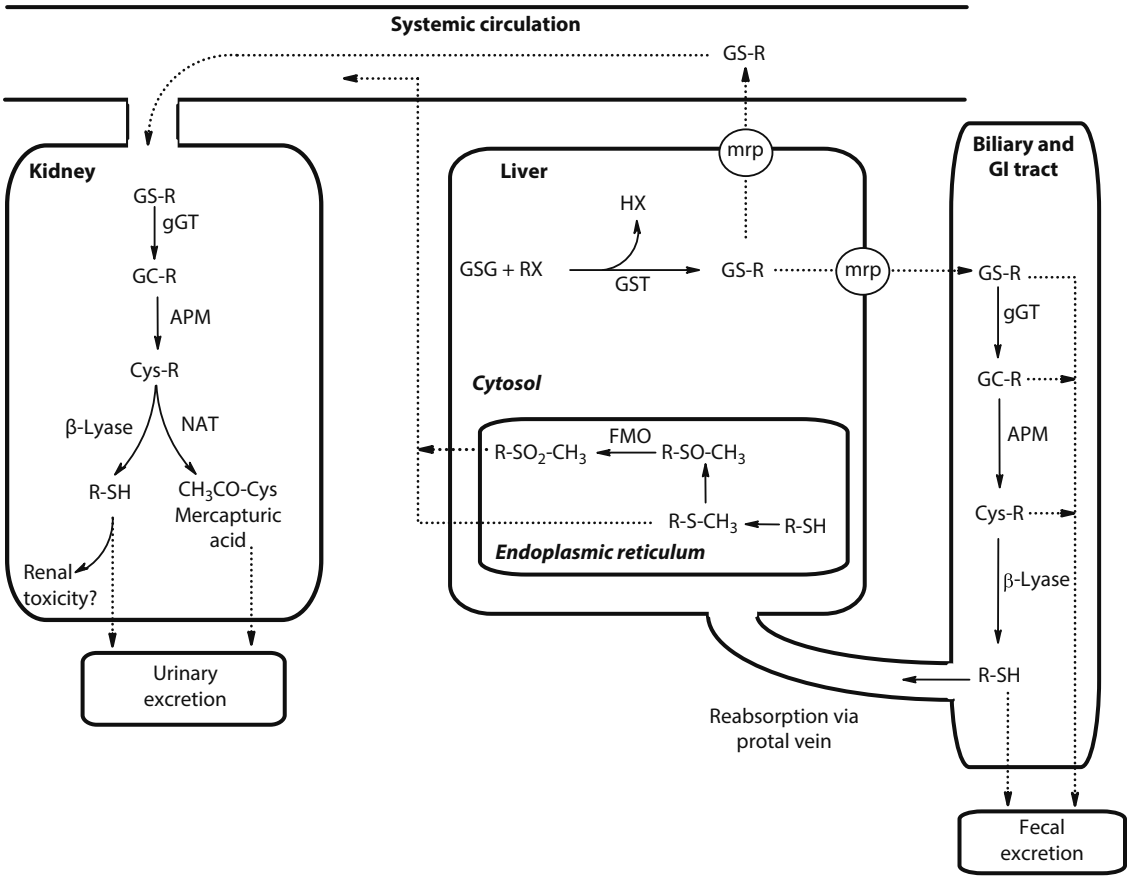

FIGURE 4.22 Summary of the metabolic fate of glutathione conjugates. GST, glutathione S-transferase; gGT, γ-glutamyltransferase; APM, aminopeptidase M; FMO, flavin-containing monooxygenases; NAT, N-acetyltransferase. Refer to text for details.

tissues are polar and partition into the aqueous phase of cells and blood. Because 25% of the blood flow passes through the kidney, GSH conjugates are transported to the kidney via systemic circulation. There, the GSH conjugate undergoes a series of reactions (shown in Figure 4.22) generally resulting in mercapturic acid formation; however, in some cases, bioactivation and nephrotoxicity are the outcomes.

The initial step in mercapturic acid synthesis is cleavage of glutamic acid from cysteine catalyzed by γ-glutamyltranspeptidase. This enzyme is embedded in the outer leaflet of the plasma membrane and is highly expressed in the brush border of the proximal tubules in the kidney.[230] Evidence that this enzyme is involved in GSH degradation comes from observations of pronounced glutathionemia and glutathionuria (high levels of GSH in the blood and urine, respectively) in patients who lack detectable γ-glutamyltranspeptidase. This enzyme not only hydrolyzes the GSH moiety but also transfers the γ-glutamyl group to a variety of amino acids and dipeptides and provides cysteine for de novo synthesis of GSH. Consistent with its role in regulating GSH concentration, gGT is upregulated in oxidative stress[231] and has been proposed as a biomarker for exposure to environmental pollutants.[232]

Next, the glycine group is cleaved from the resulting cysteinylglycine conjugate by aminopeptidase M, yielding the S-substituted cysteine conjugate of the xenobiotic. The cysteine conjugate is a substrate for N-acetyltransferases (NATs) that acetylate the free amino group of cysteine to yield the mercapturic acid, which is excreted in the urine. Alternatively, the cysteine conjugate can be cleaved by renal cysteine conjugate β-lyase, possibly resulting in bioactivation and nephrotoxicity. These two enzymes, γ-glutamyltransferase and aminopeptidase M, are also responsible for the normal turnover of GSH in mammalian cells previously shown in Figure 4.19.

Role of Glutathione S-Transferase in Detoxification

Free reactive electrophilic intermediates of xenobiotics can produce damage to important cellular constituents. Reduced GSH and the GSTs protect cells from this damage by capturing the reactive electrophiles before they can react at nucleophilic sites critical to cell viability.

The metabolism of acetaminophen, an analgesic that at high doses can produce hepatic necrosis, serves as an example of this protective system. A large body of work has shown that one of the principal ways in which acetaminophen produces its hepatotoxicity is via the reactive intermediate, *N*-acetyl-*p*-benzoquinoneimine. This intermediate is an electrophile that reacts readily with GSH and other tissue

nucleophiles. As long as the amount of glutathione present at the site of activation of acetaminophen is sufficient to bind the reactive intermediate, no toxicity ensues; however, as demonstrated in the classic study by Mitchell,[233] when glutathione is depleted by pretreatment with diethyl maleate, the benzoquinoneimine covalently binds to tissue proteins, resulting in tissue necrosis. Understanding of the role of glutathione in protection against acetaminophen-induced hepatotoxicity led to the introduction of *N*-acetylcysteine (Mucomyst®) as a standard antidote for acetaminophen poisoning. Mitchell[233] was among the first to propose that glutathione plays a fundamental role in protecting tissues against electrophilic attack by xenobiotics.

Since these early studies demonstrate the protective role of glutathione, numerous drugs and other chemicals have been shown to form conjugates with glutathione. Notable examples from the more recent pharmaceutical literature include troglitazone,[234] duloxetine,[235] and ticlopidine.[236] For a more thorough review of these reactions, see Chasseaud,[237] Koob and Dekant,[238] and Zimniak.[224]

Factors Affecting Metabolism

GSTs have been found in most species, including reptiles, birds, insects, amphibians, and plants. Factors that influence the availability of reduced glutathione drastically alter the effectiveness of GSTs. As was discussed previously, the toxicity of acetaminophen is modulated by the availability of reduced glutathione. Most xenobiotics that are highly reactive nonenzymatically with glutathione can deplete glutathione under appropriate conditions. Other mechanisms can also lower glutathione availability; for example, certain individuals have genetic defects in the γ-glutamyl cycle, resulting in low tissue concentrations of glutathione. These individuals generally are anemic due to the lack of glutathione and the resulting loss of protection from oxidative damage to erythrocytes.[239]

As discussed earlier, cysteine is the limiting factor for synthesis of glutathione via the cycle shown in Figure 4.19. Nutritional factors that limit sulfur amino acid availability decrease GST activity by reducing the availability of glutathione.[240] Methionine is an essential amino acid that can be used to synthesize cysteine and cystine via the transsulfuration pathway. Diets low in sulfur amino acids can decrease the availability of glutathione for conjugation with reactive intermediates of xenobiotics.

Regulation of Glutathione S-Transferases

GSTs are inducible by a wide variety of xenobiotics including phenolic antioxidants, PB, and planar aromatic hydrocarbons. Dietary ingredients, such as cruciferous vegetables, specific components of coffee, butylated hydroxyanisole (BHA), and organosulfur compounds of allium vegetables, can also induce GSTs. When cafestol and kahweol (diterpenes found in coffee) were administered to rats for up to 90 days, DNA adducts produced by AFB_1 were inhibited 50%. This appeared related to induction of GST and a decrease in P450 isozymes involved in the metabolic activation of aflatoxin.[241] Coffee consumption has been shown to increase salivary concentrations of the GSTs in humans.[242] Induction may be specific for one or more of the transferases and may be tissue specific.

Mechanisms of GST induction are complex and incompletely understood.[243] Induction of GSTs by antioxidants such as BHA occurs at the level of transcription and is controlled in large part by the ARE, also known as the electrophile response element (EpRE).[244,245] The major transcription factor that recognizes and binds to this response element is nuclear factor-E2-related factor 2 (Nrf2). Under basal conditions, this transcription factor is retained in the cytoplasm bound to the redox-sensitive protein Kelch-like ECH-associated protein 1 (Keap 1) and is targeted for proteasome degradation. Binding of Nrf2 to Keap 1 is controlled by at least three cysteine residues that act as redox and/or chemical sensors.[246,247] Oxidation or binding of electrophiles to these cysteines destabilizes the Keap 1/Nrf2 complex, leading to release of Nrf2 and its translocation to the nucleus, allowing interaction with the ARE. Nrf2 can form functional heterodimers with several binding partners, including Maf and c-Jun. In addition to the ARE, other regulatory elements play a role in regulation of GSTs and other phase II enzymes that respond to oxidative stress and electrophiles, including C/EBPβ and the AP-1 family of transcription factors. Some GST genes also contain an XRE in their 5′-flanking region, and this response element may play a role in GST induction by 3-methylcholanthrene and other planar aromatic compounds.[244] PB is thought to act through an AP-1 (Fos/Jun)-related mechanism[248] rather than through the CAR, which mediates CYP induction by PB. As mentioned earlier, cysteine, which catalyzes the rate-limiting step in glutathione synthesis, is also regulated by the Nrf2 and other transcription factors involved in GST induction.

Regulation of microsomal GST (MAPEG) expression has received little attention compared to cytosolic GSTs. Some isoforms, such as human MGST1 and mouse Mgst1, Mgst2, and Mgst3, are induced by oxidative stress, presumable through a Keap1/ARE-dependent mechanism.[249,250] Other microsomal isoforms such as FLAP, PGES-1, and LTC4 synthetase respond to proinflammatory mediators such as LPS, TNF-a, and IL-1b.[251–253]

Polymorphisms of Glutathione S-Transferases

GSTs exhibit polymorphic expression in humans. Among the most toxicologically relevant polymorphisms are those of the μ and θ class enzymes.[254,255] Both of these isoforms exhibit null genotypes resulting from homozygous deletion of the corresponding gene. Because these enzymes play a critical role in protecting the cell from cytotoxic and mutagenic damage, a number of population studies have been done to determine relationships between genotype and disease. Several studies have attempted to correlate lung cancer risk and transferase expression, with mixed results. A better correlation has been found between transferase genotype and diseases associated

with oxidative stress, especially for GSTM1 or GSTT1 polymorphism and colon cancer[256] and esophageal cancer.[257] No correlations were found between breast cancer and GSTM1 polymorphism.[258] The GSTM1*0 variant occurs at relatively high frequencies in Australians, Caucasians, and Africans[259] and has been associated with increased risk of cancers of the lung, colon, and bladder.[260] A fairly clear association of the GSTM1-null genotype with development of transitional cell carcinoma of the bladder has been observed, particularly among smokers and individuals with documented exposure to asbestos or chlorinated solvents.[254] A rapid metabolizer phenotype for GSTM has also been described in Arabian populations, resulting from duplication of the GSTM1 gene. High GSTM1 and GSTT1 expression has been positively associated with renal cell carcinoma and resistance to chemotherapy.[255] The GSTT1*0 genotype has been associated with an increased incidence of acute and chronic myelogenous leukemia. Polymorphic expression of other GST isoforms may also be of toxicological significance; for example, GSTO1-1 is the rate-limiting enzyme in the metabolism of inorganic arsenic, and variation of this enzyme may compromise an individual's ability to metabolize this toxic metal.[130] Similarly, GSTZ1-1 is involved in the detoxification of α-halocarboxylic acids such as dichloroacetic acid (DCA), and SNPs in the promoter region of this gene may impact DCA metabolism.[261] GSTP isoforms are overexpressed in a variety of human tumors, and this has led to their investigation as a chemotherapeutic target. GSTP1*A has been associated with the development of resistance to cisplatin and decreased response rate, while GSTP*B has been correlated with decreased cisplatin metabolism and increased chemotherapeutic response. In addition to their role in the detoxification of chemotherapeutic agents, GSTP1 may enhance tumor resistance by decreasing apoptosis via its inhibitory effect on the JNK–Jun signaling pathway.[262] Overall, it appears that some of the highest correlations between genotype and cancer susceptibility for GSTP1 are those where P450 genotype and transferase genotype are combined for analysis.[254] This again emphasizes the close relationship between metabolic activation by phase I enzymes and detoxification of reactive metabolites by phase II enzymes.

Species and Gender Differences

As mentioned earlier, GSTs have been found in most species investigated. Species differences in the expression, substrate specificity, and activity of these transferases can have a significant role in the toxicity of xenobiotics. For example, rats are susceptible to the potent hepatocarcinogen AFB_1, whereas mice are extremely resistant. This species difference results from the expression in mice of mGSTA3-3, which has a high activity toward the P450-generated activated metabolite of AFB_1 (the 8,9 epoxide). Although rats express a closely related transferase (rGSTA3-3), it has low activity toward the epoxide. These two transferases have equivalent activity toward a probe substrate (1-chloro-2,4-dinitrobeneze), but the rat form has 1000-fold less activity toward the AFB_1 epoxide compared to the mouse. This difference in activity between the transferases from the two species appears to be based on differences in as few as six critical amino acids.[263]

Hepatic GST activities are low in prepubertal male and female rats. As the rats reach sexual maturity between 30 and 50 days of age, glutathione-conjugating activity toward dichloronitrobenzene is two- to threefold higher in males than in females.[264] This difference in GST activity was not related to sex steroids but was dependent on pituitary secretions. Growth hormone may play a role in establishing GST activities,[265] as it does with P450. Although growth hormone is important in regulating adult levels of GST in the rat, it appears that other factors also play a role. The student of toxicology should be aware of the multifaceted way that xenobiotics can affect organisms; for example, monosodium glutamate, which produces lesions in the arcuate nucleus of the hypothalamus, can lower the GST activity in male rats. This, in turn, could increase their sensitivity to electrophilic chemicals.

Gender differences in the expression of GST have been suggested to be responsible for the higher susceptibility of female mice to the carcinogenicity of BP compared to males. Males express higher mGSTP1-1, mGSTA3-3, mGSTM1-1, and mGSTA4-4 compared to females. At higher doses of BP, this gender difference is lost, possibly due to the higher doses overcoming the protective role of the higher transferase activity in males.[266]

Some studies suggest that humans do not demonstrate gender differences in GSTs. No gender or age differences were seen in GSTM and GSTP activity in human lymphocytes, but an age-dependent decrease in glutathione was detected.[267]

Role of Glutathione S-Transferases in Metabolic Activation

Glutathione conjugation does not always produce an innocuous and readily excreted metabolite; for example, Elfarra and Anders[268] compiled a list of 1,2-dihaloalkanes and halogenated alkenes whose glutathione or cysteine conjugates were nephrotoxic. Glutathione reacts with these 1,2-dihaloalkanes via a GST-catalyzed reaction that yields sulfur mustards. An electrophilic episulfonium ion can be formed from the mustard when the second halogen atom is displaced by a cellular nucleophile (Figure 4.23). The episulfonium ion intermediate has been implicated in the toxicity of these chemicals. The major DNA adduct resulting from exposure to the carcinogen 1,2-dibromoethane was *S*-2-*N*^{7}-guanylethylglutathione.[269] This and other GSH-dependent bioactivation pathways for halogenated hydrocarbons have been extensively reviewed by Anders et al.,[270] Vamvakas and Anders,[271] and Anders.[272]

As shown in Figure 4.22, glutathione and cysteine conjugates (GSR and CySR, respectively) formed in the liver can be excreted in the bile. Glutathione conjugates can be hydrolyzed to cysteine conjugates by γ-glutamyltranspeptidase/aminopeptidase M, present in the bile duct epithelia, or by pancreatic peptidases in the small intestine. Cysteine conjugates originating from the bile and those formed by hydrolysis of glutathione conjugates are good substrates for microfloral

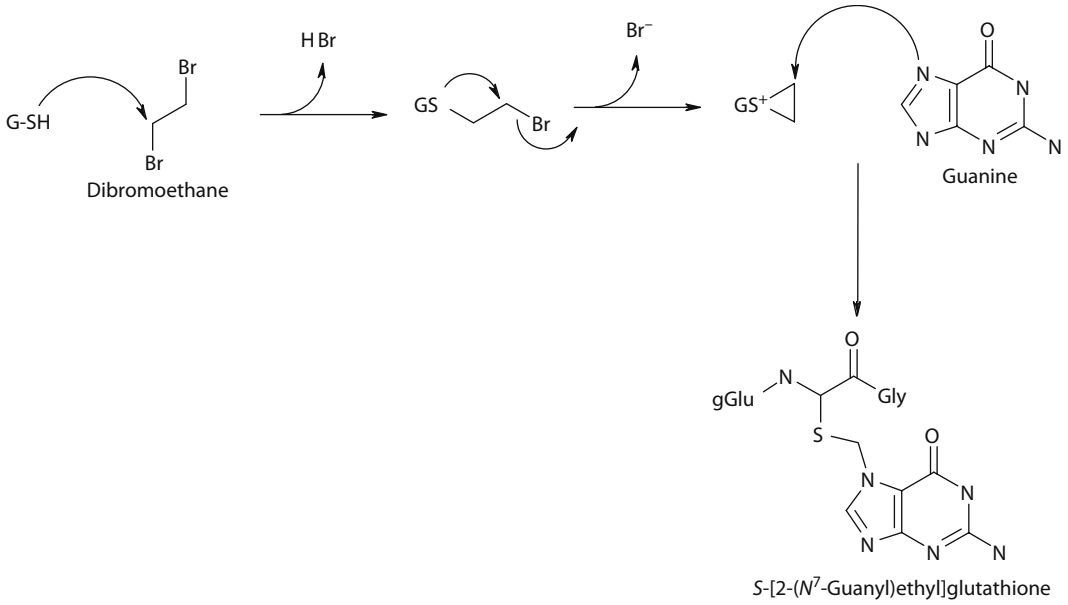

FIGURE 4.23 Bioactivation of 1,2-dibromoethane by conjugation with glutathione, resulting in formation of a DNA-reactive episulfonium ion.

β-lyase. β-Lyase, an enzyme found in liver, kidney, and intestinal microflora, cleaves thioether linkages in cysteine conjugates of xenobiotics.[273] The resulting thiol compounds are more hydrophobic than the conjugates and can be readily absorbed in the small intestine. These thiol metabolites return to the liver via the portal circulation and act as substrates for thiol S-methyltransferase that methylates the thiol group. Enterohepatic circulation of glutathione conjugates accounts for some of the unusual sulfur-containing metabolites that have been found in the urine of animals treated with xenobiotics, such as propachlor[276] and acetaminophen.[274] A portion of the glutathione-derived sulfur-containing metabolites formed in the small intestine is excreted in the feces.

Reactions of glutathione and cysteine conjugates of compounds shown in Figure 4.24 are believed to play a role in the nephrotoxicity of several xenobiotics. Cysteine conjugates are actively transported into renal tubular epithelia, where they may be bioactivated by renal β-lyase[275]; for example, the cysteine conjugate of trichloroethylene, *S*-(1,2-dichlorovinyl)-L-cysteine (DCVC), is a potent nephrotoxin and a β-lyase substrate. Inhibition of renal β-lyase with aminooxyacetic acid, an inhibitor of pyridoxyl phosphate-dependent enzymes, protected against DCVC-induced nephrotoxicity.[268] In contrast, the nephrotoxicity of hexachloro-1,3-butadiene was enhanced by the γ-glutamyltranspeptidase inhibitor acivicin, suggesting that the nephrotoxicity of this polyhaloalkene may not be mediated by its glutathione conjugate.[276,277]

Another glutathione-dependent bioactivation mechanism involves the reversible conjugation of isocyanates such as methyl isocyanate, the chemical responsible for the Bhopal disaster of 1984. Isocyanates are excellent substrates for glutathione conjugation, resulting in formation of an S-carbamoylated glutathione; however, the reaction is reversible, which can lead to regeneration of the free isocyanate.

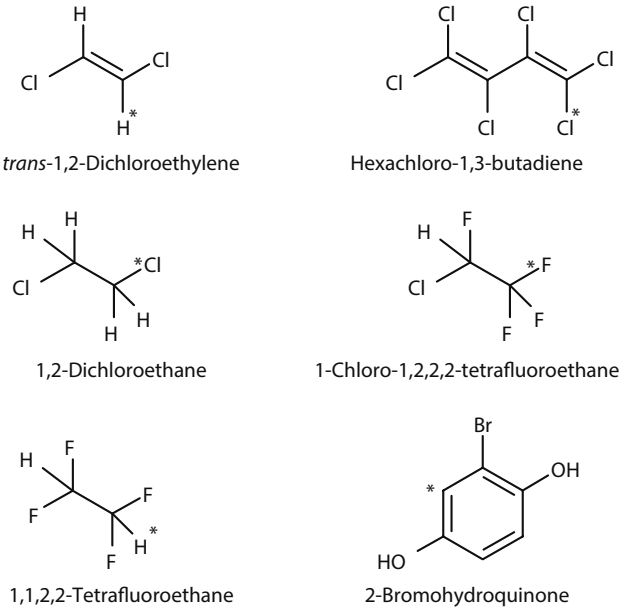

FIGURE 4.24 Representative halogenated compounds that form nephrotoxic glutathione conjugates. The site of reaction with glutathione is indicated by an asterisk (*).

Furthermore, both the glutathione and cysteine participate in transcarbamoylation reactions with tissue-free sulfhydryl groups and other nucleophiles[278]; thus, it has been suggested that glutathione conjugation may actually increase the toxicity of isocyanates by facilitating distribution and release of isocyanate within the body.[279]

In general, glutathione conjugate synthesis results in readily excreted polar metabolites; however, in some cases, the residence time of a glutathione conjugate in the body is prolonged. This can result in formation of metabolites that are

more reactive than the original parent xenobiotic or the glutathione conjugate. If these reactive metabolites interact with critical cellular sites, toxicity can ensue. For recent reviews, see Anders[276] and van Bladeren.[280]

Glutathione S-Transferases as Markers of Liver Damage

GSTs may be valuable as an adjunct to serum aminotransferases for detecting acute liver damage. In particular, GSTα is one of a series of novel candidate biomarkers currently under investigation for liver injury.[281] These transferases constitute as much as 5% of cytosolic protein in the hepatocyte and are uniformly distributed across the liver lobule, compared with aminotransferases, which are localize in the periportal region. Their plasma half-life is less than 60 min, compared to 48 h for the alanine aminotransferase. Selective use of these different characteristics between aminotransferases and GSTs may lead to more accurate diagnoses of hepatic damage produced by xenobiotics.[282] Recently, it has been suggested that the determination of GST should be included in toxicology studies, and validated methods for rats and dogs have been developed.[283]

Methylation

Methyl conjugation is an important pathway in the metabolism of many neurotransmitters, drugs, and xenobiotics. Methylation of endogenous substrates, such as histamine, amino acids, proteins, carbohydrates, and polyamines, is important in the regulation of normal cellular metabolism and accounts for the presence of this activity in mammalian cells. Only when a xenobiotic fits the requirements for the enzymes involved in these normal reactions does methylation become important in the metabolism of foreign compounds. Typical methylation reactions include O-, S-, and N-methylation.

Methylation can be achieved by two routes. First and foremost is the methyltransferase-catalyzed methylation that requires *S*-adenosylmethionine (SAM) as a cosubstrate. Most biological methylations require SAM as the methyl donor; however, some methyl transferases require SAM as a cosubstrate but vary in other requirements for optimal activity.[284] Reactions involving four of these SAM-dependent methyltransferases are shown in Figure 4.25. A secondary source of methylation is N^5-methyltetrahydrofolate (5-CH_3-THF)-catalyzed methylation. This methylation is important in the synthesis of nucleic acids; however, 5-CH_3-THF is 1000 times less reactive toward soft nucleophiles than SAM, suggesting that it plays a smaller role in xenobiotic metabolism.

The methylation of catechol oxygen atoms is catalyzed by catechol O-methyltransferase (COMT), which is most widely known as the enzyme catalyzing the methylation and deactivation of dopamine, other catecholamines, and catechol estrogens. Both cytosolic and membrane-bound forms exist and are encoded by a single gene but use two separate promoters.[285] Methylation of catechols inactivates their biological function and diverts them from secondary pathways that

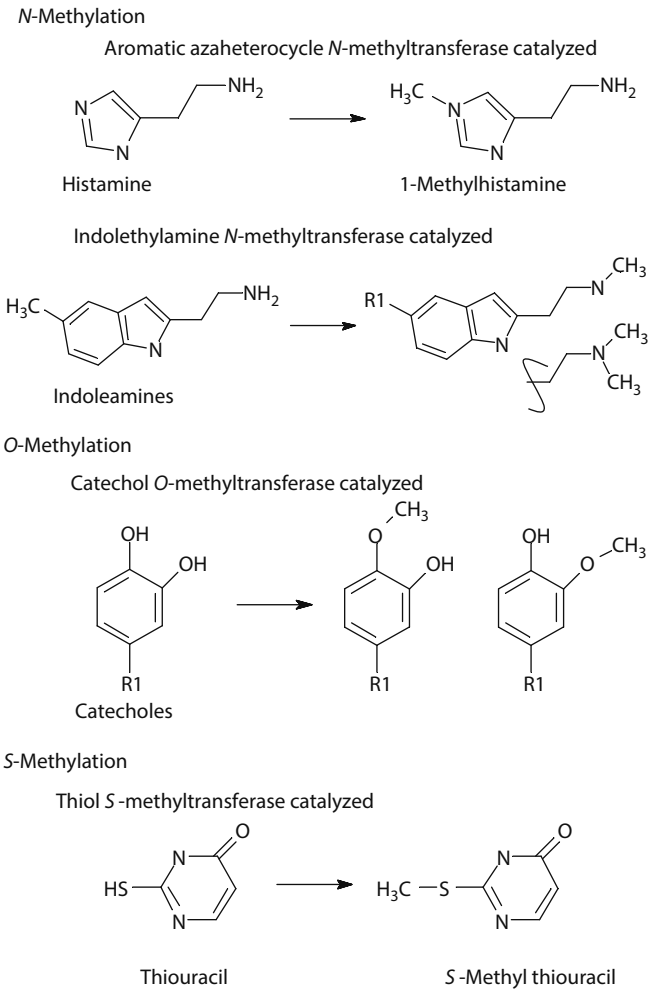

FIGURE 4.25 Methylation reactions.

lead to reactive semiquinone/quinone metabolites and oxyradicals, which are believed to damage catechol-containing neurons and vascular endothelial cells. SAM availability as a cofactor is critical to COMT activity. SAM provides the methyl group via COMT liberating *S*-adenosyl homocysteine (SAH). Because SAH can have an inhibitory effect on SAM, nutritional states that impair the removal of SAH and resynthesis of SAM can have negative consequences on SAM homeostasis and SAM-dependent methylation pathways. Thus, nutritional and biochemical deficiencies in B_6, B_{12}, and folate will disrupt SAM/SAH homeostasis.

Two enzymes catalyze nitrogen methylation: aromatic azaheterocycle N-methyltransferase and indolethylamine N-methyltransferase. N-Methylation of azaheterocycles typically leads to quaternary azaheterocycles. Examples where biotransformation has led to toxic products are more well known and include the biosynthesis of paraquat, the potent lung toxicant, and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which, following oxidation via MAO, leads to the formation of 1-methyl-4-phenylpyridinium ions (MPP^+). MPP^+ is the active metabolite associated with Parkinsonian syndrome, which has been observed in humans after self-administration of designer drugs contaminated with MPT

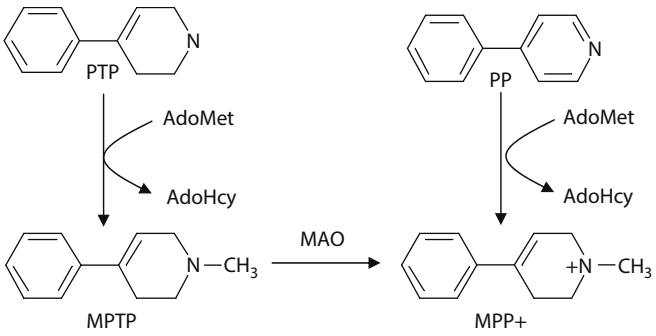

FIGURE 4.26 Metabolic conversion of 4-phenyl-1,2,3,6-tetrahydropyridine (PTP) and 4-phenylpyridine (PP) to the Parkinsonian neurotoxin 1-methyl-4-phenylpyridinium ion (MPP+): MPTP is oxidized by MAO in the brain to MPP+, which is selectively taken up into dopaminergic cells of the nigrostriatum via the dopaminergic reuptake transporter. Once in the pathway of the cells, MPP+ becomes concentrated in mitochondria, where it causes cell death by inhibiting mitochondrial respiration. (From Hoffman, J.L., *Adv. Pharmacol*., 27, 449, 1994. With permission.)

(Figure 4.26).[286] These N-methylation reactions form inhibitors of mitochondrial respiration.

The second pathway, catalyzed by indolethylamine N-methyltransferase, catalyzes the methylation of primary amines to secondary and tertiary amines. This enzyme N-methylates endogenous biogenic amines such as serotonin, tryptamine, tyramine, norepinephrine, and dopamine, as well as drugs and xenobiotics such as amphetamine, normorphine, and aniline.

Sulfur methylation occurs via thiol S-methyltransferase and is also dependent on SAM as the methyl donor. Substrates for S-methyltransferase reactions range from hydrogen sulfide to thiopurine. Hydrogen sulfide, produced by the anaerobic metabolic activity of gut microflora, is initially methylated by gut mucosal S-methyltransferase to yield methanthiol. Although a poorer substrate, methanthiol can be further methylated to dimethyl sulfide. S-Methyltransferase activity is a well-known detoxification pathway for the thiopurine drug 6-metcaptopurine and its prodrug azathioprine, the activity being known as thiopurine S-methyltransferase (TPMT). These cytotoxic drugs are effective against acute lymphoblastic leukemia and autoimmune diseases but have narrow therapeutic indexes, and toxic overdoses can be induced in patients with genetic variants of TPMT.[287] Through relatively simple measurements of TPMT activity in red blood cells, patient dose can be effectively modulated to match patient genotype and phenotype.

Amide Synthesis

Amide biosynthesis can take place via two principal routes:

- Conjugation of a carboxylic-acid-containing xenobiotic with the free amino group of an amino acid such as glycine
- Acetylation of a xenobiotic containing a primary amine ($-NH_2$)

Amino Acid Conjugation

Xenobiotics that contain a carboxylic acid moiety are susceptible to conjugation with endogenous amino acids. Xenobiotic conjugation occurs in hepatic mitochondria. The free carboxylic acid is activated by reaction with ATP followed by reaction with coenzyme A (CoA), as shown in reactions 1 and 2 of Figure 4.27. For example, the carboxylic acid of benzoic acid is activated to a thioester CoA intermediate that reacts with the primary amine of glycine to form the amide hippuric acid.

Glycine has historical significance in xenobiotic conjugation because it is one of the earliest reactions attributed to xenobiotic metabolism. Keller,[288] in 1842, administered benzoic acid to himself and then isolated and characterized the major metabolite, hippuric acid, a glycine conjugate. This reaction has been used as a liver function test in humans. The liver is the principal site of glycine conjugation. Other amino acids, such as taurine, can be used for conjugating aliphatic, aromatic, and heterocyclic carboxylic acids. Taurine conjugates of pioglitazone metabolites were identified in the bile of treated dogs.[289]

Acetylation

Acetylation, catalyzed by NATs, is the principal pathway of amide formation for primary aromatic amines, endogenous primary aliphatic amines, anutrient amino acids, hydrazines, hydrazides, and sulfonamides. NAT catalyzes the two-step transfer of an acetyl group from the donor (acetyl-CoA) to the aromatic amine. These enzymes are cytosolic, occur in many tissues, and are comprised of at least three families of isoenzymes. Acetyltransferases can also catalyze O-acetylation of xenobiotics, as has been shown especially for the acetylation of aryl hydroxylamines such as *N*-hydroxy-2-aminofluorene and 4-aminobiphenyl (Figure 4.28).

Some species, including humans, rabbits, and hamsters, express two independently regulated transferases, NAT1 and NAT2; other species, such as mouse, express three: NAT1, NAT2, and NAT3. NAT1 and NAT2 have been studied most extensively. They are structurally similar proteins with a cysteine residue at the active site, but they have different substrate specificities, although some overlap occurs. NAT1 is expressed in most tissues, whereas NAT2 is expressed only in the liver and gut. Polymorphisms in NATs are well described for the human population, and more than 26 different alleles have been reported.[290] NAT2 and more recently NAT1 have been shown to have several allelic variants resulting in fast and slow acetylator status, and simulated distributions of these alleles suggest sensitive populations.[291] Especially well described for the NAT2 enzyme, acetylator status can affect susceptibility to drugs such as dapsone and isoniazid in which slow acetylation leads to peripheral neuropathy.

Acetylation of aromatic amines is generally a detoxification pathway because the added acetyl group blocks further oxidation of the amide nitrogen; however, once oxidized, the resulting hydroxylamine can undergo O-acetylation. The resulting acetoxy ester is unstable, and heterolytic loss results in

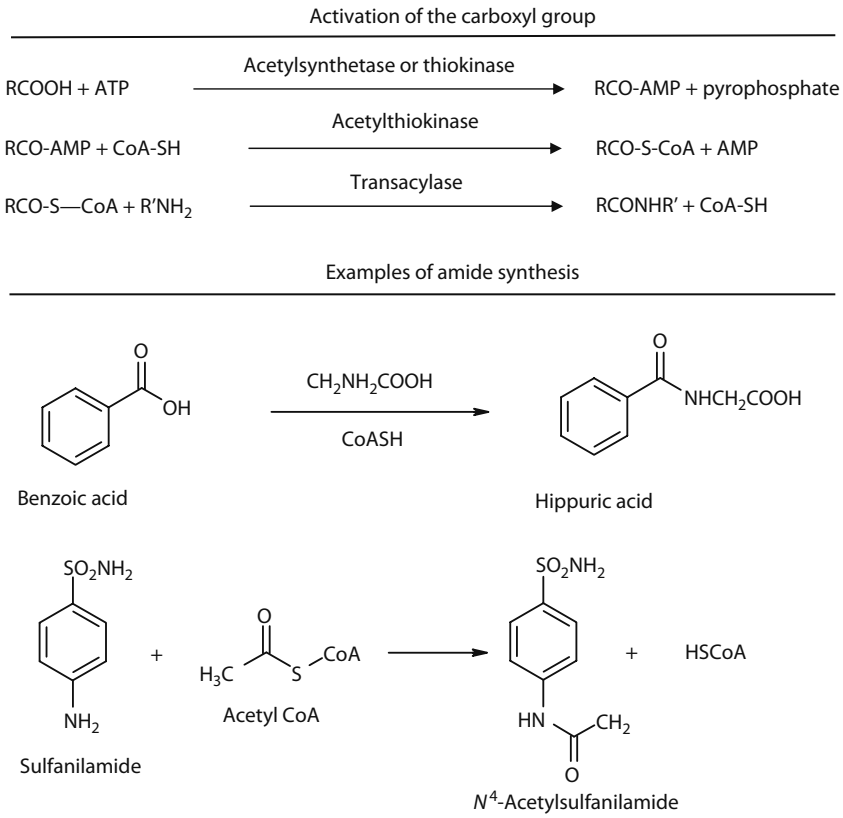

FIGURE 4.27 Series of reactions leading to amide formation from either a xenobiotic containing a carboxylic functional group (RCOOH) or a primary amine group (R′NH2).

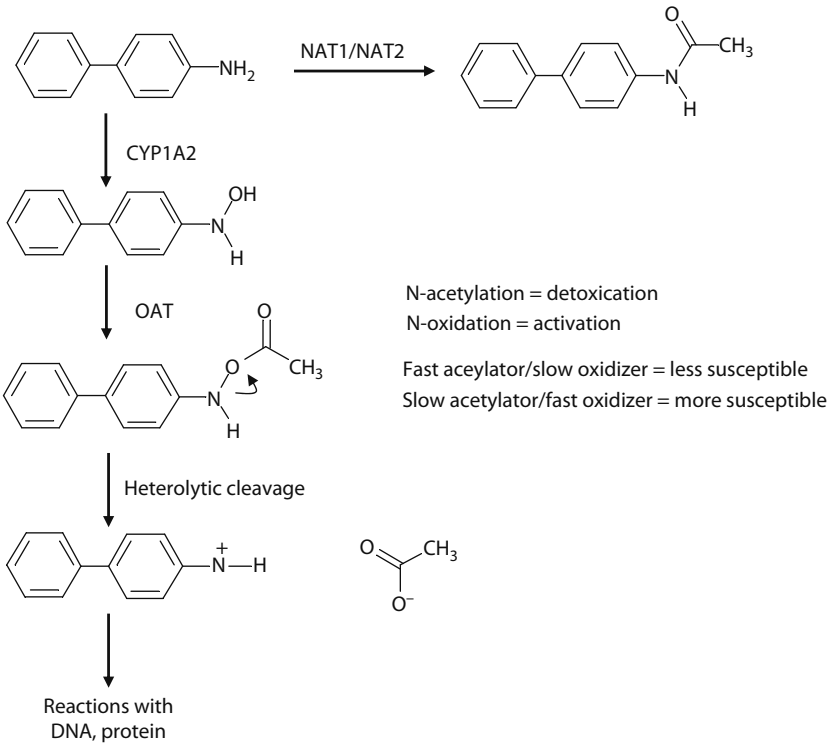

FIGURE 4.28 Metabolism of the bladder carcinogen 4-aminobiphenyl. NAT conjugation is a detoxification pathway that competes with CYP1A2 N-oxidation, which is the first step in metabolic activation that ultimately forms a highly reactive nitrenium ion. Some ethnic groups, such as those of Middle Eastern populations, have a high incidence of the slow acetylator phenotype, which, when coupled with a fast N-oxidation phenotype, results in a much higher risk of bladder cancer.

the formation of highly reactive nitrinium ions that form adducts with cellular DNA and consequently are mutagenic (Figure 4.28). It is frequently the balance between N-oxidation and N-acetylation that determines susceptibility to aromatic amine carcinogenesis. Dogs, which lack NAT activity, are highly susceptible to arylamine-induced carcinogenesis. Human susceptibility has been demonstrated for 4-aminobiphenyl in which N-oxidation and N-acetylation status is tightly associated with risk of bladder cancer among smokers. High N-oxidation status coupled with slow acetylator phenotype yields the highest bladder cancer risk among smokers.

Mercapturic acid formation in the kidney is an example of acetylation that has been presented and represents one of the unusual circumstances in which aliphatic amines undergo N-acetylation. In this reaction, the primary amine group of the cysteine conjugate of the xenobiotic is acetylated to form the mercapturic acid. This is an exception to the rule that aliphatic primary amines generally are not good substrates for the NATs.

HYDROLYSIS

Many xenobiotics and their phase I metabolites contain a carboxyl ester, an amide bond, or an epoxide that masks hydrophilic functional groups, such as alcohols, carboxylic acids, and amines. The rate at which an organism can hydrolyze these bonds and unmask these function groups can influence their toxicity. In fact, pesticides and therapeutic drugs have been synthesized with intent to modulate the bioavailability of the active species by affecting the rate of hydrolysis of the parent compound.

Hydrolysis normally competes with other detoxification reactions, but esterases are in very high content in many tissues, especially liver, and their affinity is low enough such that esterase-/amidase-mediated hydrolysis typically predominates. An example of competition is demonstrated by the metabolism of vinyl acetate (Figure 4.29). This molecule

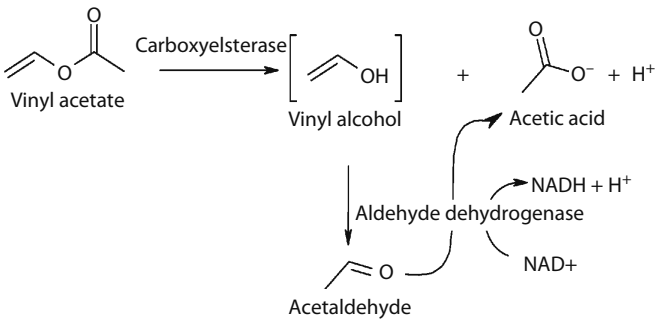

FIGURE 4.29 Carboxylesterase-mediated hydrolysis of vinyl acetate. Esterase hydrolysis is so efficient that cytochrome P450-mediated epoxidation of the double bond does not occur. Vinyl alcohol is an unstable intermediate and readily rearranges to form acetaldehyde, which undergoes further oxidation to acetic acid. The potential toxicity of acidic metabolites is often overlooked, but in the case of vinyl acetate, the acetic acid generated contributes substantially to the mechanism of toxicity.

contains both a double bond and an ester group and therefore would be expected to be a substrate for both epoxidation and carboxylesterase-mediated hydrolysis; however, the metabolism of this compound via the carboxylesterase pathway is so efficient that no epoxide is formed. Hydrolysis products such as alcohols, amines, or thiols and carboxylic acids are typically further metabolized.

Epoxide Hydrolase

Organisms may be exposed to epoxides in the environment or they may be produced during the oxidative metabolism of specific xenobiotics from their environment. Epoxides generally are reactive electrophilic compounds due to the highly strained oxirane ring. Excess strain energy can be released by ring opening in the presence of nucleophiles, which may result in covalent modification of the macromolecule. Modification of DNA results in a biochemical lesion that may be the precursor to a number of pathological lesions, including cancer. Reaction of the epoxide with cellular nucleophiles, such as proteins, could also lead to other mechanisms producing acute or subchronic toxicity.

The chemical reactivity and, consequently, the biological activity of epoxides are influenced by the constituents attached to the oxirane ring carbons. Asymmetric substitution and electron-withdrawing substituents near the oxirane ring tend to destabilize the epoxide and enhance its reactivity. Epoxides that hydrolyze in water are among the most reactive and electrophilic but may not be toxic when hydrolyzed. Alternatively, if they are generated close to or have a long enough half-life to reach and react with critical cellular macromolecules, epoxides can have both cytotoxic and genotoxic consequences. An example of a relatively stable epoxide is styrene-7,8-oxide, which is the substrate typically used as a generic assay for epoxide hydrolase activity (Figure 4.30).

A major route for biodisposition of epoxides is hydration catalyzed by epoxide hydrolase to vicinal (from the Latin vicinalis, neighboring) dihydrodiols. The membrane-bound and cytosolic forms were first characterized in 1973 and 1976, respectively. They are now known to comprise a large and heterogeneous group of enzymes. Their structure, function, and mechanism have been reviewed recently.[295] This microsomal enzyme catalyzes the biotransformation of a diverse group of arene oxides and aliphatic epoxides (Figure 4.30). In most cases, this enzymatic pathway results in less reactive diol metabolites that are more readily excreted from the organism, either as the diol or as a glucuronide or sulfate conjugate of the diol.

Epoxide hydrolases occur as membrane-bound proteins located in the endoplasmic reticulum and as a soluble enzyme in the cytosol of most mammalian cells. The membrane-bound microsomal form has broad substrate specificity, while the soluble, or cytosolic, form has a higher affinity for nonbulky trans-substituted oxiranes.[293,294] Humans demonstrate considerable variation in epoxide

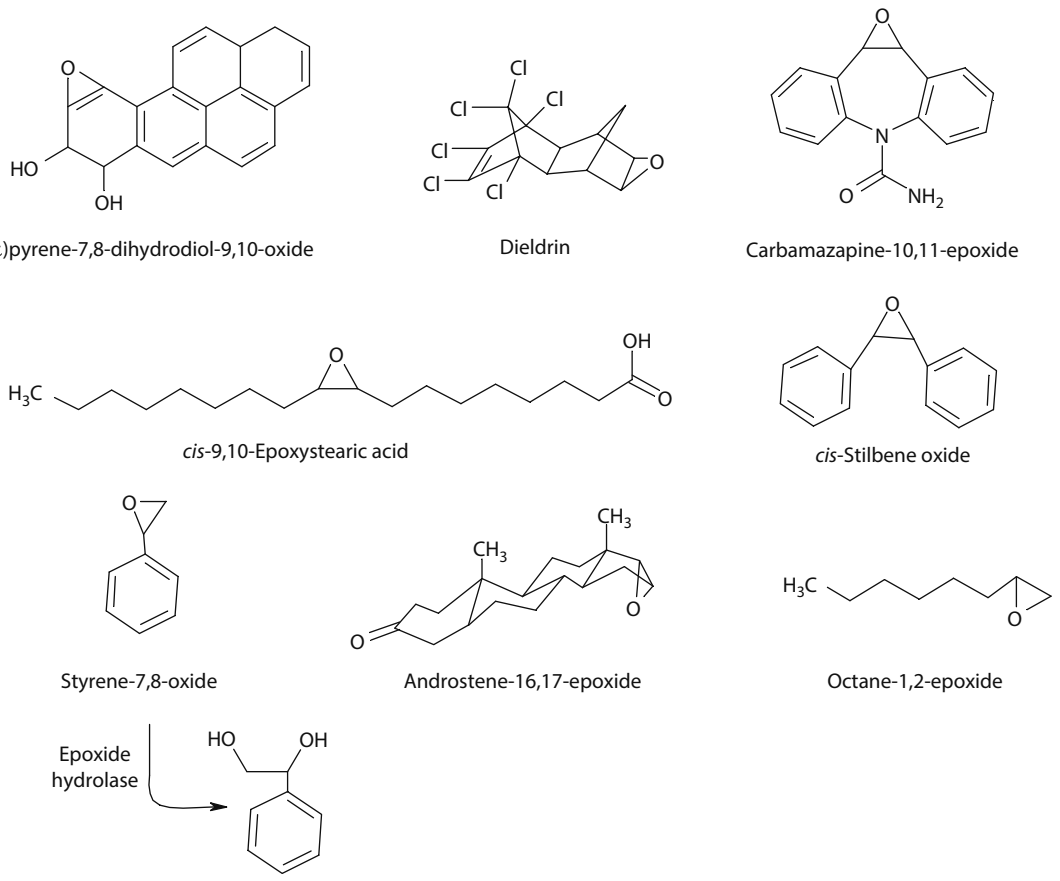

FIGURE 4.30 Structural diversity of epoxides that are substrates for epoxide hydrolase. Benzo(*a*)pyrene-7,8-dihydrodiol-9,10-oxide illustrates a potent mutagen, which is first oxidized to the 7,8-epoxide, followed by epoxide hydrolase hydrolysis of the epoxide and then secondary oxidation at the 9,10 position. The dihydrodiol imparts a steric hindrance toward the 9,10 epoxide, leaving the epoxide relatively, although not completely, resistant to hydrolysis. (Adapted from Arand, M. et al., *Drug Metab. Rev.*, 25, 365, 2003.)

hydrolase activity. These human polymorphisms may not result in significantly altered enzyme activity or posttranscriptional regulation,[295] although more work is required in this area.

Epoxide hydrolase has been found in a variety of tissues, including liver, kidney, lung, skin, intestine, colon, testis, ovary, spleen, thymus, heart, and brain. The activity of liver microsomal enzyme is relatively low in newborn rats and increases during neonatal development until adult males have about twice the activity of females. This sexual dimorphism is remarkably similar to that seen in the rat for P450. In contrast, the renal epoxide hydrolase of male and female rats does not demonstrate age-dependent changes or gender differences. Human hepatic microsomal epoxide hydrolase activities increase during gestation, but no gender difference in humans has been observed.[296]

The activity of this enzyme is induced by the classical inducers of cytochromes P450. Although trans-stilbene oxide has been shown to be an inducer of epoxide hydrolase, no specific inducer of epoxide hydrolase has been reported. Two widely used inhibitors of epoxide hydrolase are trichloropropane oxide and cyclohexene oxide.

An immunologically distinct epoxide hydrolase has also been identified in the cytosol of some species. This enzyme may play a role in the hydrolysis of more water-soluble epoxides that partition out of the endoplasmic reticulum. Epoxide hydrolases may compete with glutathione transferases for cytosolic epoxides; however, epoxide hydrolase has a higher affinity for many epoxide substrates than glutathione transferase and is therefore generally a more efficient detoxification mechanism.

Esterases and Amidases

Hydrolysis of xenobiotics containing ester linkages and amide bonds is catalyzed by a group of enzymes with broad substrate specificity. A new nomenclature system for five gene families of mammalian carboxylesterase designates the human genes as CES and the mouse and rat genes as Ces and each is followed by a family number.[297] The reactions carried out by this diverse group of enzymes are illustrated

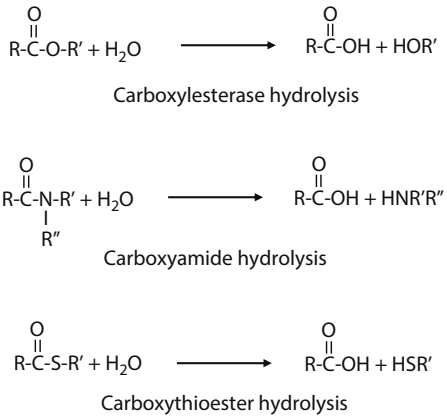

FIGURE 4.31 Reactions catalyzed by esterases and amidases.

in Figure 4.31. The specificity of carboxylesterases depends on the nature of the R groups rather than on the atom (O, N, or S) adjacent to the carbonyl carbon.[298] The esterases have been broadly grouped into three categories based on their reactivity with organophosphorous compounds.[299] Those esterases preferring carboxylesters with aryl groups in the R position and that can use organophosphate esters as substrates are classified as A-esterases (Table 4.7). Those esterases preferring esters with alkyl groups in the R position and that are inhibited by organophosphate esters are classified as B-esterases. Another group of esterases that prefer acetate esters and do not interact with organophosphates are referred to as C-esterases. The mechanism of organophosphate and carbamate insecticide toxicity is inhibition of acetylcholinesterase, a B-type esterase. Organophosphate insecticides, such as malathion, target serine hydrolases (B-esterases) and are detoxified in mammals by A-esterase hydrolysis.[300] Many insects have lower levels of A-esterases than mammals. The selective toxicity of malathion in birds and insects can be explained by the low activity of A-esterases compared to mammals.[301]

Carboxylesterases are widely distributed in the body including tissues lining the major portals of entry (i.e., skin, gastric mucosa, and respiratory tract). Liver has the highest capacity for esterase hydrolysis, but on a tissue-weight basis, other tissues, such as the olfactory mucosa, contain comparable levels.[302] Hydrolytic activity at these sites can be used to improve drug bioavailability by designing ester-containing prodrugs that are more lipid soluble than their alcohol or carboxylic acid analogs and therefore are more readily absorbed; however, carboxylesterase activity at the portal of entry can also result in metabolic activation when the hydrolysis products are toxic. Such is the case for vinyl acetate, a volatile organic monomer that, when inhaled, is absorbed and metabolized by carboxylesterases within the nasal cavity mucosal lining.[303]

MICROFLORAL METABOLISM

Because the majority of microbes that colonize various surfaces of the mammalian body reside in the intestinal tract, most of this discussion will center around intestinal microflora metabolism. The intestinal microflora can alter xenobiotic bioavailability by metabolizing the parent compound to a metabolite that may be absorbed to a greater or lesser extent. Intestinal microflora can also metabolize products of xenobiotic biotransformation that are secreted into the

TABLE 4.7
Classification of Esterases by How They Interact with Organophosphates and Substrate Specificity

Esterase	Interaction with Organophosphates	Substrates	Examples
A-Esterases (arylesterases)	Substrates	 Aromatic esters	Organophosphate and carbamate insecticides
B-Esterases	Inhibitors	 Aliphatic esters	Acetylcholine, acrylate esters Succinylcholine, propanidid
C-Esterases (acetylesterases)	No interaction	 Acetate esters	*p*-Nitrophenyl acetate, *n*-propylchloroacetate

TABLE 4.8
Types of Metabolic Reactions Carried out by Intestinal Bacteria

Reaction	Representative Substrate
Hydrolysis	
Glucuronides	Estradiol-3-glucuronide
Glycosides	Cycasin
Sulfamides	Cyclamate, amygdalin
Amides	Methotrexate
Esters	Acetyldigoxin
Nitrates	Pentaerythritol trinitrate
Dehydroxylation	
C-Hydroxy groups	Bile acids
N-Hydroxy groups	*N*-Hydroxyfluorenylacetamide
Decarboxylation	Amino acids
N-Demethylation	Biochanin A
Deamination	Amino acids
Dehydrogenase	Cholesterol, bile acids
Dehalogenation	DDT
Reduction	
Nitro groups	*p*-Nitrobenzoic acid
Double bonds	Unsaturated fatty acids
Azo groups	Food dyes
Aldehydes	Benzaldehydes
Alcohols	Benzyl alcohols
N-Oxides	4-Nitroquinoline-1-oxide
Other reactions	
Nitrosamine formation	Dimethylnitrosamine
Aromatization	Quinic acid
Acetylation	Histamine
Esterification	Gallic acid

intestine directly from the blood or via the bile, saliva, or swallowing respiratory tract mucus. Metabolism of secreted metabolites is a common mechanism by which microflora influence xenobiotic toxicity. The hallmark of metabolism by organisms colonizing the intestinal tract of mammals is reduction (Table 4.8).

Xenobiotic Biotransformation by Microbes Colonizing Mammals

The intestinal tract of mammals contains a variety of microorganisms. The majority of mammals have a gradient of microflora that increases in numbers and species diversity from the upper to the lower gastrointestinal tract. Most research on microflora metabolism has focused on microorganisms that colonize the large intestine of humans, as most of the research in toxicology is directed toward understanding the toxicity of chemicals in humans. In vivo and in vitro models have been developed for studying human colonic flora.[304] Since diet affects intestinal microflora, diet has an important influence on microbial metabolism of xenobiotics.

Examples of Xenobiotics Whose Toxicity Is Dependent on Microflora Metabolism

Nitroaromatics

The toxicity of many nitroaromatic compounds is dependent on microflora metabolism. One of the most studied nitroaromatics is 2,6-dinitrotoluene (DNT), which is hepatocarcinogenic in male rats.[305] DNT is metabolized to the 2,6-dinitrobenzylalcohol glucuronide conjugate that is preferentially excreted in the bile of male rats (Figure 4.32).[306] The glucuronide conjugate is hydrolyzed by gut microflora β-glucuronidase, and one or both of the nitro groups are reduced by microflora nitroreductase to a reduced aglycone. The resulting aminobenzyl alcohol is relatively nonpolar and reabsorbed in the intestine, where it returns to the liver via the portal circulation. In the liver, the aglycone is activated to the putative proximate carcinogen by N-hydroxylation of the amine functional group followed by sulfation of the N-hydroxy group.[307] Evidence that intestinal microflora were required for the activation of DNT was provided by studies indicating that the genotoxicity of DNT in hepatocytes isolated from rats treated with DNT was dependent on the presence of bacteria in the intestinal tract.[308] Rats raised in a germfree environment showed minimal levels of genotoxicity. Additional evidence emphasizing the role of microflora in the metabolic activation of DNT was the observation that DNT was not genotoxic when tested in vitro in isolated hepatocytes.[308] These results indicated that liver metabolism was not sufficient to activate the molecule to the ultimate carcinogen. The genotoxicity of DNT to liver cells only occurred when the compound was administered to the animal and was allowed to undergo enterohepatic circulation involving intestinal microflora. Dietary treatments that increased the microbial metabolic capacity of the rat's large intestine also increased the covalent binding of DNT-derived radioactivity to hepatic macromolecules.[309]

Cyclamate

The sodium and calcium salts of cyclamic acid (cyclohexylsulfamic acid) were used as an artificial sweetening agent until 1969 in the United States, when it was removed from the market because a metabolite (cyclohexylamine) was suspected of being a bladder carcinogen. Most of the hydrolysis of cyclamate to cyclohexylamine takes place in the gut by the microflora. Cyclohexylamine is more lipophilic than the parent acid and is readily absorbed from the intestine and excreted in the urine. Minor urinary metabolites include cyclohexanol and trans-cyclohexane-1,2-diol.

Although only trace amounts of the cyclohexylamine could be detected in human-administered cyclamate, chronic exposure to the acid increased the capacity to produce this metabolite.[312] It was found that certain individuals possessed a greater capacity to metabolize cyclamate to cyclohexylamine; these individuals were called converters. Thus, cyclamate is a good example of how prior exposure to a xenobiotic can alter the disposition of the xenobiotic. For additional

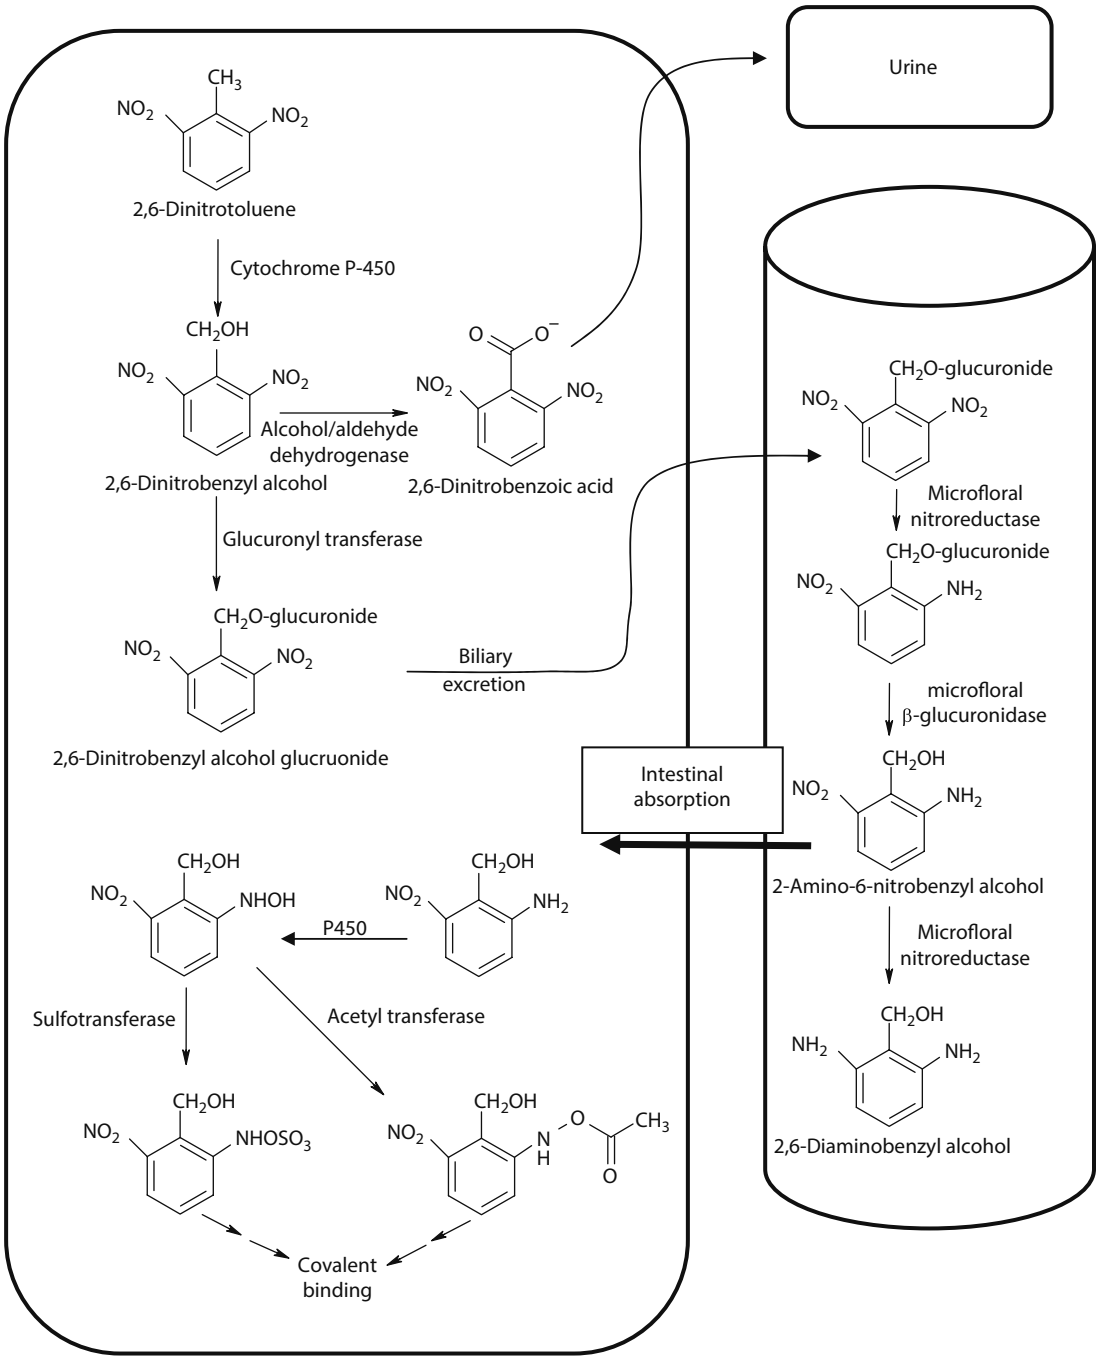

FIGURE 4.32 Putative route of disposition of DNT.

reading on intestinal microflora xenobiotic metabolism, see Goldman[310] and Scheline.[39]

TRANSPORTERS

More than 400 human uptake and efflux membrane transporters have been identified and reported. Considerable progress has been made, particularly over the last decade, regarding characterization of drug–transporter interactions, understanding potential clinical significance, and clarification of regulatory implications.[311–315] Drug transporters recognize a structurally diverse range of substrates including drugs, metabolites, and endogenous compounds. Transporters are expressed in many types of endothelial and epithelial cells where they facilitate the absorption, elimination, and distribution of drugs into various organs.[316–318] The process by which transporters function to facilitate the uptake and efflux of substrates ultimately affects overall tissue concentrations, which in turn affects rates of drug elimination via metabolism and excretion. Thus, the interaction

of a drug with membrane transporters can potentially lead to alterations in exposure that result in toxicity, or in certain instances, therapeutic failure.[319,320]

In general, efflux and uptake transporters are categorized as either ATP-binding cassette (ABC) or solute carrier (SLC) transporters. The expression, function, and relevance of ABC and SLC transporters with respect to xenobiotic transport and potential DDIs have been extensively reviewed.[144,311–315,321–324]

ABC Transporters

ABC transporters are transmembrane proteins that utilize the energy of ATP hydrolysis to translocate various substrates across cell membranes, a process that can occur against a considerable concentration gradient.[311,312,314,322,325] ABC transporters extrude a wide variety of substrates from cells, including exogenous compounds such as drugs, drug conjugates, and metabolites and endogenous compounds such as lipids, sterols, and bilirubin. Interactions involving efflux transporters have been implicated in tumor resistance, cystic fibrosis, bacterial multidrug resistance, and a range of other inherited human diseases. ABC transporters considered important in the absorption and disposition of drugs and various endobiotics include P-gp (MDR1/P-gp), the breast cancer resistance protein (BCRP), the bile salt export protein (BSEP), and the multidrug-associated resistance proteins (MRP2, MRP3, MRP2).

SLC Transporters

SLC transporters are primarily unidirectional uptake transporters, although some SLC transporters function in a bidirectional manner.[144,311,313] SLC transporters include over 300 members organized into 47 families, including both facilitative and secondary active transporters. Solutes, or substrates, that are recognized and transported across membranes by SLC transporters include charged and uncharged organic molecules as well as inorganic ions. Uptake transporters considered important in the absorption and disposition of drugs and various endobiotics include the organic anion-transporting polypeptides (OATP1B1, OATP1B3, OATP1A2, and OATP2B1), organic cation transporters (OCT1 and OCT2), organic anion transporters (OAT1 and OAT3), the multidrug and toxicant extrusion proteins (MATE1 and MATE2-K), and the oligopeptide transporters (PEPT1 and PEPT2).

Determining the relative importance of the many uptake and efflux transporters, as well as their influence on drug disposition, therapeutic efficacy and safety, and in particular DDIs, has been the focus of considerable research. Evolving from what was originally widely accepted as passive transport, it is now recognized that nearly all drugs and their metabolites enter cells to some extent, and in many cases to a significant extent, through the activity of membrane transporters.[315,321,326] However, many challenges exist for scientists in the field of drug transporters. For example, few selective substrates and inhibitors have been identified for clinical use; relatively sparse conclusive clinical data are available describing transporter-mediated DDIs; and substrates that interact with one uptake or efflux transporter typically interact with multiple uptake and/or efflux transporters.[315,335] As such, extrapolation of in vitro data to predict in vivo outcome remains quite challenging, and designing static or dynamic models incorporating transporter interactions is still a developing field.

Prediction of drug interactions has traditionally focused on the evaluation of interactions involving drug-metabolizing enzymes (DMEs) such as CYP450s; however, more recent studies describe interactions of drugs with transporters as being mechanistically responsible for clinical DDIs.[318,327–330] Many DDIs previously thought to occur via interaction of a substrate and inhibitor with DMEs have been reevaluated and are now ascribed to interactions involving DMEs and transporters with drugs that are substrates and/or inhibitors. Thus, the interplay of transporters with DMEs is a critical concern when investigating the potential impact of transporters on drug absorption and elimination.[315,331–333]

Tools Used to Study Transporter Interactions

Characterization of a drug or experimental compound as a potential substrate, inhibitor, or modulator[336] of membrane transporters is important from a safety perspective. The Caco-2 cell line, which is derived from a human colorectal adenocarcinoma, is one of the most commonly used in vitro models to evaluate the interaction of drugs with ABC transporters such as P-gp, MRP2, and BCRP.[334–338] Similarly, human embryonic kidney (HEK293) or Chinese hamster ovary (CHO) cells expressing SLC transporters are often used to study transporter-mediated uptake.[339] Interactions between drugs or compounds in development and transporters are routinely investigated by researchers in the pharmaceutical industry. As recommended by the International Transporter Consortium (ITC), these studies typically include OATP1B1, OATP1B3, OATP2B1, OAT1, OAT3, and OCT2.[315,323]

Various other in vitro systems can be used to study drug–transporter interactions, including but not limited to primary cultured proximal tubule cells, rat brush-border membrane vesicles, and more recently, human kidney slices.[340] Drug–transporter interactions, including the potential interplay between uptake transporters, efflux transporters, and DMEs, can be studied using isolated hepatocyte systems. The sandwich-cultured hepatocyte format is a well-characterized system, which allows for the estimation of biliary clearance and can maintain hepatic phenotype and transport activity for up to 10 days in the absence of serum.[341] This model promotes establishment of cell polarity, exhibits reasonable expression levels of both uptake and efflux transporters, and offers the opportunity to study the effect of nuclear receptor activation and cytotoxicity.[341,342] However, cultured hepatocyte systems have various drawbacks such as a decline in uptake and efflux transporter expression following several days in culture, which can potentially affect clearance and DDI predictions.[343,344]

In vivo and ex vivo models are also routinely used to study drug–transporter interactions. These include rat blood–brain barrier (BBB) penetration studies using P-gp and BCRP knockout models, isolated perfused rat lung, transporter knockout mice, and whole-body autoradiography. While an overestimation of the potential for changes in human brain levels based on the mouse data may occur,[320,345] use of these models can still provide valuable insights. Additionally, chemical knockout of P-gp using selective inhibitors can be used.[346] Even though rat knockout models are generally less advanced,[347] they provide an easier animal model for multisampling pharmacokinetic analysis when compared to the mouse.

Influence of Transporters on Drug Efficacy

Transporters can affect the disposition of many drugs, in particular the ability of a drug to reach tissues in which the pharmacologic target is located. For example, resistance to drugs used to treat diabetes mellitus can occur due to the function of ABC transporters expressed on target cells.[348] In cancer chemotherapy, drug efficacy can be compromised by an increase in efflux of chemotherapeutic agents out of targeted cells, leading to a reduction in intracellular chemotherapeutic concentrations. A well-established cause of multidrug resistance involves the increased expression of ABC transporters such as P-gp.[349] Overexpression of these efflux transporters, which is likely to occur in transformed cells, can eventually trigger drug insensitivity.[350] This phenomenon often compromises the efficacy of multiple chemotherapeutic agents and can include various drug classes and chemical structures.

The target organ for central nervous system (CNS) drugs is the brain; however, the presence of the BBB is a complicating factor in the design of efficacious CNS drugs. The BBB is composed of microvessel endothelial cells sealed by tight junctions that effectively restrict the entry of many drugs into the CNS. Additionally, efflux transporters such as P-gp, BCRP, and various MRPs are densely expressed on the BBB surface and effectively restrict the distribution of CNS drugs into the brain.[324,351] The primary target organ for many human hepatitis C (HCV) drugs is the liver. In vitro models can be instrumental in helping to determine the potential for a compound to undergo active, or transporter-mediated, absorption into hepatocytes. HCV infection has been shown to trigger an increase in the expression of MDR1, MRP1, and MRP3,[352] but also triggers a decrease in the expression of CYP1A2, CYP2E1, CYP3A4, NTCP, OATP1B1, MRP2, and OCT1.[353,354] Interestingly, the expression of transporters and DMEs is frequently altered during active HCV infection, other inflammatory diseases, and cancer, an effect that can be correlated with the elevated production of inflammatory cytokines.[355]

Influence of Transporters on Safety/Toxicology

The role of transporters in cellular toxicity is recognized and increasingly appreciated by researchers and clinicians, especially when transporter activity is compromised by alteration of function via xenobiotics, disease states, or genetic polymorphisms.[331] To date, most safety-related concerns involving transporters include DDIs. Transporter-mediated DDIs can involve transporters expressed in the intestine, liver, and kidney, which can affect not only the pharmacokinetic profile of a drug but also its pharmacodynamics.[323] Researchers are continuously developing a more advanced understanding of drug–transporter interactions that may result in an unwanted toxicological effect. Two examples of transporters that are known to be implicated in a toxicological response are outlined in the following: muscle toxicity/myopathy from an increase in statin exposure caused by interactions involving OATP1B1 and cholestasis caused by inhibition of bile salt transporters. As this field of study continues to mature, there will undoubtedly be a better understanding of how the interplay between transporters and DMEs can affect toxic response.

Statin-Induced Myopathy

Statins are a frequently prescribed class of drugs that are generally considered safe and well tolerated. However, an unexpected increase in the plasma exposure of statins, for example, simvastatin and pravastatin, has been associated with an increase in the risk of muscle toxicity, or myopathy, which can range from relatively mild to severe.[356,357] While statins differ with respect to their metabolism by DMEs, all statins are substrates of the liver uptake transporter OATP1B1, the product of the SLCO1B1 gene, which has been shown to be polymorphic. Individuals carrying the c.521TT genotype of SLCO1B1 are at significantly higher risk of statin-induced myopathy compared to individuals who do not possess this allelic variant.[321,356,357] Two haplotypes that demonstrate compromised uptake activity, SLCO1B1*5 and SLCO1B1*15, are quite prevalent in Caucasians (~15%–20%), somewhat less prevalent in Asians (~10%–15%), and are much less common in sub-Saharan Africans and African Americans (~2%).[358] Many drugs have been identified as inhibitors of OATP transporters as well; this inhibition can also result in an increase in the plasma exposure of statins and other drugs that are OATP substrates.[331] Thus, careful analysis of the pharmacogenomic influence of OATP1B1 and the potential for DDIs triggered by inhibition of OATPs is an important consideration, especially when evaluating the potential for toxicity of a drug that will be administered to patients taking statins or other drugs that are known substrates of OATP transporters. Interestingly, it has recently been reported that Rotor syndrome, which is a rare autosomal disorder causing conjugated hyperbilirubinemia and mild jaundice, is caused by deficiency of OATP1B1 and OATP1B3.[359] While Rotor syndrome is rare and hyperbilirubinemia can be caused by other factors such as polymorphisms or chemical inhibition of UGT1A1,[360] this finding provides insight into previously unexplored mechanisms of toxicity involving interactions with drug transporters.

Cholestasis

Bile flow is driven by the vectorial transport of bile acid across hepatocytes. Interference with this process by

inhibition of bile acid transporters located on the sinusoidal and canalicular hepatocellular membranes can trigger hepatotoxicity.[361,362] The sodium taurocholate-cotransporting polypeptide (NTCP) is a sodium-dependent transporter located on the sinusoidal hepatocellular membrane that facilitates the transport of bile acids into hepatocytes.[363,364] The bile salt export pump (BSEP) is an ABC transporter located on the canalicular hepatocellular membrane that pumps bile acids out of hepatocytes and into bile.[365,366] Maintaining proper functionality of bile salt transporters is vital, as evidenced by mutations in BSEP that have been shown to cause progressive familial intrahepatic cholestasis type II, which is fatal.[367] Certain drugs such as rifampicin, glibenclamide, and cyclosporine A have been reported to inhibit NTCP and BSEP, resulting in cholestasis.[361] Inhibition of BSEP as a contributor to cholestatic liver injury has been described for various drugs, for example, troglitazone, ketoconazole, lapatinib, nefazodone, and bosentan.[362,368] In vitro systems such as inverted membrane vesicles expressing BSEP,[362] or cultured cells expressing BSEP and NTCP,[361] are commonly used to evaluate the interaction of a compound with these transporters. However, it should be noted that in vitro inhibition of BSEP does not automatically implicate a test compound or drug as a causative agent in cholestatic liver disease in humans, as the therapeutic concentrations in plasma (and liver) need to be compared with the potency of BSEP inhibition.[368] Researchers in the pharmaceutical industry are currently exploring the value of using early determination of BSEP inhibition as a way in which to benchmark compounds for further development, in order to minimize the risk of liver injury later in clinical development.[362]

INTEGRATION OF METABOLIC PATHWAYS

From the sections presented earlier, it is clear that pathways of xenobiotic metabolism range from simple, such as carboxylesterases, to complex, such as the various pathways capable of introducing oxidations. Also clear is the fact that a xenobiotic is not necessarily subject to a single metabolic transformation; rather, xenobiotics are more typically metabolized and eliminated following multiple transformations. Thus, it is important that an integrated view of xenobiotic metabolism be considered when assessing the extent to which metabolism is a determinant of toxicity.

Consider the case of acetaminophen, a drug whose three primary metabolic transformations (oxidation, sulfonation, and glucuronidation) have been discussed in multiple sections earlier. It is the balance of the transformations, the predominance of one pathway over the other, and the factors that determine the predominant pathway that determine toxicity (Figure 4.33). Acetaminophen is eliminated metabolically in the liver primarily by sulfate conjugation of the phenyl hydroxyl group; however, competing with this high-affinity, low-capacity pathway is elimination via glucuronidation also of the hydroxyl group. At high doses of acetaminophen, PAPS pools become depleted and rate limiting, and the secondary pathway of glucuronidation predominates. Glucuronidation thus provides a backup route of elimination. Saturation of these two elimination pathways allows more acetaminophen to flow through the oxidation pathways.

In liver, acetaminophen is oxidized predominantly by CYP2E1 to yield the *N*-acetyl-*p*-benzoquinoneimine. This pathway of metabolic activation forms reactive species that bind to critical macromolecules in the liver and is believed responsible for hepatotoxicity. Thus, inducers of CYP2E1, such as ethanol, increase hepatic capacity for CYP2E1-mediated oxidation and may enhance hepatotoxicity.

Acetaminophen has been associated with analgesic nephropathy. Acetaminophen can also be oxidized by prostaglandin synthase to a reactive metabolite capable of binding to macromolecules. The realization that a pathway other than the well-characterized P450 route was involved occurred through observations that acetaminophen was covalently bound in the inner medulla of the rabbit kidney, a site nearly devoid of P450 activity.[369] Covalent binding has been attributed to prostaglandin synthase-mediated oxidation in the inner medulla; however, acetaminophen-induced renal toxicity is largely limited to the renal cortex, which contains P450 activity. This is because prostaglandin synthase activity of the inner medulla is inhibited at high acetaminophen doses, but the P450 pathway of the cortex is not inhibited and is thus responsible for the cortical damage. This gradient of oxidation pathways across the kidney (with the cortex possessing higher P450 activity than prostaglandin synthase, the outer medulla being intermediate, and the inner medulla possessing far greater prostaglandin synthetase activity) results in certain xenobiotics being more toxic to one region of the kidney than another.[370] The example of acetaminophen highlights that many factors, including species, organ of metabolism, and dose, can influence the expression of xenobiotic-metabolism-mediated toxicity.

COMPUTATIONAL APPROACHES FOR PREDICTION OF BIOTRANSFORMATION

Currently, tens of thousands of chemical entities can be found in commerce and in the environment for which little or no toxicological or metabolism data are available, and chemical manufacturers and pharmaceutical companies continue to develop new compounds at a prodigious rate. Individual testing of such large numbers of chemicals and drugs is time-consuming, costly, resource intensive, and, in the case of whole-animal testing, ethically unsupportable. For these reasons, a great deal of interest has developed in computational (in silico) methodologies to predict chemical toxicity and, more recently, metabolism based on structure and physicochemical properties. The two basic computational approaches to the prediction of chemical metabolism are quantitative structure–activity relationships (QSARs) and expert systems. QSAR, as the name implies, seeks to quantitatively correlate physicochemical, electronic, quantum mechanical, spatial, and other descriptors of a molecule with rates of metabolism, generally focusing on a particular reaction at a particular site within a series of structurally related compounds. These

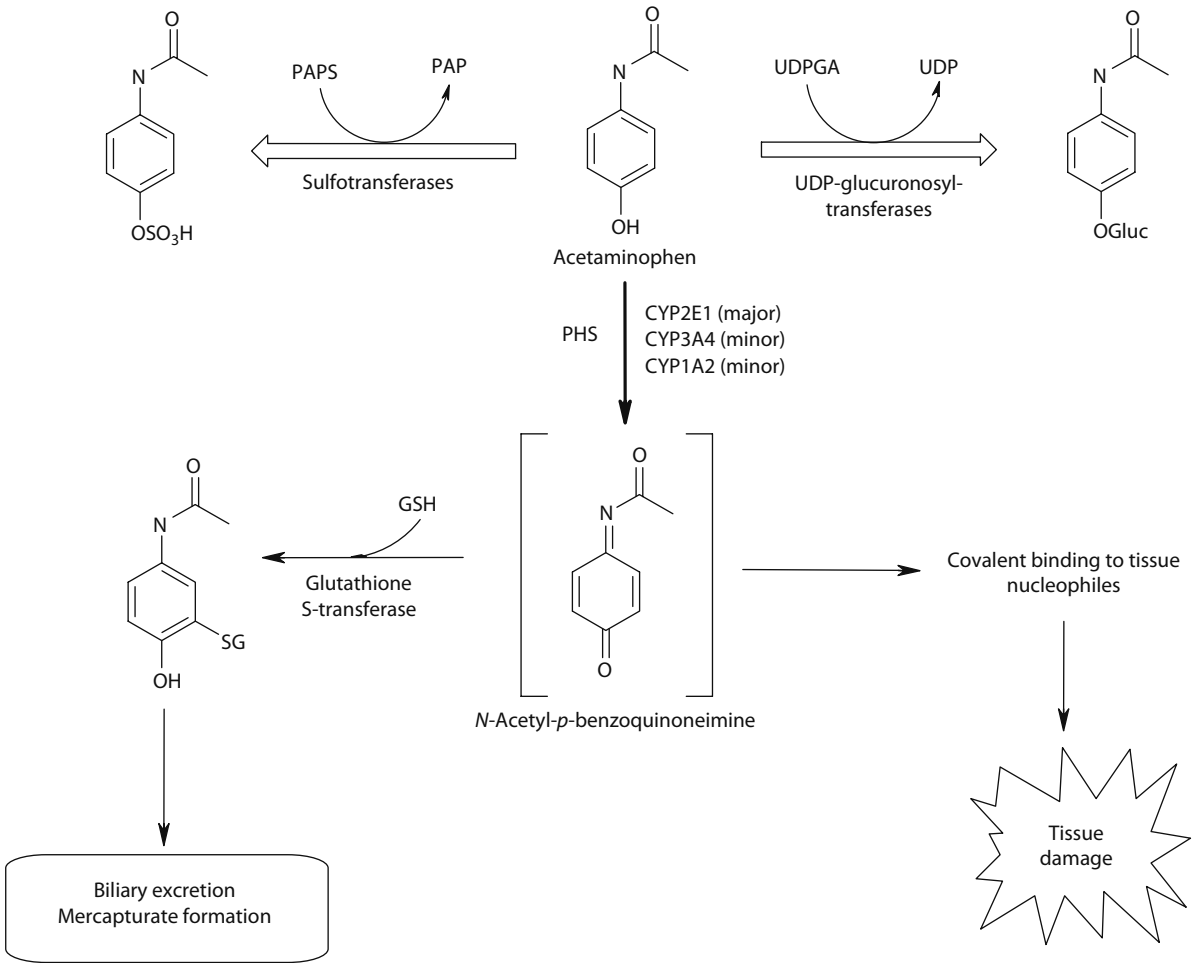

FIGURE 4.33 Integration of metabolic pathways: acetaminophen. Major detoxification pathways are indicated by open arrows and include sulfonation and glucuronidation. Bioactivation of acetaminophen involves oxidation to *N*-acetyl-*p*-benzoquinoneimine (NAPQI), and it may be catalyzed by several P450 isozymes as well as PHS. At therapeutic doses, conjugation pathways predominate and bioactivation is negligible. Following overdose, conjugation pathways become saturated and oxidation to the reactive intermediate NAPQI becomes significant. NAPQI may be detoxified by reaction with reduced GSH, either by a spontaneous or GST-catalyzed reaction and excreted as the corresponding mercapturate. At high exposure levels, GSH may become depleted, allowing NAPQI to react with tissue nucleophiles, resulting in toxicity.

techniques can be very useful in understanding the molecular and electronic determinants of substrate–enzyme interactions and in optimizing (or minimizing) the interaction of a compound with a particular enzyme.

Perhaps of greater interest to the toxicologist is the so-called expert system approach, which seeks to predict global biotransformation pathways based on chemical structure.[139] Expert systems are based on libraries of generalized metabolism rules distilled from large sets of experimental metabolism data. Each rule describes an individual metabolic transformation on a particular substructure or molecular fragment. Several metabolism expert systems are currently commercially available, including METEOR®,[371] TIMES®,[372] META®,[373] and MetabolExpert®.[374] These programs allow the user to draw structures using a graphical interface or to input structures in a variety of file formats. Most are capable of calculating some physicochemical parameters based on the query structure and use these as additional inputs for metabolite prediction. In general, expert system predictions are qualitative, but some programs, such as TIMES, also provide a quantitative estimate of metabolite production.

A major strength of rule-based expert systems is that they incorporate mechanistic insight into predictions and can be used to guide chemistry efforts in designing desirable biotransformation properties into new compounds. A downside to these systems is the potential to generate excessive numbers of unrealistic metabolites via multiple pathways, leading to a so-called combinatorial explosion.[375] To address this problem, most programs have cutoff filters based on properties such as molecular weight and lipophilicity, or they allow the user to constrain the analysis as to types of transformations predicted (phase I vs. phase II) or the total number of metabolites predicted in any given pathway. In addition to predicting the products of biotransformation, many of these programs also allow assessment of potential toxicity of metabolites, either through an integrated toxicity prediction

engine or through links to external companion programs. Newer approaches to combined prediction of metabolism and toxicity seek to integrate rule-based systems for metabolism prediction with biochemical pathway analysis and high-throughput biology techniques (omics technologies) in a systems biology approach.[376] Although still in its relative infancy, systems biology promises significant advances in our ability to understand and predict the interactions among biotransformation, biological activity, and toxicity of chemicals and drugs.

REGULATORY AND PRODUCT DEVELOPMENT ASPECTS OF XENOBIOTIC METABOLISM

International regulatory agencies require information about the metabolism of drugs and other chemicals that fall under their jurisdiction. The amount of data required will depend on the use of the chemical, its potential exposure to humans, and the potential role of metabolism in its efficacy and toxicity. Early information on the metabolism of drugs is becoming essential for the selection of drug candidates for further development. With the development of combinatorial synthetic chemistry and high-throughput pharmacological screening, the number of potential drug candidates that must be rapidly screened for their potential metabolism has increased dramatically. This is leading to the development of rapid methods to predict metabolism and potential DDIs. Data are needed from in vitro and in vivo animal models that will be used in safety assessments to allow the toxicologist to design appropriate studies during the preclinical phase of a safety assessment. Data are also needed concerning the potential human metabolism of the drug candidate to allow the toxicologist to extrapolate animal safety data to humans. In the recent past, it was difficult to obtain in vitro data from human tissues. With the current knowledge of the human P450 isozymes and the commercial availability of human hepatic preparations and cells that express human P450s, it is possible to obtain data concerning human metabolism of drug candidates, pesticides, and other chemicals.

The U.S. Food and Drug Administration (FDA) has recently released a guidance document concerning in vitro drug metabolism and DDI studies during the drug development process.[377] This document stresses the importance of obtaining information on the metabolism of a drug candidate during the early stages of development. This information is important in predicting potential individual differences based on polymorphic expression of xenobiotic metabolism enzymes and in predicting DDIs. The guidance document is based on the following general observations:

- The concentrations of a drug or its active metabolite circulating in the body determine the extent of its desirable and/or adverse effects.
- A major determinant of the concentration of a drug is clearance, and metabolism is a major determinant of clearance.
- Drugs that are not substantially metabolized may impact the metabolism of other drugs.
- Large differences in blood concentrations can occur because of polymorphic metabolism. DDIs can also produce large changes in the blood concentration of a drug.
- Major advances have been made in availability of human tissue and recombinant enzymes for in vitro studies of drug metabolism.

The guidance document suggests that the goals of in vitro metabolism and interaction studies should be to (1) identify major metabolic pathways and the specific isozymes involved and (2) explore and extrapolate the effects of the drug candidate on the metabolism of other drugs and the effect of other drugs on the metabolism of the candidate. To accomplish these goals, the FDA suggests starting from human hepatic microsomes, now commercially available, then moving to cell-based systems that express specific human P450s, which are also commercially available. They note that it is possible to move to hepatocytes and precision-cut liver slices but recognize the technical difficulties associated with these preparations.

A companion guidance document outlining recommendations for in vivo characterization of drug metabolism and potential DDIs was released shortly after the in vitro guidance document.[378] The conceptual basis for this document is similar to the in vitro guidance and stresses the importance of determining whether excretion or metabolism is the major mechanism of drug clearance, as well as the identification of major metabolic routes in the latter case. Further, the guidance lays out recommendations on study designs for the investigation of both inhibition and induction of metabolism of the drug of interest. These studies are useful in determining changes in dosage regimen for the target and interacting drugs during polypharmacy.

QUESTIONS

4.1 During the development of a new drug, it was decided that the introduction of a hydroxyl group onto the molecule would make the compound more water soluble, which offered the advantages of increasing gastric solubility and improving the pharmaceutics properties. An initial study of the plasma concentrations of the nonhydroxylated analog in rats had been completed in anticipation of beginning a subchronic toxicity study. When the plasma concentrations of the less lipophilic, hydroxylated drug were determined, it was found that the plasma concentrations were maintained for a longer period of time than with the nonhydroxylated analog. How would you explain this finding?

4.2 As a toxicologist, you have been asked to design a program to assess the potential hazard of a chemical. What type of information concerning its metabolism would you want to have before you design the hazard

assessment program? Based on the metabolism information you have requested, how would you choose the species to be used in the hazard assessment program?

4.3 A cancer chemotherapeutic drug has been shown effective in treating a specific type of cancer; however, the drug is also cytotoxic and produces severe side effects if it is not rapidly metabolized by cytochromes P450. It is important, therefore, not to treat a patient with doses of the drug that are too high for the patient's capacity to rapidly metabolize it to the less toxic product. What characteristics of the patient should be considered when attempting to choose a dose that will minimize the side effects?

4.4 A compound is functionalized by the P450 system and then forms sulfate and glucuronide conjugates and a mercapturic acid before being excreted. How may its metabolism be altered as the dose is increased from a no-observable-effect level (NOEL) to a dose that produces severe toxicity?

4.5 Many chemical carcinogens are metabolized by routes that represent detoxification and by other routes that represent metabolic activation. What are the various phenomena that may shift the balance between detoxification and metabolic activation?

5 Toxicokinetics

A. Roberts and Andrew Gordon Renwick

CONTENTS

It has been recognized for many years[1] that the relationship between drug administration and therapeutic response can be subdivided into two aspects:

1. *Pharmacokinetics*, which relates to the movement of the drug within the body
2. *Pharmacodynamics*, which is concerned with the pharmacological effects once the drug is delivered to its site of action/receptor

The principles of *pharmacokinetics* apply to any environmental nonnutrient (xenobiotic), and many of the biological processes involved in the absorption, distribution, and elimination, such as the metabolizing enzymes, are nonspecific and shared by drugs and other low-molecular-weight organic molecules such as additives, pesticides, and contaminants. The term *toxicokinetics* is now widely accepted to describe *pharmacokinetic* processes for potentially toxic chemicals, which do not have a therapeutic effect. Toxicokinetics is the application of pharmacokinetic principles to animal toxicity studies and to human toxicity data, in order to provide information on internal exposure to the parent compound and its metabolites, and other aspects such as accumulation during chronic exposure.

The incorporation of toxicokinetic data from animal studies into risk assessment requires data from related in vivo studies in humans at appropriate doses, or from the results of in vitro data incorporated into a physiologically based pharmacokinetic (PBPK) model (see later and Chapter 6).

The understanding and interpretation of toxicological findings require information on two key areas: (1) delivery of the compound to its site of action (toxicokinetics) and (2) the mechanism of action and potency of the chemical at the site of action (toxicodynamics) (Figure 5.1). Toxicokinetic data may assist in understanding the dose–response relationship in animal toxicity studies and its relevance to humans, and allow the identification of potentially at-risk subgroups of the exposed human population.

The term *toxicokinetics* means the movement of a toxicant around the body and is primarily concerned with the relationship between the external dose, as usually measured in toxicity studies (e.g., mg kg^{-1} body weight), and a measure of the internal dose of the active compound delivered to the target for toxicity (Figure 5.1), such as the concentration in the general circulation or at the target for toxicity. The concentration in the general circulation is influenced by absorption, distribution, and elimination processes, as shown in Figure 5.2, and frequently, the compound has to pass many lipid and metabolic barriers prior to reaching the site of toxicity. Knowledge of the concentrations of the parent compound and any metabolites in plasma and tissues, allied to the rate of change on further dosing or cessation of administration, allows logical selection of the animal species most appropriate for toxicity testing and extrapolation of any toxicity observed in animals to the likely risk for humans.[2–14]

Such information may be derived by various methods and approaches including

1. Data from studies in which the chemical contains a radiolabel, usually ^{3}H, ^{14}C, or ^{35}S
2. Chemical-specific data using a sensitive analytical method

Radiolabeled studies are valuable for following the fate of the chemical skeleton as it moves from the site of administration into the blood, is distributed to the tissues, and finally is eliminated from the body in air, urine, or bile. Measurement of total radiolabel is nonspecific and reflects both the chemical and its metabolites; this is both an advantage and a disadvantage. The advantage is that it

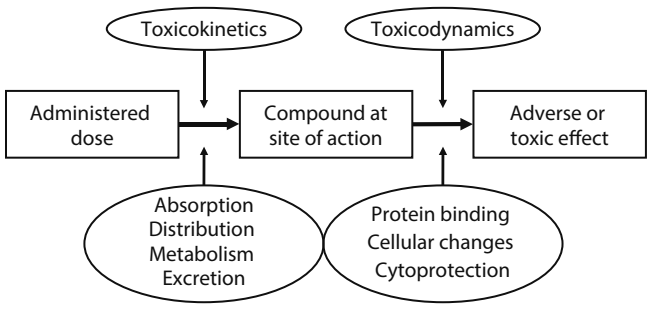

FIGURE 5.1 The relationship between in vivo response and toxicokinetics and toxicodynamics.

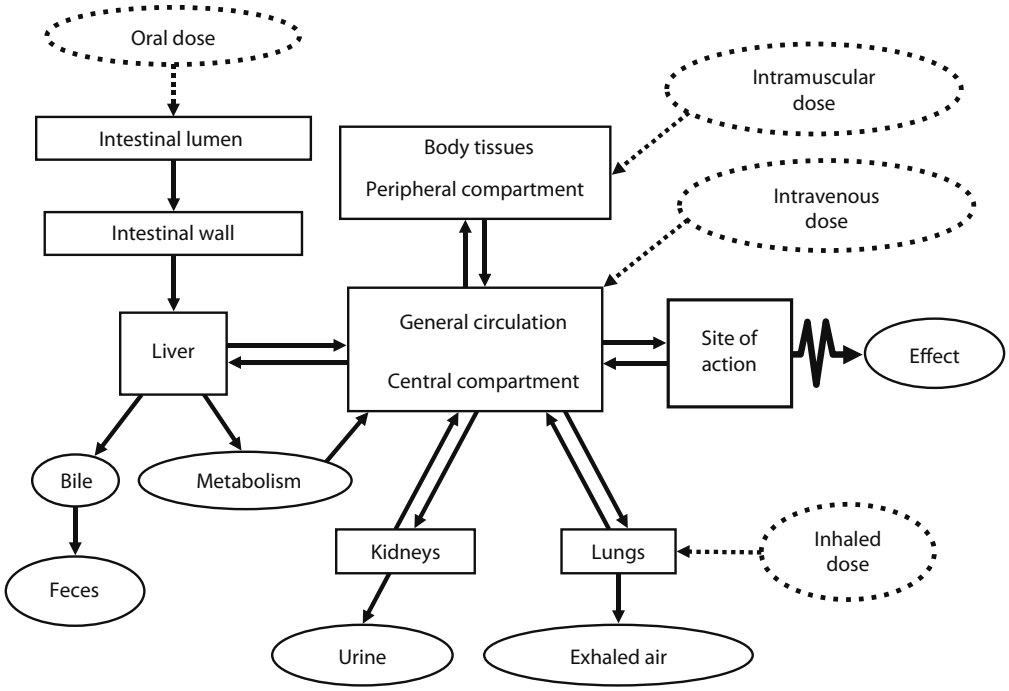

FIGURE 5.2 Toxicity in relation to pharmacokinetics. The chemical may be given orally or by injection or inhalation. The concentration at the target organ is in equilibrium with that in the systemic circulation, which is itself in equilibrium with a large number of other physiological processes, which can increase or decrease that concentration. The transfer from one tissue to another usually involves transfer across a lipid membrane and frequently entails entering a tissue with high elimination capacity such as the liver or kidneys. The parent chemical is eliminated from the body when it is converted into a different structure by metabolism or is eliminated in the urine, bile, or expired air.

allows quantitative balance studies to be performed, for example, to determine how much of the dose is absorbed, which organs accumulate the compound and/or its metabolites, the pathways of metabolism, and the routes of excretion. The disadvantage is that radiolabeled *ADME* (absorption, distribution, metabolism, and excretion) studies do not allow an assessment of how much of the chemical is absorbed intact and how much is distributed around the body as the parent chemical or as metabolites. Combining radiolabeled ADME studies with chromatographic separation methods is useful to define the overall fate of the chemical in the body and identify the main chemical species (parent compound and/or metabolites) that are present in the circulation and delivered to the site of toxicity. The development of automated analytical techniques of high sensitivity and specificity (such as HPLC, LC-MS, and LC-MS-MS) has allowed toxicokinetics to provide useful information on in vivo absorption, distribution, and elimination in laboratory animals and the magnitude and the duration of exposure of targets for toxicity. The key to interpreting plasma concentration–time curves was the development of suitable mathematical models to derive rates of absorption, metabolism, and excretion. Problems of accumulation on repeated dosing and saturation of elimination are particularly pertinent to high-dose animal toxicity studies, and information on these areas can be obtained only from suitably designed in vivo toxicokinetic studies.

Toxicokinetic data have the potential to define

1. The internal exposure (internal dose) in animals based on plasma or blood concentrations of the parent compound or its active metabolite in relation to the dose given to the animals
2. The relationship between plasma or blood concentrations and those at the site of toxicity
3. The information allowing quantitative interspecies comparisons derived from appropriate blood/plasma data after the administration of tracer doses to human volunteers

This chapter concentrates on the derivation and interpretation of chemical-specific toxicokinetic data based on measurements of the concentrations in plasma and urine. Toxicokinetic data are also useful in extrapolating between species and across different routes of exposure or administration, as well as from single doses to chronic administration. Chemical-specific toxicokinetic measurements are essential if the results of in vitro toxicity tests are to be interpreted logically, because they can define the upper limit of biologically plausible in vivo concentrations.

BIOLOGICAL PRINCIPLES

Certain general principles governing the disposition of therapeutic drugs are applicable to nearly all low-molecular-weight organic compounds. The processes involved in absorption,

distribution, and elimination of foreign compounds were outlined in previous editions of this book, and only essential concepts are now presented under the discussion of mathematical principles.

MATHEMATICAL PRINCIPLES

In order to describe adequately the changes in blood or plasma concentrations of foreign compounds, it is necessary to assign a suitable mathematical model that accurately describes the shape of the concentration–time curve. However, certain aspects are model independent and are considered first, because they are usually constituent parts of the various mathematical models. In recent years, there has been a trend away from multicompartmental mathematical analysis, which offers little apart from mathematical predictability, toward physiologically more relevant model-independent concepts such as clearance.[15] Physiologically related parameters such as clearance and bioavailability represent an intermediate level of information between mathematical multicompartment models and full PBPK models.

Model-Independent Considerations

Biochemical and physiological processes are usually either zero-order or first-order reactions. In zero-order reactions, the rate of change in concentration with time occurs at a fixed amount per unit of time, that is,

$$\frac{dC}{dt} = k$$

where
- C is the concentration
- t is the time
- k is a constant with units of amount per time, for example, micrograms per minute

Zero-order reactions are particularly important at high concentrations, when enzymes are working at maximum rate and an increase in C cannot result in an increase in rate. This situation produces nonlinear or saturation kinetics, which can assume considerable importance in toxicity studies and is discussed later.

In first-order reactions, the rate of change in concentration is proportional to the concentration of the chemical available for the reaction, that is,

$$\frac{dC}{dt} = kC$$

where k is a constant that represents a proportional change with time and has units of time^{-1}, for example, min^{-1}.

Most kinetic processes (e.g., diffusion, carrier-mediated uptake, metabolism, and excretion) are first-order reactions at low concentrations. *Most of the following equations given make this assumption*.

First-order reactions can be described by equations that include exponential functions. In many cases, the entry of a foreign compound into the body or into a tissue follows an exponential increase, which may be described mathematically by

$$\text{Uptake} = 1 - e^{-kt} \tag{5.1}$$

where the uptake is the concentration present at time t divided by the final concentration when all the compound has entered the body or tissue. This equation assumes that there is no elimination process. The elimination of a compound (by a first-order process) once it has entered the body or tissue may be described by an exponential with a negative slope

$$C = C_0 \cdot e^{-kt} \tag{5.2}$$

where
- C is the concentration present at time t
- C_0 is the initial concentration

In Equations 5.1 and 5.2, k is the rate constant for that process.

Exponential equations of the type given in Equation 5.2 may be solved as

$$\ln C = \ln C_0 - kt$$

or using $\log_{10}$

$$\log C = \log C_0 - \frac{kt}{2.303}$$

These are equations of the generalized form

$$y = A + Bx$$

where
- x and y are variables
- A and B are constants

In such cases, a plot of x against y gives a straight-line graph with a slope of B and an intercept of A. Thus, for toxicokinetics, a graph of ln C against time gives a slope of $-k$ and an intercept of ln C_0. Because the units of k are time^{-1}, which is a difficult unit to visualize, the rates of a first-order processes are usually described by their half-life or $t_{½}$ (see later).

Usually, the equation necessary to describe the kinetics of a compound in the body requires the use of at least two exponential rate terms. This is illustrated in Figure 5.3 in which two phases are seen in the plasma concentration–time curve

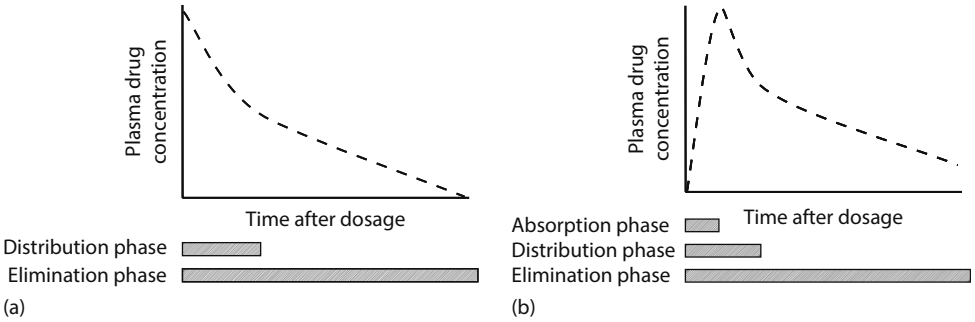

FIGURE 5.3 The plasma concentration–time profile of a chemical following intravenous and oral dosage. The concentration is on a logarithmic scale. Rapid processes, such as absorption and distribution, do not significantly affect later time points that are determined largely by the slowest process (elimination in the diagrams shown). (a) Intravenous administration and (b) oral administration—rapid absorption.

after an intravenous dose and three different phases after an oral dose. Each phase requires a different rate constant, and the early time points in the concentration–time curve are influenced by all rates. Eventually, the influence of the component with the higher rate (the faster component) becomes negligible, while the slower component (with the smaller rate constant) still affects the concentration. Thus the terminal phase of the concentration–time curve is determined by the slower process, that is, the one with the smaller rate constant, and the earlier phase by the sum of both processes. This process allows both rate constants to be determined by the procedure known as the method of residuals or stripping (see later).

Absorption

Absorption describes the processes involved in the transfer of a chemical from the site of administration into the systemic blood circulation. Absorption from the gut is of greatest importance because most toxicity studies are performed using oral administration. Absorption may involve first-order or zero-order processes or a mixture of the two. The extent of absorption can be determined by the comparison of concentrations in plasma or urine after oral and intravenous administration. The fraction absorbed may be low due to either poor uptake from the site of administration or metabolism between the site of administration and the systemic circulation (first-pass metabolism).

Tissue Extraction

The rate constant for tissue uptake may depend on either the tissue blood flow (*perfusion limited uptake*), where k is related to the tissue flow rate, or the rate of diffusion through membranes (*diffusion-limited uptake*) where k is related to the diffusion rate constant and is not readily measurable. In general, diffusion rate limitation applies to highly water-soluble compounds, whereas perfusion rate limitation applies to the entry of lipid-soluble compounds into slowly perfused tissues, such as adipose tissue. The extent of tissue uptake depends on the relative affinities of the blood and the different tissues.[16,17]

Plasma Protein Binding

Protein binding is an equilibrium reaction:

$$P^r + C_f \leftrightarrow C_b$$

where

P^r is the free protein
C_f is the unbound or free chemical
C_b is the chemical–protein complex

The fraction unbound α is given by

$$\alpha = \frac{C_f}{C_f + C_b} = \frac{C_f}{C} \tag{5.3}$$

where C is total plasma concentration. The binding of organic compounds to albumin can involve two or more binding sites. It should be appreciated that the extent of plasma protein binding is not incorporated into most pharmacokinetic analyses because the plasma kinetic parameters are calculated using the total concentrations ($C_f + C_b$). If the free nonbound concentration of the chemical is used to calculate kinetic parameters, this has to be specified in the description of the parameters; in the absence of such a description, it is assumed that the total plasma concentration has been used. Because plasma protein binding is a saturable process (see later), in vitro binding studies should be performed over a range of concentrations.

Clearance

There are two main mechanisms by which the circulating levels of a foreign compound may be reduced: metabolism and excretion. Metabolism is a major source of both species differences and human variability,[18–22] and its toxicological consequences are discussed in an earlier chapter (Chapter 4).

Clearance (CL) is defined as the ratio

$$CL = \frac{\text{Rate of elimination}}{\text{Plasma concentration}}$$

and may be regarded as the volume of plasma or blood that is cleared of compound in unit time by the route under

consideration. The units are volume time^{-1}, for example, frequently mL min^{-1} because if rate is μg min^{-1} and plasma concentration is μg mL^{-1}, the plasma clearance will be mL min^{-1}.

Renal Clearance

The renal clearance (CL_R) is given by

$$CL_R = \frac{\text{Rate of elimination in urine}}{\text{Plasma concentration}} = \frac{C_u \times F_u}{C} \qquad (5.4)$$

where

C_u is the urine concentration
F_u is the urine flow (volume in unit time)
C is the plasma concentration at the midpoint of the urine collection period

The concentration in urine is dependent on three main variables.

Glomerular Filtration

The glomerular membrane has pores of 70–80 A, and all molecules smaller than about 20,000 Da are filtered. Thus proteins and protein-bound compounds remain in the plasma.

The rate of removal in the glomerulus is given by

$$\text{GFR} \times C_f = \text{GFR} \times C \times \alpha \qquad (5.5)$$

where

GFR is the glomerular filtration rate
C_f is the unbound concentration in plasma
C is the total plasma concentration
α is the fraction unbound

Compounds that are extensively bound to plasma proteins show limited elimination by glomerular filtration. The chemical–protein complex does not dissociate in the glomerulus, but releases more unbound compound when the plasma is diluted by water reabsorbed in the distal parts of the renal tubule.

The glomerular filtration rate is about 130 mL min^{-1} in men and 120 mL min^{-1} in women, or approximately 2 mL min^{-1} kg^{-1}, which is lower than that of the Wistar rat (3.4 mL min^{-1} kg^{-1}).[23]

Reabsorption

Reabsorption from the renal tubule back into the blood is variable and dependent on the lipid solubility of the compound, the pH of the urine, the pKa of the chemical, and the extent of concentration of the urine due to water reabsorption. The pH of the urine can be altered appreciably by treatment with weak acids or bases, whereas the plasma shows little change because its pH is buffered by the high protein content. It is therefore possible to affect the pH partitioning of foreign compounds between renal tubule contents and plasma, and this possibility should be considered when preparing dose solutions.

Tubular Secretion

A number of different transporters, including OAT—transporters for organic acids, OCT—transporters for bases, peptide transporters, and nonspecific transporters (members of the MRP family), have been identified on either the basolateral or apical membranes of the renal tubule or on both.[24–26] They show relatively low substrate specificities and differences between species and sexes. The extent of their involvement for a particular compound is dependent on the affinity between the compound and the carrier protein. The transporters give active saturable processes, and saturation of secretion causes a dose-dependent decrease in elimination at high plasma concentrations.

All three processes described earlier can alter, simultaneously and independently, and the overall renal clearance may be regarded as a composite expression:

$$\text{Renal excretion} = \text{Glomerular filtration} - \text{Reabsorption} + \text{Tubular secretion}$$

$$\text{Rate of excretion} = \text{GFR } C\alpha - \text{Rate of reabsorption} + \text{Rate of tubular secretion}$$

The values of GFR, C, and α can be determined experimentally. Measurement of inulin clearance (or creatinine clearance in humans) determines the GFR, because this compound does not undergo significant reabsorption, tubular secretion, or protein binding. The extent of reabsorption and secretion of a compound may be inferred by comparison of its renal clearance with the value of GFR × α. If $CL_R < \text{GFR} \times \alpha$, then reabsorption must be occurring and is greater than any secretion (which may or may not be present); if $CL_R = \text{GFR} \times \alpha$, then reabsorption, which may or may not be present, is negated by an equal rate of secretion; and if $CL_R > \text{GFR} \times \alpha$, then tubular secretion must be occurring and is greater than any reabsorption (which may or may not be present).

The mathematical implications of the renal elimination process have been the subject of a number of reviews.[27–29]

Hepatic Clearance

The clearance of a compound by the liver may be regarded as dependent on the rate of delivery to the organ (blood flow) and the efficiency of removal from the blood.

The uptake and metabolism of nutrients, hormones, and absorbed chemicals are a primary function of the liver. Hepatocytes and hepatic sinusoids show a number of features that facilitate these processes, including fenestrae in the endothelium, which allow even large molecules to leave the circulation and enter the space of Disse, a fluid collagen containing matrix in the space of Disse, a brush-border on the hepatocytes that greatly increases the surface area for absorption, active uptake transporters for some chemicals, and very high enzyme activity (intrinsic clearance) within the hepatocytes.

If the internal cellular metabolic clearance (CL_{int}) is high, then the hepatic clearance approximates to the hepatic blood flow and becomes dependent on the hepatic blood flow (which is constant under normal physiological conditions). If CL_{int} is low, then the hepatic clearance is relatively constant and independent of blood flow and is a first-order rate constant.

The relationship between internal cellular metabolic clearance and enzyme kinetics is given by

$$CL_{\text{int}} = \frac{V_{max}}{K_m + C_f} \tag{5.6}$$

where

V_{max} and K_m are Michaelis–Menten constants for the enzyme metabolizing the chemical
C_f is the hepatic venous concentration of unbound chemical

If C_f is low and is much less than K_m for the enzyme (i.e., well below saturation levels and a first-order reaction), this term may be ignored and

$$CL_{int} = \frac{V_{max}}{K_m} = \text{Constant}$$

When the value of C_f approaches or exceeds K_m, the substrate concentration is sufficient to saturate the enzyme, and the kinetics become zero order and nonlinear in relation to dose. This situation is a distinct possibility in high-dose toxicity testing and is discussed later in more detail.

The concepts given are important for the use of V_{max} and K_m values in interspecies comparisons. Species differences in clearance will relate to differences in V_{max}/K_m for low-clearance metabolized compounds, but will relate to liver blood flow for high-clearance compounds (irrespective of differences in V_{max}/K_m). This possible source of error in extrapolation across species is avoided when both the enzyme activity and organ blood flows are part of a PBPK model.

Biliary Clearance

The bile is an important route allowing foreign compounds to move from the general circulation into the gut.[30] Organic cation transporters on the sinusoidal membrane transfer large polar cations into the hepatocyte and from the hepatocyte in the bile.[31,32] Species differences exist in the molecular weight threshold for significant biliary excretion, which has been estimated as 325 ± 50 Da in the rat, 440 ± 50 Da in the guinea pig, 475 ± 50 Da in the rabbit, and about 500 in humans.

The clearance via the bile CL_B is given, by analogy with renal clearance, as

$$CL_B = \frac{\text{Rate of elimination in bile}}{C} = \frac{C_B \times F_B}{C} \tag{5.7}$$

where

C_B is the concentration in bile
F_B is the volume of bile in unit time (bile flow)
C is the plasma concentration

Plasma Clearance

Plasma clearance (CL) may be defined as

$$CL = \frac{\text{Rate of elimination from plasma}}{C}$$

The plasma clearance is the sum of the various contributory clearance processes:

$$CL = CL_R + CL_H + CL_B + \text{etc.}$$

Plasma clearance, which is one of the most valuable toxicokinetic constants, is determined from the plasma concentration–time curve and is discussed in detail later.

Physiologically Based Pharmacokinetic Models

In recent years, disposition models have been developed, which are based on the principles discussed earlier, that is, organ blood flow, tissue extraction, and rates of metabolism and excretion. These models are derived from the physiology of the test animal and are discussed in detail in the chapter by Clewell and colleagues in this volume (Chapter 6). PBPK models have been applied successfully to a number of compounds and have been particularly successful for organic solvents, for example, benzene.[33] This approach represents a powerful method, capable of dealing with saturation of metabolism[6,34,35] and valuable for the extrapolation of animal data to humans.[6,34–42] However, its ability to predict concentrations is dependent on the precision of the parameter estimates used and the model chosen.[43] Therefore, PBPK modeling should be considered as one of three possible approaches to the analysis and interpretation of toxicokinetic data:

1. Simple physiologically related concepts, such as bioavailability and clearance (this chapter)
2. Compartmental analysis, which gives mathematical precision but is difficult to relate directly to metabolic or physiological processes (this chapter)
3. PBPK modeling, which can be used to predict target organ concentrations (Chapter 6)

Compartmental Analysis: Modeling

In order to describe plasma concentration–time curves mathematically, an appropriate predictive model has to be fitted to the data. The correlation between the actual data and the plasma or blood concentration–time curve generated using the model shows the suitability of the model in describing the experimental results.

Considering the data presented in Figure 5.4, it is apparent that the same model cannot describe the properties of both compounds, although in both cases, the initial and final plasma concentrations were the same. The differences in the plasma concentration–time profiles originate in the number of rates at which the compound may leave and enter the plasma. When the tissues show instantaneous equilibration with plasma, there is a simple exponential decrease in plasma concentrations that results from the elimination process(s) (Figure 5.4a). Alternatively, the compound may leave the plasma to enter *other tissues* at measurable rates, as well as

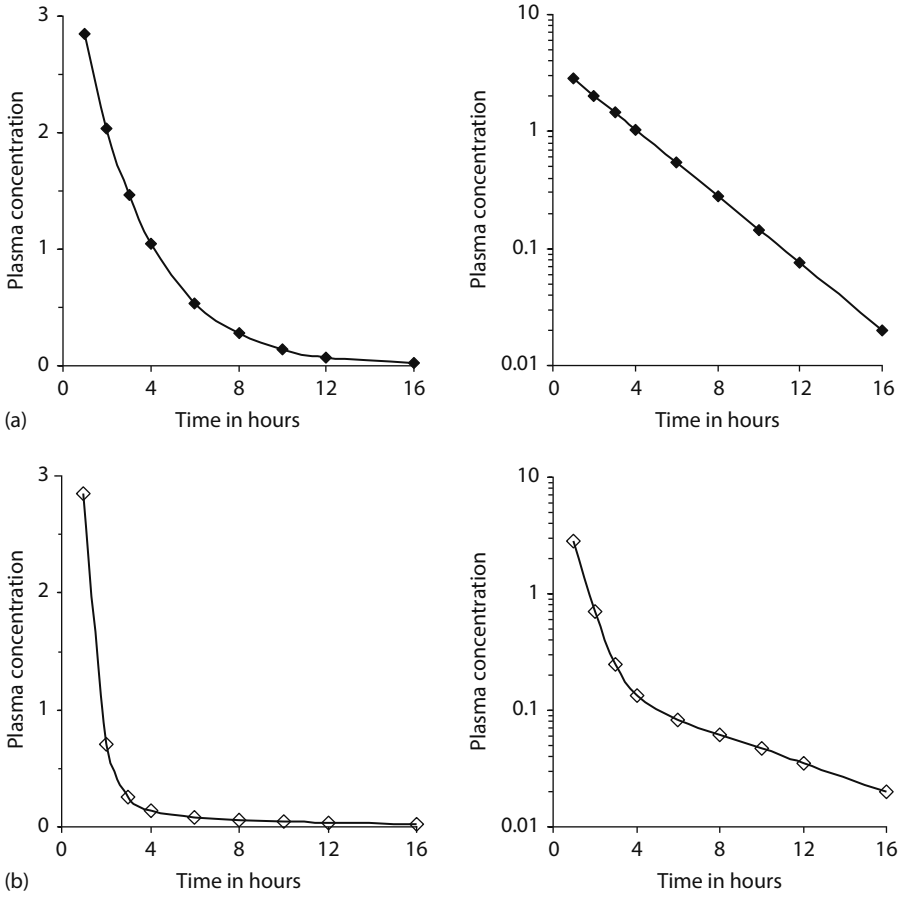

FIGURE 5.4 Plasma concentration–time data for two compounds with the same initial and final measured concentrations but with different distribution characteristics. The results are plotted in linear and semilogarithmic forms.

undergoing elimination from the plasma (Figure 5.4b). Under such circumstances, the *other tissues* may be adequately described mathematically by a second exponential term. It is important to realize that these *other tissues* share only one criterion, that is, their associated rate of uptake and transfer back into plasma, and biologically diverse tissues may be part of the same mathematical compartment. In some cases, two or more additional compartments are required, and elimination may occur from compartments other than the central compartment (plasma plus tissues that reach equilibrium before the first plasma measurement). Multicompartment analysis can be extremely complex,[44] but in many cases, knowledge of the best model for fitting to the data is not necessary.

Because the aim of this chapter is to provide an introduction to toxicokinetics (i.e., samples needed, data handling, and the type of information that can be obtained), only simple models are discussed in detail. The two models discussed show widespread applicability, and an understanding of the principles underlying these simple models is essential, if the data generated by computer analysis using more complex models are to have any meaning.

Texts recommended for further reading include those by Gibaldi and Perrier,[45] a classic text, which is a mathematical approach that is well explained and illustrated using actual experimental data; Rowland and Tozer,[46] a well-written readable text with many excellent illustrations and study problems at the end of each section; and Wagner,[47] an approach similar to that of Gibaldi and Perrier[45] but with a useful biological introductory chapter and expanded sections on dosage regimen calculations, pharmacological response, and automated pharmacokinetic analysis. An additional useful book is that by Gabrielsson and Weiner,[48] which gives a clear account of different models in relation to the use of WinNonlin and provides excellent explanations of the basics of data fitting.

One-Compartment Open Model

Intravenous Bolus Dose

The compound is dissolved in and evenly distributed within a single compartment of volume V (Figure 5.5). Elimination of the compound, by both excretion and metabolism, is by first-order processes, and changes in plasma concentration are reflected in similar and simultaneous decreases in the tissue concentrations, because all tissues represent part of the single compartment. In Figure 5.5, V is the volume of distribution, k_{ex} is the excretion rate constant, and k_m is the metabolism rate constant. In mathematical terms, such a system may be described adequately by a simple first-order

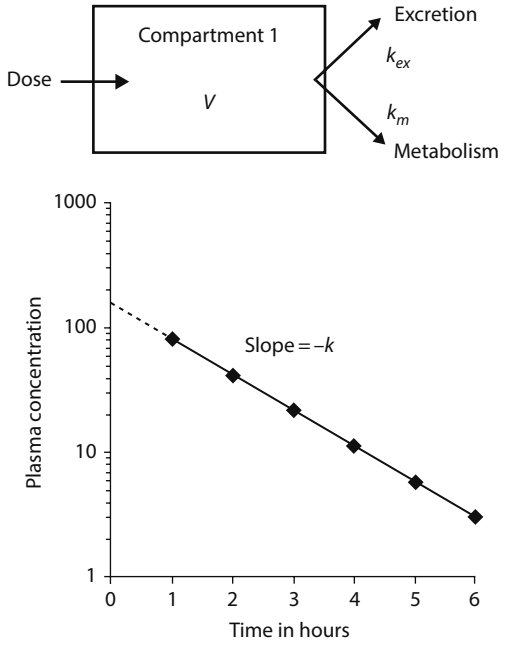

FIGURE 5.5 Plasma concentration–time curve after a bolus intravenous dose for a one-compartment system. The concentrations have been shown on a logarithmic scale for illustrative purposes; the slope $-k$ would be calculated by plotting the natural logarithms of the concentrations against time.

equation, where the rate of removal of a compound from the body (e.g., in milligrams per hour) is proportional to the body load (e.g., in milligrams):

$$\frac{dAb}{dt} = -kAb \tag{5.8}$$

where

Ab is the amount of compound in the body
k is the elimination rate constant (k equals $[k_{ex} + k_m]$)

A solution to this equation to give the amount remaining in the body at time t after injection is given by

$$Ab = Ab_0 e^{-kt} \tag{5.9}$$

where

Ab is the amount of compound at time t
Ab_0 is the amount at time zero

For a one-compartment model, the concentration in the plasma (C) may be related to Ab by the *apparent volume of distribution* (V). This volume may be regarded as the volume of plasma in which the body burden (body load or Ab) would have to be dissolved, in order to give the plasma concentration measured:

$$C = \frac{Ab}{V} \tag{5.10}$$

where

C is the plasma concentration
V is the apparent volume of distribution

Thus, Equation 5.10 may be rewritten in its more usual form

$$C = C_0 e^{-kt} \tag{5.11}$$

where

C is the plasma concentration at time t
C_0 is the concentration at time zero

For such a system, we can define the following parameters.

Apparent Volume of Distribution

The apparent volume of distribution (V) is the volume of plasma into which the dose *appears* to have been dissolved to give the initial plasma concentration, C_0, that is,

$$V = \frac{Ab}{C} = \frac{\text{Dose}}{C_0} \tag{5.12}$$

The units are usually liters, milliliters, liters per kilogram, or milliliters per kilogram.

For a chemical that is lipid soluble or that readily binds to tissue components, the plasma concentration represents a small fraction of the total amount in the body, and thus the compound appears to have been dissolved in a large volume of plasma that may greatly exceed the physiological volume of plasma. In practice, such compounds usually require a model with at least two compartments to describe the concentration–time curve (see later).

Elimination Rate Constant

The elimination rate constant (k) represents the fractional loss of compound from the body per unit time, that is,

$$k = \frac{\text{Amount of chemical eliminated in unit time}}{\text{Amount of chemical in the body}} = \frac{(dAb/dt)}{Ab}$$

Equation 5.11 may be rewritten as

either $\ln C = \ln C_0 - kt$

or $\log C = \log C_0 - \dfrac{kt}{2.303}$

Thus a graph of $\ln C$ against time (illustrated using a logarithmic scale in Figure 5.5) has a slope of $-k$ and an intercept of $\ln C_0$. The units of k are time^{-1} (e.g., h^{-1} or min^{-1}). If the elimination rate constant is 0.4 h^{-1}, it means that 40% of the body load is removed each hour. The value of k is the summation of component elimination rate constants (e.g., k_{ex}, k_m).

Elimination Half-Life

The elimination half-life ($t_{1/2}$) is the time taken for the amount in the body (Ab) or the plasma concentration (Ab/V) to decrease to one-half. Thus, after one half-life, C in Equation 5.11 equals $C_0/2$, that is,

$$\frac{C_0}{2} = C_0 e^{-kt_{1/2}} \quad \text{or} \quad \frac{1}{2} = e^{-kt_{1/2}}$$

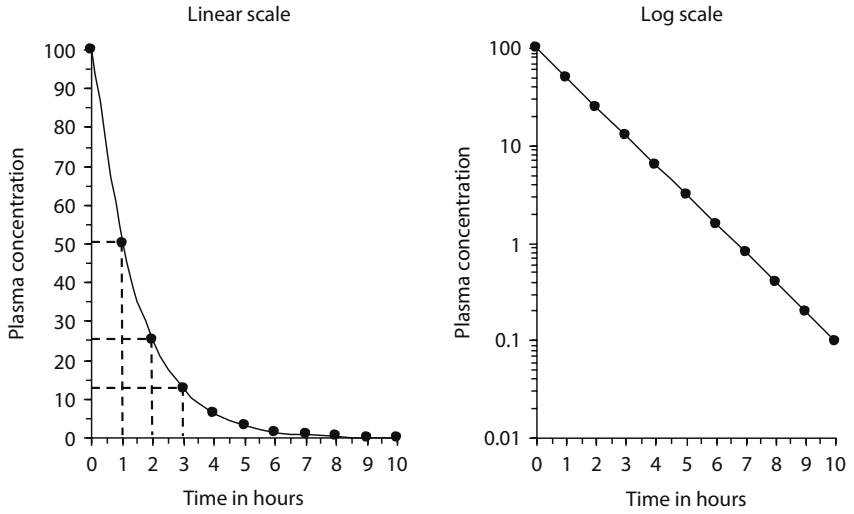

FIGURE 5.6 The elimination of a chemical with a half-life of 1 h from a one-compartment model, plotted on linear and semilogarithmic scales.

Therefore, $\ln 0.5 = -kt_{½}$ or $-0.693 = -kt_{½}$

$$t_{1/2} = \frac{0.693}{k} \tag{5.13}$$

where the units are time (e.g., hours or minutes).

For first-order reactions, the half-life is independent of dose, body burden, and plasma concentration (Figure 5.6).

Plasma Clearance

Plasma clearance (*CL*) relates the amount of chemical eliminated in unit time to the plasma concentration and may be regarded as *the volume of blood that is cleared of chemical in unit time*. *CL* is a constant for first-order reactions. In many respects, *CL* is a better reflection of the inherent capacity of the tissues to eliminate the compound than is the half-life or elimination rate constant:

$$CL = \frac{\text{Rate of elimination from the body}}{\text{Plasma concentration}}$$
$$CL = \frac{\left(dAb/dt\right)}{C} \tag{5.14}$$

Substituting from Equation 5.8,

$$CL = \frac{kAb}{C}$$

The amount in the body at any time (*Ab*) is given by Equation 5.10; therefore,

$$CL = \frac{kCV}{C} = kV \tag{5.15}$$

where the units are in L h^{-1}, L min^{-1}, mL h^{-1}, or mL min^{-1}. Rearranging Equations 5.15 and 5.13,

$$k = \frac{CL}{V} \quad \text{and} \quad t_{1/2} = \frac{0.693V}{CL} \tag{5.16}$$

This equation shows clearly that the elimination rate constant (*k*) is derived from two independent variables, each of which can be related to physiological processes: the *clearance*, which reflects the capacity of the organs of elimination to remove the compound from the plasma, and the *apparent volume of distribution*, which reflects the proportion of the total body burden that is circulated to the organs of elimination. Plasma clearance may depend on the rate of the active process(es) in the organs of elimination or on the plasma flow to the principal organ(s) of elimination.

Clearance may be obtained without knowing the value of *V*. Rearranging Equation 5.14,

$$\frac{\mathrm{d}Ab}{\mathrm{d}t} = CL \times C$$

or in time d*t*, the amount lost $\mathrm{d}Ab = CL \times C \times \mathrm{d}t$. Integrating between time = 0 and infinity (∞), the total dose will have been eliminated, so that $\mathrm{d}Ab = dose$

$$\text{Dose} = CL \int_0^\infty C\mathrm{d}t$$
$$\text{Dose} = CL \times \text{AUC} \tag{5.17}$$
$$CL = \frac{\text{Dose}}{\text{AUC}}$$

where AUC is the area under the plasma concentration–time curve extrapolated to infinity. For Equation 5.17 to be valid, the dose has to be fully available to the organs of elimination (i.e., an intravenous dose), and the AUC has to be extrapolated to infinity.

This relationship can also be used to calculate *V*; substituting *CL* from Equation 5.16 into Equation 5.17,

$$V = \frac{\text{Dose}}{\text{AUC} \times k} \tag{5.18}$$

The importance of Equations 5.17 and 5.18 is that both the clearance and the apparent volume of distribution can be derived from infusion administration, where the determination of V using Equation 5.12 is not possible. These equations may also be applied to oral administration, providing that allowance is made for incomplete absorption of the dose (see later). This method of calculating CL is also applicable to multicompartment linear systems with elimination from the central compartment.

Information Obtainable from Urinary Data

Renal clearance can be calculated using Equation 5.4. Equation 5.4 can be rearranged as

$$\text{Rate of urinary excretion} = CL_R \times C$$

where

CL_R is the renal clearance
C is the concentration in plasma

Thus from Equation 5.15,

$$CL_R \times C = k_R \times V \times C = k_R \times Ab$$

where k_R is the renal excretion rate constant.

However, from Equation 5.9, Ab at any time = Dose $\times e^{-kt}$. Therefore,

$$\text{Rate of urinary excretion} = k_R \times \text{Dose} \times e^{-kt} \quad (5.19)$$

or

$$\ln(\text{rate of urinary excretion}) = (\ln k_R \times \text{Dose}) - kt \quad (5.20)$$

The significance of this is that a plot of the natural logarithm of the rate of urinary excretion (amount excreted per time interval) against time gives a straight line with a slope of $-k$, and an intercept of ($\ln k_R \times$Dose), and the decrease in the amount appearing in the urine mirrors the overall decrease in the plasma concentration. It is not possible to obtain CL or V without sampling the central (blood) compartment.

This approach is subject to considerable errors in the measurement of the excretion rate at different times after dosage due to factors such as incomplete bladder emptying. To overcome this problem, the rate constant can be derived more reliably from the amount remaining to be excreted, using the *sigma-minus* method. This method is based on the following equation, which is derived from integration between time zero and infinity of Equation 5.19:

$$A_{ex} = \frac{k_R \times \text{Dose}}{k}\left[1 - e^{-kt}\right] \quad (5.21)$$

where A_{ex} is the total amount excreted up to time t. At infinite time, $[1 - e^{-kt}]$ equals unity, so that

$$A_{ex}^{\infty} = \frac{k_R \times \text{Dose}}{k}$$

where A_{ex}^{∞} is the cumulative total amount excreted in urine up to time infinity. Substituting back into Equation 5.21,

$$A_{ex} = A_{ex}^{\infty}\left[1 - e^{-kt}\right]$$

or

$$A_{ex}^{\infty} - A_{ex} = A_{ex}^{\infty} e^{-kt} \quad (5.22)$$

The left-hand side of Equation 5.22 is equivalent to the amount finally excreted minus the amount excreted up to that time (ΔA_{ex}). Taking natural logarithms,

$$\ln \Delta A_{ex} = \ln A_{ex}^{\infty} - kt \quad (5.23)$$

A plot of $\ln \Delta A_{ex}$ against time gives a straight line of slope $-k$.

By analogy with Equation 5.17, CL_R may be calculated from the total amount excreted and the plasma AUC:

$$CL_R = \frac{A_{ex}}{\text{AUC}}$$

where A_{ex} and AUC refer to the same time interval.

Combining this with Equation 5.22 gives the following relationships:

$$\text{AUC}_0^{\infty} = \frac{\text{Dose}}{CL} = \frac{A_{ex}^{\infty}}{CL_R} \quad \text{or} \quad CL_R = CL \times \frac{A_{ex}^{\infty}}{\text{Dose}}$$

where AUC_0^{∞} is the AUC from zero to infinity after an intravenous dose.

In other words, renal clearance (CL_R) equals plasma clearance (CL) multiplied by the fraction of the dose eliminated unchanged in urine.

Constant Intravenous Infusion

During infusion, the plasma concentration (C) increases to reach a plateau or steady-state concentration (C_{ss}), at which time the rate of infusion equals the rate of elimination (Figure 5.7). The extent of accumulation to steady-state is given by analogy with Equation 5.1.

$$\frac{C}{C_{ss}} = \left(1 - e^{-kt}\right)$$

or

$$C = C_{ss}(1 - e^{-kt}) \quad (5.24)$$

The various kinetic parameters may be derived from the plasma concentration–time curve for infusion.

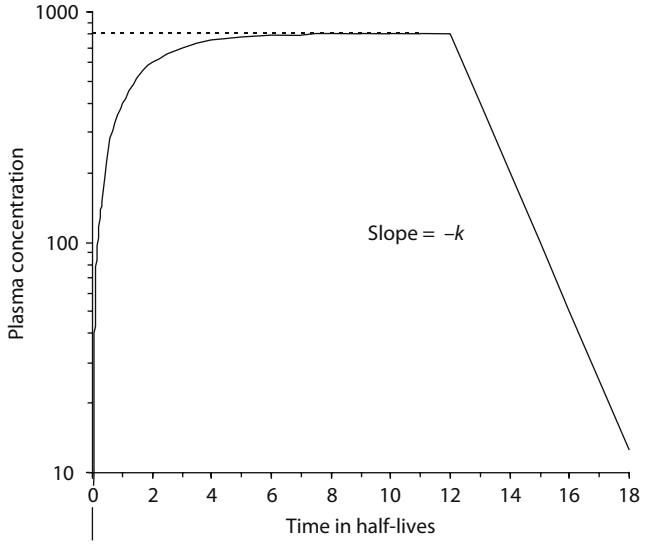

FIGURE 5.7 Plasma concentration–time curve for constant intravenous infusion into a single-compartment system. The foreign compound was infused at a constant rate from time = 0 to time = 12 half-lives when the infusion was stopped. The concentrations have been shown on a logarithmic scale for illustrative purposes; the slope $-k$ would be calculated by plotting the natural logarithms of the concentrations against time or $-k/2.303$ by plotting the logarithms to the base 10 of the concentrations against time.

Increase to Plateau

Rearranging Equation 5.24,

$$C_{ss} - C = C_{ss}e^{-kt}$$

Therefore, a plot of the natural logarithm of $(C_{ss} - C)$ against time gives a straight line with a slope equal to $-k$. The time taken to reach the plateau is therefore similar to the time taken to eliminate the compound after infusion or about 97% of the final steady-state level within five times the elimination half-life.

Steady-State Plasma Concentration: C_{ss}

At steady-state, the rate of infusion (R) equals the rate of elimination:

$$R = CL \times C_{ss}$$

or

$$CL = \frac{R}{C_{ss}} = V \times K$$

Decrease at End of Infusion

The slope of the decrease at the end of the infusion equals $-k$ because on cessation of entry, $C = C_0e^{-kt}$. The same slope would be obtained if the infusion was stopped at any stage during the infusion.

Area under the Curve

Both CL and V may be derived using Equations 5.17 and 5.18.

Oral Administration

Absorption frequently obeys first-order kinetics, but may involve a lag time due to delayed gastric emptying. The various pharmacokinetic parameters are related by the equation

$$C = \frac{F \times \text{Dose} \times k_a\left(e^{-kt} - e^{-kat}\right)}{V\left(k_a - k\right)} \tag{5.25}$$

where

F is the fraction of the dose absorbed (bioavailability)
k_a is the absorption rate constant

Increase to Peak

The increase to peak is determined by the more rapid of the two processes, absorption and elimination; for lipid-soluble compounds, absorption is usually more rapid than elimination. Measurement of the absorption rate constant must allow for the excretion occurring throughout the postdosing period, which can be done using the method of residuals (see Gibaldi and Perrier[45] for the mathematical basis of this method). The method is illustrated in Figure 5.8. In cases where elimination is more rapid than absorption, the rate of increase will be determined by the elimination rate constant (as is the case for a constant intravenous infusion—see earlier text). Thus the value of k_a can be assigned to the increase to peak only after demonstration that the value of k for the decrease is similar to that seen after intravenous dosing.

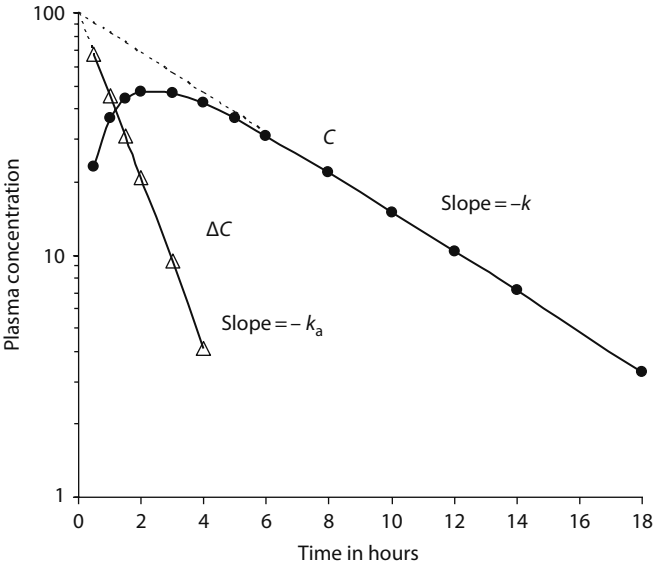

FIGURE 5.8 Use of the method of residuals to calculate the absorption rate constant for a one-compartment system. The dose was given at time 0, and plasma levels (C) were measured at intervals. The linear terminal phase was extrapolated to yield the values corresponding to the measurement times. The difference values (C extrapolated $-$ C measured) are plotted (ΔC) to yield slopes $-k_a$ or $-k$ (see text on flip-flop kinetics and Figure 5.9). The concentrations have been shown on a logarithmic scale for illustrative purposes; the slopes $-k$ and $-k_a$ would be calculated by plotting the natural logarithms of the concentrations against time.

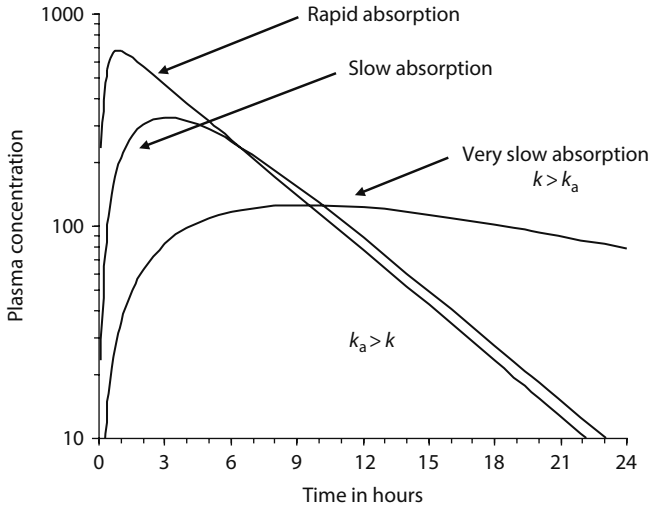

FIGURE 5.9 The effect of absorption rate on the shape of the plasma concentration–time curve.

Peak Plasma Concentration

The peak plasma concentration is determined by the dose, the bioavailability, the apparent volume of distribution (V), and the relative rates of k_a and k. The peak concentration may be more important toxicologically than the average internal exposure, especially for acute effects.

Decrease after the Peak

The decrease after the peak concentration is determined by the slower of the two processes (absorption or elimination), but it is usually elimination. Very polar compounds show slow absorption and rapid elimination, and the postpeak decrease is equivalent to $-k_a$, a situation described as *flip-flop* kinetics (see Figure 5.9). Flip-flop kinetics are very common after topical (dermal) application.

Area under the Curve

Both CL and V may be derived using Equations 5.17 and 5.18, providing that the dose used in the calculation is adjusted for the fraction absorbed (F), that is,

$$CL = \frac{\text{Dose}_{\text{oral}} \times F}{\text{AUC}_{\text{oral}}}$$

It is common to see CL_{oral} calculated as oral dose/AUC_{oral} in the absence of any information on F. Such a term is meaningless because what is calculated is CL/F, which is dependent on two physiological processes that are often unrelated. Intravenous data are necessary to relate a nonlinear change in AUC at high oral doses to either altered CL or F.

The value of F is determined by comparison of the plasma concentration–time curves after oral and intravenous dosing. Because of the different shapes after oral and intravenous administration (Figure 5.10), comparisons at a single time point are not valid. Instead, the overall systemic exposures, as indicated by the AUCs extrapolated to infinity (Figure 5.10), after oral and intravenous dosage are compared:

$$CL = \frac{\text{Dose}_{\text{oral}} \times F}{\text{AUC}_{\text{oral}}} = \frac{\text{Dose}_{\text{iv}}}{\text{AUC}_{\text{iv}}}$$
$$F = \frac{\text{Dose}_{\text{iv}} \times \text{AUC}_{\text{oral}}}{\text{AUC}_{\text{iv}} \times \text{Dose}_{\text{oral}}} \quad (5.26)$$

These relationships are valid only if the AUC/dose ratio is constant. If this ratio is dose-dependent, then the value of either F or CL must change with an increase in dose, suggesting saturation of absorption or elimination (see later).

An alternative method to estimate the fraction of the dose absorbed as the parent compound (F) may also be

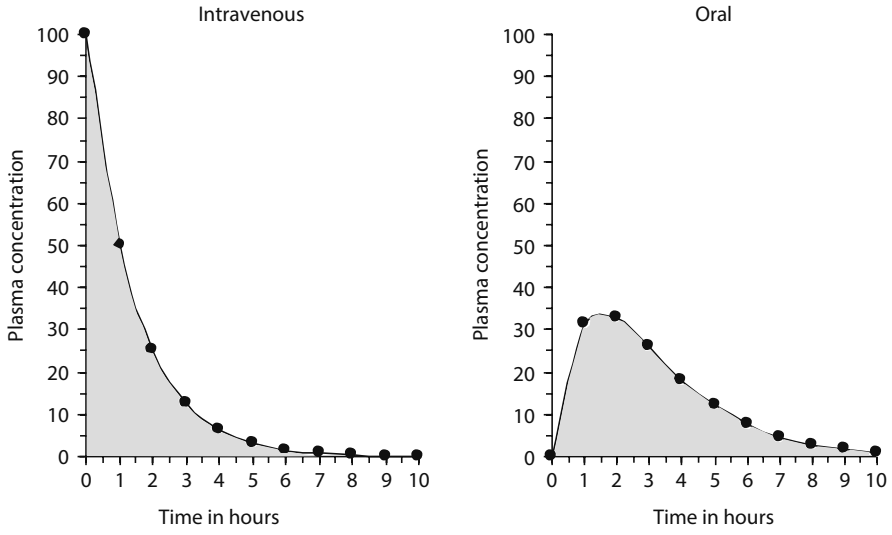

FIGURE 5.10 The shape of the plasma concentration–time curve after intravenous and oral administration. The shaded area is the AUC, which is used to calculate the bioavailability (F).

derived from the cumulative urinary excretion as the parent compound:

$$F = \frac{A^{\infty}_{ex\ \text{oral}}}{A^{\infty}_{ex\ \text{iv}}} \times \frac{\text{Dose}_{\text{iv}}}{\text{Dose}_{\text{oral}}} \tag{5.27}$$

Metabolite Kinetics

As discussed elsewhere, the biotransformation of xenobiotics usually results in detoxication, but is frequently associated with the formation of a toxic metabolite. Measurement of the rate of metabolism in vivo can provide much useful information on detoxication and/or bioactivation processes. In most cases, the rate of metabolite formation is governed by in vivo enzyme kinetics; enzyme reactions are first order only over a limited substrate concentration range. Saturation of metabolism is discussed in more detail later, and the following analysis relates to metabolite formation under first-order reaction conditions and when *CL* depends on enzyme activity rather than liver blood flow.

The one-compartment model for the parent compound (Figure 5.5) can be extended by a second compartment from the metabolism arrow with characteristics for the metabolite of V^m and an overall elimination rate constant of k^m. The concentration of the metabolite is given by

$$C^m = \frac{k_m \text{Dose}\left(e^{-kmt} - e^{-kt}\right)}{V^m\left(k - k^m\right)} \tag{5.28}$$

where C^m is the plasma concentration of the metabolite at time = t.

The elimination rate of the metabolite (k^m) is often greater than the overall elimination rate of the parent compound (k). In such cases, the term e^{-kmt} approaches zero before e^{-kt}, and thus at late time points, Equation 5.28 may be rewritten and solved omitting e^{-km} when it becomes

$$\ln C^m = \ln \frac{k_m \times \text{Dose}}{V^m\left(k^m - k\right)} - kt \tag{5.29}$$

Thus, a plot of the natural logarithm of the plasma concentration of the metabolite against time has a terminal slope similar to that of the parent compound (i.e., $-k$). In this case, the metabolite is present only as long as the parent compound remains in the body, and the ratio of metabolite:compound remains constant during the elimination phase.

In those cases where the elimination rate of the metabolite (k^m) is less than that of the parent compound (k), the term e^{-kt} approaches zero before e^{-kmt}, and thus Equation 5.28 may be written as

$$\ln C^m = \ln \frac{k_m \times \text{Dose}}{V^m\left(k - k^m\right)} - k^m t \tag{5.30}$$

and a plot of the natural logarithm of the plasma concentration of the metabolite against time has a slope of $-k^m$. In this case, the ratio metabolite/compound increases during the elimination phase. Such cases are of particular interest to toxicologists because on repeated exposure, the concentrations of metabolite increase more than the parent compound and may exceed those of the parent compound.

The overall elimination rate constants may also be derived from urinary metabolite levels as described earlier for the parent compound, although again the derived rate may be either k or k^m. However, if metabolite kinetics are based solely on urinary excretion data, the formation of more lipid-soluble metabolites may be missed because negligible amounts of such metabolites would be excreted in the urine.

Two-Compartment Open Model

Mathematically and physiologically, it is often more appropriate to regard the body as representing a simple two-compartment open system in which the distribution to certain peripheral tissues is not an instantaneous process. In such a system, the chemical initially enters a central compartment (the plasma and those tissues in which distribution is instantaneous) and is subsequently distributed to a second peripheral compartment. Elimination normally occurs from the central compartment, so that chemical in the peripheral compartment must transfer back to the central compartment in order to be eliminated. In Figure 5.11, k_{12} and k_{21} are the rate constants for transfer from compartments 1 to 2 and from 2 to 1, respectively, and k_{10} is the elimination rate from the central compartment. The relationships between these parameters and measurable rate constants (α and β) are outlined later.

Intravenous Bolus Dose

After a single intravenous bolus dose into a two-compartment system, the plasma concentration (C) at time t may be described by

$$C = Ae^{-\alpha t} + Be^{-\beta t} \tag{5.31}$$

where

- A and B may be regarded as analogous to C_0 for each compartment, and $A + B = C_0$
- α and β correspond to hybrid rate constants, each influenced by the individual distribution, redistribution, and elimination rate constants, that is, k_{12}, k_{21}, and k_{10}

The shape of a typical plasma concentration–time curve following a bolus intravenous dose is illustrated in Figure 5.11. As outlined for the determination of the absorption rate constant (see earlier), the method of residuals or line stripping is used to separate α and β. At later time points, $Ae^{-\alpha t}$ approaches zero, and the data are described by $C = Be^{-\beta t}$. At early time points, the difference between the actual C values and the concentrations derived by back-extrapolation of the $Be^{-\beta t}$ line are due to the contribution from $Ae^{-\alpha t}$. The values of A and α may be similarly derived by calculated linear regression analysis of the residuals or ΔC (C actual − C extrapolation).

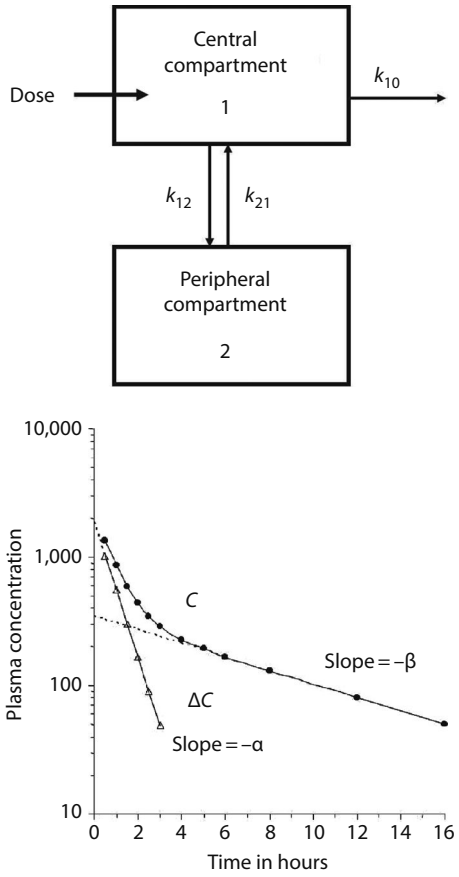

FIGURE 5.11 Plasma concentration–time curve for two-compartment system. The concentrations have been shown on a logarithmic scale for illustrative purposes; the slopes α and β would be calculated by plotting the natural logarithms of the concentrations against time and by fitting the two exponential terms simultaneously or using the method of residuals.

The rate constants α and β are composite rate constants, from which it is possible to derive k_{12}, k_{21}, and k_{10} using the following equations (see Ref. 45 for derivations):

$$C_0 = A + B$$

$$\alpha + \beta = k_{12} + k_{21} + k_{10}$$

$$V_1 = \frac{\text{Dose}}{A + B}$$

where V_1 is the volume of the central compartment, and

$$k_{21} = \frac{A\beta + B\alpha}{A + B}$$

$$k_{10} = \frac{\alpha\beta}{k_{21}}$$

$$k_{12} = \alpha + \beta - k_{21} - k_{10}$$

It is important to note that k_{10} and β do not relate to the same process, because k_{10} refers to the elimination from the central compartment, whereas β refers to the overall elimination from the body (and is slower due to transfer out of tissues as well as elimination from the central compartment).

As with the one-compartment system, an intravenous bolus allows derivation of most pertinent pharmacokinetic parameters:

1. A, B, α, and β may be derived from plasma data (see earlier).
2. k_{10}, k_{12}, k_{21}, and V_1 may be derived by manipulation of α, β, etc. (see earlier).
3. α, β, k_{10}, k_{12}, and k_{21} may be derived from urine by plotting either the excretion rate against time or by the sigma-minus method, where $\ln\left(A_{ex}^{\infty} - A_{ex}\right)$ (see Equation 5.22) is plotted against time.
4. The renal elimination constant, k_R, may be derived also from the renal clearance

$$CL_R = \frac{C_u \times F_u}{C}$$

and V_1 because $CL_R = k_R V_1$.

5. The concentration in the peripheral compartment (C_2) may be calculated from the following equation (which is analogous to Equation 5.25 for absorption into a single compartment):

$$C_2 = \frac{\text{Dose} \times k_{12}\left(e^{-\beta t} - e^{-\alpha t}\right)}{V_2(\alpha - \beta)} \qquad (5.32)$$

where V_2 is the volume of the peripheral or deep compartment. During the terminal phase of the concentration–time curve, $e^{-\alpha t}$ approaches zero, and therefore Equation 5.32 may be simplified as

$$C_2 = \frac{\text{Dose} \times k_{12} \times e^{-\beta t}}{V_2(\alpha - \beta)}$$

Therefore, a graph of $\ln C_2$ against time has a slope of −β. Thus the terminal rate of decrease in the peripheral compartment of a two-compartment system is identical to the decrease in the central compartment. In absolute terms, the calculation of C_2 is not particularly valuable, because the peripheral tissues comprising the deep compartment are not homogeneous, and the compound may not show a uniform distribution. If the concentration in the target organ is measured, then subsequent concentrations may be calculated using β defined from the central compartment.

A further useful kinetic parameter (V_β), which relates the total amount of chemical in the body to the plasma concentration, is given by the equation

$$V_\beta = \frac{\text{Dose}}{\text{AUC} \times \beta}$$

Just as β is a hybrid term reflecting the overall elimination from the body, so is V_β a composite but valuable function.

Constant Intravenous Infusion

The shape of the plasma concentration–time curve on intravenous infusion into a two-compartment open system is similar to that given in Figure 5.7, but with a biphasic increase at the start of the infusion and a biphasic decrease at the end. The kinetic parameters may be derived from the graph similarly to the one-compartment model, as follows.

Increase to Plateau

The increase to plateau follows a complex exponential function with 90% and 99% of the steady-state concentration being reached after, respectively, four and seven times the terminal (β-phase) half-life.

Plateau Level (Css)

At steady-state, the rate of infusion (R) equals the rate of elimination. Therefore,

$$\frac{R}{C_{ss}} = CL = V_1 \times k_{10} = V_\beta \times \beta$$

Decrease after Plateau

The decrease after plateau follows the equation:

$$C = A^* e^{-\alpha t^*} + B^* e^{-\beta t^*}$$

where

- A^* and B^* are the intercepts by back-extrapolation to the end of the infusion of the α and β slopes (determined as described for Figure 5.11)
- t* is the time since cessation of infusion

In many cases, a biexponential decrease is not seen in postinfusion data, because distribution will have occurred throughout the infusion.

Area under the Curve

The AUC can be used to derive the plasma clearance using Equation 5.17.

Oral Administration

Assuming first-order absorption into compartment 1, the plasma concentration at time t is given by

$$C = A^{\ddagger} e^{-\alpha t} + B^{\ddagger} e^{-\beta t} + C^{\ddagger} e^{-k_a t}$$

Graphical analysis by a semilogarithmic plot of ln C against time may reveal three separate phases from which α, β, and k_a should be measurable using the method of residuals. However, in practice, the value of k_a is frequently similar to α, and compounds that require a two-compartment model after an intravenous bolus dose appear to fit first-order absorption into a one-compartment model following oral dosing.[49,50] Thus detailed analysis is not possible without reference to intravenous data to determine which rate constant refers to the absorption rate.[45,47] The absorption rate is likely to be of greatest importance in acute toxicity studies, whereas the bioavailability (F) may be more significant in chronic studies; the latter may be measured using model-independent equations (Equation 5.26 or 5.27).

Metabolite Kinetics

Frequently, both the parent compound and the metabolites each require a two-compartment open model. The resulting equation requires four exponential terms, but often the concentration–time curve for the metabolite appears to be a simple biexponential decrease. The slow terminal phase of the metabolite is given by either β for the parent compound or the terminal rate for the metabolite (see earlier), and the faster rate is a composite of the other three rate constants.

Multiple Oral Dosing: Chronic Administration

On multiple dosing or continuous intake, the plasma levels increase over a period of four to five times the terminal half-life to establish a plateau concentration, similar to that seen with intravenous infusion (Figure 5.7). The average plateau (steady-state) level is subject to variations around a mean because material is eliminated between doses. In oral toxicity studies, these doses may represent either repeated single gavage doses or the feeding habits of the animals if the test compound is incorporated into the diet and fed *ad libitum*. On cessation of chronic intake, the rate of decrease in blood levels is usually but not always similar to that seen after a single dose.

One-Compartment Open Model

The average plateau level is given (by analogy with intravenous infusion) as

$$C_{ss\ mean} = \frac{\text{Dose} \times F}{V \times k \times T} \tag{5.33}$$

where

- F is the fraction absorbed
- T is the dose interval
- k is the elimination rate constant

However, it is important to realize that this equation includes the *elimination* rate constant k, which may or may not be the terminal rate observed following oral administration (flip-flop kinetics).

An alternative and more useful form of this equation can be derived from the fact that at steady-state, the rate of input ($F \times \text{dose}/T$) is balanced by the rate of elimination ($C_{ss\ mean} \times CL$); therefore,

$$C_{ss\ mean} = \frac{\text{Dose} \times F}{T \times CL}$$

The fluctuations around the mean plateau level depend on the dosing interval in relation to the terminal elimination rate. Thus compounds with a short half-life (2–3 h) show large fluctuations, as more of the chemical is eliminated between each dose, and with single daily dosing, the plasma levels

will approach zero prior to each dose. Inter-dose fluctuations may be reduced and blunted by slow absorption. The equations relating to these processes were summarized in the previous edition of this book.

$C_{ss\ mean}$ may be related to the AUC_{oral} for a single dose since

$$AUC_{oral} = \frac{Dose \times F}{V \times k} = \frac{Dose \times F}{CL}$$

and therefore

$$C_{ss\ mean} = \frac{AUC_{oral}}{T} \tag{5.34}$$

It is important to realize that this relationship assumes that the AUC is directly proportional to the dose and that *CL* does not alter during chronic administration. If a compound can induce its own metabolism on chronic treatment, then *CL* increases over the first few days of the study so that the steady-state concentrations and body burden are lower than would have been predicted from the AUC, *CL*, or *CL/F* measured after a single dose. Induction of cytochrome P450 (CYP) isoenzymes is a well-recognized phenomenon that can have toxicological implications in humans[51] and could also affect the outcome of animal toxicity studies.[52] Changes in *CL* may be assessed by comparison of $AUC_{0-\infty}$ for a single dose, with the AUC for a dose interval at steady-state (AUC_{0-T}). If AUC_{0-T} (chronic) < $AUC_{0-\infty}$ (single), this indicates either induction of metabolism or a decrease in bioavailability; conversely, if AUC_{0-T} (chronic) > $AUC_{0-\infty}$ (single), then inhibition or saturation of metabolism and/or an increase in bioavailability is indicated.

The extent of accumulation on repeated intake may be measured by the average amount in the body at steady-state ($Ab_{ss\ mean}$) divided by the amount in the body after a single dose (*Ab*), that is,

$$\text{Extent of accumulation} = \frac{Ab_{ss\ mean}}{Ab} = \frac{Ab_{ss\ mean}}{Dose \times F}$$

The amount in the body at steady-state is given by Equation 5.33:

$$Ab_{ss\ mean} = VC_{ss\ mean} = \frac{F \times Dose}{k \times T}$$

Therefore,

$$\text{Extent of accumulation} = \frac{1}{k \times T} = \frac{1}{0.693/t_{1/2} \times T} = \frac{1.44 \times t_{1/2}}{T}$$

Two-Compartment Open Model

The equations giving the plasma concentration at time *t* at steady-state into a two-compartment system with first-order absorption are considerably more complex than those for the one-compartment system. However, the simplified equation (Equation 5.33) applies in the form

$$C_{ss\ mean} = \frac{Dose \times F}{V_1 \times k_{10} \times T} = \frac{Dose \times F}{V_B \times \beta \times T}$$

and the value of $C_{ss\,mean}$ may still be derived from Equation 5.34:

$$C_{ss\ mean} = \frac{AUC_{oral}}{T} = \frac{Dose \times F}{CL \times T}$$

In addition, the relationship between the AUC between $t = 0$ and $t = \infty$ for a single dose and the AUC for a dose interval at steady-state applies providing that neither *CL* or *F* changes on chronic intake (see earlier text); a difference between these AUC estimates indicates changes in *CL* or *F* during chronic treatment.

Statistical Moment Analysis

In recent years, both clinical pharmacokinetic and animal toxicokinetic studies have moved away from compartmental models, because they involve multiple variables, which require numerous properly timed blood samples to characterize them adequately. Also, curve fitting is dependent on the terminal slope, which is frequently measured using plasma concentrations that approach the limit of detection of the assay method, that is, the weakest data. In contrast, terms such as clearance are measured from dose and AUC, the latter being determined largely from the highest and most accurately measured concentrations. Such *time-averaged* parameters may be extended to *time-related* parameters by the use of statistical moment theory, which allows assessment of additional useful kinetic parameters such as *mean residence time* (MRT) and *mean absorption time* (MAT).

The plasma concentration–time curve may be regarded as a statistical distribution curve[53] for which the zero and first moments are the AUC and MRT, respectively:

$$AUC = \int_0^\infty C\,dt$$

$$MRT = \frac{AUMC}{AUC} \tag{5.35}$$

where AUMC is the area under the first moment of concentration–time curve. That is, $\int_0^\infty t \times C\,dt$.

The AUC and AUMC may be calculated using the trapezoid rule applied to the observed data.

The measured plasma concentrations and time points are used for AUC calculation with extrapolation to infinity calculated as C_{last}/β.

For AUMC calculation, the measured plasma concentrations (*C*) and time (*t*) are multiplied to give *Ct* values for

each time point, and these are used with the time points. The AUMC for two consecutive time points is given by $[(C_1 \times t_1 + C_2 \times t_2)/2] \times (t_2 - t_1)$, and the total AUMC for the period of observation is the sum of the calculated AUMC segments. The AUMC from the last data point to infinity has to be calculated as

$$\frac{t_{\text{last}} \times C_{\text{last}}}{\beta} + \frac{C_{\text{last}}}{\beta^2}$$

Intravenous Administration

Following an intravenous bolus dose, the MRT can be calculated by Equation 5.35. The *apparent volume of distribution at steady-state* (V_{ss})[54] may be calculated as

$$V_{\text{ss}} = CL \times \text{MRT} = \frac{\text{Dose}}{\text{AUC}} \times \frac{\text{AUMC}}{\text{AUC}} = \frac{\text{Dose} \times \text{AUMC}}{\text{AUC}^2} \quad (5.36)$$

The MRT can be calculated from the AUMC following an intravenous infusion using the equation:

$$\text{MRT}_{\text{infusion}} = \text{MRT} + \frac{\text{T}}{2} \quad (5.37)$$

where

$\text{MRT}_{\text{infusion}}$ is calculated from the AUMC and AUC by Equation 5.35 from the infusion data
T is the infusion time

The V_{ss} cannot be calculated from infusion data.

In the same way that CL may be related to V by the rate constant k (Equation 5.15), so CL may be related to V_{ss} by the first-order rate constant k_{ss}.[45,53,54]

$$CL = k_{\text{ss}} V_{\text{ss}} = \frac{V_{\text{ss}}}{\text{MRT}}$$

The half-life derived from k_{ss} ($0.693/k_{\text{ss}}$ or $0.693 \times \text{MRT}$) is a composite half-life for compounds showing a distribution phase and may be regarded as the *effective* half-life and represents a useful kinetic parameter, particularly for a single dose.

Oral Administration

Absorption from the gut may involve more than one first-order rate or a zero-order component, or both. A major strength of the statistical moment approach is its ability to derive meaningful data following oral administration, because it is both more reliable and easier to use than most other methods[50,55] and does not rely on assumptions about the presence of a first-order or zero-order process. The most useful absorption parameter is the MAT, which is the difference between the MRTs following oral and intravenous dosing:

$$\text{MAT} = \text{MRT}_{\text{oral}} - \text{MRT}_{\text{iv}} \quad (5.38)$$

The statistical moment theory is a valuable technique for comparisons on the influence of dosage formulations on absorption.[50,55]

Dose-Dependent or Nonlinear Kinetics

Whereas simple diffusion obeys first-order kinetics at all concentrations, most other toxicokinetic processes involve an interaction between the foreign chemical and a specific site on a protein (examples being active transport across the gut, plasma and tissue protein binding, metabolism, and renal tubular secretion). Because of the limited availability of the protein, these processes have a finite capacity, and all of the specific sites on the protein may be occupied at high concentrations of chemical. Addition of further chemical cannot result in further interaction between the chemical and protein, and the concentration of free compound increases rapidly.

Depending on the nature of the protein–chemical interaction, there are a number of possible consequences, which are summarized in Table 5.1. This table represents a considerable simplification because the effect of saturation at one site may affect another protein–chemical interaction. Almost all of the processes listed in Table 5.1 may be described by a Michaelis–Menten equation of the type introduced in Equation 5.6, and

$$-\frac{\text{d}C}{\text{d}t} = \frac{V_{max} \times C}{K_m + C}$$

where

V_{max} is the theoretical maximum rate of the reaction
K_m is the Michaelis constant (which reflects the concentration giving 50% saturation of the protein)

At low concentrations, $C \ll K_m$, and $K_m + C$ approximates to K_m so that

$$-\frac{\text{d}C}{\text{d}t} = \frac{V_{max} \times C}{K_m}$$

and V_{max}/K_m is equivalent to a first-order rate constant k.

At higher concentrations, $C \gg K_m$, and $K_m + C$ approximates to C so that

$$-\frac{\text{d}C}{\text{d}t} = \frac{V_{max} \times C}{C} = V_{max}$$

and thus the elimination is a zero-order reaction.

The shape of the plasma concentration–time curve for a hypothetical compound showing saturation kinetics is given in Figure 5.12, which clearly shows that although low doses are indistinguishable from first-order elimination, the decrease at high plasma concentrations shows zero-order and then first-order reaction components.

It is important to note that the terminal slope and terminal half-life are derived from low plasma concentrations and do

TABLE 5.1
Consequences of Saturation of Chemical–Protein Interactions

Site	Interaction	Possible Consequences of Saturation at High Dose
Absorption	Active uptake	Reduced plasma levels and AUC after oral but not iv doses.
	First-pass metabolism	Increased plasma levels and AUC after oral but not iv doses.
Distribution	Plasma protein	Increased volume of distribution; increased glomerular filtration; increased hepatic clearance if extraction ratio is low.
	Tissue protein	Decreased volume of distribution; a graph of C_f/C against C will be nonlinear.
Metabolism	Metabolizing enzyme (saturation by substrate, depletion of cofactors, product inhibition)	Decreased clearance; AUC/dose ratio increases for parent compound, whereas AUC of metabolite/dose ratio may decrease for both oral and iv doses; enzymes with high K_m values may handle a larger proportion of the dose.
Excretion	Renal tubular secretion	Decreased renal clearance; AUC/dose ratio increases for oral and iv doses; nonrenal routes of elimination become of more importance; total excretion in urine per dose may decrease depending on the availability of other routes of elimination.
	Renal tubular reabsorption (rare)	Opposite of effects for saturation of renal tubular secretion.
	Biliary excretion	Decreased biliary clearance; decreased enterohepatic recirculation; renal route may become more important; AUC/dose ratio increases for oral and iv doses.

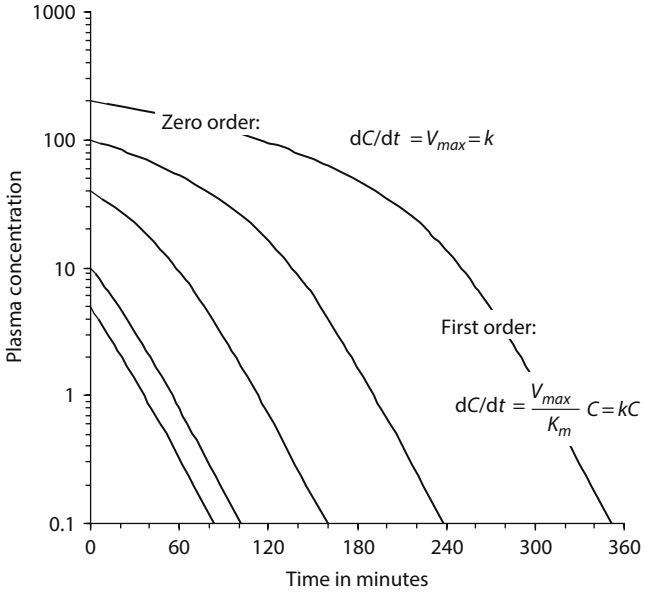

FIGURE 5.12 Plasma concentration–time curve for a compound showing saturation kinetics. The data were generated using an apparent V_{max} of 1 μg min^{-1} and a K_m of 20 μg mL^{-1} for initial concentrations of 5, 10, 40, 100, and 200 μg mL^{-1}. Data points were obtained using the equation $V_{max}(t - t_0) = C_0 - K_m \ln(C_0/C)$.

not provide evidence of dose-dependent kinetics. However, the plasma clearance, which is derived from AUC data and which reflects the capacity of the organs of elimination to remove the chemical from plasma, provides the best evidence of saturation.

An increased understanding of saturation kinetics can be obtained by the determination of K_m and V_{max} from in vivo data. The value of K_m that reflects the plasma concentration necessary to give 50% saturation of the active process is particularly useful for interpreting toxicity dose–response relationships. Derivation of these constants using the *Lineweaver–Burk*, *Hanes–Woolf*, and *Woolf–Augustinsson–Hofstee plots* was described in the previous edition of this book.

Of greatest importance for toxicology is the clear demonstration of saturation at high doses, an estimation of the plasma concentration above which first-order kinetics cease to apply, and the plasma concentrations present in animals showing overt toxicity. Simple methods for showing the absence of dose-dependent kinetics include graphs of *C*/dose against time that are superimposable, kinetic parameters derived by fitting the same model that have similar values at different doses, and the ratio of AUC/dose, which is constant.

A consequence of nonlinear kinetics is that the time to reach steady-state is also dose-dependent. This situation should be borne in mind when planning short-term studies.

PRACTICAL METHODS

It must be emphasized at the outset that the key to successful kinetic studies is the development of an assay of high specificity that measures the chemical without interference by its metabolites, and that is of sufficient sensitivity to define the terminal slope accurately (see later).

It is essential that the necessary legal and ethical approvals are obtained prior to any in vivo experiment in animals. This applies to noninvasive procedures, such as the incorporation of a chemical into an animal's feed, as well as invasive procedures such as the collection of blood samples. Under UK legislation, separate Home Office licenses are required for the premises, the individual and the procedure.

General information on techniques for blood sampling may be obtained from the texts by Waynforth[56] and Cocchetto and Bjornsson,[57] the latter providing 501 references and an extensive and invaluable literature review of methods for the collection of body fluids.

The methods for dosing, blood sampling, urine collection, etc., outlined later are largely related to the rat, as this is the species most commonly used in toxicological studies.

Administration Techniques

Oral Dosing

Rats, guinea pigs, and mice may be dosed by gavage using a syringe fitted with a suitable intubation needle: in rabbits, a polyethylene cannula is passed into the stomach while the jaws are held open by a gag.

Certain precautions should be taken to prevent artifacts. For example, if the chemical is given as a suspension, the apparent absorption rate may include a component due to dissolution of the chemical, which may be rate limiting. The ideal vehicle for dissolution is water or a small volume of a water-miscible solvent such as ethanol, propylene glycol (propane-l,2-diol), or dimethylsulfoxide, although for very lipid-soluble compounds, it may be necessary to give the dose in corn oil or as an emulsion. Excess acids or bases should not be used to dissolve the test compound, and the pH of the dose solution should be near pH 7.

The volume of water or solvent/water used to dissolve the chemical should be kept low in order to avoid artifacts. If dose-dependent absorption is suspected, the different doses should be given in the same volume of solution. The maximum volume of an aqueous solution that can be administered without the possibility of interference with absorption is approximately 5–10 mL kg^{-1}. Larger volumes may be given, although nonlinear kinetics seen under such circumstances may be due to solvent-induced alteration of intestinal function.

The use of water-immiscible solvents such as corn oil, which are sometimes used for gavage doses, should be avoided if possible, because mobilization from the vehicle may be rate limiting. However, such a vehicle would obviously be appropriate if it was the method of administration used in toxicity studies.

The rate of absorption can affect not only the time to maximum concentration and the maximum concentration, but also the total amount entering the systemic circulation, by saturating hepatic uptake and first-pass metabolism. An example of this is the hepatotoxicity of oral carbon tetrachloride, which is markedly higher after a bolus oral dose compared with gastric infusion.[58]

When toxicity studies are performed by mixing the compound into the animals' diet, it is important to measure the concentration–time curve over a 24-h period at steady-state using dietary administration, because both the peak concentration and the AUC may be different from data obtained from bolus gavage studies.

Nasal Administration

Methods have been described for assessing absorption from the nasal cavity based on plasma pharmacokinetics following intranasal and intravenous dosing and by in situ perfusion experiments.[59,60] A technique for inhalation with nose-only exposure has been described for studies in guinea pigs.[61]

Rectal Administration

Because a number of therapeutic compounds are given as suppositories, an indication of the bioavailability after rectal administration is sometimes required. Normally, toxicity studies and initial drug formulations of such compounds are performed by the oral route, and the rectal formulation comes late in development and marketing.

Inhalation

A major problem associated with determining the kinetics of inhalation concerns the measurement of the extent to which the chemical is absorbed across the lung, rather than passed back into the mouth to be swallowed, exhaled in the expired air, or absorbed across the nasal mucosa or skin. Comparison of the plasma AUC or the total urinary excretion of unchanged compound, after a period of inhalation with the same parameter after a known intravenous dose, can be used to determine the total dose entering via the lungs plus gut, etc.

A method used successfully by McKenna et al.[62] to obtain kinetic data involved a 6 h exposure to the vapor of [^{14}C] vinylidene chloride in rats, after which the animals were transferred to a metabolism cage. The body load at the time of removal was determined by the total recovery of radioactivity in the expired air, excreta, cage washings, and carcass. This method is appropriate for determining the total dose because the nonspecific measurement of ^{14}C includes parent compound and all metabolites. If the parent compound alone is measured, the inhalation data must be compared to intravenous data in order to measure the extent of exposure after inhalation.

The metabolism rate constants of inhaled 1,1-dichloroethylene have been determined by the measurement of the rate of removal of the compound from circulating air in a closed chamber system containing the experimental animal.[63] The air was recirculated, with oxygen added to maintain the concentration at 19%–21%, and the air was sampled at regular intervals and analyzed for unabsorbed 1,1-dichloroethylene by gas–liquid chromatography. The rate of removal showed two phases; a rapid initial phase and a slower second phase, which showed saturation kinetics and the constants K_m and V_{max} were derived in terms of the concentration of chemical in the chamber. This approach is interesting because the data are obtained by a noninvasive method, and the kinetic constants are derived in terms of vapor or gas concentrations, which are most appropriate when interpreting inhalation studies in relation to human exposure to volatile agents.

Percutaneous Absorption

The dermal absorption of vapors can be assessed in rats using a body-only chamber,[64] but there may be major species differences related to the presence of hair follicles and the barrier function of the stratum corneum. Shaving the hair from the backs of rats can provide a suitable site for in vivo absorption studies,[65] but this can change the permeability characteristics of the stratum corneum. In reality, in vitro data can provide a suitable model for extrapolation to humans.

Intravenous Injection

The bolus intravenous dose is the most important single technique for deriving toxicokinetic information. Aqueous or aqueous miscible solvents should be used, although the maximum dosage volume is about 2 mL kg^{-1} for aqueous and 1 mL kg^{-1} for solvent–aqueous mixtures. Ideally, the solution should be isotonic. The data processing assumes that the material is administered instantaneously at time zero and that 100% of the dose is intravenous, and none ends up in a perivascular site.

The tail and hind paw veins of rats are convenient for dosing, but neither is particularly easy to use or gives 100% intravascular dosing repeatedly and routinely without the necessary expertise. Cannulation of a vein, such as the external jugular or femoral vein, under anesthesia provides a more secure method of intravenous administration. The same cannula can be used for subsequent sampling, providing that the compound is known not to be adsorbed onto the cannula. The external jugular vein may also be used for intravenous dosing of guinea pigs. For rabbits, the vein running around the periphery of the ear lobe is of sufficient size and visibility to give reliable intravenous dosing.

Intravenous Infusion

For intravenous infusion studies, the dose must be given via an indwelling cannula. If the infusion period is prolonged, such that recovery from anesthesia is envisaged, the cannula can be run under the skin from the ventral surface of the neck and exteriorized on the dorsal surface behind the ears. If the cannula is then secured on the dorsal surface, the animal should be prevented from damaging it while being permitted a degree of movement. This method of exteriorization is also valuable as a method of long-term sampling.

The delivery of compound during intravenous infusion must be at a constant but low rate such that the animal is not subjected to excessive hemodilution. Methods include the use of a high-quality infusion pump and osmotically driven minipumps, which can be implanted into the animal, and deliver a constant rate as low as 0.5 μL h^{-1} for up to 2 weeks.[66]

Sampling Techniques

Blood (Plasma and Serum)

When considering the frequency, timing, and duration of blood sampling, it is important that an adequate number of samples are taken to define each section of the plasma concentration–time curve. A three-compartment system can be accurately analyzed by about 12 samples provided that they are correctly timed. It has been suggested that plasma samples be collected during the first four to five half-lives, during which time 93%–97% of the compound will have been eliminated. However, it is possible that such a restriction may mask a quantitatively minor distribution component, and as a general guideline, the plasma concentrations should be measured until the limit of detection of the analytical method is reached. Obviously, if the limit of detection allows analysis over a large number of half-lives, less frequent sampling is required during the slow terminal phase. The corollary is that a relatively insensitive analytical method may be incapable of yielding full pharmacokinetic data.

Using the methods described later, it is possible to withdraw a significant fraction of the total blood volume (64 mL kg^{-1} in the rat), thereby modifying the perfusion of the organs of elimination and corrupting the derived pharmacokinetic data. This problem can be avoided by taking the smallest samples consistent with accurate analysis and the minimum number of samples necessary to define adequately the various phases (i.e., smaller samples at early time points). As guidance, individual blood samples should be restricted to a maximum of about 0.5 mL kg^{-1} body weight, providing the total number of samples is small (i.e., less than 10).

Various methods have been used successfully to obtain small serial blood samples from anesthetized and conscious rats. Whole-blood samples, of approximately 100–200 μL, can be obtained from the tail vein, either by snipping the very end off the tail under local anesthesia or by making a small incision closer to the base of the tail. An advantage of this method is that usually only a single manipulation is necessary, since washing the tail vein with warm water will often remove the blood clot and reinstigate blood flow. A disadvantage is that the sampling site may be contaminated by urine and feces, although washing the tail may remove the polar metabolites excreted in urine and feces. Other published methods that have been used to obtain blood samples include clipping the toe nail into the vascular bed, multiple cardiac sampling, and rupture of the sinus membrane at the back of the orbit, although these produce considerably more trauma and, depending on national or local legislation, may have to be performed in nonrecovery animals (i.e., under terminal anesthesia).

Alternative and more reliable methods require the insertion, under anesthesia, of a cannula into an exposed vein, such as the external jugular vein. Such tubing can then be used for sampling and may remain patent for periods up to 2 months. The use of silicon tubing is preferred to polyethylene for long-term studies because it is more flexible for exteriorization on the dorsal surface and less apt to cause thrombosis. For long-term studies, the cannula is exteriorized such that the animal cannot damage the tubing.[57,67] Cannulation of both the external jugular vein and carotid artery under general anesthesia in nonrecovery animals can be used for both intravenous dosage (venous) and blood sampling (arterial). For experiments performed under anesthesia in other species, a major vein or artery (e.g., jugular, carotid, femoral) can be cannulated.

The orbital sinus is a reliable site for the collection of blood from the mouse while under terminal anesthesia. The marginal ear vein can be used for the rabbit without anesthesia.

Urine

Knowledge of the urinary excretion rate is necessary for calculating the overall renal clearance of a compound. The bladder causes variable slowing of the output, and for compounds with a short half-life, a method of overcoming sporadic

urination is necessary. Calculating results by the sigma-minus method (Equation 5.22), rather than using excretion rate data, reduces the importance of incomplete bladder emptying and the resultant scatter in the data. For a compound with a half-life of many hours, sufficiently frequent samples may be obtained from daily urine collections using a metabolism cage.[57]

In nonrecovery animals under anesthesia, the effect of the bladder may be overcome by cannulation of the urinary bladder via the urethra and allowing the urine to be expelled naturally or with the aid of gentle massage or by cannulation of both ureters directly.

Renal clearance studies may be performed either after single doses or during infusion at steady-state (when the clearance can be related to total clearance and plasma concentration). Insights into the extent of reabsorption and tubular secretion can be obtained by measuring the renal clearance of inulin given simultaneously (1–20 μCi of [^{14}C] inulin kg^{-1} or 50–100 μCi of [^{3}H]inulin kg^{-1}).

Bile

In rats, bile may be collected from a cannula inserted into the common bile duct under general anesthesia such that the tip is located at the point of bifurcation near the hilar region of the liver. Bile, which usually flows at a rate 0.5–1.0 mL h^{-1} in the rat, may be collected either by exteriorizing the cannula or by passing the tubing into a suitable container (sealed plastic sachet) placed subcutaneously. A problem with biliary excretion studies is that changes in bile composition occur if the bile salts are not allowed to recirculate. To minimize this, the biliary excretion can be measured soon after establishing the cannula or the bile can be recirculated back into the gastrointestinal tract while the animal recovers from surgery.[68]

In animal species that possess a gallbladder (i.e., guinea pig and rabbit), it is necessary to prevent this organ from delaying elimination by ligation around its base.

DATA HANDLING

Data on the concentrations of a chemical in plasma and urine can be analyzed graphically, but the availability of powerful personal computers means that such approaches are largely redundant. Computerized analysis by fitting multiexponential equations is the method of choice because data handling is optimized.

Computation

There are a number of suitable programs available for nonlinear least-squares regression analysis, which is the most appropriate method (e.g., BLIN, NONLIN, SIPHAR), and readers are referred to Gibaldi and Perrier,[45] Wagner,[47] and Gabrielsson and Weiner[48] for further details. Such programs automatically put the best fit line through the data. In the analysis of data by computer program, it is common to apply a suitable weight to each data point to ensure the most appropriate fit. The weights that can be applied to the concentration data include

1. All weights equal, which is applicable if the errors in measurement are a constant amount, for example, ±2 μg mL^{-1}
2. Weighted by 1/y, which is applicable if the errors of measurement are a constant proportion, for example, ±2%
3. Weighted by 1/y^2, which can be used to force the fit through the later time points at the expense of the early higher values.

The second option, 1/y, closely represents the accuracy of most assay procedures and is used most frequently.

It is important that errors arising from the choice of an inappropriate model or incorrect weighting should be assessed by either a graphical representation or analysis of the deviation between observed and calculated concentrations (error analysis). Another factor to consider is that although use of more complex models may give a closer fit to the data, the available data may not be adequate to estimate accurately the larger numbers of parameters.

USE AND INTERPRETATION OF IN VITRO DATA

In vitro data can provide important qualitative insights into the metabolic fate of the compound, but care must be taken in their quantitative incorporation into risk assessment.

There is a wide variety of in vitro systems of increasing cell integrity,[69,70] which can be used, for example, subcellular fractions (such as microsomes), cell homogenates, isolated cells and cell lines, and tissue slices. Each preparation has strengths and weaknesses, and these can be exploited to provide useful information.[71–73]

Strengths of In Vitro Systems

Microsomes comprise the smooth endoplasmic reticulum and its associated enzymes—cytochromes P450 and UDP-glucuronyl transferases. The rates of reaction in vitro are determined by the availability of appropriate cofactors, and it is possible to study oxidation by the addition of NADPH, and glucuronidation by addition of UDPGA. Addition of NADPH but not UDPGA allows the rates of P450-mediated oxidation to be studied directly, because part of the primary oxidation produced is not lost due to conjugation. An additional major value for such simple systems is that they can be used to generate metabolites for structural analysis.

More complex systems, such as isolated cells and tissue slices, provide a more comprehensive picture of the metabolic fate of the compound. All enzyme systems are present, including cytoplasmic and mitochondrial enzymes, and the cell architecture can affect cell uptake and intracellular distribution of the chemical. Perhaps the most integrated in vitro system is the isolated perfused rat liver, which can give excellent correlations with in vivo clearance.[74,75] In consequence,

these systems can provide information on the relative importance of alternative metabolic pathways.

A major advantage of in vitro systems is that they allow data to be generated on the potential metabolism in humans, without the need for in vivo exposure. This has been particularly valuable for carcinogens, where the generation of in vivo data would be unethical. Identification of the specific isoenzymes of cytochrome P450 is important in understanding the potential variability in metabolism within the human population. Such information can be generated by in vitro studies in three ways:

1. Comparisons of the rates of metabolism in stored (banked) liver preparations from individuals with characterized isoenzyme profiles
2. The use of isoenzyme-specific inhibitors or inducers (in cell-intact preparations)
3. The use of expression systems, in which the DNA for specific isoenzymes is incorporated into and expressed by a suitable host, such as a yeast or bacteria[76,77]

The generation of in vitro data using human tissues allows characterization of qualitative and quantitative species differences both by generating appropriate enzyme constants V_{max} and K_m. Such data represent critical components of PBPK models[78] and for the prediction of in vivo clearance.[79–83]

The outline given earlier should be sufficient to indicate the huge potential for in vitro studies and explain why these methods have been the basis for much of our understanding of pathways of xenobiotic metabolism.

Precautions with In Vitro Systems

A number of limitations need to be remembered when considering in vitro data:

1. Many studies give data on the extent of metabolism at a single high concentration in vitro and therefore represent V_{max}, which may be of limited relevance to in vivo concentrations. A full analysis of the enzyme kinetics is necessary to give both V_{max} and K_m.
2. Changes in enzyme expression occur in vitro, for example, isolated cell lines show a different complement of cytochrome P450 activities to those in the same cells at isolation.
3. Many human data are generated from stored liver samples obtained at postmortem. The in vitro enzyme activity could be affected by both in vivo aspects, such as drugs given in attempts at resuscitation, disease, etc., and ex vivo aspects, such as the period between death and freezing and storage.[84]
4. In vitro data may still be misleading, even if all of these aspects are optimal. An important example of this is when the clearance of compound is limited by organ blood flow rather than enzyme activity (see earlier). Under these conditions, both interspecies differences and interindividual variability will reflect organ blood flow, rather than V_{max} and K_m. A good example of this is furan[85] for which the rate of oxidation in vitro would greatly exceed delivery via the liver blood flow. This problem can be avoided if the in vitro data are incorporated into a PBPK model that will take into account organ blood flow, partitioning between blood and tissue, and enzyme kinetics.

The increasing use of in vitro test systems facilitates a quantitative analysis of the dose–toxicity curve and may provide information on mechanisms of action.[71,86,87] The logical interpretation of such data with respect to human risk requires information on

- The steady-state concentrations of the active chemical species in the target organ and plasma of the test animals during chronic toxicity testing
- The toxicokinetics of the chemical in the test animal at toxic doses
- The toxicokinetics in humans at the likely exposure level

USE AND INTERPRETATION OF IN VIVO TOXICOKINETIC DATA

There are three principal aims of in vivo toxicokinetic studies:

1. Toxicokinetics can provide an understanding of the physiological processes that are involved in the fate of the chemical in the body.
2. The relation between dose and toxicokinetics may be the key to either the establishment of appropriate dose levels for chronic studies or the interpretation of data from such studies.
3. Comparative toxicokinetics can reduce uncertainty involved in the extrapolation from animals to humans.

Toxicokinetic studies are important in compound development, and such information is considered necessary before proceeding with long-term and carcinogenicity tests.[2] If the kinetic evidence indicates tissue accumulation on prolonged dosing, saturation of elimination at subtoxic doses, the formation of chemically reactive metabolites, or that the main route of metabolism is via an enzyme that shows a major genetic polymorphism,[88,89] then chemical analogs without these problems may be selected for development.

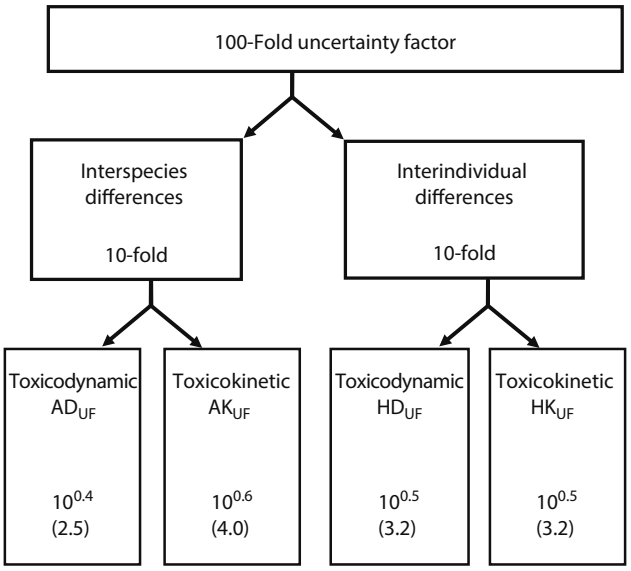
The relationship between kinetics, dose, and toxicity is probably the single most important contribution that kinetics can make to the field of toxicity testing. Although a few therapeutic drugs show nonlinear kinetics at the doses normally given to humans, the plasma levels of foreign chemicals in humans are usually well below those necessary to saturate

any protein-mediated reactions. In contrast, the maximum dose in toxicity tests is designed to show some degree of toxicity, and nonlinear kinetics are a distinct possibility. At doses above saturation, the body load of free compound increases steeply with increase in dose, and plasma and tissue concentrations of the chemical will also be considerably higher than predicted by extrapolation from lower doses. Nonlinear kinetics may result in an extremely steep dose–response curve for the toxic effect and must be taken into account when extrapolating effects detected in animal studies to humans.

A possible consequence of saturation of elimination is that normally minor pathways of metabolism may become of major significance. Thus, if a chemical undergoes metabolism by two routes, one with a low K_m (high affinity) and the other with a high K_m (low affinity), then at low doses, most chemical in the cell is eliminated by the high-affinity route, but more of the chemical will be eliminated by the low-affinity enzyme at plasma levels that saturate the high-affinity enzyme.

Different risk assessment approaches have been used traditionally for cancer (and other nonthreshold effects), compared with adverse effects believed to show a biological threshold.[2–4]

- Toxicokinetic data are sometimes incorporated into the risk assessment process for genotoxic carcinogens by the use of a PBPK model that corrects the external administered doses in the animal study to internal doses and also allows for differences between animals and humans in the relationship between external dose and target organ dose.
- For threshold toxicity, risk assessment involves estimating a level of human intake that would be without appreciable health effects, that is, a health-based guidance value such as a reference dose (RfD), an acceptable daily intake (ADI), or a tolerable daily intake (TDI). The guidance value is usually derived by dividing the intake of animals treated at the no-observed-adverse effect level (NOAEL) (expressed in mg kg^{-1} body weight) by an appropriate uncertainty factor. A default uncertainty factor of 100 has been applied for over 50 years, with a 10-fold factor to allow for extrapolation from animals to humans and a 10-fold factor to allow for interindividual differences in the exposed human population.[3,4] The use of chemical-specific adjustment factors (CSAFs)[90–92] allows appropriate toxicokinetic or mechanistic data to replace part of the relevant 10-fold default factor (Figure 5.13). This subdivision has the potential to replace uncertainty with scientific data and has been used in recent evaluations of the sweetener cyclamate (see cyclohexylamine mentioned later) and of dioxins, but replacement of one of the factors requires extensive data. The use of such a scheme would produce a more secure and scientific basis for the establishment of an ADI/TDI/RfD and will encourage the investment of time and money necessary to generate of such data.



Chemical-specific data can be used to replace a default uncertainty factor (UF)

A—animal to human; H—human variability; D—toxicodynamics; K—toxicokinetics

FIGURE 5.13 Subdivision of the 10-fold uncertainty factors to allow for species differences and human variability in toxicokinetics or toxicodynamics.[92] The total composite factor would be the product of any chemical-specific adjustment values and the remaining default uncertainty factors that had not been replaced, for example, if the interspecies toxicokinetic UF were replaced by chemical specific value of 20, then the total factor would be $2.5 \times 20 \times 3.2 \times 3.2 = 500$.

Extrapolation of animal toxicokinetic data to humans may be by either a PBPK model or compartmental modeling methods.[93,94] The physiological approach relies on the scale-up between animals and humans of parameters such as tissue volume and blood flow and their relationship to body weight.[95] PBPK models may be scaled up from animals to humans based on the known physiological differences. Alternatively, the plasma kinetics in various species may be fitted by compartmental modeling and then scaled up empirically according to the body mass of the species studied and extrapolated to humans.[96,97]

In general, species differences in basic physiological processes such as cardiac output and relative tissue weights usually result in lower clearances and longer half-lives in humans than in animals. Thus, comparisons of animals and humans on the basis of plasma levels or AUC values, rather than intake or exposure data (expressed per kg body weight), remove important variables from interspecies comparisons and provide a more secure basis for the safety assessment.[2,9,98]

The increased use of kinetic data, especially when combined with the knowledge of the mechanism of toxicity, allows the safety of potentially toxic chemicals to be based on scientific principles and understanding.[2,5–7,11] The following examples illustrate the contribution of toxicokinetic studies

to understanding the biological basis of toxicity and to the interpretation of toxicity data in terms of risk assessment.

Cyclohexylamine

Cyclohexylamine is a metabolite of the intense sweetener cyclamate, which is formed by the intestinal bacteria in the lower gut. Cyclohexylamine produces testicular toxicity when given chronically to rats, but not to mice.[99] Toxicokinetic studies indicated that the plasma clearance was higher in mice than in rats, and that rats but not mice showed evidence of nonlinear kinetics at high doses.[100] The steady-state concentrations in the plasma and testes during chronic administration confirmed dose-dependent kinetics in the rat, which coincided with the dose–response for testicular atrophy in this species.[100] These toxicokinetic data thus provide a possible explanation for the steepness of the dose–response curve in the rat and the apparent species difference in sensitivity.

Cyclohexylamine is an indirectly acting sympathomimetic amine in rats,[101] but it does not increase blood pressure in humans following its formation from cyclamate metabolism.[102] The apparent difference in response arises from the different concentration–time profiles when cyclohexylamine is absorbed rapidly following oral administration of a bolus dose or when it is formed slowly by the intestinal microflora from cyclamate,[102] illustrating further the importance of kinetics in the interpretation of dose–effect relationships.

The ADI for cyclamate established by the Joint Expert Committee on Food Additives (JECFA)[103] and the Scientific Committee on Foods (SCF) in Europe[104] is based on the NOAEL for testicular toxicity of cyclohexylamine in a 90-day study in rats. There are extremely wide person-to-person differences in the conversion of cyclamate into cyclohexylamine, and this has to be taken into account in calculating an ADI for cyclamate. The majority of the population cannot form cyclohexylamine, but 3%–4% of the population metabolizes 20% or more of the daily intake. Early evaluations[103,104] used a value of 18.9% metabolism with a 100-fold uncertainty factor. A recent study[105] showed that up to 85% of the daily intake could be converted to cyclohexylamine on individual days during chronic intake, but that the highest detected 7-day average was 58%. The most recent SCF evaluation[106] used a value of 85% metabolism and reduced the uncertainty factor to 32 because human variability in kinetics had been taken into account by the use of a worst-case % metabolism.

Dioxins (TCDD: 2,3,7,8-Tetrachlorodibenzo-*p*-Dioxin)

A major problem with deriving a health-based guidance value for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) from animal toxicity data is that there is considerable accumulation due to the very long half-life. The usual 10-fold default uncertainty used for extrapolating from rats to humans would be inadequate for TCDD, because there is an approximately 90-fold difference in half-life between rats (about 30 days) and humans (about 7.5 years). Evaluations of dioxins by the JECFA[107] and the SCF[108,109] illustrate how toxicokinetic data can be used (and to some extent misused) in risk assessment.

These risk assessments have been based on the body burden, rather than the daily intake because this would take into account species differences in half-life and accumulation. Based on the relationship

$$\text{Extent of accumulation} = \frac{1.44 \times t_{1/2}}{T}$$

a 90-fold difference in half-life would give a 90-fold difference in body burden at steady-state.

The steady-state body burden of TCDD was estimated in rats and humans using the following relationship:

$$\text{Steady-state body burden (ng kg}^{-1}) = \frac{\left\{\left[\text{Dose}\left(\text{ng kg}^{-1}\right) \times t_{1/2}\left(\text{days}\right)\right] \times \text{F}\right\}}{\text{Ln } 2}$$

where

Dose is the daily administered dose or intake
F is the fraction absorbed (highly lipid-soluble compounds such as TCDD are incompletely absorbed from the gut and a bioavailability of 50% was assumed)
$t_{1/2}$ is the species-specific half-life of TCDD

This relationship is based on Equation 5.33, using 1 day as the dose interval, with the body burden as ($C_{mean} \times V$) and 1/k converted to $t_{1/2}$/ln 2 ($t_{1/2}$/0.693).

Because interspecies differences are taken into account by the use of body burden as a dose metric, the usual default uncertainty factor of 4.0 (Figure 5.13) was replaced by a CSAF of 1.0.[107–109] In addition, it was recognized that the most sensitive human would not be more sensitive than the rat strains used to define the NOAEL, so that the interspecies and human variability toxicodynamic CSAFs were set at 1.0. In consequence, only the factor of 3.2 for human variability in toxicokinetics was applied to the rodent NOAEL, instead of the usual default factor of 100-fold.

These recent risk assessments of dioxins illustrate how suitable chemical-specific data can be used quantitatively in derivation of a health-based guidance value. Despite this welcome scientific development, a number of difficulties remained and were only partially resolved:

1. The majority of human exposure to dioxin-like compounds (polyhalogenated dibenzodioxins, polyhalogenated dibenzofurans, and coplanar polychlorinated biphenyls) is to congeners other than TCDD. This is taken into account by the use of toxic equivalency factors (TEFs),[110] which relate the in vivo potency of the individual congener in animals to that of TCDD. The application of the relationship

given earlier for TCDD to non-TCDD congeners assumes that the 90-fold species difference in the half-life of TCDD applies equally to the TEFs of other congeners.

2. The JECFA and SCF assessments were based on postnatal effects in male rats following in utero exposure to a single oral dose given on day 15 of gestation (GD15).[111–115] Initially, these studies could not be interpreted because of potential and undefined differences in the distribution of the body burden following a bolus dose and following slow accumulation from the diet. TCDD and related compounds are highly lipid soluble and show very high fat to blood concentration ratios, such that the majority of the body burden at steady-state is in adipose tissue and not in potential sites of toxicity, such as the fetus. The toxicokinetic studies on TCDD performed in pregnant rats specifically to address this issue[116,117] allowed the fetal concentrations on GD16 to be estimated following different methods of exposure. Risk assessments were based on conversion of the maternal body burden in rats following a bolus oral dose on GF15,[111–113,115] or following a loading dose and weekly doses,[114] into a chronic maternal daily intake that would give the same fetal concentrations at steady-state. Extrapolation to humans was made using the relationship given earlier and the known species differences in half-life.
3. The risk of cancer was determined from occupational cohort studies (see Ref. 107 for details) in which the body burden was estimated some time after exposure had ceased, and the relationship between exposure and cancer risk was determined by back-extrapolation of the body burden to the period of occupational exposure. The average half-life in humans was used for back-extrapolation, but TCDD is a known enzyme inducer,[52] and if enzyme induction had occurred at occupational exposures, then a shorter half-life should have been used to back-extrapolate. A shorter half-life would result in a higher estimate of the body burden during the period of occupational exposure so that any cancer risk could have been overestimated by the use of an inappropriately long half-life (because the association would be with lower predicted body burdens).
4. The best dose metric for a chemical with a very long half-life would be the steady-state concentration in plasma, which is given by

$$C_{ss\ mean} = \frac{\text{Dose} \times F}{T \times CL}$$

Because *CL* is not known for humans, the JECFA and SCF used the half-life, which had the effect of changing $C_{ss\ mean}$ into $Ab_{ss\ mean}$. However, half-life is affected by both *CL* and *V*: rearrangement of Equation 5.16 gives the relationship between half-life, *CL* and *V*:

$$t_{1/2} = \frac{0.693 \times V}{CL}$$

The risk assessments of TCDD based on estimated body burdens in animals and humans assume that the pattern of tissue distribution is similar, so that the concentration at the site of action represents a similar proportion of the body burden in animals and humans. However, rats and humans have different body compositions, with fat representing about 10% of the body mass of rats, but about 20%–25% of humans. In consequence, the value of *V* would be over twofold higher per kg body weight in humans, so that the concentrations in all tissues, including sites of toxicity would be twofold lower in humans for any given body burden. Body composition was not taken into account in the JECFA[107] and SCF[108,109] evaluations, which ignored the contribution of differences in *V* to differences in half-life.

SELF-ASSESSMENT EXERCISES

5.1 A new chemical has been administered to rats and humans by both oral and intravenous routes. Basic toxicokinetic measurements (extrapolated to infinity) are given as follows:

	Rat	Human
Intravenous		
Dose (mg kg^{-1})	10	1
AUC (μg mL^{-1} min)	2000	500
Terminal slope (min^{-1})	0.0025	0.001
% Dose excreted unchanged in urine	1	15
Oral		
Dose (mg kg^{-1})	100	1
AUC (μg mL^{-1} min)	8000	490
Terminal slope (min^{-1})	0.0025	0.001

Calculate appropriate toxicokinetic parameters and suggest biochemical and physiological mechanisms that could explain the species difference.

5.2 The pharmaceutical company for which you work has synthesized a new antianxiety drug, which is a basic compound, structurally related to the old drug debrisoquine. The parent drug, which is the active form, causes enzyme (cytochrome P450) induction and liver enlargement; the hydroxylated metabolite, which is formed on incubation of the drug with liver microsomes, is inactive. After an oral dose, 40% is excreted in the urine within 24 h as the parent compound, 40% is in urine as a hydroxylated metabolite, and 20% is in feces as the parent drug. After an intravenous dose, 80% is in urine as the parent drug,

and 20% is in urine as the metabolite. What advice would you give the company about the following issues:

a. Is the drug likely to be toxic after oral dosage?
b. Would the oral and intravenous doses associated with toxicity be the same?
c. What are the likely sources of variability in kinetics in young physically healthy adults (20–30 years old)?
d. Would the kinetics be different in the elderly (70–80 years old)?
e. How much would a 50% decrease in liver or kidney function affect the kinetics, and would the toxicity be increased or decreased?
f. How much would a 50% increase in liver or kidney function affect the kinetics, and would the toxicity be increased or decreased?
g. Should the pharmaceutical group develop a slow-release formulation, and would this be likely to affect the toxicity?

5.3 The company you work for has developed a novel opioid for the treatment of intractable pain. The drug is 20 times more potent than morphine in relation to both analgesia and respiratory depression when given to rats by intravenous injection, and binding studies show that it has a high and similar affinity for μ-receptors of rats and humans. Initial kinetic studies in humans after a single intravenous bolus dose of 10 mg gave the following data:

Time after Dose (h)	Plasma Concentration (ng mL^{-1})
0.5	367
1.0	336
2	283
4	200
6	141
10	71
24	6.3

The area under the plasma concentration–time curve (AUC) extrapolated to infinity was 2310 ng mL^{-1} h. Urine was collected over a period of 2–4 h after dosing and contained a total of 1.85 mg of the parent drug and 0.1 mg of a hydroxy metabolite: the plasma concentration of parent drug at 3 h was 238 ng mL^{-1}.

After a single oral dose of 10 mg, the maximum plasma concentration occurred at 8 h and was only 48 ng mL^{-1}; the blood concentration reached 6 ng mL^{-1} by 36 h. The AUC to infinity was 1155 ng mL^{-1} h.

Plot the intravenous data on graph paper. Calculate appropriate pharmacokinetic parameters to describe the elimination rate, clearance, distribution, and absorption of the drug. Describe the probable overall fate of the drug in the body (e.g., routes of elimination).

Your research director needs the following advice:

a. What extra studies/data could support your description of the fate of the drug?
b. What route(s) of administration should the company use for its first trials of clinical effect for pain relief?
c. How should the drug be administered to provide relief of chronic pain?

Hints and Clues

Question 5.1

a. Calculate clearance (per kg body weight)—why is it different? (See b.)
b. Use urinary excretion data to think about pathways of elimination.
c. Use clearance and *terminal slope* (k or β—we don't know) to calculate the apparent volume of distribution.
d. Use AUC data to calculate bioavailability.
e. Are terminal rates different after oral dosage? What would it mean if they were?
f. What are the likely causes of differences between species? Could clearance and bioavailability be interrelated (if so how)?
g. Would scaling to body surface area affect the calculations and conclusions? If so, how?

Question 5.2

a. Use urinary excretion data to interpret the potential for exposure (or not) of the liver to the parent compound (obviously, the dose will affect the response—but is toxicity possible?).
b. Use urinary excretion data to calculate bioavailability. What processes are giving rise to the low bioavailability?
c. Variability in adults—what are the routes of elimination? What is the relevance of debrisoquine?
d. Consider 50% changes in liver in relation to bioavailability and clearance. Then, consider changes in renal function similarly. Will kidney function affect bioavailability?
e. A slow-release formulation is necessary when a drug has a very short half-life (e.g., 3–4 h or less). There is information on the rate of elimination in the question—what can you conclude about half-life? (*Clue*—could it be 24 h?)

Question 5.3

a. You can calculate clearance, apparent volume of distribution, and half-life from the intravenous data. But what route is important for elimination? (*Clue*—use urine data to calculate renal clearance and compare with plasma clearance.)
b. The extra studies should relate to kinetics. (*Clue*—what studies would we normally have before giving the first dose to humans?)
c. What is happening with the oral data? What is the extent of absorption? Why are blood levels at 36 h higher after oral dosage? (*Clue*—you can calculate the concentration at 36 h after iv dosage using the exponential terms derived from the iv data.)

d. Phase 1 studies (initial human studies) are usually by the oral route. Is this likely to produce analgesia or side effects with this compound?
e. Chronic pain relief requires the maintenance of constant concentrations of the analgesic. Which route would be likely to give this profile? If oral dosage could not give effective plasma levels without unacceptable side effects (such as constipation), how could you give the drug parenterally to provide similar constant concentrations?

6 Physiologically Based Pharmacokinetic and Toxicokinetic Models

Harvey J. Clewell III, Rebecca A. Clewell, and Melvin E. Andersen

CONTENTS

INTRODUCTION

Physiologically based pharmacokinetic (PBPK) models provide sets of equations that simulate the time courses of chemicals and their metabolites in various tissues throughout the body.* The interest in PBPK modeling in toxicology and pharmacology arose from the need to relate internal concentrations of active compounds at their target sites with the doses of chemical given to an animal or human subject [1]. The reason, of course, is a fundamental tenet in pharmacology or toxicology that both beneficial and adverse responses to compounds are related to the concentrations of active chemicals reaching target tissues rather than the amounts of chemical at the site of absorption regimen [1–3]. The relationships between tissue dose and administered dose can be complex, especially in high-dose toxicity testing studies, with multiple, repeated daily dosing, or when metabolism or toxicity at routes of entry alters uptake processes for various routes of exposure. PBPK models of all kinds are primarily a tool to assess chemical dosimetry at target tissues for a wide range of exposure situations.

In PBPK modeling, compartments correspond to discrete tissues or to groupings of tissues with appropriate volumes, blood flows, and pathways for the metabolism of test chemicals [4]. These PBPK models include pertinent biochemical and physicochemical constants for metabolism and solubility in each compartment. Routes of dosing (routes of administration) are included in their proper relationship to the overall physiology. For instance, dermally absorbed compounds penetrate the skin, enter the mixed venous blood, and then travel through the heart and lungs to the arterial blood for distribution. Orally absorbed compounds move through intestinal tissues and portal blood to the liver before moving to the mixed venous blood for distribution to the remainder of the body. The equations that form the basis of the PBPK model also account for the time sequence of dose input into test subjects and permit input by multiple routes if necessary for specific exposure situations. Each compartment in the model is described with a mass balance differential equation whose terms mathematically represent biological processes. The set of equations is solved by numerical integration to simulate tissue time-course concentrations of chemicals and their metabolites.

Among the opportunities offered by PBPK approaches are (1) creating models from physiological, biochemical, and anatomical information, entirely separate from collection of detailed concentration time-course curves; (2) evaluating mechanisms by which biological processes govern disposition of a wide range of compounds by comparison of PK results with model predictions; (3) using chemicals as probes of the biological processes to gain more general information on the way chemical characteristics govern the importance of various transport pathways in the body; (4) applying the models in risk assessments for setting exposure standards; and (5) using annotation of a modeling database as a repository of information on the toxicity and kinetics of specific compounds.

Some PBPK models account for interactions of circulating compounds with specific receptors or the covalent interactions of chemicals with tissue constituents. Modeling these reversible and irreversible molecular interactions with cell constituents is the initial step in developing physiologically based pharmacodynamic (PBPD) models for effects of chemicals on biological processes [5]. Several excellent reviews are available that focus on the early stages of the development of PBPK modeling approaches [6–10], including a volume on PBPK modeling in chemical risk assessment [11], and a comprehensive review of the application of PBPK modeling in toxicology has been performed [12]. A number of recent publications provide additional insights into the application of PBPK modeling in risk assessment [13–18], drug development [19–24], and food/nutrition research [25]. Some of the aims of this chapter are to provide an overview of the fundamental concepts of PBPK modeling, the range of applications of PBPK modeling, and the insights that can be derived from the application of PBPK models to the distribution of chemicals in intact animals.

The advent of biologically structured PBPK models had a dramatic influence on the nature of the experiments conducted to determine PK behavior and to estimate tissue dosimetry. In PBPK descriptions, time-course behavior is not an intrinsic property of the organism accessible only by direct experimentation. Instead, it is a composite behavior, governed by more fundamental physiological and biochemical processes. More importantly, these fundamental processes

* Toxicokinetics (TK) is the quantitative study of factors that control the time course for absorption, distribution, metabolism, and excretion (ADME) of toxic compounds within the body. The time course of drugs, on the other hand, has traditionally been referred to as pharmacokinetics (PK). Similarly, the effect of a drug or toxic compound in the target tissue has been referred to as pharmacodynamics (PD) and toxicodynamics (TD), respectively. This practice, of course, ignores the wisdom of Paracelsus: "…only the dose differentiates a poison and a remedy." To avoid this false distinction, the terms *biokinetic* and *biodynamic* have sometimes been used.

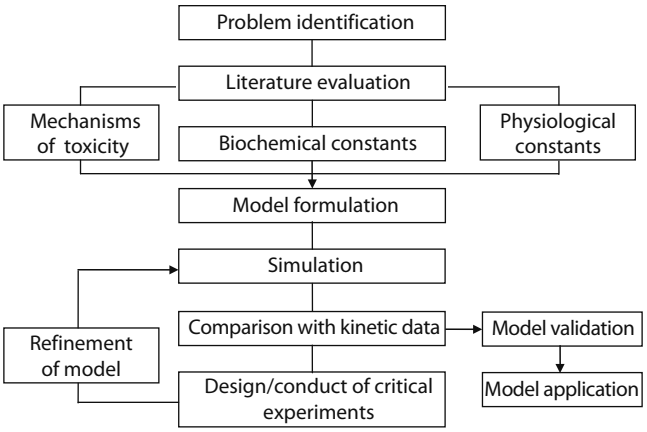

FIGURE 6.1 Schematic of the steps involved in the development of PBPK models.

can be studied in simpler systems to obtain the necessary PBPK model parameters in experiments separate from the collection of time-course concentration curves. Based on these parameters and an appropriate model structure, tissue time-course behaviors can be predicted by computer simulation with PBPK models and compared to data as a test of model performance.

The basic approach to PBPK model development is illustrated in Figure 6.1. The process of model development begins with the identification of the chemical exposure and toxic effect of concern, as well as the species and target tissue in which it is observed. Literature evaluation involves the integration of available information about the mechanism of toxicity; the pathways of chemical metabolism; the nature of the toxic chemical species (i.e., whether the parent chemical, a stable metabolite, or a reactive intermediate produced during metabolism is responsible for the toxicity); the processes involved in absorption, transport and excretion; the tissue partitioning and binding characteristics of the chemical and its metabolites; and the physiological parameters (i.e., tissue weights and blood flow rates) for the species of concern (i.e., the experimental species and the human). Using this information, the investigator develops a PBPK model that expresses mathematically a conception of the animal–chemical system [26]. To the extent that the structure of the model reflects the important determinants of the kinetics of the chemical, the result of this approach is a model that can predict the qualitative behavior of an experimental time course without having been based directly on it [27]. Refinement of the model to incorporate additional insights gained from comparison with experimental data yields a model that can be used for quantitative extrapolation well beyond the range of experimental conditions on which it was based. The model itself can then be used to help design critical experiments to collect data needed for its own refinement [28]. In particular, a properly validated PBPK model can be used to perform the high-to-low dose, dose route, and interspecies extrapolations necessary for estimating human risk on the basis of toxicology studies [29].

History of PBPK Modeling

Inhalation anesthesiologists have maintained a long tradition on understanding the role of ventilation rates, blood flow rates, and tissue solubility on the uptake and distribution of volatile anesthetics to the central nervous system. In the 1920s, Haggard [30,31] quantitatively described the importance of physiological factors for the uptake of ethyl ether into the body during the first few breaths. Accomplishing this analysis required writing an equation for the relationship between inhaled ether and the concentration of ether in blood. Tools for solving this equation over time were not available, so the mathematical analysis was limited to the first few breaths when venous concentrations remained small.

In the 1930s, Teorell [32,33] provided a set of equations for uptake, distribution, and elimination of drugs from the body. These papers are rightly regarded as providing the first physiological model for drug distribution. However, computational methods were not available to solve the sets of equations at this time. Exact mathematical solutions for distribution of compounds in the body could be obtained only for simplified models in which the body was reduced to a small number of compartments that did not correspond directly with specific physiological compartments. Over the next 30 years, PK modeling focused on these simpler descriptions with exact solutions rather than on developing models more concordant with the structure and content of the biological system itself. These approaches are sometimes referred to as *data-based* compartmental modeling since the work generally took the form of a detailed collection of time-course blood/excreta concentrations at various doses (Figure 6.1). Time-course curves were analyzed by assuming particular model structures and estimating a small number of model parameters by curve fitting. In the earliest of these models, all processes for metabolism, distribution, and elimination were treated as first order (i.e., they increased in direct proportion to the concentration of the chemical species). Two areas of concern that particularly affected data-based compartmental PK modeling arose in the 1960s and early 1970s: (1) the saturation of elimination pathways and (2) the possibility that blood flow rather than metabolic capacity of an organ might limit clearance. Saturation led to models that were not first order, making it difficult to derive exact solutions to the sets of equations. Blood flow–limited metabolism in an organ meant that the removal rate constant from a central compartment could not increase indefinitely as the metabolic capacity increased.

More complete PBPK models for inhalation were later provided by Kety [34], Mapleson [35], and Riggs [36]. In these models, body tissues were lumped together based on blood perfusion rates, giving sets of tissues referred to as richly perfused or poorly perfused. Mapleson [35] solved the set of equations using an analog computer to give solutions to the complete time course within the various tissue groups. These analog computer PBPK models for inhaled gases and vapors were extended by Fiserova-Bergerova and colleagues [37–39] to focus on compounds in the occupational environment and to describe the metabolism of these compounds in

the liver. The extension to include metabolism was particularly important for subsequent work in toxicology because most compounds of interest in occupational toxicology are metabolized, and metabolites are often involved in toxic responses.

Data-based compartmental models were brought to toxicology and risk assessment in a series of innovative studies by the late Dr. Perry Gehring (1938–2003) and his colleagues at the Dow Chemical Company in Midland, Michigan, in order to examine PK behavior where specific elimination pathways, both metabolic and excretory, become saturated at high doses [40–42]. In these studies, nonlinear data-based compartmental models were ingeniously applied to a series of compounds of toxicological and commercial importance including herbicides [43,44], solvents [45], plastic monomers [46,47], and hydrocarbons [48,49]. The final piece of technology needed to bring a full PBPK approach to studying factors that determine chemical disposition came with the rapid development of digital computation by the engineering community and the availability of these tools within the research laboratory.

Scientists trained in chemical engineering and computational methods developed PBPK models for chemotherapeutic compounds, that is, chemicals used in cancer therapy [4]. Many of these compounds are highly toxic and have therapeutic efficacy by being slightly more toxic to rapidly growing cells (the cancer cells) than to normal tissues. Initial successes with methotrexate [50] led to PBPK models for other compounds, including 5-fluorouracil [51] and cisplatin [52]. These seminal contributions showed the ease with which realistic descriptions of physiology and relevant pathways of metabolism could be incorporated into PBPK models for chemical disposition and paved the way for more extensive use of PBPK modeling in toxicology and chemical risk assessment. These models took advantage of the increasing availability of digital computation on main frame computers for solving sets of simultaneous differential equations.

Ramsey and Andersen [53] applied a PBPK modeling approach to describe the disposition of styrene in rats and humans for a range of concentrations and for several routes of administration. One of these two scientists (J. C. Ramsey) was a member of the PK group developing nonlinear PK models for chemicals at Dow Chemical Company and solving these models with a modern software package for solving sets of MB-DEs by numerical integration. The other (M. E. Andersen) had worked in inhalation toxicology laboratories at the Wright-Patterson Air Force Base, Ohio, and developed a steady-state analysis of PBPK models for inhalation of metabolized vapors [2]. This interinstitutional collaboration with styrene [53,54] relied on advances from inhalation anesthesia, data-based compartmental modeling, pharmaceutics, chemical engineering, and digital computation, to create PBPK models that would support extrapolation across species, between exposure routes, and from high to low doses. Using scale-up methods common for engineering models [55], the interspecies PBPK model for styrene (Figure 6.2) was able to predict blood and exhaled air time-course curves for oral and intravenous dosing in the rat and for inhalation exposures in human volunteers. This ability to support extrapolation to untested (and sometimes untestable) conditions is an essential part of risk assessment and has made these PBPK models attractive tools in human health risk assessments of various kinds [11,29]. In the styrene PBPK model, the liver was split off as a separate compartment (i.e., rather than embedded in a central compartment), metabolism in the liver was saturable (i.e., followed Michaelis–Menten kinetics), and styrene clearance from tissues was directly based on blood flow and metabolic characteristics of tissues. From that point in time, the application of PBPK modeling to environmental risk assessment has gained widespread acceptance in both the scientific and regulatory communities.

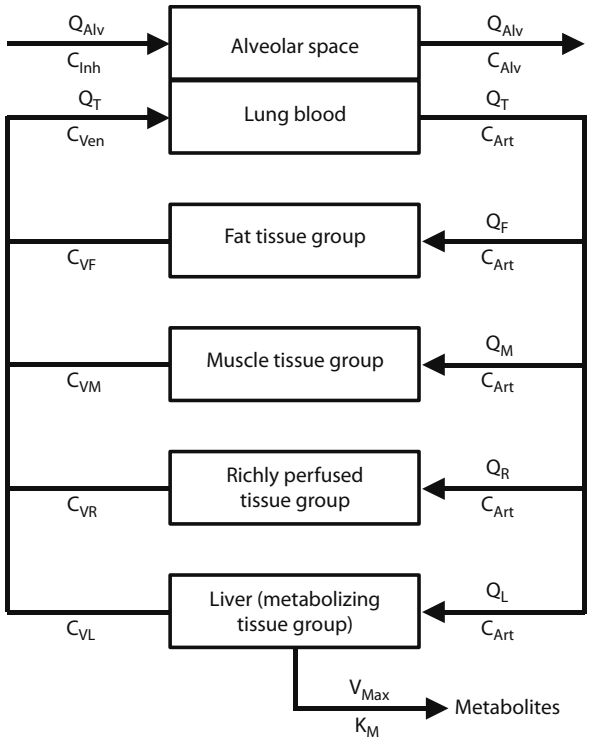

FIGURE 6.2 Diagram of a PBPK model for styrene. In this description, groups of tissues are defined with respect to their volumes, blood flows (Q), and partition coefficients for the chemical. The uptake of vapor is determined by the alveolar ventilation (QALV), the cardiac output (QT), the blood/air partition coefficient (PB), and the concentration gradient between arterial and venous pulmonary blood (C_{Art} and C_{Ven}). The dashed line (no dashed lines, author) reflects the fact that the lung compartment is described by a steady-state equation assuming that diffusion between the alveolar air and lung blood is fast compared to ventilation and perfusion. Metabolism is described in the liver with a saturable pathway defined by a maximum velocity (V_{max}) and affinity (K_M). The mathematical description assumes equilibration between arterial blood and alveolar air as well as between each of the tissues and the venous blood exiting from that tissue. (Adapted from Ramsey, J.C. and Andersen, M.E., *Toxicol. Appl. Pharmacol.*, 73, 159, 1984.)

PBPK Model Example: Styrene

The experience with styrene serves as a useful example of the advantages of the PBPK modeling approach. In this case, blood and tissue time-course curves of styrene had been obtained for rats exposed to four different concentrations of 80, 200, 600, and 1200 ppm [56]. Data were obtained during a 6-h exposure period and for 18 h after cessation of the exposure. The initial analysis of these data had been based on a simple compartmental model, which had a zero-order input related to the amount of styrene inhaled, a two-compartment description of the rat, and linear metabolism in the central compartment. The compartmental model was successful with lower concentrations but was unable to account for the more complex behavior at higher concentrations (note the different behavior of the data at the two concentrations shown in Figure 6.3).

In an attempt to provide a more successful description, a PBPK model was developed with a realistic equilibration process for pulmonary uptake and Michaelis–Menten saturable metabolism in the liver. A diagram of the PBPK model that was used by Ramsey and Andersen [53] to describe styrene inhalation in both rats and humans is shown in Figure 6.2. In this diagram, the boxes represent tissue compartments and the lines connecting them represent blood flows. The model contained several *lumped* tissue compartments: fat tissues, poorly perfused tissues (muscle, skin, etc.), richly perfused tissues (viscera), and metabolizing tissues (liver). The fat tissues were described separately from the other poorly perfused tissues due to their much higher partition coefficient for styrene, which leads to different kinetic properties, while the liver was described separately from the other richly perfused tissues due to its key role in the metabolism of styrene.

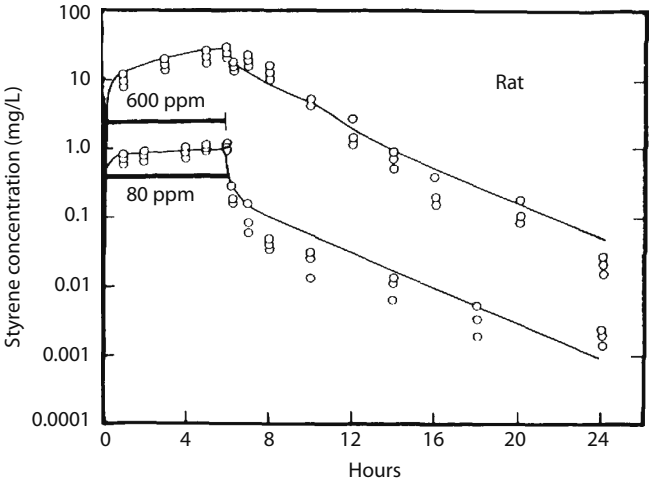

FIGURE 6.3 Model predictions (solid lines) and experimental blood styrene concentrations in rats during and after 6 h exposures to 80 and 600 ppm styrene. The thick bars represent the chamber air concentrations of styrene and are shown to highlight the nonlinearity of the relationship between administered and internal concentrations. The model contains sufficient biological realism to predict the very different behaviors observed at the two concentrations.

Each of these tissue groups was defined with respect to their blood flow, tissue volume, and their ability to store (partition) the chemical of interest.

The model equations represented by the diagram are described in the original publication [53]. For each compartment, the various time-dependent chemical transport and metabolic processes are described as a system of simultaneous differential equations. As an example, the differential equation defining the liver compartment in Figure 6.2 is shown as follows:

$$dA_L/dt = Q_L \times \left(C_{Art} - C_L/P_L\right) - V_{max} \times C_L/P_L/\left(K_M + C_L/P_L\right)$$

where

- A_L is the amount of chemical in the liver (mg)
- C_{Art} is the concentration of chemical in the arterial blood (mg/L)
- C_L is the concentration of chemical in the liver (mg/L)
- Q_L is the total (arterial plus portal) blood flow to the liver (L/h)
- P_L is the liver/blood partition coefficient
- V_{max} is the maximum rate of metabolism (mg/h)
- K_M is the concentration at half-maximum rate of metabolism (mg/L)

Although the model diagram in Figure 6.3 shows a lung compartment, a steady-state approximation for the equilibration of lung blood with alveolar air was used in the mathematical formulation of the model to eliminate the need for an actual lung tissue compartment. This simple model structure, with realistic constants for the physiological, partitioning, and metabolic parameters, very accurately predicted the behavior of styrene in both fat and blood of the rat at all concentrations. Figure 6.3 compares the model-predicted time course in the blood with the experimental data for the highest and lowest exposure concentrations in the rat studies.

The structure of the PBPK model for styrene reflects the generic mammalian architecture. Organs are arranged in a parallel system of blood flows with total blood flow through the lungs. This model can easily be scaled up to examine styrene kinetics for other mammalian species. In the case of styrene, exposure experiments had also been conducted with human volunteers [49]. In order to model these data, the PBPK model parameters were changed to human physiological values, the human blood/air partitioning was determined from human blood samples, and the metabolism was scaled allometrically so that capacity (V_{max}) was related to basal metabolic rate (BW raised to the 0.7 power) and affinity (K_m) was the same in the human as in the rat, 0.36 mg/L. Ramsey and coauthors [49] measured both venous blood and exhaled air concentrations in these human volunteers. Although the rat PBPK model was developed for blood and fat, not for exhaled air, the physiologically based description automatically provides information on expected exhaled air concentrations. It was straightforward then to predict expected exhaled air concentrations in humans and compare

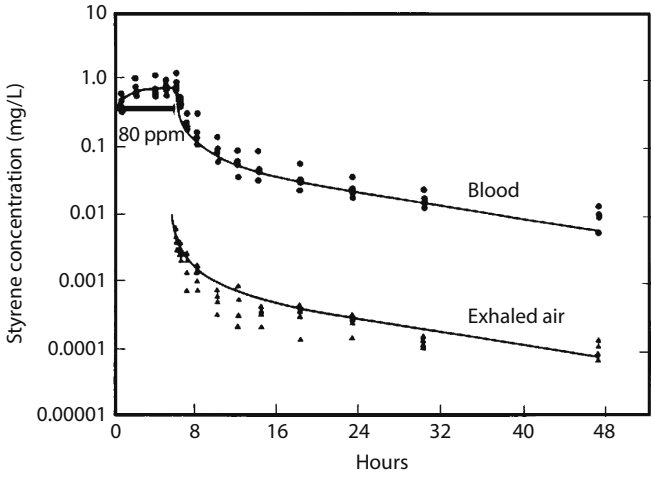

FIGURE 6.4 Model predictions and experimental blood and exhaled air concentrations in human volunteers during and after 6 h exposures to 80 ppm styrene. The model is identical to that used for rats. The model parameters have been changed to values appropriate for humans on the basis of physiological and biochemical information and have not been adjusted to improve the fit to the experimental data.

the predictions with the concentrations measured during the experiments (Figure 6.4).

A similar comparison of the model's predictions with another human data set from Stewart et al. [57] also demonstrated the ability of the PBPK structure to support extrapolation of styrene kinetics from the rat to the human (Figure 6.5).

The specific structure of a particular model is driven by the need to estimate the appropriate measure of tissue dose under the various exposure conditions of concern in both the experimental animal and the human. Before the model can be used in risk assessment, it has to be validated against kinetic, metabolic, and toxicity data and, in many cases, refined based on comparison with the experimental results. Importantly, the model itself can frequently be used to help design critical experiments to collect data needed for its own validation. Perhaps the most desirable feature of a PBPK model is that it provides a conceptual framework for employing the scientific method: Hypotheses can be described in terms of biological processes, quantitative predictions can be made on the basis of the mathematical description, and the model (hypothesis) can be revised on the basis of comparison with targeted experimental data. Refinement of the model to incorporate additional insights gained from comparison with experimental data yields a model that can be used for quantitative extrapolation well beyond the range of experimental conditions on which it was based.

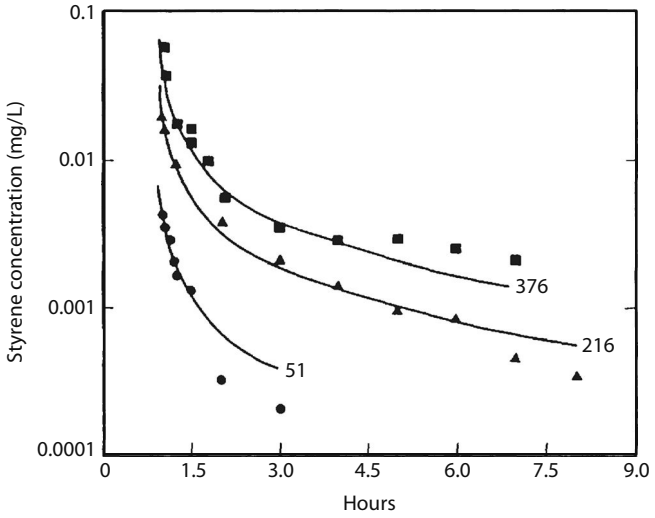

FIGURE 6.5 Model predictions and experimental exhaled air concentrations in human volunteers following 1 h exposures to 51, 216, and 376 ppm styrene.

Modeling Philosophy

This basic PBPK model for styrene has several tissue groups that were lumped according to their perfusion and partitioning characteristics. In the mathematical formulation, each of these several compartments is described by a single mass balance differential equation. It would be possible to describe individual tissues in each of the lumped compartments, if necessary. This detail is usually unnecessary unless some particular tissue in a lumped compartment is the target tissue. One might, for example, want to separate brain from other richly perfused tissues if the model were for a chemical that had a toxic effect on the central nervous system [58–60]. Other examples of additional compartments include the addition of placental and mammary compartments to model pregnancy and lactation [61–63]. The interactions of chemical mixtures can even be described by including compartments for more than one chemical in the model [64–66]. Increasing the number of compartments does increase the number of differential equations required to define the model. However, the number of equations does not pose any problem due to the power of modern desktop computers.

On the other hand, as the number of compartments in the PBPK model increases, the number of input parameters increases correspondingly. Each of these parameters must be estimated from experimental data of some kind. Fortunately, the values of many of these can be set within narrow limits from nonkinetic experiments. The PBPK model can also help to define those experiments that are needed to improve parameter estimates by identifying conditions where the sensitivity of the model to the parameter is the greatest [67]. The demand that the PBPK fit a variety of data also restricts the parameter values that will give a satisfactory fit to experimental data. For example, the styrene model (described earlier) was required to reproduce both the high and low concentration behaviors, which appeared qualitatively different, using the same parameter values. If one were independently fitting single curves with a model, the different parameter values obtained under different conditions would be relatively uninformative for extrapolation.

As the renowned statistician George Box has said, "All models are wrong but some are useful [68]." Even a relatively complex description such as a PBPK model will sometimes

fail to fit reliable experimental data. When this occurs, the investigator needs to think how the model might be changed, that is, what extra biological aspects must be added to the physiological description to bring the predictions in line with experimental observation. In the case of the work with styrene cited earlier, continuous 24-h styrene exposures could not be modeled with a time-independent maximum rate of metabolism, and induction of enzyme activity had to be included to yield a satisfactory representation of the observed kinetic behavior [54].

When a PBPK model is unable to adequately describe kinetic data, the nature of the discrepancy can provide the investigator with additional insight into time dependencies in the system. This insight can then be utilized to reformulate the biological basis of the model and improve its fidelity to the data. The resulting model may be more complicated, but it will still be useful if the pertinent kinetic constants can be estimated for human tissues. Indeed, as long as the model maintains its biological basis, the additional parameters can often be determined directly from separate experiment, rather than estimated by fitting the model to kinetic data. As the models become more complex, they necessarily contain larger numbers of physiological, biochemical, and biological constants. The crucial task during model development is to keep the description as simple as possible and to ensure the identifiability of new parameters that are added to the model; every attempt should be made to obtain or verify model parameters from experimental studies separate from the modeling exercises themselves [69].

MODEL DEVELOPMENT

The following section explores some of the key issues associated with the development of PBPK models. It is meant to provide a general understanding of the basic design concepts and mathematical forms underlying the PBPK modeling process and is not meant to be a complete exposition of the PBPK modeling approach for all possible cases. It must be understood that the specifics of the approach can vary greatly for different types of compounds and for different applications.

Model building is an art and is best understood as an iterative process in the spirit of the scientific method [26,70,71]. The literature includes many examples of successful PBPK models for a wide variety of compounds that provide a wealth of insight into various aspects of the PBPK modeling process [12]. These should be consulted for further detail on the approach for applying the PBPK methodology in specific cases.

Tissue Grouping

The first aspect of PBPK model development that will be discussed is determining the extent to which the various tissues in the body may be grouped together. Although tissue grouping is really just one aspect of model design, which is discussed in the next section, it provides a simple context for introducing the two alternative approaches to PBPK model development: *lumping* and *splitting* (Figure 6.6). In the context of tissue grouping, the guiding philosophy in the lumping approach can be stated as "Tissues that are pharmacokinetically and toxicologically indistinguishable may be grouped together." In this approach, model development begins with information at the greatest level of detail that is practical, and decisions are made to combine physiological elements (tissues and blood flows) to the extent justified by their similarity [72]. The common grouping of tissues into richly (or rapidly) perfused and poorly (or slowly) perfused on the basis of their perfusion ratio (ratio of blood flow to tissue volume) is an example of the lumping approach. The contrasting philosophy of splitting is "Tissues that are pharmacokinetically or toxicologically distinct must be separated." This approach starts with the simplest reasonable model structure and increases the model's complexity only to the extent required to reproduce data on the compound of concern for the application of interest. Lumping (starting with a large number of compartments and then testing whether they can be combined) requires the greater initial investment in data collection and, if taken to the extreme, could paralyze model development. On the other hand, splitting (starting with a small number of compartments and increasing complexity only if the simple model fails) is more efficient but runs a greater risk of overlooking compound-specific determinants of disposition.

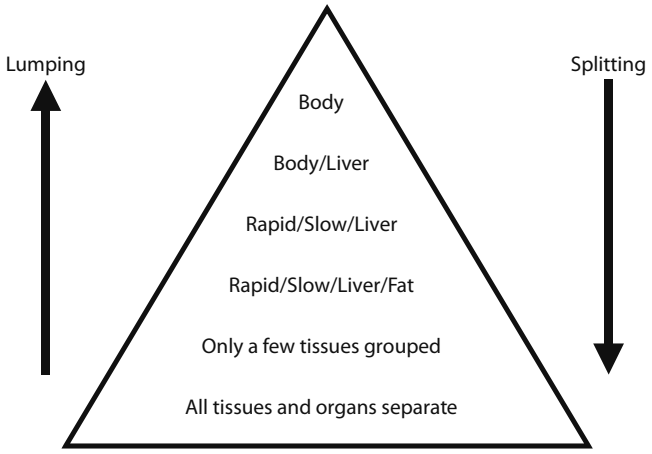

FIGURE 6.6 The role of lumping and splitting processes in PBPK model development.

There are two alternatives for determining whether tissues are kinetically distinct or can be lumped together. In the first approach, the tissue rate constants are compared. The rate constant (k_t) for a tissue is similar to the perfusion ratio except that the partitioning characteristics of the tissue are also considered:

$$k_T = \frac{Q_T}{\left(P_T * V_T\right)}$$

where

Q_T is the blood flow to the tissue (L/h)

P_T is the tissue/blood partition coefficient for the compound

V_T is the volume of the tissue (L)

Thus, the units of the tissue rate constant are the same as for the perfusion ratio, h^{-1}, but the rate constant more accurately reflects the kinetic characteristics of a tissue for a particular chemical. It was the much smaller rate constant for fat in the case of a lipophilic chemical such as styrene that required the separation of the fat compartment from the other poorly perfused tissues (muscle, skin, etc.) in its PBPK model [53]. The tissue time constant, 1/k, provides a measure of the time required for loading or unloading of compound under idealized conditions.

The second, less rigorous, approach for determining whether tissues should be lumped together is simply to compare the performance of the model with the tissues combined and separated. The reliability of this approach depends on the availability of data under conditions where the tissues being evaluated would be expected to have an observable impact on the kinetics of the compound. Sensitivity analysis can sometimes be used to determine the appropriate conditions for such a comparison [67].

Model Design Principles

There is no easy rule for determining the structure and level of complexity needed in a particular modeling application. The wide variability of PBPK model design for different chemicals can be seen by comparing the diagram of the PBPK model for methotrexate [50], shown in Figure 6.7, with the diagram for the styrene PBPK model shown in Figure 6.3. Model elements that are important for a volatile lipophilic chemical such as styrene (lung, fat) do not need to be considered in the case of a nonvolatile water-soluble compound such as methotrexate. Similarly, while kidney excretion and enterohepatic recirculation are important determinants of the kinetics of methotrexate, only metabolism and exhalation are significant for styrene. The decision of which elements to include in the model structure for a specific chemical and application draws on all of the modeler's experience and knowledge of the animal–chemical system.

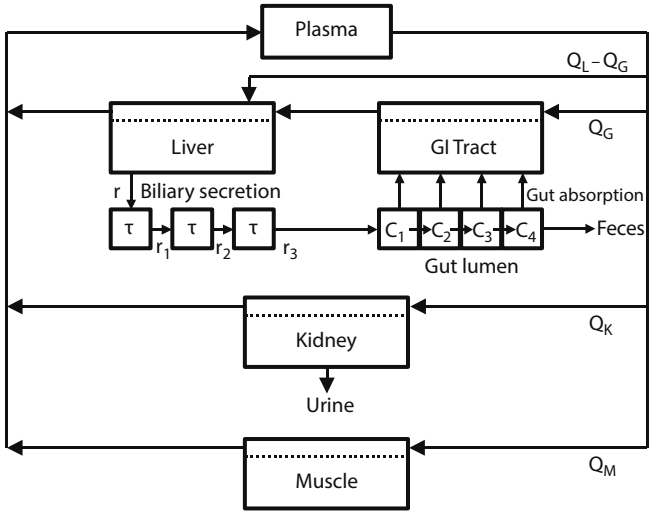

FIGURE 6.7 PBPK model for methotrexate. (Adapted from Bischoff, K.B. et al., *J. Pharm. Sci.*, 60, 1128, 1971.)

The alternative approaches to tissue grouping discussed earlier are actually reflections of two competing criteria that must be balanced during model design: parsimony and plausibility. The principle of parsimony simply states that a model should be as simple as possible for the intended application (but no simpler). This *splitting* philosophy is related to that of Occam's razor: "Entities should not be multiplied unnecessarily." That is, structures and parameters should not be included in the model unless they are needed to support the application for which the model is being designed.

There is no easy rule for determining the structure and the level of complexity needed in a particular modeling application. The decision regarding which elements to include in the model structure for a specific compound and application draws on all of the modeler's experience and knowledge of the animal–chemical system. For example, model elements such as inhalation and fat storage, which are important for a volatile lipophilic chemical such as styrene [53], do not need to be considered in the case of a nonvolatile water-soluble compound such as methotrexate [50,73]. Similarly, while kidney excretion and enterohepatic recirculation are important determinants of the kinetics of methotrexate (Figure 6.7), they are not needed in the model of styrene. As another example, a simple description of inhalation uptake as a one-compartment gas exchange (Figure 6.3) may be adequate for some model applications, as in the case of modeling of the systemic uptake of a lipophilic vapor like styrene. However, a more complicated description is required in the case of water-soluble vapors, to account for a *wash-in, wash-out* effect in the upper respiratory tract [74,75].

The desire for parsimony in model development is driven not only by the desire to minimize the number of parameters whose values must be identified, but also by the recognition that as the number of parameters increases, the potential for unintended interactions between parameters also increases. A generally accepted rule of software engineering warns that it is relatively easy to design a computer program that is too complicated to be completely comprehended by the developer. As a model becomes more complex, it becomes increasingly difficult to validate, even as the level of concern for the trustworthiness of the model should increase.

Countering the desire for model parsimony is the need for plausibility of the model structure. The credibility of a PBPK model's predictions of kinetic behavior under conditions different from those under which the model was validated rests to a large extent on the correspondence of the model design to known physiological and biochemical structures, and an accurate description of the mode of action for the effects of the chemical [1,76,77]. In general, the ability of a model to adequately simulate the behavior of a physical system depends on the extent to which the model structure is homomorphic (having a one-to-one correspondence) with the essential features determining the behavior of that system [26].

Model Identification

The process of determining the most appropriate structure for the model, which is also known as model identification, begins with the selection of those model elements that the modeler considers to be minimum essential determinants of the behavior of the particular animal–chemical system under study, from the viewpoint of the intended application of the model. Comparison with appropriate data, relevant to the intended purpose of the model, then can provide insights into defects in the model that must be corrected either by reparameterization or by changes to the model structure. Unfortunately, it is not always possible to separate these two elements. In models of biological systems, estimates of the values of model parameters will always be uncertain, due to both biological variation and experimental error. At the same time, the need for biological realism unavoidably results in models that are overparameterized, that is, they contain more parameters than can be identified from the kinetic data the model is used to describe.

As an example of the interaction between model structure and parameter identification, the two metabolic parameters, V_{max} and K_m, in the model for styrene discussed earlier could both be identified relatively unambiguously in the case of the rat. Indeed, as pointed out previously, the inclusion of capacity-limited metabolism in the model was necessary in order to reproduce the available data at both low and high exposure concentrations. In the case of the human, however, data were not available at sufficiently high concentrations to saturate metabolism. Therefore, only the ratio, V_{max}/K_m, would actually be identifiable. The use of the same model structure, including a two-parameter description of metabolism, in the human as in the rat was justified by the knowledge that similar enzymatic systems are responsible for the metabolism of chemicals such as styrene in both species. However, if the model were to be used to extrapolate to higher concentrations in the human, the potential impact of the uncertainty in the values of the individual metabolic parameters would have to be carefully considered.

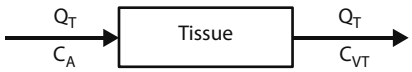
Model identification is the selection of a specific model structure from several alternatives, based on the conformity of the model's predictions to experimental observations. The practical reality of model identification in the case of biological systems is that regardless of the complexity of the model, there will always be some level of *model error* (lack of homomorphism), which will result in systematic discrepancies between the model and the experimental data. This model structural deficiency interacts with deficiencies in the identifiability of the model parameters, potentially leading to misidentification of the parameters or misspecification of structures. This most dangerous aspect of model identification is exacerbated by the fact that, in general, adding equations and parameters to a model increases the model's degrees of freedom, improving its ability to reproduce data, regardless of the validity of the underlying structure. Therefore, when a particular model structure improves the agreement of the model with kinetic data, it can be said that the model structure is only *consistent* with the kinetic data; it cannot be said that the model structure has been *proved* by its consistency with the data. In such circumstances, it is imperative that the physiological or biochemical hypothesis underlying the model structure is tested using nonkinetic data.

Elements of Model Structure

The process of selecting a model structure can be broken down into a number of elements associated with the different aspects of uptake, distribution, metabolism, and elimination. In addition, there are several general model structure issues that must be addressed, including mass balance and allometric scaling. The following section treats each of these elements in turn.

Storage Compartments

Naturally, any tissues that are expected to accumulate significant quantities of the compound or its metabolites need to be included in the model structure. As discussed earlier, these storage tissues can be grouped together to the extent that they have similar time constants. The muscle tissue in the methotrexate model (Figure 6.7) is an example of a storage compartment. The generic mass balance equation for storage compartments such as these is



$$\frac{dA_T}{dt} = Q_T * C_A - Q_T * C_{VT}$$

where

A_T is the mass of compound in the tissue (mg)
C_A is the concentration of compound in the arterial blood reaching the tissue (mg/L)
C_{VT} is the concentration of the compound in the venous blood leaving the tissue (mg/L)

Thus, this mass balance equation simply states that the rate of change in the amount of compound in the tissue with respect to time (dA_T/dt) is equal to the difference between the rate at which the compound enters the tissue and the rate at which the compound leaves the tissue. We can then calculate the concentration of the compound in the storage tissue (C_T) from the amount in the tissue and the tissue volume (V_T):

$$C_T = \frac{A_T}{V_T}$$

In PBPK models, it is common to assume *venous equilibration*, that is, in the time that it takes for the blood to perfuse the tissue, the compound is able to achieve its equilibrium distribution between the tissue and blood. Therefore, the concentration of the compound in the venous blood can

be related to the concentration in the tissue by the equilibrium tissue/blood partition coefficient, P_T:

$$C_{VT} = \frac{C_T}{P_T}$$

Therefore, we obtain a differential equation in A_T:

$$dA_T/dt = Q_T{*}C_A - Q_T{*}A_T/(P_T{*}V_T)$$

If desired, we can reformulate this mass balance equation in terms of concentration:

$$dA_T/dt = d(C_T{*}V_T)/dt = C_T{*}dV_T/dt + V_T{*}dC_T/dt$$

If (and only if) V_T is a constant (i.e., the tissue does not grow during the simulation), $dV_T/dt = 0$, and

$$dA_T/dt = V_T{*}dC_T/dt$$

so we have the alternative differential equation:

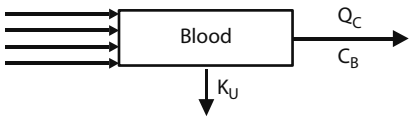
$$dC_T/dt = Q_T{*}(C_A - C_T/P_T)/V_T$$

This alternative mass balance formulation, in terms of concentration rather than amount, is popular in the pharmacokinetic literature. However, in the case of models with compartments that change volume over time (e.g., in a model incorporating growth of a single or multiple tissues), it is preferable to use the formulation in terms of amounts in order to avoid the need for the additional term reflecting the change in volume ($C_T{*}dV_T/dt$).

Depending on the compound, many different tissues can potentially serve as important storage compartments. The use of a fat storage compartment is typically required for lipophilic compounds. The gut lumen can also serve as a storage site for compounds subject to enterohepatic recirculation, as in the case of methotrexate. Important storage sites for metals, on the other hand, can include the kidney, red blood cells, intestinal epithelial cells, skin, bone, and hair [78]. Transport to and from a storage compartment does not always occur via the blood, as was described earlier, for example, in some cases, the storage is an intermediate step in an excretion process (e.g., hair, intestinal epithelial cells). As with methotrexate, it may also be necessary to use multiple compartments in series, or other mathematical devices, to model plug flow (i.e., a time delay between entry and exit from storage).

Blood Compartment

The description of the blood compartment can vary considerably from one PBPK model to another depending on the role the blood plays in the kinetics of the compound being modeled. In some cases, the blood may be treated as a simple storage compartment, with a mass balance equation describing the summation (Σ) of the venous blood flows from the various tissues and the return of the total arterial blood flow (Q_C) to the tissues, as well as any urinary clearance (if, as in the case of glomerular filtration, clearance is described as occurring from the blood compartment):



$$\frac{dA_B}{dt} = \Sigma\left(Q_T * C_{VT}\right) - Q_C * C_B - K_U * C_B$$

where

A_B is the amount of compound in the blood (mg)
Q_C is the total cardiac output (L/h)
C_B is the concentration of compound in the blood (mg/L)
K_U is the urinary clearance (L/h)

The value for K_U can often be estimated from the unbound fraction in plasma (f_{ub}) and the glomerular filtration rate (GFR), unless active transport processes contribute to renal elimination. An alternative method for estimating human renal clearance based on rat renal clearance and incorporating species-specific physiological differences in GFR has been proposed [79,80].

Usually, concentrations are measured in plasma or serum and not in whole blood; hence, plasma or serum is the reference fluid for the derived pharmacokinetic parameters such as clearances and volumes of distribution. However, whole blood, not plasma or serum, is flowing through the vessels of the human body. Therefore, provided that there is evidence in support of fast equilibration of the compound between red blood cells and plasma [81], whole blood rather than plasma is the more appropriate reference fluid for calculating and interpreting clearances and volumes of distribution. For this reason, parameterization of the PBPK model is often performed in terms of blood flows. To compare calculated plasma concentrations to experimental data, the calculated blood concentration must then be divided by the blood-to-plasma ratio (BPR), which is often measured experimentally.

In cases where a compound is not taken up by the red blood cells, plasma flow can be used in place of blood flow in the model [50]. For some compounds, where exchange between plasma and red blood cells is slow compared to tissue perfusion, it may be necessary to model the red blood cells as a storage compartment in communication with the plasma via diffusion-limited transport. Typically, however, exchange between red blood cells and plasma is fast compared to tissue distribution, and the blood can be treated as a single compartment.

For some chemicals, such as methotrexate, all of the chemical is present in the plasma rather than the red blood cells, so plasma flows and volumes are used instead of blood. For other chemicals, it may be necessary to model the red blood cells as a storage compartment in communication with the plasma via diffusion-limited transport. If the blood is

an important storage compartment for a compound, it may be necessary to carefully evaluate data on tissue concentrations, particularly the richly perfused tissues, to determine whether compound in the blood perfusing the tissue could be contributing to the measured tissue concentration. For other compounds, such as styrene, the amount of compound actually in the blood may be relatively small, in which case only the concentration may be of interest. In this case, instead of having a true blood compartment, a steady-state approximation can be used to estimate the concentration in the blood at any time. Assuming the blood is at steady state with respect to the tissues,

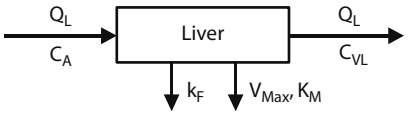
$$\frac{dA_B}{dt} = 0$$

Therefore, solving the blood equation for the concentration,

$$C_B = \frac{\Sigma\left(Q_T * C_{VT}\right)}{Q_C}$$

Metabolism/Elimination

The liver is frequently the primary site of metabolism, though other tissues such as the kidney, placenta, lung, skin, and blood may be important metabolism sites depending on the chemical. The following equation is an example of the mass balance equation for the liver in the case of a compound that is metabolized through both saturable and nonsaturable components:



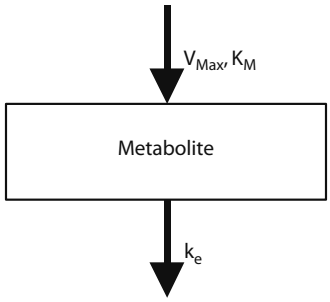
$$dA_L/dt = Q_L*(C_A - C_{VL}) - k_F* C_{Lfree}* V_L - V_{max}*C_{Lfree}/(K_m + C_{Lfree})$$

where

Q_L is the total blood flow (arterial and portal) to the liver
C_{Lfree} is the free (unbound) concentration in the liver

In the equation given earlier, the first term on the right-hand side of the equation represents the mass flux associated with transport in the blood and is essentially identical to the case of the storage compartment described previously. In the case of the liver, however, it should be noted that there are two sources of blood flow: the arterial flow directly to the liver and the portal flow that first perfuses the intestines. When appropriate, these two blood flows can be differentiated in the model (Figure 6.7).

The second term in the equation given earlier describes metabolism by a linear (first-order) pathway with rate constant k_F (h^{-1}), and the third term represents metabolism by a saturable (Michaelis–Menten) pathway with capacity V_{max} (mg/h) and affinity K_m (mg/L). If it were desired to model a water-soluble metabolite produced by this saturable pathway, an equation for its formation and elimination could also be added to the model:



$$dA_M/dt = R_{stoch} * V_{max} * C_{Lfree}/(K_m + C_{LFree}) - k_e * A_M$$

$$C_M = \frac{A_M}{V_D}$$

where

A_M is the amount of metabolite in the body (mg)
R_{stoch} is the stoichiometric fractional yield of the metabolite (unitless)
(times the ratio of its molecular weight to that of the parent compound if the modeling is in terms of weight rather than moles)
k_e is the rate constant for the clearance of the metabolite from the body (h^{-1})
C_M is the concentration of the metabolite in the plasma (mg/L)
V_D is the apparent volume of distribution for the metabolite (L)

The definition of free concentration in the liver (C_{Lfree}) in these equations is not as straightforward as it may at first appear. In cases where hepatic clearance is relatively low, the free concentration in the liver is often assumed to be equal to the free (unbound) concentration in the blood, that is, $C_{Lfree} = f_u * C_B$. However, when hepatic clearance is high, the free concentration in the liver can be drawn well below the free concentration in the blood, and such an assumption may be inappropriate. An alternative assumption that is often made is that the free concentration in the liver can be estimated by dividing the total liver concentration by the liver/blood partition coefficient, that is, $C_{Lfree} = C_L/P_L$ [50]. This approximation is particularly useful for compounds whose metabolism is limited by hepatic blood flow at low concentrations. If the intent is to use in vitro estimates of the metabolic parameters (V_{max}, K_m, k_f) in the model, then the definition of the in vivo free concentration should be consistent with the conditions under which the in vitro estimates of intrinsic clearance were obtained. In principle, this could require adjusting for differences in binding between the in vitro medium and the tissue in vivo, although such adjustments are seldom performed in practice.

Clearance may occur through urinary or fecal excretion, exhaled air, or even through loss via hair. This loss may often be successfully described using first-order clearance terms. However, more elaborate descriptions are sometimes

required for chemicals that are substrates for transporters that transfer the chemical against a concentration gradient. Some transporters in the kidney and bile can increase the clearance of xenobiotics, while others, such as those responsible for reabsorption, may decrease clearance [82].

Metabolite Compartments

In principle, the same considerations that drive decisions regarding the level of complexity of the PBPK model for the parent chemical must also be applied for each of its metabolites, and their metabolites, and so on. As in the case of the parent chemical, the first and most important consideration is the purpose of the model. If the concern is direct parent chemical toxicity and the chemical is detoxified by metabolism, then there is no need for a description of metabolism beyond its role in the clearance of the parent chemical. The models for styrene and methotrexate discussed earlier are examples of parent chemical models. Similarly, if reactive intermediates produced during the metabolism of a chemical are responsible for its toxicity, as in the case of methylene chloride, a very simple description of the metabolic pathways might be adequate [64]. The cancer risk assessment model for methylene chloride described the rate of metabolism for two pathways: the glutathione conjugation pathway, which was considered responsible for the carcinogenic effects, and the competing P450 oxidation pathway, which was considered protective.

If one or more of the metabolites are considered to contribute to the toxicity of a compound, it may also be necessary to provide a more complete description of the kinetics of the metabolites themselves [83–85]. Fortunately, the metabolism of xenobiotic compounds often produces metabolites that are relatively water soluble, simplifying the description needed. In many cases, a classical one-compartment description may be adequate for describing the metabolite kinetics [86,87]. In other cases, however, the description of the metabolite (or metabolites) may have to be as complex as that of the parent compound. For example, in the case of teratogenicity from all-trans-retinoic acid, both the parent compound and several of its metabolites are considered to be toxicologically active; therefore, in developing the PBPK model for this compound, it was necessary to include a fairly complete description of the metabolic pathways [85]. On the other hand, if reactive intermediates produced during the metabolism of a compound are responsible for toxicity, a very simple description of the metabolic pathways might be adequate [64].

Target Tissues

Typically, a PBPK model used in risk assessment applications will include compartments for any target tissues for the toxicity of the compound. The target tissue description may in some cases need to be fairly complicated, including such features as in situ metabolism, binding, and pharmacodynamic processes in order to provide a realistic measure of biologically effective tissue exposure. For example, whereas the lung compartment in the styrene model was represented only by a steady-state description of alveolar vapor exchange, the PBPK model for methylene chloride that was applied to perform a cancer risk assessment [64] included a two-part lung description in which alveolar vapor exchange was followed by a lung tissue compartment with in situ metabolism. This more complex lung compartment was required to describe the dose–response for methylene chloride–induced lung cancer, which was assumed to result from the metabolism of methylene chloride in lung clara cells.

In other cases, describing a separate compartment for the target tissue may be unnecessary. For example, the styrene model described earlier could be used to relate acute exposures associated with neurological effects without the necessity of separating out a brain compartment. Instead, the concentration or area under the concentration curve (AUC) of styrene in the blood could be used as a metric, on the assumption that the relationship between brain concentration and blood concentration would be the same under all exposure conditions, routes, and species, namely, that the concentrations would be related by the brain/blood partition coefficient. In fact, this is probably a reasonable assumption across different exposure conditions in a given species. However, while tissue/air partition coefficients for volatile lipophilic chemicals appear to be similar in dog, monkey, and man [88], human blood/air partition coefficients appear to be roughly half of those in rodents [89]. Therefore, the human brain/blood partition would probably be about twice that in the rodent. Nevertheless, if the model were to be used for extrapolation from rodents to humans, this difference could easily be factored into the analysis as an adjustment to the blood metric, without the need to actually add a brain compartment to the model.

A fundamental issue in determining the nature of the target tissue description required is the need to identify the toxicologically active form of the chemical. In some cases, a chemical may produce a toxic effect directly, either through its reaction with tissue constituents (e.g., ethylene oxide) or through its binding to cellular control elements (e.g., dioxin). Often, however, it is the metabolism of the chemical that leads to its toxicity. In this case, toxicity may result primarily from reactive intermediates produced during the process of metabolism (e.g., chlorovinyl epoxide produced from the metabolism of vinyl chloride) or from the toxic effects of stable metabolites (e.g., trichloroacetic acid produced from the metabolism of trichloroethylene).

The specific nature of the relationship between tissue exposure and response depends on the mechanism, or mode of action, involved. Rapidly reversible effects may result primarily from the current concentration of the compound in the tissue, while longer-term effects may depend on both the concentration and the duration of the exposure. In general, the appropriate measure of tissue exposure for one toxic effect of a compound may be different from the appropriate measure for another of its effects. For example, the mitogenic effect of a compound may depend on the prolonged maintenance of a relatively high concentration sufficient to occupy a receptor in the target tissue, while cytotoxicity may result from transient high rates of metabolism occurring shortly after dosing. In such a case, PBPK modeling of the concentration

time course in the target tissue for different dosing routes or regimens might be necessary. For developmental toxicity, the concentration time course might also have to be convoluted with the window of susceptibility for a particular gestational event. The evaluation of the various modes of action for the beneficial and toxic effects of a compound is the most important step in a pharmacokinetic analysis and a principal determinant of the structure and level of detail that will be required in the PBPK model.

Uptake Routes

Each of the relevant uptake routes for the compound must be described in the model. Often, there are a number of possible ways to describe a particular uptake process, ranging from simple to complex. As with all other aspects of model design, the competing goals of parsimony and realism must be balanced in the selection of the level of complexity to be used. The following examples are meant to provide an idea of the variety of model code that can be required to describe the various possible uptake processes.

Intravenous Administration (Bolus Dosing)

$$A_{B0} = \text{Dose} * BW$$

where

A_{B0} is the amount of compound in the blood at the time of dosing (t = 0)
Dose is administered dose (mg/kg)
BW is body weight (kg)

Intravenous Administration (Infusion)

For example, in the case where a steady-state approximation has been used to eliminate the blood compartment,

$$C_B = \left(Q_L * C_{VL} + \cdots + Q_F * C_{VF} + k_{IV}\right)$$

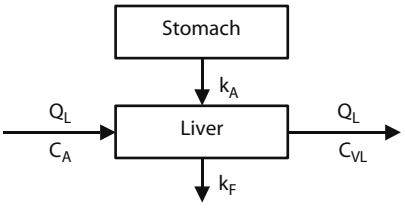
where

$k_{IV} = \text{Dose} * BW/t_{IV}$ $(t < t_{IV})$
$= 0$ $(t > t_{IV})$
t_{IV} is the duration of time over which the infusion takes place (h)

In this case, the model code must be written with a *switch* to change the value of k_{IV} to zero at $t = t_{IV}$.

Oral Gavage

For a compound that is completely absorbed in the stomach,



$$A_{ST0} = \text{Dose} * BW$$

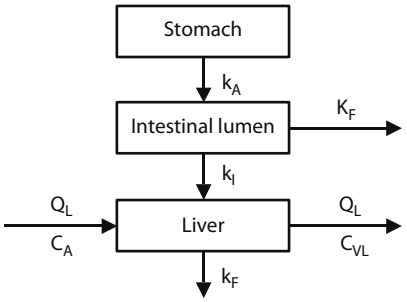
$$dA_{ST}/dt = -k_A * A_{ST}$$

$$dA_L/dt = Q_L*(C_A - C_L/P_L) - k_F * C_L * V_L/P_L + k_A * A_{ST}$$

where

A_{ST0} is the amount of compound in the stomach at the beginning of the simulation
A_{ST} is the amount of compound in the stomach at any given time
k_A is a first-order rate constant (h^{-1}) describing uptake from the stomach

For a compound that is incompletely absorbed,



$$A_{ST0} = \text{Dose} * BW$$

$$dA_{ST}/dt = -k_S * A_{ST}$$

$$dA_I/dt = k_S * A_{st} - k_I * A_I - K_F * A_I/V_I$$

$$dA_L/dt = Q_L * (C_A - C_{VL}) - k_F * C_{Lfree} * V_L + k_I * A_I$$

where

A_I is the amount of compound in the intestinal lumen (mg)
k_I is the rate constant for intestinal absorption (h^{-1})
K_F is the fecal clearance (L/h)
V_I is the volume of the intestinal lumen (L)

The rate of fecal excretion of the compound is then

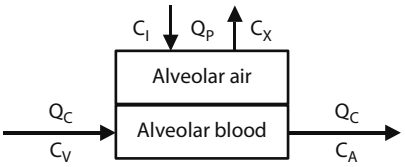
$$dA_F/dt = K_F * A_I/V_{Is}$$

The examples described earlier are highly simplified descriptions. For example, they describe uptake from the stomach or intestinal lumen directly to the liver, when in fact the uptake is into the tissues of the gastrointestinal (GI) tract with subsequent transport to the liver in the portal blood. While this simplification is adequate in some cases, a more accurate description may be necessary in others, such as when metabolism in the gut tissues is important [87] or portal blood flow could limit uptake. The equations shown earlier also do not describe biliary excretion or other processes that might be important determinants of the intestinal concentration and fecal excretion of a compound over time. Again, these processes would need to be included in the full model description for compounds where these processes are important [85]. Note, also, that this simple formulation does not consider the

plug flow of the intestinal contents and will not reproduce the delay that actually occurs in the appearance of a compound in the feces. Such a delay could be added using a delay function available in common simulation software, or multiple compartments could be used to simulate plug flow, as shown in the diagram of the methotrexate model (Figure 6.7).

Inhalation

For compounds that are volatile, it is necessary to describe the exchange of vapor between the lung air and blood in the alveolar region. This is true even if the compound is not administered by inhalation, because exhalation can be an important route of clearance for volatile compounds regardless of the dose route:



$$\frac{dA_{AB}}{dt} = Q_C * (C_V - C_A) + Q_P * (C_I - C_X)$$

where

- A_{AB} is the amount of compound in the alveolar blood (mg)
- C_V is the concentration of compound in the pooled venous blood (mg/L)
- C_A is the concentration of compound in the alveolar (arterial) blood (mg/L)
- Q_P is the alveolar (not total pulmonary) ventilation rate (L/h)
- C_I is the concentration of compound in the inhaled air (mg/L)
- C_X is the concentration of compound in the alveolar air (mg/L)

Assuming the alveolar blood is at steady state with respect to the other compartments,

$$\frac{dA_{AB}}{dt} = 0$$

Also, assuming lung equilibration (i.e., the blood in the alveolar region has reached equilibrium with the alveolar air prior to exhalation),

$$C_X = \frac{C_A}{P_B}$$

Substituting into the equation for the alveolar blood and solving for C_A,

$$C_A = \frac{(Q_C * C_V + Q_P * C_I)}{(Q_C + Q_P/P_B)}$$

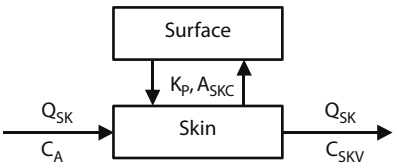
Note that the rate of elimination of the compound by exhalation is just $Q_P * C_X$. The alveolar ventilation rate, Q_P, does not include the *dead-space* volume (the portion of the inhaled air that does not reach the alveolar region) and is therefore roughly 70% of the total respiratory rate. The concentration C_X represents the *end-alveolar* air concentration; in order to estimate the average exhaled concentration (C_{EX}), the dead-space contribution must be included:

$$C_{EX} = 0.3 * C_I + 0.7 * C_X$$

PBPK models including more detailed physiological descriptions of inhalation exposures developed to understand toxicological effects of reactive vapors in the nasal cavity have been reviewed [90].

Dermal

A simple model can be used to describe dermal absorption from a constant-concentration vehicle on the skin surface:



$$dA_{SK}/dt = K_P * A_{SFC} * (C_{SFC} - C_{SK}/P_{SKV})/1000 + Q_{SK} * (C_A - C_{SK}/P_{SKB})$$

where

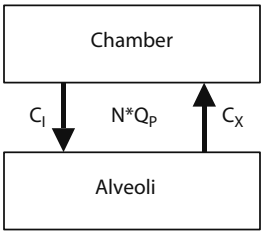
- A_{SK} is the amount of compound in the skin (mg)
- K_P is the skin permeability coefficient (cm/h)
- A_{SFC} is the skin surface area (cm^2)
- C_{SFC} is the concentration of compound on the surface of the skin (mg/L)
- C_{SK} is the concentration of the compound in the skin (mg/L)
- P_{SKV} is the skin/vehicle partition coefficient (i.e., the vehicle containing the compound on the surface of the skin)
- Q_{SK} is the blood flow to the skin region (L/h)
- C_A is the arterial concentration of the compound (mg/L)
- P_{SKB} is the skin/blood partition coefficient

Due to addition of this compartment, the equation for the blood in the model must also be modified to add a term for the venous blood returning from the skin ($+ Q_{SK} * C_{SK}/P_{SKB}$), and the blood flow and volume parameters for the slowly perfused tissue compartment must be reduced by the amount of blood flow and volume for the skin. Approaches used to include the dermal exposure route in PBPK models have been reviewed [12]. Several reviews discuss the wide variety of available compartment models and provide guidance for choosing among them [91,92].

Experimental Apparatus

In some cases, in addition to compartments describing the animal–chemical system, it may also be necessary to include

model compartments that describe the experimental apparatus in which measurements were obtained. An example of such a case is modeling a closed-chamber gas uptake experiment [93–96]. In a gas uptake experiment, several animals are maintained in a small enclosed chamber while the air in the chamber is recirculated, with replenishment of oxygen and scrubbing of carbon dioxide. A small amount of a volatile chemical is then allowed to vaporize into the chamber, and the concentration of the chemical in the chamber air is monitored over time. In this design, any loss of the chemical from the chamber air reflects uptake into the animals [93]. In order to simulate the change in the concentration in the chamber air as the chemical is taken up into the animals, an equation is required for the chamber itself:



$$\frac{dACH}{dt} = N * QP * (CX - CI)$$

$$CI = \frac{ACH}{VCH}$$

where

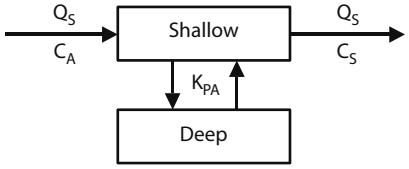
ACH is the amount of chemical in the chamber (mg)
N is the number of animals in the chamber
CX is the concentration of chemical in the air exhaled by the animals (mg/L)
QP is the alveolar ventilation rate for a single animal (L/h)
CI = the chamber air concentration (mg/L)
VCH is the volume of air in the chamber (L)

Distribution/Transport

Chemical transfer between the blood and tissue compartments may be governed by passive diffusion (flow or diffusion limited) or active transport. Many published PBPK models are flow limited, that is, they assume that the rate of tissue uptake of the chemical is limited only by the flow of the chemical to the tissue in the blood. While this assumption is generally reasonable, for some chemicals and tissues, the uptake may instead be limited by other factors such as diffusion. Examples of tissues for which diffusion-limited transport has often been described include the skin, placenta, mammary glands, brain, and fat [61,62,97,98]. Some chemicals may be transported against the concentration gradient through energy-dependent processes. These processes are sometimes limited by the availability of transporter proteins, and such saturable processes are often well described using Michaelis–Menten-type kinetics [82,99–101].

Diffusion-Limited Transport

Most of the PBPK models in the literature are flow-limited models, that is, they assume that the rate of tissue uptake of the chemical is limited only by the flow of the chemical to the tissue in the blood. While this assumption appears to be reasonable in general, for some chemicals and tissues, uptake may instead be diffusion limited. Examples of tissues for which diffusion-limited transport has often been described include the skin, placenta, brain, and fat. The model compartments described thus far have all assumed flow-limited transport. If there is evidence that the movement of a compound between the blood and a tissue is limited by diffusion, a two-compartment description of the tissue can be used with a *shallow* exchange compartment in communication with the blood and a diffusion-limited *deep* compartment that represents the actual tissue:



$$dA_S/dt = Q_S * (C_A - C_S) - K_{PA} * (C_S - C_D/P_D)$$

$$dA_D/dt = K_{PA} * (C_S - C_D/P_D)$$

where

A_S is the amount of the compound in the shallow compartment (mg)
Q_S is the blood flow to the shallow compartment (L/h)
C_S is the concentration of the compound in the shallow compartment (mg/L)
K_{PA} is the permeability–area product for diffusion-limited transport (L/h)
C_D is the concentration of the compound in the deep compartment (mg/L)
P_D is the tissue/blood partition coefficient
A_D is the amount of compound in the deep compartment (mg)

Saturable Tissue Binding

When there is evidence that saturable binding is an important determinant of the distribution of a compound into a tissue (such as evidence of dose-dependent tissue partitioning), a simple description of tissue binding can be added to the model. In this description, only free (unbound) compound is considered to be available for transport or clearance at any given moment in time. For example, in the case of saturable binding in the liver,

$$dA_L/dt = V_L dC_L/dt = Q_L * (C_A - C_{Lfree}/P_{Lfree}) - k_F * C_{Lfree}/P_{Lfree}$$

where

A_L is the total (free plus bound) concentration of the compound in the liver (mg)
C_{Lfree} is the concentration of free (unbound) compound in the liver (mg/L)
P_{Lfree} is the liver/blood partition coefficient for free (unbound) compound
k_F is the rate constant for metabolism (h^{-1})

The apparent complication in adding this equation to the model is that the change in the total amount of compound in the tissue (dA_L/dt) is needed for the mass balance, but the determinants of the kinetics are described in terms of the free concentration in the tissue (C_{Lfree}). To solve for free in terms of total, we note that

$$C_L = C_{Lfree} + C_{Lbound}$$

where C_{Lbound} is the concentration of bound compound in the tissue (mg/L).

We can describe the saturable binding with an equation similar to that for saturable metabolism,

$$C_{Lbound} = B_m * C_{Lfree}/(K_d + C_{Lfree})$$

where

B_m is the binding capacity (mg/L)
K_d is the binding affinity (mg/L)

Substituting this equation in the previous one,

$$C_L = C_{Lfree} + B_m * C_{Lfree}/(K_d + C_{Lfree})$$

Rewriting this equation to solve for the free concentration in terms of only the total concentration would result in a quadratic equation, the solution of which could be obtained with the quadratic formula. However, taking advantage of the iterative algorithm by which these PBPK models are exercised (as will be discussed later), it is not necessary to go to this effort. Instead, a much simpler implicit equation can be written for the free concentration (i.e., an equation in which the free concentration appears on both sides):

$$C_{Lfree} = \frac{C_L}{\left(1 + B_m/\left(K_d + C_{Lfree}\right)\right)}$$

In an iterative algorithm, this equation can be solved at each time step using the previous value of C_{Lfree} to obtain the new value! A new value of C_L is then obtained from the mass balance equation for the liver using the new value of C_{Lfree}, and the process is repeated. An underlying assumption for this simple description of tissue binding is that the binding is rapidly reversible compared to the movement or clearance of free compound, such that equilibrium between free and bound chemicals can be maintained.

In fact, at least two different computational approaches have been used to describe saturable binding in PBPK models. The concentration of free compound can be estimated either, as described earlier, from solving a conservation equation for total mass that apportions the total amount of compound between free and bound forms using the equilibrium dissociation constants, K_ds, and binding maxima, B_ms [102], or by explicitly including both *on* (association) and *off* (dissociation) rate constants, k_a and k_d [101,103]. In the latter case, the dissociation binding constant (with units of concentration) is the ratio of the two rate constants, k_d/k_a. The advantage of the rate constant approach is that it does not require the assumption that binding is fast compared to transport and clearance.

While these two computational approaches have usually been applied within tissues, they can also be readily applied to binding in blood if the concentrations and affinities of binding proteins are known. However, in most cases, protein binding in blood is linear (not saturable at relevant concentrations) and can be characterized by a single parameter, fraction unbound, rather than estimates of concentrations of binding sites and their affinities for binding. Nevertheless, there are cases where protein binding is more appropriately described as a nonlinear process [104]. Alternative descriptions of blood binding will be discussed in more detail in the next section.

Binding in Blood

Protein binding in blood can be a key determinant of disposition, affecting compound availability for uptake into target tissues as well as for clearance. A high fraction bound in the blood also gives rise to concerns regarding potential competitive binding by other compounds that could produce a transient increase in concentrations to potentially toxic levels. Methodologies to estimate binding and approaches for the quantitative description of this binding in pharmacokinetic models have been areas of intense interest over the past four to five decades. Consideration of blood binding faces two parallel challenges: first, when compounds are bound in capillary blood, what fraction should be regarded as available for transport into tissue, and, second, how does the binding in blood influence blood/tissue partitioning. Historically, these questions have been addressed both in empirical descriptions and in PBPK models, and some care is required to reconcile the different approaches and arrive at a consistent quantitative treatment of blood binding and transport of compound throughout the body in both types of modeling approaches.

In the standard description of clearance of a compound from blood by tissue metabolism, binding in the blood is assumed to be linear and the fraction unbound, f_u, is simply multiplied by the intrinsic clearance, leading to a straightforward relationship:

$$CL = Q_T * f_u * CL_{int}/(Q_T + f_u * CL_{int})$$

In this relationship, the maximal tissue clearance, even with a low fraction unbound, is total tissue blood flow. That is, all of the compound in the blood, whether bound or unbound, becomes available for clearance as long as the intrinsic clearance is sufficiently large. Note that in this description, the fraction unbound is not a function of the clearance. In fact, the derivation of this equation rests on the assumption that dissociation of bound compound in the blood is fast

compared to the rate of tissue clearance. If the uptake of a compound into the tissue is limited by the rate of dissociation of the compound from binding proteins in the blood, the earlier simple formula will overestimate its clearance.

In PBPK models, blood concentrations of bound and free compounds can be described separately, as discussed in the previous section, and only free compound is generally considered to be available to participate in processes such as diffusion, metabolism, tissue reaction, and intercompartmental transfer. As in the case of tissue binding, the relationship of free to bound concentrations in the blood is generally calculated by knowledge of dissociation binding constants (K_ds) and maximum concentrations of binding proteins (B_ms), as described previously. An example of this approach has been described in the case of a PBPK model for estradiol [104]. This approach differs from the simple clearance formula given earlier in that the fraction unbound can be a nonlinear function of the concentration of the compound in the blood. It shares, however, the assumption that the *on* and *off* rates for binding are fast compared to rates of clearance. The alternative description of binding described in the previous section, which explicitly includes the binding rate constants, would be preferred in cases where this assumption may be violated.

Pharmacokinetic models need to carefully consider the manner in which binding can be introduced into the basic equations and track free concentrations at sites of action or at least within the plasma. Introduction of blood binding in PBPK models raises some conceptual challenges, especially in comparing conventional empirical approaches with PBPK approaches intended to track thermodynamically free concentrations throughout the body. Although simple descriptions are often adequate, careful consideration of the underlying kinetic processes and their relative rates for the compound and tissues of interest is required to assure that a particular modeling approach is appropriate [105].

Tissue/Blood Partitioning

Regardless of the manner in which blood binding is implemented in PBPK models, another challenge arises in describing equilibration between blood and tissues. In general, both the blood and the tissues will contain free and bound forms of the compound. For equilibration, only the free compound in the plasma diffuses across the tissue capillary interface into the tissue, and at equilibrium between blood and tissue, the free concentration in the plasma and the tissue is expected to be equal (except in the case of active transport). However, the equilibrium relationship of the concentrations in tissues compared to the blood or plasma is typically described with empirical partition coefficients based on measurements of total concentrations of the compound. Differential binding in plasma and tissue will therefore influence apparent tissue partitioning.

The relationship between apparent tissue/blood partitioning and binding in blood vs. tissue can be straightforwardly described, as long as no other factors affect distribution. Assuming that (a) there is no need to adjust for the effect of clearance and (b) there is no evidence of active transport of the compound between blood and tissue, the free fraction in the tissue, f_{ut}, can then be estimated:

$$P_{tb} = P_{tp}/BPR = (f_{up}/f_{ut})/BPR$$

where

P_{tb} is the tissue/blood partition coefficient
P_{tp} is the tissue/plasma partition coefficient
BPR is the blood-to-plasma ratio
f_{up} is the fraction unbound in the plasma
f_{ut} is the fraction unbound in the tissue
then, $f_{ut} = f_{up}/(P_{tb} * BPR)$

In fact, there are quite a number of different determinants of the apparent partitioning between blood and tissues:

- Partitioning due to lipophilicity
- Plasma binding
- Tissue binding
- Active transport
- Clearance processes
- BPR (for converting tissue/plasma partitions to tissue/blood)

A measured or estimated partition coefficient may reflect any combination of these factors, and the modeler must be aware of this potential complexity in attempting to use a particular set of data on a compound. For example, if partition coefficients have been estimated from quantitative structure–activity relationship (QSAR), they are likely to primarily reflect lipophilic partitioning and may need to be adjusted for differences in binding in plasma and tissues. Alternatively, the model can be designed to separately describe lipophilic partitioning, using the estimated partition coefficients, and binding, based on other data. In vitro–derived partition coefficients, on the other hand, may reflect both thermodynamic partitioning and binding, although disruption of the tissue architecture may alter the binding characteristics of the tissue. It is also necessary to ensure that no metabolic clearance of the compound occurs in either blood or tissue during the measurements. In vivo–derived partition coefficients may reflect lipophilicity, binding, and active transport, as well as the effect of any clearance processes [106]. Due to this complexity, it may in some cases be preferable to estimate model parameters for tissue partitioning by fitting the in vivo blood and tissue concentration data rather than trying to use it directly to calculate *partition coefficients* for the model. This latter method can be misleading for compounds with dose-dependent, tissue-specific binding, such as dioxin [107].

Model Parameterization

Once the model structure has been determined, it still remains to identify the values of the input parameters in the model.

Physiological Parameters

Estimates of the various physiological parameters needed in PBPK models are available from a number of sources in the literature, particularly for the human, monkey, dog, rat, and mouse [4,108–112]. Estimates for the same parameter often vary widely, however, due both to experimental differences and to differences in the animals examined (age, strain, and activity). Ventilation rates and blood flow rates are particularly sensitive to the level of activity [108,109]. Data on some important tissues are relatively poor, particularly in the case of fat tissue. Table 6.1 shows typical values of a number of physiological parameters in several species.

Biochemical Parameters

For volatile chemicals, partition coefficients may be measured using a relatively simple in vitro technique known as vial equilibration [88,89,113,114]. Partition coefficients for nonvolatile compounds can be determined by either in vivo or in vitro measurements [106,115,116]. Alternatively, partition coefficients can be estimated from QSAR modeling [117–129].

Metabolism parameters can be obtained from parent chemical disappearance (or metabolite formation) curves in intact cells, tissue homogenate, or microsomal fractions [130–140]. Rapid in vivo approaches may also be used to estimate metabolic constants based on steady-state extraction [54] or gas uptake experiments [93,95,96,141,142], as well as information on the total amount of chemical metabolized in a particular exposure situation [143]. Determination of stable end-product metabolites after exposure can also be useful in some cases [94,144].

Allometry

The different types of physiological and biochemical parameters in a PBPK model are known to vary with BW in different ways [145]. Typically, the parameterization of PBPK models is simplified by assuming standard allometric scaling [109,146], as shown in Table 6.2, where the scaling factors, b, can be used in the following equation:

$$Y = aX^b$$

where

Y is the value of the parameter at a given BW, X (kg)
a is the scaled parameter value for a 1 kg animal

While standard allometric scaling provides a useful starting point, or hypothesis, for cross-species scaling, it is not sufficiently accurate for some applications, such as risk assessment. In the case of the physiological parameters, the

TABLE 6.1
Typical Physiological Parameters for PBPK Models

Species		Mouse	Rat	Monkey	Human
Ventilation					
Alveolar	(L/h-1 kg)[a]	29.0[b]	15.0[b]	15.0[b]	15.0[b]

[c] Varies with activity level (range, 15.0–20.0).
[d] Varies substantially (lower in young animals, higher in older animals).

TABLE 6.2
Standard Allometric Scaling for PBPK Model Parameters

Parameter Type (Units)	Scaling (Power of Body Weight)
Volumes	1.0
Flows (volume per time)	0.75
Ventilation (volume per time)	0.75
Clearances (volume per time)	0.75
Metabolic capacities (mass per time)	0.75
Metabolic affinities (mass per volume)	0
Partition coefficients (unitless)	0
First-order rate constants (inverse time)	−0.25

species-specific parameter values are generally available in the literature [4,108–112] and can be used directly in place of the allometric estimates. For compound-specific parameters, in vitro data for metabolism, distribution, or absorption relevant to the species under consideration are used in most of the cases in preference to allometric estimates. However, allometric scaling might provide first parameter estimates when data are lacking.

Parameter Optimization

In many cases, important parameter values needed for a PBPK model may not be available in the literature. In such cases, it is necessary to measure them in new experiments, to estimate them by QSAR techniques, or to identify them by optimizing the fit of the model to an informative data set. Even in the case where an initial estimate of a particular parameter value can be obtained from other sources, it may be desirable to refine the estimate by optimization. For example, given the difficulty of obtaining accurate estimates of the fat volume in rodents, a more reliable estimate may be obtained by examining the impact of fat volume on the kinetic behavior of a lipophilic compound [98]. Of course, being able to uniquely identify a parameter from a kinetic data set rests on two key assumptions: (1) that the kinetic behavior of the compound under the conditions in which the data were collected is sensitive to the parameter being estimated and (2) that other parameters in the model that could influence the observed kinetics have been determined by other means and are held fixed during the estimation process. When it is necessary to estimate multiple parameters from in vivo pharmacokinetic data, using sensitivity analysis to verify that sufficient data are available and optimizing on individual parameters before performing a global optimization have been recommended [147].

The actual approach for conducting a parameter optimization can range from simple visual fitting, where the model is run with different values of the parameter until the best correspondence appears to be achieved or by a quantitative mathematical algorithm. The most common algorithm used in optimization is the least-squares fit. To perform a least-squares optimization, the model is run to obtain a set of predictions at each of the times a data point was collected. The square of the difference between the model prediction and data point at each time is calculated, and the results for all of the data points are summed. The parameter being estimated is then modified, and the sum of squares is recalculated. This process is repeated until the smallest possible sum of squares is obtained, representing the best possible fit of the model to the data.

In a variation on this approach, the square of the difference at each point is divided by the square of the prediction. This variation, known as relative least squares, is preferable in the case of data with an error structure that can be described by a constant coefficient of variation (i.e., a constant ratio of the standard deviation to the mean). The former method, known as absolute least squares, is preferable in the case of data with a constant variance. From a practical viewpoint, the absolute least-squares method tends to give greater weight to the data at higher concentrations and results in fits that look best when plotted on a linear scale, while the relative least-squares method gives greater weight to the data at lower concentrations and results in fits that look best when plotted on a logarithmic scale.

A generalization of this weighting concept is provided by the extended least-squares method. In the extended least-squares algorithm, the heteroscedasticity parameter can be varied from 0 (for absolute weighting) to 2 (for relative weighting) or can be estimated from the data. In general, setting the heteroscedasticity parameter from the knowledge of the error structure of the data is preferable to estimating it from a data set.

A common example of identifying PBPK model parameters by fitting kinetic data is the estimation of tissue partition coefficients from experiments in which the concentration of compound in the blood and tissues is reported at various time points. Using an optimization approach, the predictions of the model for the time course in the blood and tissues could be optimized with respect to the data by varying the model's partition coefficients. There is little difference in the strength of the justification for estimating the partition coefficients in this way as opposed to estimating them directly from the data (by dividing the tissue concentrations by the simultaneous blood concentration). In fact, the direct estimates would probably be used as initial estimates in the model when the optimization was started.

A major difficulty in performing parameter optimization results from correlations between the parameters. When it is necessary to estimate parameters that are highly correlated, it is best to generate a contour plot of the objective function (sum of squares) or confidence region over a reasonable range of values of the two parameters [148]. An example of a contour plot for two of the metabolic parameters in a PBPK model for methylene chloride is shown in Figure 6.8. The contours in the figure outline the joint confidence region for the joint values of the two parameters, and the fact that the confidence region is aligned diagonally reflects correlation between the two parameters.

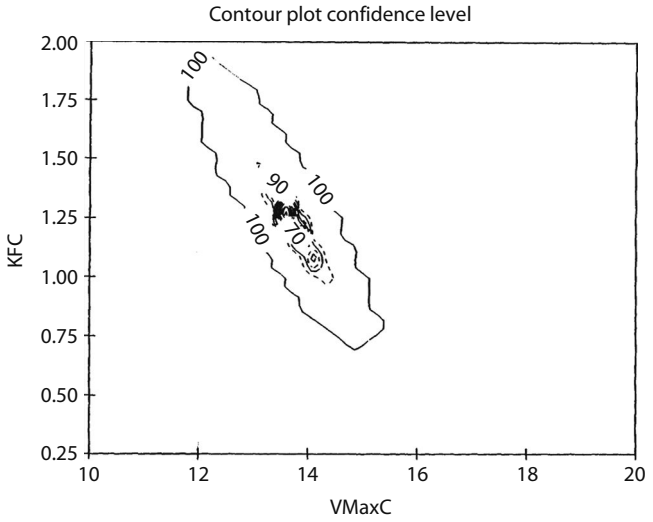

FIGURE 6.8 Contour plot for correlated metabolic parameters in the PBPK model for methylene chloride. KFC is the first-order rate constant for metabolism by glutathione conjugation, and VMaxC is the maximum rate of metabolism by oxidation.

Mass Balance Requirements

One of the most important mathematical considerations during model design is the maintenance of mass balance. Simply put, the model should neither create nor destroy mass. This seemingly obvious principle is often violated unintentionally during the process of model development and parameterization. A common violation of mass balance, which typically leads to catastrophic results, involves failure to exactly match the arterial and venous blood flows in the model. As described earlier, the movement of compound in the blood (in units of mass per time) is described as the product of the concentration of compound in the blood (in units of mass per volume) times the flow rate of the blood (in units of volume per time). Therefore, to maintain mass balance, the sum of the blood flows leaving any particular tissue compartment must equal the sum of the blood flows entering the compartment. In particular, to maintain mass balance in the blood compartment (regardless of whether it is actually a compartment or just a steady-state equation), the sum of the venous flows from the individual tissue compartments must equal the total arterial blood flow leaving the heart:

$$\Sigma Q_T = Q_C$$

Another obvious but occasionally overlooked aspect of maintaining mass balance during model development is that if a model is modified by splitting a tissue out of a lumped compartment, the blood flow to the separated tissue (and its volume) must be subtracted from that for the lumped compartment. Moreover, even though a model may initially be designed with parameters that meet the earlier requirements, mass balance may unintentionally be violated later if the parameters are altered during model execution. For example, if the parameter for the blood flow to one compartment is increased, the parameter for the overall blood flow must be increased accordingly or an equivalent reduction must be made in the parameter for the blood flow to another compartment. Particular care must be taken in this regard when the model is subjected to sensitivity or uncertainty analysis; inadvertent violation of mass balance during Monte Carlo sampling can lead to erroneous sensitivity results [67].

A similar mass balance requirement must be met for transport other than blood flow. For example, if the compound is cleared by biliary excretion, the elimination of compound from the liver in the bile must exactly match the appearance of compound in the gut lumen in the bile. Put mathematically, the same term for the transport must appear in the equations for the two compartments, but with opposite signs (positive vs. negative). For example, if the following equation were used to describe a liver compartment with first-order metabolism and biliary clearance,

$$dA_L/dt = Q_L*(C_A - C_L/P_L) - k_F * C_L * V_L/P_L - K_B * C_L$$

where K_B is the biliary clearance rate (L/h).

The equation for the intestinal lumen would then need to include the term $+K_B * C_L$.

As a model grows in complexity, it becomes increasingly difficult to assure its mass balance by inspection. Therefore, it is a worthwhile practice to check for mass balance by including equations in the model that add up the total amount of compound in each of the model compartments, including metabolized and excreted compound, for comparison with the administered or inhaled dose.

Model Diagram

As described in the previous sections, the process of developing a PBPK model begins by determining the essential structure of the model based on the information available on the compound's toxicity, mechanism of action, and pharmacokinetic properties. The results of this step can usually be summarized by an initial model diagram, such as those depicted in Figures 5.3 and 5.7. Generally, a well-constructed model diagram, together with a table of the input parameter values and their definitions, is all that an accomplished modeler should need in order to create the mathematical equations defining a PBPK model. In general, there should be a one-to-one correspondence of the boxes in the diagram to the mass balance equations (or steady-state approximations) in the model. Similarly, the arrows in the diagram correspond to the transport or metabolism processes in the model. Each of the arrows connecting the boxes in the diagram should correspond to one of the terms in the mass balance equations for both of the compartments it connects, with the direction of the arrow pointing from the compartment in which the term is negative to the compartment in which it is positive. Arrows connected only to a single compartment, which represent uptake and excretion processes, are interpreted similarly.

The model diagram should be labeled with the names of the key variables associated with the compartment or process

represented by each box and arrow. Interpretation of the model diagram is also aided by the definition of the model input parameters in the corresponding table. The definition and units of the parameters can indicate the nature of the process being modeled (e.g., diffusion-limited vs. flow-limited transport, binding vs. partitioning, and saturable vs. first-order metabolism).

MODEL IMPLEMENTATION

The previous sections have focused on the process of designing the PBPK model structure needed for a particular application. At this point, the model consists of a number of mathematical equations: differential equations describing the mass balance for each of the compartments and algebraic equations describing other relationships between model variables. The next step in model development is the coding of the mathematical form of the model into a form that can be executed on a computer. There are many options available for performing this process, ranging from programming languages such as FORTRAN, C, and MATLAB® to more sophisticated simulation software packages such as acslX and Berkeley Madonna.

Mathematical Formulation

Mathematically, a PBPK model is represented by a system of simultaneous ordinary differential equations. Each of the differential equations describes the mass balance for one of the *state variables* (compartments) in the model. There may also be additional differential equations to calculate other necessary model outputs, such as the AUC in a particular compartment, which is simply the integral of the concentration over time. The resulting system of equations is referred to as simultaneous because the time courses of the compound in the various compartments are so interdependent that solving the equations for any one of the compartments requires information on the current status of all the other compartments, that is, the equations for all of the compartments must be solved at the same time. This kind of mathematical problem, in which a system is defined by the conditions at time zero together with differential equations describing how it evolves over time, is known as an initial value problem, and matrix decomposition methods can be used to obtain the simultaneous solution.

A number of numerical algorithms are available for solving such problems. They all have in common that they are step-wise approximations, that is, they begin with the conditions at time zero and use the differential equations to predict how the system will change over a small time step, resulting in an estimate of the conditions at a slightly later time, which serves as the starting point for the next time step. This iterative process is repeated as long as necessary to simulate the experimental scenario.

The more sophisticated methods, such as the Gear algorithm (named after the mathematician, David Gear, who developed it), use a predictor–corrector approach, in which the corrector step essentially amounts to *predicting backward* after each step forward, in order to check how closely the algorithm is able to reproduce the conditions at the previous time step. This approach allows the time step to be increased automatically when the algorithm is performing well and to be shortened when it is having difficulty, such as when conditions are changing rapidly. However, due to the wide variation of the time constants (response times) for the various physiological compartments (e.g., fat vs. richly perfused), PBPK models often represent *stiff* systems. Stiff systems are characterized by state variables (compartments) with widely different time constants, which cause difficulty for predictor–corrector algorithms. The Gear algorithm was specifically designed to overcome this difficulty. It is therefore generally recommended that the Gear algorithm (or an alternative stiff system solver such as the Rosenbrock method) be used for executing PBPK models. An implementation of the Gear algorithm is available in a popular Fortran subroutine, LSODE, developed by Alan Hindmarsh at Lawrence Livermore National Laboratory and available in the public domain [149].

Regardless of the specific algorithm selected, the essential nature of the solution will be a step-wise approximation. However, all of the algorithms made available in computer software are convergent, that is, they can stay arbitrarily close to the true solution, given a small enough time step. On modern personal computers, even large PBPK models can be run to more than adequate accuracy in a reasonable timeframe.

Model Coding

Once a PBPK model structure has been defined with a model diagram or expressed as a set of mass balance equations, it can be coded into a computer language, such as FORTRAN, C, or MATLAB, or into a simulation language, such as acslX or Berkeley Madonna. The advantage of a simulation language is that it frees the modeler from the task of implementing the code necessary to solve the set of mass balance differential equations over time. In either case, the model code should be written and annotated in such a way to facilitate understanding by individuals other than the original program developer. The model can then be exercised for particular conditions necessary to reproduce available data sets collected by the investigator or available in the literature. The model can also be used to make specific risk calculations for particular exposure situations. As part of the model documentation, it is imperative to provide other potential users with the detailed steps that are required to reproduce these figures and calculations. This step usually entails provision of *scripts* that allow reproduction of the figures and calculations by entering specified programming commands or by invoking specified sets of instructions (procedures).

There are a number of available simulation languages and other multipurpose models that can be used to construct PBPK models for chemicals and their metabolites, including acslX, Berkley Madonna, and MATLAB (Table 6.3). Some of these are code based (i.e., require text that defines the equations of

TABLE 6.3
PBPK Modeling Software

Package	Source	Website
General-purpose high-level scientific computing software. These high-level programming language packages are very general modeling tools. They are not specifically designed for PBPK modeling but do offer more complexity to the user.		
acslX	AEgis Technologies Group, Inc.	http://www.aegistg.com
Berkeley Madonna	University of California at Berkeley	http://www.berkeleymadonna.com
MATLAB/Simulink	MathWorks, Inc.	http://www.mathworks.com
GNU Octave	University of Wisconsin	http://www.octave.org
MLAB	Civilized Software, Inc.	http://www.civilized.com
Biomathematical modeling software. These packages have been specifically designed for modeling biological systems, and some are user-friendly. Their usefulness in PBPK modeling is determined by their graphical interfaces, computational speed, and language flexibility. Some of these packages provide mixed-effects (population) capabilities allowing for the analysis of sparse data sets.		
ADAPT II	Biomedical Simulations Resource, USC	http://bmsr.usc.edu
ModelMaker	ModelKinetix	http://www.modelkinetix.com
NONMEM	University of California at San Francisco and Globomax Service Group	http://www.globomaxservice.com
SAAM II	SAAM Institute, Inc.	http://www.saam.com
SCoP	Simulation Resources, Inc.	http://www.simresinc.com
Stella	High Performance Systems, Inc.	http://www.hps-inc.com
WinNonlin	Pharsight Corp.	http://www.pharsight.com
WinNonMix	Pharsight Corp.	http://www.pharsight.com
Toxicokinetic software. These packages were designed specifically for PBPK and PBTK modeling and are extremely flexible. They are based on modeling languages developed in the aerospace industry for modeling complex systems.		
SimuSolv	Dow Chemical	Not maintained or subject to further development
Physiologically based custom-designed software. These are custom-designed proprietary software programs specifically for biomedical systems or applications. They provide a high level of biological detail; however, they are not easily customized.

the model) and others utilize a graphical interface for model construction in which boxes and arrows serve as input rather than equations. Code-based representations ease the task of model verification. Model verification is the process of determining whether the model is accurately calculating the desired outputs. The verification step entails ensuring that the equations are appropriate to describe the model and checking the mass balance for all compounds tracked by the model. The validation step involves establishing that the model reproduces within some error available in PK data on the substance relevant to the purposes for which the model was developed.

Currently, there exists a very diverse group of modeling software packages that vary in both complexity and range of application. Because of these diversities, there is a software package designed for every user from the expert to the first-time modeler. However, not all modeling packages are created equal, and some of the more user-friendly software can lack the capabilities of the more complex programs. Consequently, no single software package available can meet all needs of all users, and the diverse complexity of the programs can often make converting a model from one program to be used in another rather difficult. Table 6.3 provides a list of some of the available software packages that may be used for PBPK modeling [19].

A list of additional pharmacokinetic software may be located at http://boomer.org/pkin/soft.html. However, not all of this software listed on this website is PBPK software.

The first three programs listed in Table 6.3 are popular for modeling of environmental compounds. AcslX is an updated version of Advanced Continuous Simulation Language (ACSL), one of the first widely used PBPK modeling

platforms [150]. It has a graphical as well as a text interface with automatic linkage to the integration algorithm. It allows for the use of discrete blocks (for scheduled events) and script files (m-files) and automatically sorts equations in the derivative block. Sensitivity analysis and Monte Carlo analysis are supported. A fully functional free demo is available.

Berkeley Madonna has many of the same features as acslX; however, it does not allow for the use of discrete blocks or script files. It does currently have both an optimization and a sensitivity analysis feature, but does not have a Monte Carlo feature.

MATLAB is a powerful engineering programming language that has a text interface, but not a graphical interface. It does allow for the use of script files but not discrete blocks. It does not sort the code in the model so the user must be very careful not to use a parameter or variable before it has been defined. This can often be a problem for systems of simultaneous differential equations, when one variable is used in another equation to define a variable that is used in the equation for the first variable. An optimization package is available through an add-on toolbox, but sensitivity analysis and Monte Carlo analysis must be performed through the use of script files. A graphic interface for MATLAB is available through the Simulink add-on. The use of discrete blocks is also added with the use of Simulink. Since Simulink uses only a graphical interface, there is no code to be viewed for model verification.

Coding Example: ACSL

The following section contains typical elements of the ACSL code for a PBPK model, interspersed with comments, which will be written in *italics* to differentiate them from the actual model code. The code shown is for an early version of ACSL; however, with only minor modifications, it could be run in either acslX or Berkeley Madonna. During a typical modeling session, the input parameters (constants) in the model are changed, the model is run, and the model outputs are displayed or plotted. The model used in this example is a simple multiroute model for volatile chemicals, similar to the styrene model discussed earlier, except that it also has the ability to simulate closed-chamber gas uptake experiments.

Typical Elements in an ACSL Source (.CSL) File

An ACSL source file follows the structure defined in the Standard for Continuous Simulation Languages (just like there's a standard for FORTRAN). Thus, for example, there will generally be an INITIAL block defining the initial conditions followed by a DYNAMIC block which contains DISCRETE and/or DERIVATIVE subblocks that define the model. In addition, conventions which have been generally adopted by the PBPK modeling community (most of which started with John Ramsey at Dow Chemical during the development of the styrene model) help to improve the readability of the code. The following file shows typical elements of "Ramseyan code."

The first line in the code must start with the word "PROGRAM." The rest of the line is ignored by the ACSL translator and can be used to identify the model:

```
PROGRAM:  PHYSIM93—  Physiologically  Based
  Pharmacokinetic Model
```

Lines starting with an exclamation point (and portions of lines to the right of one) are ignored by the ACSL translator and can be used for comments:

```
! Generic model for halogenated methanes
```

The first section of an ACSL source file is the INITIAL block, which is used to define parameters and perform calculations that do not need to be repeated during the course of the simulation:

```
INITIAL ! Beginning of pre-execution section
```

Only parameters defined in a CONSTANT statement can be changed during a session using the SET command:

```
LOGICAL CC ! Flag set to.TRUE. for closed chamber
runs

! Physiological parameters (rat)

CONSTANT QPC=14. ! Alveolar ventilation rate (L/h)
CONSTANT QCC=14. ! Cardiac output (L/h)
CONSTANT QLC=0.25 ! Fractional blood flow to liver
CONSTANT QFC=0.09 ! Fractional blood flow to fat
CONSTANT BW=0.22 ! Body weight (kg)
CONSTANT VLC=0.04 ! Fraction liver tissue
CONSTANT VFC=0.07 ! Fraction fat tissue

!— — — -Chemical specific parameters (styrene)

CONSTANT PL=3.46 ! Liver/blood partition coefficient
CONSTANT PF=86.5 ! Fat/blood partition coefficient
CONSTANT PS=1.16 ! Slowly perfused tissue/blood
  partition
CONSTANT PR=3.46 ! Richly perfused tissue/blood
  partition
CONSTANT PB=40.2 ! Blood/air partition coefficient
CONSTANT MW=104. ! Molecular weight (g/mol)
CONSTANT VMAXC=8.4 ! Maximum velocity of
  metabolism (mg/h-1 kg)
CONSTANT KM=0.36 ! Michaelis–Menten constant
  (mg/L)
CONSTANT KFC=0. ! First order metabolism (/h-1 kg)
CONSTANT KA=0. ! Oral uptake rate (/h)

!— — — -Experimental parameters

CONSTANT PDOSE=0. ! Oral dose (mg/kg)
CONSTANT IVDOSE=0. ! IV dose (mg/kg)
CONSTANT CONC=1000. ! Inhaled concentration (ppm)
CONSTANT CC =.FALSE.! Default to open chamber
CONSTANT NRATS=3. ! Number of rats (for closed
  chamber)
```

```
CONSTANT KLC=0. ! First order loss from closed chamber (/h)
CONSTANT VCHC=9.1 ! Volume of closed chamber (L)
CONSTANT TINF =.01 ! Length of IV infusion (h)
```

It is an understandable requirement in ACSL to define when to stop and how often to report. The parameter for the reporting frequency ("communication interval") is assumed by the ACSL translator to be called CINT unless you tell it otherwise using the CINTERVAL statement. The parameter for when to stop can be called anything you want, as long as you use the same name in the TERMT statement (see the following text), but the Ramseyan convention is TSTOP:

```
CONSTANT TSTOP=24. ! Length of experiment (h)
CONSTANT POINTS=96 ! Number of points in plot
   CINT=TSTOP/POINTS ! Communication interval
```

The calculation of CINT shown earlier is motivated by wanting a certain plot resolution regardless of the duration of the run, but wanting to save disk space for long runs. If accuracy of calculation is important, using a fixed interval may be preferable:

```
CINTERVAL CINT=0.1
```

The following parameter name is generally used to define the length of inhalation exposures (the name LENGTH is also used by some):

```
CONSTANT TCHNG=6. ! Length of inhalation exposure (h)
```

The INITIAL block is a useful place to perform logical switching for different model applications, in this case between the simulation of closed-chamber gas uptake experiments and normal inhalation studies. It is also sometimes necessary to calculate initial conditions for one of the integrals ("state variables") in the model (the initial amount in the closed chamber in this case):

```
IF (CC) RATS=NRATS ! Closed chamber simulation
IF (CC) KL=KLC
IF (.NOT.CC) RATS=0. ! Open chamber simulation
IF (.NOT.CC) KL=0.
! (Turn off chamber losses so concentration in chamber remains constant)
IF (PDOSE.EQ.0.0) KA=0. ! If not oral dosing, turn off oral uptake
VCH=VCHC-RATS*BW    ! Net chamber air volume (L)
AI0=CONC*VCH*MW/24450. ! Initial amount in chamber (mg)
```

After all the constants have been defined, calculations using them can be performed. In contrast to the DERIVATIVE block (of which more later), the calculations in the INITIAL block are performed in the order written, just like in FORTRAN or MATLAB, so a variable must be defined before it can be used.

Note how allometric scaling is used for flows (QC, QP) and metabolism (VMAX, KFC). Also note how the mass balance for the blood flows and tissue volumes is maintained by the model code. Run-time changes in the parameters for fat and liver are automatically balanced by changes in the slowly and richly perfused compartments, respectively. The fractional blood flows add to one, but the fractional tissue volumes add up to only 0.91, allowing 9% of the BW to reflect nonperfused tissues:

```
!— — — Scaled parameters

QC=QCC*BW**0.74 ! Cardiac output
QP=QPC*BW**0.74 ! Alveolar ventilation
QL=QLC*QC ! Liver blood flow
QF=QFC*QC ! Fat blood flow
QS=0.24*QC-QF ! Slowly-perfused tissue blood flow
QR=0.76*QC-QL ! Richly-perfused tissue blood flow
VL=VLC*BW ! Liver volume
VF=VFC*BW ! Fat tissue volume
VS=0.82*BW-VF ! Slowly-perfused tissue volume
VR=0.09*BW-VL ! Richly-perfused tissue volume
VMAX=VMAXC*BW**0.7 ! Maximum rate of metabolism
KF=KFC/BW**0.3 ! First-order metabolic rate constant
DOSE=PDOSE*BW ! Oral dose
IVR=IVDOSE*BW/TINF ! Intravenous infusion rate
```

An END statement is required to delineate the end of the initial block:

```
END ! End of initial section
```

The next (and often last) section of an ACSL source file is the DYNAMIC block, which contains all of the code defining what is to happen during the course of the simulation:

```
DYNAMIC ! Beginning of execution section
```

ACSL possesses a number of different algorithms for performing the simulation, which mathematically speaking consists of solving an initial value problem for a system of simultaneous linear differential equations. (although it is easier to just refer to it as integrating). Available methods include the Euler, Runge–Kutta, and Adams–Moulton, but the tried and true choice of most PBPK modelers is the Gear predictor–corrector, variable step-size algorithm for stiff systems, which PBPK models often are (stiff, that is):

```
ALGORITHM IALG=2 ! Use Gear integration algorithm
```

One of the structures which can be used in the DYNAMIC block is called a DISCRETE block. The purpose of a DISCRETE block is to define an event which is desired to occur at a specific time or under specific conditions. The integration algorithm then keeps a lookout for the conditions and executes the code in the DISCRETE block at the proper moment during the execution of the model. An example of a pair of discrete blocks that are used to control repeated dosing in another PBPK model is shown:

```
DISCRETE DOSE1    ! Schedule events to turn exposure on and off daily
INTERVAL DOSINT=24.    ! Dosing interval
          !(Set interval larger than TSTOP to prevent multiple exposure)
```

```
  IF (T.GT.TMAX) GOTO NODOSE
  IF (DAY.GT.DAYS) GOTO NODOSE
     CONC = CI    ! Start inhalation exposure
   TOTAL = TOTAL + DOSE    ! Administer oral dose
   TDOSE = T !    Record time of dosing
  SCHEDULE DOSE2.AT. T + TCHNG    ! Schedule end
    of exposure
  NODOSE..CONTINUE
  DAY = DAY + 1.
   IF (DAY.GT.7.) DAY = 0.5
END ! of DOSE1

DISCRETE DOSE2
        CONC = 0.    ! End inhalation exposure
END ! of DOSE2
```

Within the DYNAMIC block, a group of statements defining a system of simultaneous differential equations is put in a DERIVATIVE block. If there's only one it doesn't have to be given a name:

```
DERIVATIVE    ! Beginning of derivative definition block
```

The main function of the derivative block is to define the "state variables" that are to be integrated. They are identified by the INTEG function. For example, in the code below, AI is defined to be a state variable which is calculated by integrating the equation defining the variable RAI, using an initial value of AI0. For most of the compartments, the initial value is zero:

```
!— — — — -CI = Concentration in inhaled air (mg/L)
        RAI = RATS*QP*(CA/PB-CI) - (KL*AI) ! Rate
equation
      AI = INTEG(RAI,AI0)    ! Integral of RAI
      CI = AI/VCH*CIZONE    ! Concentration in air
 CIZONE = RSW((T.LT.TCHNG).OR.CC,1.,0.)
        CP = CI*24450./MW    ! Chamber air concentra-
tion in ppm
```

Any experienced programmer would shudder at the previously showncode, because several variables appear to be used before they have been calculated (e.g., CIZONE is used to calculate CI and CI is used to calculate RAI). However, within the derivative block, writing code is almost too easy because the translator will automatically sort the statements into the proper order for execution. That is, there's no need to be sure a variable is calculated before it is used.

The downside of the sorting is you can't be sure that two statements will be calculated in the order you want just because you place them one after the other. Also, because of the sorting (as well as the way the predictor–corrector integration algorithm hops forward and backward in time), IF statements won't work right. The RSW function earlier works like an IF statement, setting CIZONE to 1 whenever T (the default name for the time variable in ACSL) is less than TCHNG, and setting CIZONE to 0 (and thus turning off the exposure) whenever T is greater than or equal to TCHNG.

Another way to be sure statements are executed in order is to put them in a PROCEDURAL, which is left alone by the sorter:

```
PROCEDURAL
  if (recovery) then
    goto out
  elseif (t.gt.tendexp) then
    recovery =.true.
  endif
  out..continue
END !of procedural
```

The double dot (..) after the word "out" identifies it as a label, that is, a point that the program can be told to jump to, as in the if statement earlier.

The following blocks of statements each define one of the compartments in the model. These statements can be compared with the mathematical equations described in the previous sections of the manual. One of the advantages of models written in ACSL following the Ramseyan convention is that they are easier to comprehend and reasonably self-documenting:

```
!— — MR = Amount remaining in stomach (mg)
  RMR = -KA*MR
  MR = DOSE*EXP(-KA*T)
```

Note that the stomach could have been defined as one of the state variables:

```
MR = INTEG(RMR,DOSE)
```

But instead the exact solution for the simple integral has been used directly.

Similarly, instead of defining the blood as a state variable, the steady-state approximation is used:

```
!— — CA = Concentration in arterial blood (mg/L)
CA = (QC*CV+QP*CI)/(QC+[QP/PB])
AUCB = INTEG(CA,0.)

!— — AX = Amount exhaled (mg)
CX = CA/PB ! End-alveolar air concentration (mg/L)
CXPPM = (0.7*CX+0.3*CI)*24450./MW    !    Average
   exhaled air concentration (ppm)
RAX = QP*CX
AX = INTEG(RAX,0.)

!— — AS = Amount in slowly perfused tissues (mg)
RAS = QS*(CA-CVS)
AS = INTEG(RAS,0.)
CVS = AS/(VS*PS)
CS = AS/VS

!— — AR = Amount in rapidly perfused tissues (mg)
RAR = QR*(CA-CVR)
AR = INTEG(RAR,0.)
CVR = AR/(VR*PR)
CR = AR/VR
```

```
!— — AF = Amount in fat tissue (mg)
RAF = QF*(CA-CVF)
AF = INTEG(RAF,0.)
CVF = AF/(VF*PF)
CF = AF/VF

!— — AL = Amount in liver tissue (mg)
RAL = QL*(CA-CVL) - RAM + RAO
AL = INTEG(RAL,0.)
CVL = AL/(VL*PL)
CL = AL/VL
AUCL = INTEG(CL,0.)

!— — AM = Amount metabolized (mg)
RAM = (VMAX*CVL)/(KM+CVL) + KF*CVL*VL
AM = INTEG(RAM,0.)

!— — AO = Total mass input from stomach (mg)
RAO = KA*MR
AO = DOSE-MR

!— — IV = Intravenous infusion rate (mg/h)
IVZONE = RSW(T.GE.TINF,0.,1.)
IV = IVR*IVZONE

!— — CV = Mixed venous blood concentration (mg/L)
CV = (QF*CVF + QL*CVL + QS*CVS + QR*CVR + IV)/QC

!— — TMASS = mass balance (mg)
TMASS = AF+AL+AS+AR+AM+AX+MR

!— — DOSEX = Net amount absorbed (mg)
DOSEX = AI+AO+IVR*TINF-AX
```

Last, but definitely not least, you have to tell ACSL when to stop:

```
TERMT(T.GE.TSTOP)  !Condition for terminating
   simulation

END   ! End of derivative block
END   ! End of dynamic section
```

Another kind of code section, the TERMINAL block, can also be used here to execute statements that should only be calculated at the end of the run (e.g., increase the concentration, go back to a labelled statement in the INITIAL block, and start again).

```
END   ! End of program
```

MODEL EVALUATION

The following section discusses various issues associated with the evaluation of a PBPK model. Once an initial model has been developed, it must be evaluated on the basis of its conformance with experimental data. In some cases, the model may be exercised to predict conditions under which experimental data should be collected in order to verify or improve model performance. Comparison of the resulting data with the model predictions may suggest that revision of the model will be required. Similarly, a PBPK model designed for one compound or application may be adapted to another compound or application, requiring modification of the model structure and parameters. It is imperative that revision or modification of a model is conducted with the same level of rigor applied during initial model development, and that structures are not added to the model with no justification other than that they improve the agreement of the model with a particular data set.

In addition to comparing model predictions to experimental data, model evaluation includes assessing the biological plausibility of the model structures and input parameters, and the resulting confidence that can be placed in extrapolations performed by the model [151]. Both elements of testing the model, kinetic validation and mechanistic validation, are necessary to provide confidence in the model. Unfortunately, there is a temptation to accept kinetic validation alone, particularly when data for mechanistic validation are unavailable. It should be remembered, however, that the simple act of adding equations and parameters to a model will, in itself, increase the flexibility of the model to fit data. Therefore, every attempt should be made to obtain additional experimental data to provide support for the mechanistic hypothesis underlying the model structure.

Model Documentation

In cases where a model previously developed by one investigator is being evaluated for use in a different application by another investigator, adequate model documentation is critical for the evaluation of the model. The documentation for a PBPK model should include sufficient information about the model so that an experienced modeler could accurately reproduce its structure and parameterization. Usually the suitable documentation of a model will require a combination of one or more *box-and-arrow* model diagrams together with any equations that cannot be unequivocally derived from the diagrams. Model diagrams should clearly differentiate blood flow from other transport (e.g., biliary excretion) or metabolism, and arrows should be used where the direction of transport could be ambiguous. All tissue compartments, metabolism pathways, routes of exposure, and routes of elimination should be clearly and accurately presented. All equations should be dimensionally consistent and in standard mathematical notation. Generic equations (e.g., for tissue i) can help to keep the description brief but complete. The values used for all model parameters should be provided, with units. If any of the listed parameter values are based on allometric scaling, a footnote should provide the BW used to obtain the allometric constant as well as the power of BW used in the scaling.

Model Validation

Internal validation (verification) consists of the evaluation of the mathematical correctness of the model [71]. It is best accomplished on the actual model code but, if necessary, can be performed on appropriate documentation of the model structure and parameters, as described earlier (assuming, of course, that the actual model code accurately reflects the

model documentation). A more important issue regards the provision of evidence for external validation (sometimes referred to as evaluation). The process of evaluating the sufficiency of the model for its intended purpose requires a demonstration of the ability of the model to predict the behavior of experimental data different from that on which it was based.

Whereas a simulation is intended simply to reproduce the behavior of a system, a model is intended to confirm a hypothesis concerning the nature of the system. Therefore, model validation should demonstrate the ability of the model to predict the behavior of the system under conditions that test the principal aspects of the underlying hypothetical structure. While quantitative tests of goodness of fit may often be a useful aspect of the verification process, the more important consideration may be the ability of the model to provide an accurate prediction of the general behavior of the data in the intended application.

Where only some aspects of the model can be verified, it is particularly important to assess the uncertainty associated with the aspects that are untested. For example, a model of a compound and its metabolites that is intended for use in cross-species extrapolation to humans would preferably be verified using data in different species, including humans, for both the parent compound and the metabolites. If only parent compound data are available in the human, the correspondence of metabolite predictions with data in several animal species could be used as a surrogate, but this deficiency should be carefully considered when applying the model to predict human metabolism.

In some cases, it is necessary to use all of the available data to support model development and parameterization. Unfortunately, this type of modeling can easily become a form of self-fulfilling prophecy: models are logically strongest when they fail, but psychologically most appealing when they succeed [70]. Under these conditions, model verification can be particularly difficult, putting an additional burden on the investigators to substantiate the trustworthiness of the model for its intended purpose. Nevertheless, a combined model development and verification can often be successfully performed, particularly for models intended for interpolation, integration, and comparison of data rather than for true extrapolation.

Parameter Verification

In addition to evaluating the performance of the model against experimental data, the model should be evaluated in terms of the plausibility of its parameters. This evaluation is particularly important in the case of PBPK models, where the parameters generally possess biological significance and can therefore be evaluated for plausibility independent of the context of the model. The source of each model input parameter value should be identified, whether it was obtained from prior literature, determined directly by experiment, or estimated by fitting a model output to experimental data. Parameter estimates derived independently of tissue time course or dose–response data are preferred. To the extent feasible, the degree of uncertainty regarding the parameter values should also be evaluated. The empirically derived *law of reciprocal certainty* states that the more important the model parameter, the less certain will be its value. In accordance with this principle, the most difficult, and typically most important, parameter determination for PBPK models is the characterization of the metabolism parameters.

When parameter estimation has been performed by optimizing model output to experimental data, the investigator must assure that the parameter is adequately identifiable from the data [71]. Due to the confounding effects of model error, overparameterization, and parameter correlation, it is quite possible for an optimization algorithm to obtain a better fit to a particular data set by modifying a parameter that in fact should not be identified on the basis of that data set. Also, when an automatic optimization routine is employed, it should be restarted with a variety of initial parameter values to assure that the routine has not stopped at a local optimum. These precautions are particularly important when more than one parameter is being estimated simultaneously, since the parameters in biologically based models are often highly correlated, making independent estimation difficult. Estimates of parameter variance obtained from automatic optimization routines should be viewed as lower-bound estimates of true parameter uncertainty since only a local, linearized variance is typically calculated. In characterizing parameter uncertainty, it is probably more instructive to determine what ranges of parameter values are clearly inconsistent with the data than to accept a local, linearized variance estimate provided by the optimization algorithm.

It is usually necessary for the investigator to repeatedly vary the model parameters manually to obtain a sense of their identifiability and correlation under various experimental conditions, although some simulation languages include routines for calculating parameter sensitivity and covariance or for plotting confidence region contours. Sensitivity analysis and Monte Carlo uncertainty analysis techniques can serve as useful methods to estimate the impact of input parameter uncertainty on the uncertainty of model outputs. However, as stated earlier, care should be taken to avoid violation of mass balance when parameters are varied by sensitivity or Monte Carlo algorithms, particularly where blood flows are affected.

Sensitivity Analysis

To the extent that a particular PBPK model correctly reflects the physiological and biochemical processes underlying the pharmacokinetics of a compound, exercising the model can provide a means for identifying the most important physiological and biochemical parameters determining the pharmacokinetic behavior of the compound under different conditions [67]. The technique for obtaining this information is known as sensitivity analysis and can be performed by two different methods. Analytical sensitivity coefficients are defined as the ratio of the change in a model output to the change in a model parameter that produced it. To obtain

a sensitivity coefficient by this method, the model is run for the exposure scenario of interest using the preferred values of the input parameters, and the resulting output (e.g., brain concentration) is recorded. The model is then run again with the value of one of the input parameters varied slightly. Typically, a 1% change is appropriate. The ratio of the resulting incremental change in the output to the change in the input represents the sensitivity coefficient. It is usually more convenient to use log-normalized sensitivity coefficients, which represent the ratio of the fractional change in output to the fractional change in input. For example, if a 1% increase in an input parameter resulted in a 0.5% decrease in the output, the log-normalized sensitivity coefficient would be −0.5. Log-normalized sensitivity coefficients >1.0 in absolute value represent amplification of input error and indicate that any uncertainty in the value of the parameter will result in even greater uncertainty in the output. An alternative approach is to conduct a Monte Carlo analysis, as described later, and then to perform a simple correlation analysis of the model outputs and input parameters. This type of approach is often referred to as global sensitivity analysis [152]. Both methods have specific advantages. The analytical sensitivity coefficient most accurately represents the functional relationship of the output to the specific input under the conditions being modeled. The advantage of the global sensitivity analysis is that it also reflects the impact of interactions between the parameters during the Monte Carlo analysis.

Uncertainty and Variability Analysis

Evaluations of the uncertainty and/or the variability associated with the predictions of a PBPK model are often performed using the Monte Carlo simulation approach [153–155]. In a Monte Carlo simulation, a probability distribution for each of the PBPK model parameters is randomly sampled, and the model is run using the chosen set of parameter values. This process is repeated a large number of times until the probability distribution for the desired model output has been created. Generally speaking, 1000 iterations or more may be required to ensure the reproducibility of the mean and standard deviation of the output distributions as well as the 1st through 99th percentiles. To the extent that the input parameter distributions adequately characterize the uncertainty in the inputs, and assuming that the parameters are reasonably independent, the resulting output distribution will provide a useful estimate of the uncertainty associated with the model outputs. If simulations are performed so that the probability distribution for PBPK model parameters represents the variability expected in the human population, then the Monte Carlo analysis will result in the simulation of the pharmacokinetics expected for a population.

Due to its physiological structure, many of the parameters in a PBPK model are interdependent. For example, the blood flows must add up to the total cardiac output, and the tissue volumes (including those not included in the model) must add up to the BW. In addition, some physiological parameters are naturally correlated, such as cardiac output and respiratory ventilation rate, and these correlations should be taken into account during the Monte Carlo analysis.

In performing a Monte Carlo analysis, it is important to distinguish uncertainty from variability. As it relates to the impact of pharmacokinetics in risk assessment, uncertainty can be defined as the possible error in estimating the *true* value of a parameter for a representative (*average*) person. Variability, on the other hand, should only be considered to represent true interindividual differences. Understood in these terms, uncertainty is a defect (lack of certainty) that can typically be reduced by experimentation, and variability is a fact of life that must be considered regardless of the risk assessment methodology used. An elegant approach for separately documenting the impact of uncertainty and variability is 2D Monte Carlo, in which distributions for both uncertainty and variability are developed and multiple Monte Carlo runs are used to convolute the two aspects of overall uncertainty. Unfortunately, in practice, it is often difficult to differentiate the contribution of variability and uncertainty to the observed variation in the reported measurements of a particular parameter [156]. A hierarchical Bayesian approach, known as Markov chain Monte Carlo (MCMC) simulation, has the potential to refine prior estimates of parameter uncertainty and variability on the basis of the agreement of model predictions to experimental data. MCMC has been used to characterize the uncertainty and variability in PBPK model predictions [157].

Although sophisticated methods of uncertainty analysis can provide valuable information, very simple techniques can also be used as a way to effectively communicate uncertainty. By simply determining the minimum and maximum value of an uncertain but important model parameter, and performing a simulation for a range of values, the impact of that parameter on pharmacokinetic predictions can be illustrated. When predicting human pharmacokinetics based on animal data, there is always uncertainty. Quantifying key uncertainties and providing a range of possible outcomes that could all be reasonable based on the current knowledge of the pharmacokinetic properties of the compound will allow for more informed decision-making.

Collection of Critical Data

As with model development, the best approach to model evaluation is within the context of the scientific method. The most effective way to evaluate a PBPK model is to exercise the model to generate a quantitative hypothesis, that is, to predict the behavior of the system of interest under conditions *outside the envelope* of the data used to develop the model (at shorter/longer durations, higher/lower concentrations, different routes, different species, etc.). In particular, if there is an element of the model that remains in question, the model can be exercised to determine the experimental design under which the specific model element can best be tested. For example, if there is uncertainty regarding whether uptake into a particular tissue is flow or diffusion limited, alternative forms of the model can be used to compare predicted

tissue concentration time courses under each of the limiting assumptions under various experimental conditions. The experimental design and sampling time that maximize the difference between the predicted tissue concentrations under the two assumptions can then serve as the basis for the actual experimental data collection. Once the critical data have been collected, the same model can also be used to support a more quantitative experimental inference. In the case of the tissue uptake question just described, not only can the a priori model predictions be compared with the observed data to test the alternative hypotheses, but the model can also be used a posteriori to estimate the quantitative extent of any observed diffusion limitation (i.e., to estimate the relevant model parameter by fitting the data). If, on the other hand, the model is unable to reproduce the experimental data under either assumption, it may be necessary to reevaluate other aspects of the model structure. The key difference between research and analysis is the iterative nature of the former. It has wisely been said, "If we knew when we started what we had to do to finish, they'd call it search, not research."

Model Revision

An attempt to model the metabolism of allyl chloride [67] serves as an excellent example of the process of model refinement and validation. As mentioned earlier, in a gas uptake experiment, several animals are maintained in a small enclosed chamber while the air in the chamber is recirculated, with replenishment of oxygen and scrubbing of carbon dioxide. A small amount of a volatile chemical is then allowed to vaporize into the chamber, and the concentration of the chemical in the chamber air is monitored over time. In this design, any loss of the chemical from the chamber air reflects uptake into the animals. After a short period of time during which the chemical achieves equilibration with the animals' tissues, any further uptake represents the replacement of chemical removed from the animals by metabolism. Analysis of gas uptake data with a PBPK model has been used successfully to determine the metabolic parameters for a number of chemicals [93].

In an example of a successful gas uptake analysis, Gargas et al. [94] described the closed-chamber kinetics of methylene chloride using a PBPK model, that included two metabolic pathways: one saturable, representing oxidation by cytochrome P450 enzymes, and one linear, representing conjugation with glutathione (Figure 6.9). As can be seen in this figure, there is a marked concentration dependence of the observed rate of loss of this chemical from the chamber. The initial decrease in chamber concentration in all of the experiments results from the uptake of chemical into the animal tissues. Subsequent uptake is a function of the metabolic clearance in the animals, and the complex behavior reflects the transition from partially saturated metabolism at higher concentrations to linearity in the low-concentration regime. The PBPK model reproduced this complex behavior with a single set of parameters because the model structure appropriately captures the concentration dependence of the rate of metabolism.

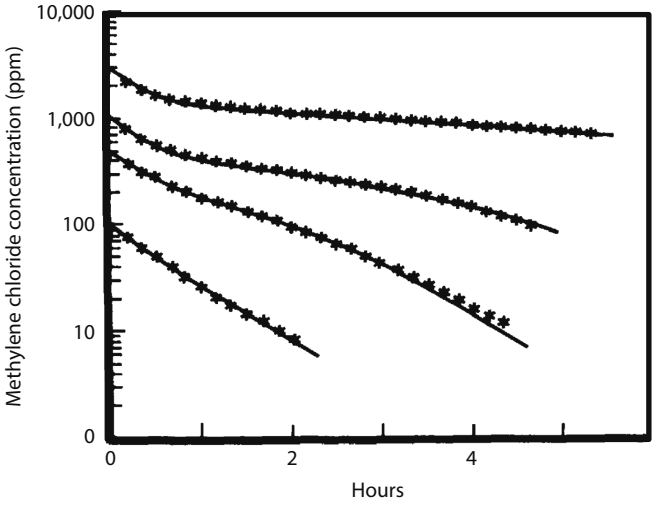

FIGURE 6.9 Gas uptake experiment. Concentration (ppm) of methylene chloride in a closed, recirculated chamber containing three Fischer 344 rats. Initial chamber concentrations were (top to bottom) 3000, 1000, 500, and 100 ppm. Solid lines show the predictions of the model for a V_{max} of 4.0 mg/h/kg, a K_m of 0.3 mg/L, and a first-order rate constant of 2.0/h/kg, while symbols represent the measured chamber atmosphere concentrations.

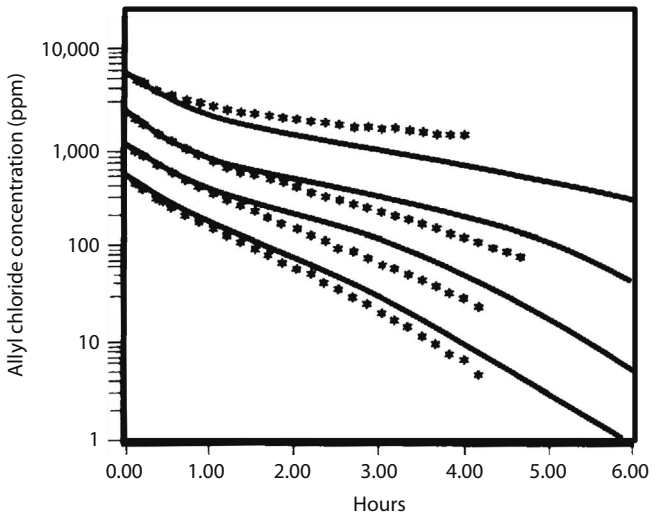

FIGURE 6.10 Model failure. Concentration (ppm) of allyl chloride in a closed, recirculated chamber containing three Fischer 344 rats. Initial chamber concentrations were (top to bottom) 5000, 2000, 1000, and 500 ppm. Symbols represent the measured chamber atmosphere concentrations. The curves represent the best result that could be obtained from an attempt to fit all of the data with a single set of metabolic constants using the same closed-chamber model structure as in Figure 6.9.

A similar analysis of gas uptake experiments with allyl chloride using the same model structure was less successful. The smooth curves shown in Figure 6.10 are the best fit that could be obtained to the observed allyl chloride chamber concentration data assuming a saturable pathway and a first-order pathway with parameters that were independent of concentration. Using this model structure, there were large systematic

errors associated with the predicted curves. The model predictions for the highest initial concentration were uniformly lower than the data, while the predictions for the intermediate initial concentrations were uniformly higher than the data. A much better fit could be obtained by setting the first-order rate constant to a lower value at the higher concentration; this approach would provide a better correspondence between the data and the model predictions, but would not provide a basis for extrapolating to different exposure conditions.

The nature of the discrepancy between the PBPK model and the data for allyl chloride suggested the presence of a dose-dependent limitation on metabolism not included in the model structure. This indication was consistent with other experimental evidence indicating that the conjugative metabolism of allyl chloride depletes glutathione, a necessary cofactor for the linear conjugation pathway. The conjugation pathway for reaction of methylene chloride and glutathione regenerates glutathione, but in the case of allyl chloride, glutathione is consumed by the conjugation reaction. To adequately reflect the biological basis of the kinetic behavior, it was necessary to model the time dependence of hepatic glutathione. To accomplish this, the mathematical model of the closed-chamber experiment was expanded to include a more complete description of the glutathione-dependent pathway. The expanded model structure used for this description [158] included a zero-order production of glutathione and a first-order consumption rate that was increased by reaction of the glutathione with allyl chloride; glutathione resynthesis was inversely related to the instantaneous glutathione concentration. This description provided a much improved correspondence between the data and predicted behavior (Figure 6.11). Of course, the improvement in fit was obtained at the expense of adding several new glutathione-related parameters to the model. To ensure that the improved fit is not just a consequence of the additional parameters providing more freedom to the model for fitting the uptake data, a separate test of the hypothesis underlying the added model structure (depletion of glutathione) was necessary. Therefore, the expanded model was also used to predict both allyl chloride and hepatic glutathione concentrations following constant-concentration inhalation exposures. Model predictions for end-exposure hepatic glutathione concentrations compared very favorably with actual data obtained in separate experiments (Table 6.4).

Note: Glutathione depletion data were graciously supplied by John Waechter, Dow Chemical Co., Midland, Michigan. For the purpose of this comparison, the basal glutathione consumption rate in the model was adjusted to obtain rough agreement with the controls in each experiment. This basal consumption rate was then used to simulate the associated exposure.

Reiterating the key points of this example as follows:

1. A PBPK model that had successfully described experimental results for a number of chemicals was unable to reproduce similar kinetic data on another chemical.

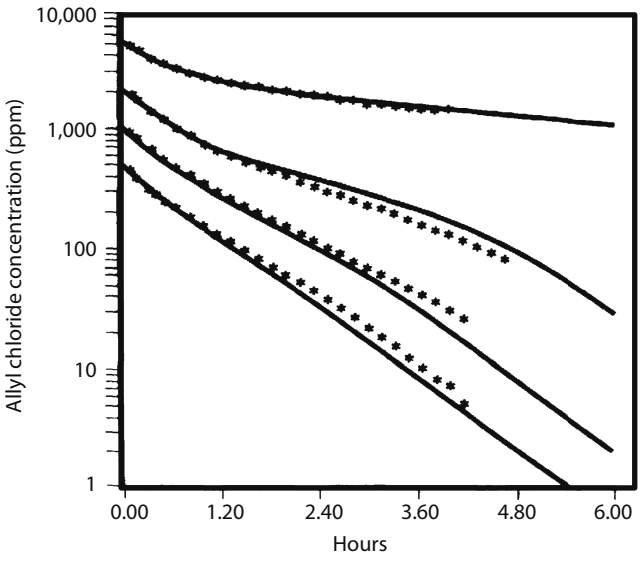

FIGURE 6.11 Cofactor depletion. Symbols represent the same experimental data as in Figure 6.10. The curves show the predictions of the expanded model, which not only included depletion of glutathione by reaction with allyl chloride, but also provided for regulation of glutathione biosynthesis on the basis of the instantaneous glutathione concentration, as described in the text.

2. A hypothesis was developed that depletion of a necessary cofactor was affecting metabolism. This hypothesis was based on
   a. The nature of the discrepancy between the model predictions and the kinetic data
   b. Other available information about the nature of the chemical's biochemical interactions
3. The code for the PBPK model was altered to include additional mass balance equations describing the depletion of this cofactor, and its resynthesis, as well as the resulting impact on metabolism.

TABLE 6.4
Predicted Glutathione Depletion Caused by Inhalation Exposure to Allyl Chloride

Concentration (ppm)	Depletion (μM)	
	Observed	Predicted
0	7080 ± 120	7088
10	7290 ± 130	6998
0	7230 ± 80	7238
100	5660 ± 90	5939
0	7340 ± 180	7341
1000	970 ± 10	839
0	6890 ± 710	6890
2000	464 ± 60	399

4. The modification to the model was then tested in two ways:
   a. By testing the ability of the new model structure to simulate the kinetic data that the original model was unable to reproduce
   b. By testing the underlying hypothesis regarding cofactor depletion against experimental data on glutathione depletion from a separate experiment

Both elements of testing a model, kinetic validation and mechanistic validation, are necessary to provide confidence in the model. Unfortunately, there is a temptation to accept kinetic validation alone, particularly when data for mechanistic validation are unavailable. It should be remembered, however, that the simple act of adding equations and parameters to a model will, in itself, increase the flexibility of the model to fit data. Therefore, every attempt should be made to obtain additional experimental data to provide support for the mechanistic hypothesis underlying the model structure.

PBPK MODEL APPLICATIONS

The following sections will highlight three areas of application: cancer risk assessment, drug development, and evaluation of developmental toxicity.

Risk Assessment

A properly validated PBPK model can be used to perform the high-to-low dose, dose route, and interspecies extrapolations necessary for estimating human risk on the basis of animal toxicology studies [29,64,84,159–172]. Target tissue dosimetry provided by PBPK modeling is also an essential component in models of pharmacodynamics, such as acetylcholinesterase inhibition [59,173] or mixture interactions [170,174–176]. A number of reviews, some quite extensive, have been published on the application of PBPK modeling in toxicity testing and risk assessment [12–18].

Example of PBPK Modeling in Risk Assessment: Cancer Risk Assessment for Methylene Chloride

In 1985, the National Toxicology Program reported the final results of animal studies indicating that lifetime inhalation of high concentrations (2000 and 4000 ppm) of methylene chloride produced significantly increased incidences of lung and liver tumors in B6C3F1 mice. As a result, the Environmental Protection Agency (EPA) classified methylene chloride as a probable human carcinogen. The risk estimate for methylene chloride was calculated using the approach typically employed by the agency for animal studies: a low-dose linear dose–response model was used to relate tumor outcomes in the bioassay with the dose of methylene chloride in mg/kg/day. Since the studies in this case were inhalation exposures, the doses were calculated as the product of ventilation rate, concentration, and duration of exposure. The animal doses were then decreased by a factor of roughly 13 to obtain the equivalent human doses, calculated as the cube root of the ratio of human BW to bioassay animal BW. This factor, known as the body surface area (BSA) correction, is included in the default EPA approach to account for the possibility that chemical carcinogens could be more potent in humans than in experimental animals.

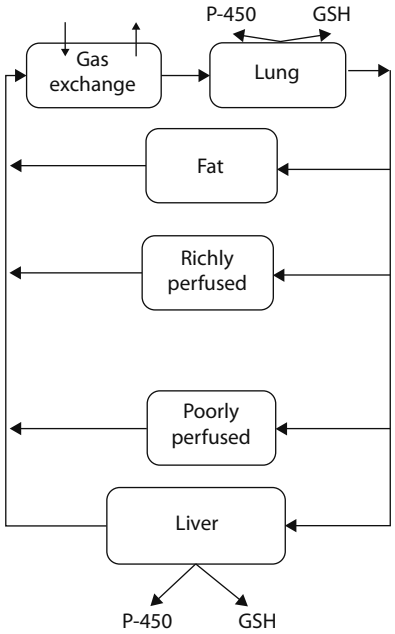

FIGURE 6.12 PBPK model used in the cancer risk assessment for methylene chloride. (Adapted from Andersen, M.E. et al., *Toxicol. Appl. Pharmacol.*, 87, 185, 1987.)

In 1986, Andersen and coworkers at Wright-Patterson Air Force Base and at Dow Chemical Company provided the EPA with their PBPK model for methylene chloride (Figure 6.12) and proposed its use in support of the EPA's carcinogenic risk assessment on that chemical. The suggestion resulted in considerable controversy and eventually led to a workshop sponsored by the National Academy of Science to consider the usefulness of PBPK modeling for chemical risk assessment. The scientific consensus following the workshop was that "relevant PBPK data can be used to reduce uncertainty in extrapolation and risk assessment" [11].

The pharmacokinetic model used in the methylene chloride risk assessment [64] was actually a minor modification of a more extensive model [94,159] that had previously been developed to study the kinetics and metabolism of dihalomethanes. The model was capable of predicting the time course of the parent chemical, as well as the production of metabolites by both a glutathione transferase pathway, which is linear in the physiologically relevant range, and a saturable mixed function oxidase pathway. The model was also capable of describing the production of carbon monoxide during the oxidative metabolism and its subsequent binding to hemoglobin in the blood to produce carboxyhemoglobin (HbCO), which could be measured in experiments to test the model's predictions for saturable metabolism. The model provided a coherent

TABLE 6.5
Comparison of Dose Metrics with Tumor Incidence in Methylene Chloride Bioassays

	Inhalation			Drinking Water	
	Control	2000 ppm	4000 ppm	Control	250 mg/kg/day

description of data from both rodents and humans for several routes of exposure and a number of different dihalomethanes.

One of the crucial steps in the pharmacokinetic risk assessment was the determination of the appropriate measure of dose to use in extrapolating from the tumor incidence found in the animal studies to the tumor incidence expected for human exposure. To support the determination of the appropriate dose surrogate, the PBPK model of methylene chloride [159] was expanded to include metabolism in the principal target tissues identified by the National Toxicology Program bioassay: mouse lung and liver. The expanded model could then be used to estimate the amount of oxidation and conjugation expected in these tissues for comparison with the tumor incidence observed in the methylene chloride bioassays (Table 6.5). Both metabolic pathways were thought to produce reactive intermediates that theoretically could be responsible for the carcinogenic activity. However, the calculated dose–response for the tissue dose from the oxidative pathway at the two inhalation bioassay concentrations (2000 and 4000 ppm) was essentially flat, while the number of tumors observed increased (Table 6.5). Moreover, similarly high tissue doses from the oxidative pathway were also predicted at the concentrations used in a negative drinking water study. It was therefore considered very unlikely that the tumor induction was caused by the activity of this metabolic pathway. However, the expected yield of the glutathione-dependent pathway was calculated to increase linearly at the inhalation bioassay concentrations, and very little activity was predicted under the drinking water bioassay conditions. These results were most consistent with the possibility of a reactive glutathione metabolite, presumably chloromethylglutathione, being involved in cancer induction. In this analysis, the possible role of the parent chemical itself in the observed tumorigenicity was discounted due to its chemical inertness and the lack of evidence for any potential mechanism of action.

Once the dose surrogate was selected, the PBPK model predictions for the effective dose to the target tissues at the bioassay concentrations could be used in place of the default *inhaled dose* calculations as inputs for the calculation of carcinogenic potency in the animal bioassay. The same PBPK model, but with human parameter values, was then used to relate an inhaled concentration in the human to the target tissue dose corresponding to a given risk. In these calculations, the risks associated with a given target tissue dose were considered to be equivalent in humans and rodents. The resulting pharmacokinetic risk estimates were roughly a factor of 100 lower than those obtained with the default approach. However, in adopting the pharmacokinetic approach, the EPA included their standard BSA factor for calculating the equivalent human doses, increasing the pharmacokinetic risk estimates by a factor of roughly 13, and resulting in a net reduction from the default risk estimates of about ninefold. Since that time, the use of BSA scaling has been discontinued in cases where cross-species dosimetry is performed with a PBPK model [177].

Drug Development

PBPK models can be developed using pharmacokinetic data typically generated during drug discovery and can be used to address important issues throughout the drug development process. At early stages, a PBPK model can be developed using available in vitro data and verified against in vivo PK data. Because the model links in vitro data to in vivo PK, it can be used to determine which in vitro data are most important for improving the PK of a series of compounds. These early models can be used to understand kinetic properties of a compound. At later stages, PBPK/PD models can be used to predict the therapeutic window and to provide a rational basis to choose the compound most likely to have success

in the clinic. Also, PBPK models can be used to understand the quantitative implications of uncertainties and therefore to prioritize experimentation. During clinical development, PBPK models provide a rational basis for predicting variability of human PK resulting from differences in age, gender, and genetic polymorphisms (e.g., CYP 2D6 weak or strong metabolizers) and from physiological changes resulting from a disease state. Therefore, PBPK models can help to predict the therapeutic window even in subpopulations with PK differing from the norm.

The past 10 years have seen tremendous advances in the capabilities of generic PBPK models that can simulate PK for humans or preclinical species based on a combination of physicochemical properties and in vitro data. Such generic PBPK models can, of course, be constructed using programming packages such as MATLAB, acslX, or Berkeley Madonna. However, powerful commercial PBPK simulation platforms, which incorporate detailed physiologically based absorption models into the traditional whole-body PBPK model, are also now available. Such packages include GastroPlus™ (Simulations Plus Inc., www.simulations-plus.com), SimCyp (Simcyp, www.simcyp.com), and PK-Sim® (Bayer Technology Services, www.pksim.com). These tools allow easy incorporation of preclinical ADME data into a PBPK model for preclinical species and humans. The availability of such tools has greatly simplified the technical use of PBPK models; however, a good understanding of the models and underlying equations is still essential in order to guarantee good interpretation of output.

A number of recent publications provide useful insights into the application of PBPK modeling in drug development [19–24].

Example of PBPK Modeling in Drug Development: Safety Assessment for All-trans Retinoic Acid

A PBPK model for all-trans retinoic acid (ATRA; tretinoin) was developed in order to provide a coherent description of the absorption, distribution, metabolism, and excretion of the compound and its metabolites across species and routes of administration [85]. The goal of developing such a model was to provide a more biologically relevant dose measure than administered dose for assessing the human teratogenic risk from ATRA.

The PBPK model developed for ATRA (Figure 6.13) provided a full physiological description for ATRA, with compartments for plasma, liver, gut, intestinal lumen, fat, skin, richly perfused tissues, slowly perfused tissues, placenta, and embryo. Both oxidation (to the 4-oxo derivative) and glucuronidation of ATRA were described with saturable kinetics. Conversion to the 13-cis isomer (13-cis-RA; isotretinoin) and the subsequent metabolism of that compound were also included (not shown in Figure 6.13). Simpler compartmental descriptions were used for the metabolites of ATRA, since there was no evidence that they preferentially partitioned into any of the body tissues. A third metabolic pathway, side chain oxidation producing CO_2, was also included. Dermal uptake was described by a two-compartment model, with

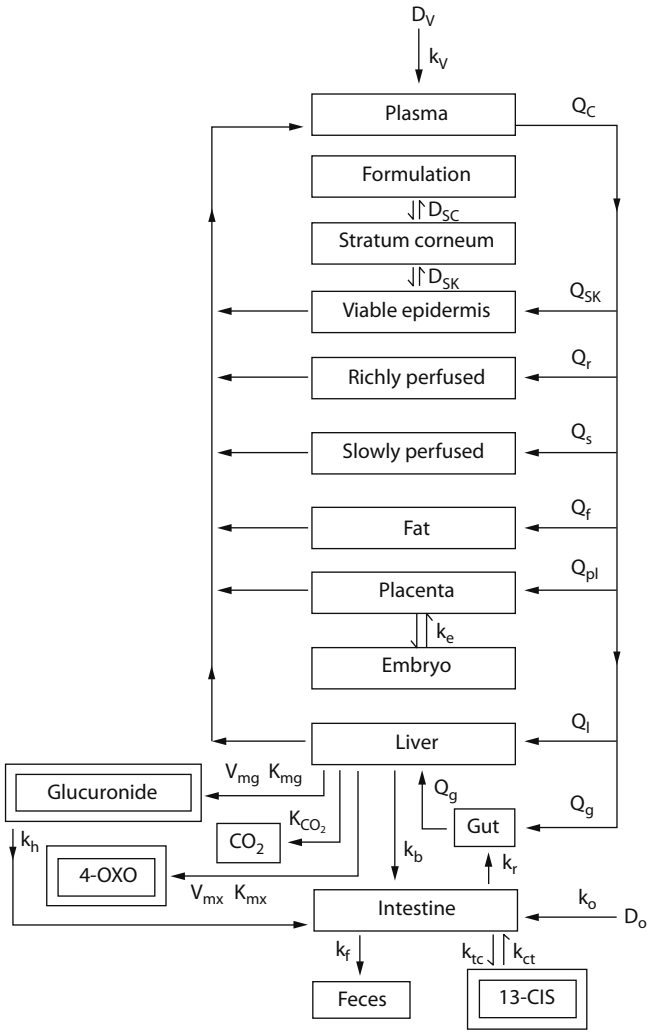

FIGURE 6.13 PBPK model used in safety assessment for all-trans retinoic acid. (Adapted from Clewell, H.J. et al., *J. Am. Acad. Dermatol.*, 36, S77, 1997.)

compartments representing the stratum corneum and viable epidermis. Excretion into urine and that into feces were modeled as first-order processes, with all chemicals being excreted in the feces and only glucuronides being excreted in the urine. Enterohepatic recirculation of ATRA and its metabolites was also described.

A key difference in the metabolism of ATRA across species is the predominance of the oxidative pathway in the rodent, in contrast with the predominance of the glucuronide pathway in the primate; therefore, the kinetic parameters in the human model were based on data from studies with nonhuman primates. The PBPK model for iv dosing of ATRA in the monkey was successfully scaled allometrically to predict the kinetics for oral dosing of human leukemia patients with 1.1 mg/kg ATRA. The only parameters adjusted in this extrapolation were those describing the rate of oral uptake. All other parameters were calculated from those for the monkey, except of course for the use of human physiological parameters. The model was also able to reproduce the observed kinetics for total radioactivity following

topical administration of ATRA. In contrast to the kinetic data, which could provide only an estimate of total exposure to ATRA plus its metabolites, the PBPK model was able to provide separate estimates of internal exposure to ATRA and its active and inactive metabolites. An important result of the modeling was to demonstrate that the low dose rate associated with dermal exposure results in high-efficiency clearance of ATRA to its inactive glucuronide metabolites, as opposed to oral dosing, where the higher dose rate leads to a greater proportion of active oxidative metabolites.

The model was used to simulate oral clinical dosing with ATRA, as well as minimal teratogenic doses of ATRA in the primate and rodent. Based on literature data on the teratogenic potential of the various chemical species, the most appropriate dose surrogate could be either Cmax or AUC for the total concentration of active retinoids. The glucuronides were not included in this dose measure since they do not cross the placenta. On the other hand, based on the activity at retinoic acid receptors, it could be argued that the most appropriate dose surrogate could be the peak concentration or AUC for ATRA alone. In either case, maternal plasma levels were used as a surrogate for fetal levels, based on evidence from animal studies that concentrations achieved in maternal and fetal plasma are similar. The calculated dose surrogates, as well as the estimated peak plasma level for total retinoids (which includes the glucuronides) for several species, are shown in Table 6.6.

One test of a useful dose surrogate is that similar values should be calculated at similar effect levels across species. For a minimal teratogenic effect, all of the dose surrogates in Table 6.6 (including administered dose) are within a factor of two to three across species. The most consistent dose surrogate is the Cmax for total active retinoids, which is essentially constant across species. Based on this dose measure, the internal exposure of patients receiving oral ATRA treatment for cancer is below the threshold for teratogenic effects by about a factor of 7–10. However, this comparison assumes that the maternal plasma concentration profile is representative of fetal exposure. If one takes into consideration the longer period of organogenesis in the human (around 35 days) as compared to the rodent (around 10 days) and assumes, as a worst case, fetal exposure at the maximum maternal concentration throughout the entire period, the margin of safety could be as low as 2–3. It is of interest that the kinetics of 13-*cis*-RA in the human are considerably different from those of ATRA. The compound 13-*cis*-RA has a much longer half-life than ATRA in the human, and oxidation, rather than glucuronidation, is the dominant form of metabolism. The calculated plasma concentrations and AUCs for total active retinoids following oral treatment with 13-*cis*-RA are in the same range as those causing teratogenic effects in animals. This result is consistent with the observation of teratogenic effects associated with the human use of 13-*cis*-RA (isotretinoin; Table 6.6). This PBPK model was used by FDA in their evaluation of the safety of a topical skin treatment containing ATRA, marking the first time a PBPK model had been used in a regulatory decision for a pharmaceutical.

Developmental Toxicity

The physiological structure of PBPK models is particularly useful for examining the effects of changing physiology on target tissue dosimetry, as in the case of exposure during the developmental period [61,62,178–180]. The past decade has seen a significant expansion of PBPK approaches to describe specific life stages in order to examine factors that may affect differential susceptibility of various populations to chemical exposure [87,99,100,162,163,181–191]. Developmental PBPK models show promise for predicting exposure and target tissue dose in the perinatal period, including periods of both gestation and lactation. More than for any other of its applications, the PBPK technologies applied to reproductive and

TABLE 6.6
Comparison of Dose Surrogates for Retinoic Acid Teratogenicity

			All-trans Retinoic Acid		Total Active Retinoids		Total Retinoids
	Route	Dose (mg/kg)	Cmax (ng/mL)	AUC (ng*h/mL)	Cmax (ng/mL)	AUC (ng*h/mL)	Cmax (ng-eq/mL)
Minimal teratogenic doses (all-trans RA)							
Mouse	oral	4.0	1048	1852	2681	12,658	3107
Rat	oral	2.5	943	2029	1918	13,554	2051
Monkey	oral	5.0	1830	3714	2294	5962	4983
Clinical doses (human)							
ATRA	oral	1.1	218	695	264	1088	1237
13-cis	oral	1.1	654[a]	3154[a]	1033	7103	1148

[a] Reflects concentration of 13-cis-RA rather than all-trans RA.

developmental toxicology can (1) reduce the use of animals in toxicity testing and (2) improve estimates of human exposure based on the extrapolation of kinetics across species. The ability to perform these cross-species extrapolation is particularly important, since these populations (i.e., fetus, neonate) are unlikely to be the targets of specific studies in human cohorts. Nevertheless, the application of PBPK techniques to perinatal periods adds to the complexity of model design—the modeler must account for many processes that are often omitted or simplified when describing adult pharmacokinetics.

In general, extension of a PBPK model to gestation or lactation requires revisions to model structures and alternative descriptions of physiological and kinetic parameters. Models describing gestation and lactation will have a larger number of compartments compared to those for the adult. These models may include descriptions of maternal tissues that participate in chemical transfer to the offspring (uterus, placenta, or mammary gland) and some level of detail for the fetus or neonate. New model compartments are necessary. As opposed to the adult, where tissue growth and blood flow often scale directly to BW, many tissues in the pregnant and lactating mother and in the fetus and neonate undergo complex changes in volume and blood flow over time. Biochemical processes that govern chemical kinetics are highly dynamic during the perinatal period. The developing liver and kidney often require time-dependent descriptions of metabolism and clearance. This final section on PBPK modeling applications discusses special considerations for the perinatal period and describes current approaches for describing chemical kinetics during gestation and lactation using PBPK models.

Considerations for Modeling of Gestation

Gestation model structure: At minimum, a gestational model must include both the mother and the fetus and account for transfer of chemicals between them (Figure 6.14). Placental transfer between dam and fetus is bidirectional. The placenta may act as a barrier, a site of metabolism, or a site of accumulation and active transport of chemicals from the mother to the fetus. The complexity of the model description for maternal–fetal kinetics depends on the characteristics of the test chemical. Usually, passive diffusion suffices for describing transfer between the maternal and fetal blood [61,85,178,179]. Other chemicals may require descriptions of the placenta to account for processes, such as active transport and metabolism, which can lead to dose-dependent chemical transfer kinetics [100,185]. Likewise, the description of the fetus can vary from a one-compartment (volume of distribution) model describing fetal blood or plasma [178,181,192–194] to more complex multitissue models that describe target tissue concentrations within the fetus [87,100,163,185,190,191]. As with simpler adult period PBPK models, the structure of life-stage-specific models should provide an appropriate level of detail to accurately describe chemical kinetics in the tissue of interest without adding unnecessary parameters.

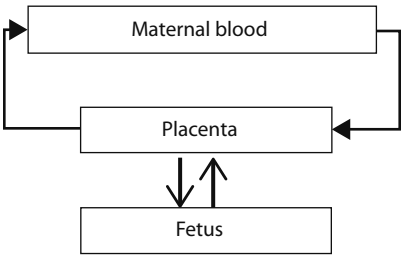

FIGURE 6.14 Simple PBPK model for gestation.

Maternal physiology during gestation: In gestation, several tissues experience rapid growth with changes in tissue volumes over time that cannot be accurately described using allometric scaling. In the rat, the mammary gland and maternal fat volumes increase more or less linearly over the course of gestation. The placenta has a more complex growth curve. The individual rat placenta has three stages of growth: (1) increase in yolk sac to day 10, (2) decrease in yolk sac after day 10, and (3) increase in chorioallantoic placenta from day 10 through term [195,196]. Neither the volumes of these tissues nor their blood flows are proportional to the BW. The fraction of maternal cardiac output to the mammary gland, fat, and yolk sac is likely proportional to tissue volumes; however, the blood flow to the chorioallantoic placenta increases more rapidly than does tissue volume. In rats and mice, these models must account for multiple pups per litter, each with its own placenta. The volume of the individual placenta multiplied by the number of fetuses gives the overall placental weight.

There are two common approaches to implement time-dependent changes in tissue volumes. One model method uses linear interpolation between the measured data to predict tissue volumes over time [61]. Another uses explicit equations to calculate growth curves [63,179]. The output from best-fit equation for tissue volumes over time gives the volumes. Blood flows then follow the volumes.

Maternal BW increases significantly during the course of gestation, primarily from increasing volumes of the fat, placenta, mammary gland, fat, and total fetal/litter volume. Therefore, the total change in maternal BW is the sum of the changes in these four tissue volumes and the initial (prepregnancy) BW (BW_{init}):

$$\text{Total BW} = BW_{init} + \Delta\text{Fat} + \Delta\text{Mammary Gland} + \Delta\text{Placenta} + \Delta\text{Fetal Weight}$$

Total cardiac output also increases over gestation and is modeled in the same way as the BW: cardiac output is described as the sum of the initial cardiac output and the increased blood flow to the fat, mammary gland, and placenta.

Fetal physiology: Fetal growth can be incorporated into the model using linear interpolation to predict the BW between measured data points or by using more explicit equations. The growth of the fetus is complex. In both the rodent and the human, PBPK models generally use a series of equations to describe the increase in fetal weight over time [179,192]. In the method of O'Flaherty et al. [179], a series of three equations describe fetal growth in the rat over the entire period

of gestation. The first equation described fetal growth from conception (day 1) to day 11 with an exponential curve with a starting value of zero and a final value equal to measured fetal weights on day 11. Due to the lack of measured data at earlier time points, the fetal volumes in early gestation were predicted based on the assumption of exponential growth. The following two equations—developed by fitting specific data on tissue volumes over time—described growth from days 11 to 18 and from day 18 to birth (day 21). The series of equations employed by O'Flaherty et al. [179] for describing volume for one rat fetus are shown as follows:

Days 1–11: $BW1_{Fet} = 1 * ((0.1206 * Days)**4.53)$
Days 11–18: $BW1_{Fet} = 1 * ((1.5 * [Days - 10])**2.8)$
Days 18–21: $BW1_{Fet} = (1 * (BW_{FetD18} + (BW_{Pup} - BW_{FetD18})/4) * (Days - 18))$

$BW1_{Fet}$ is the weight of one fetus, days is the number of days postconception, BW_{Pup} is the BW of the pup at birth, and BW_{FetD18} is the value for $BW1_{Fet}$ on day 18 calculated from the equation shown for days 11–18. In species that have multiple fetuses, such as the rat, the model describes the total fetal volume as the sum of the individual fetuses. Any subsequent descriptions of fetal kinetics are then generally calculated as an average for the entire litter, rather than describing each fetus individually. At very early time points (GD 11 in the rat), very little data are available for fetal volume. Some modelers limit simulations to later time points where data are available [61], while others predict early time points assuming exponential growth and passive diffusion of chemicals at early time points where the placenta is not fully developed (<GD 11) [179]. Allometric scaling is generally sufficient for estimating tissue volumes across species and ages in adult rats. However, it is unreliable when applied to the fetus. During fetal development, organs develop at different rates. When tissues are included as separate compartments in a model, these tissue volumes must be explicitly defined as time-varying model parameters.

Fetal exposure: The dose to the fetus depends on maternal kinetics (absorption, clearance, etc.) and placental transfer. Thus, the model must recapitulate maternal blood or plasma kinetics first, before achieving confidence in modeling the maternal–fetal transfer kinetics. Placental transfer is chemical specific. The physicochemical properties of the parent chemical or metabolites generally determine the extent of placental transfer as well as the possible differential retention of chemicals in the fetus. High-molecular-weight chemicals, including highly lipophilic chemicals, may be less efficiently transferred across the placenta. However, once in the fetus, these lipophilic chemicals are likely to have higher concentrations than in the mother (due to decreased placental transfer from the fetus to the mother). Passive diffusion between the maternal and fetal blood often provides a sufficient description of placental transfer for these chemicals.

The functions of the placenta are complex and diverse. The placenta may act as a barrier, a facilitator of transport for essential nutrients, and a site of metabolism. For chemicals that reach higher placental concentrations compared to dam or fetus or ones that are metabolized in the placenta, a placenta compartment provides necessary detail including equations for active transport from the maternal blood or metabolism of the parent chemical, followed by transfer of the chemical from the placenta to the fetus.

Maternal kinetic parameters during gestation: In addition to the many physiological changes occurring during pregnancy, the tissues in the mother undergo changes in the capacity for various metabolic processes. In particular, alterations in serum-binding protein concentrations, GFRs, and hepatic metabolic activity all contribute to different kinetics in the pregnant vs. naive female. Glomerular filtration increases during gestation, leading to increased clearance of chemicals that are eliminated in the urine. Reduced P450 and UGT activity in the liver, however, would result in reduced clearance of chemicals eliminated by phase I and II metabolism.

The use of these altered biochemical parameters in PBPK models is common in the human and rat [87,100,163,192]. Two approaches may be taken to describe these changing biochemical parameters. The parameters may be determined by fitting the model output to data collected in the tissues of pregnant animals. This is feasible in laboratory animals, but not the human. The parameters may also be set for the naive animal, based on ADME data, and then altered using published data on protein activity, protein concentration, or glomerular filtration during gestation. This second method has been used successfully in the rodent and human and is more useful for extrapolating to populations where tissue data are not available.

Kinetic parameters in the fetus: It is customary to describe fetal kinetics using first-order transfer rates between the mother and the fetal blood. Occasionally, however, fetal metabolism may play a role in fetal kinetics. Some phase I and phase II enzymes are present in fetal intestine and liver [197,198] and, especially in the late-term infant, may alter fetal/maternal transfer kinetics. For example, glucuronide conjugation of a chemical substrate in the fetus may reduce placental transfer and fetal clearance. Limited data are available for metabolizing enzyme protein concentrations in the rodent and human fetus. In vitro metabolism data may provide relative activities of fetal metabolizing enzymes for particular substrates compared to the adult. These relative metabolic capacities determined in vitro may be used to predict the fetal parameters for metabolism in vivo, particularly when the parameters are well characterized and validated in the adult.

Example of PBPK Modeling of Gestation: Di-n-Butyl Phthalate

In vivo, di-*n*-butyl phthalate (DBP) is quickly and efficiently hydrolyzed to monobutyl phthalate (MBP) in the gut (prior to absorption). MBP is then metabolized by P450 enzymes or conjugated to glucuronic acid by UDPGT in the liver. In rats, the major metabolites are the MBP and the MBP-glucuronide conjugate (MBP-G). The simple model schematic for the DBP PBPK model (Figure 6.15) shows only the fetus and the

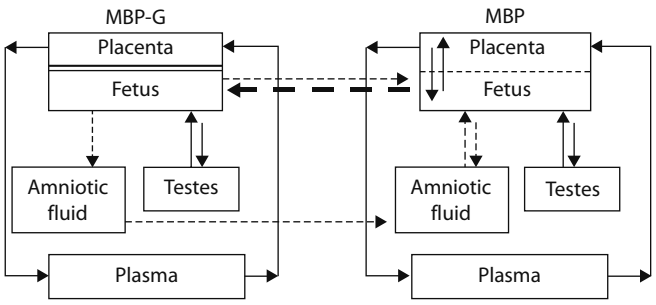

FIGURE 6.15 Model structure for DBP metabolite kinetics in the fetal rat. Dashed arrows indicate first-order processes and clearance rates (deconjugation). Bold dashed arrows represent saturable processes (glucuronide conjugation). Solid arrows represent blood flows to the tissue compartments.

maternal compartments responsible for fetal exposure. Full model structure, including all maternal compartments, is shown elsewhere [87]. The transfer of free MBP used passive diffusion between the placental plasma and the fetal plasma.

In the case of MBP, there was evidence that glucuronide conjugation took place in the fetus itself [87]. Rates for fetal glucuronidation were predicted based on in vitro data and implemented as follows. In vitro, phthalates are similar to steroidal substrates in terms of the isoforms of UDPGT for which they are substrates. Therefore, the fetal UDPGT activity in the model was estimated from the ratio of measured fetal/adult UDPGT activities toward several steroidal substrates from measured in vitro values on GD 17, 18, 19, 20, and 21 [199,200]. These relative activities served as the basis for calculating the value for maximum capacity of fetal UDPGT (VmaxLf) for GD 17, 18, 19, and 20:

$$\text{VmaxLf} = \text{VmaxL} * \text{RAfL} * \text{RMPC} * \text{RLW} * \text{numfet}$$

where VmaxL is the maximum capacity for glucuronide conjugation in the adult male rat (after scaling for BW), RAfL is the in vitro relative activity expressed as the ratio of fetal to maternal activity per mg microsomal protein, RMPC is the ratio of the microsomal protein content of the fetal and maternal liver (mg/g liver), RLW is the ratio of the fetal to maternal liver weight (g), and numfet is the number of fetuses per litter.

Using this description, together with the literature-derived parameters for glucuronide conjugation and hydrolysis, the model successfully described the MBP-G kinetics in the fetal plasma, lending support to the use of in vitro metabolism data in predicting kinetic parameters that change with time.

The final values for VmaxLf were coded into the ACSL model using a TABLE function. That is, a list of values for VmaxLf at specific times was created, and the program used linear interpolation to determine values at intermediate time points.

Considerations for Modeling of Lactation

Model structure: As with gestation, a lactation period mode must include the mother and the neonate and the transfer of chemicals between the two. Lactational exposure is by

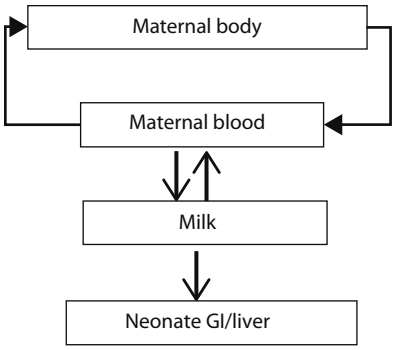

FIGURE 6.16 Simple PBPK model for lactational transfer.

transfer in milk through suckling, a process that is primarily unidirectional—from the mother to the neonate. In rodents, some transfer can occur from the neonate to the dam during grooming. Typically, the maternal model has a compartment for the mammary gland and the milk. Transfer to the neonate is described as a first-order rate, which serves as an oral dose to the neonate. Figure 6.16 shows a simple description of maternal–neonate chemical transfer by suckling.

Maternal physiology during lactation: During lactation, the volumes of some tissues change rapidly. The fat volume decreases from the late gestation weight, while the mammary gland tissue continues increasing after parturition. In these models, the volume of the milk must also be taken into account. Milk production and secretion are highly dynamic. The description of the milk compartment in the mother usually assumes the presence of a relatively static volume (averaging out the daily fluctuations). This residual volume has little effect on maternal BW. Maternal BW during lactation is calculated by adjusting the postbirth BW (end of gestation minus the placenta and fetus) by the change in the fat and mammary tissues and adding the weight of the residual milk [192]. The calculation for the maternal BW during lactation is based on BW_P, the maternal weight at parturition.

$$\text{Maternal BW} = BW_P - \text{placenta} - \text{fetus} + \Delta\,\text{mammary gland} + \Delta\,\text{fat} + \text{residual milk}$$

The maternal cardiac output decreases during lactation compared to gestation, due to the reduced demand in the absence of the uterus/placenta. However, blood flow to the mammary gland increases proportionally to the mammary gland volume.

Neonatal physiology: As opposed to the fetus, a large body of data exists for changes in BW, tissue growth, and even tissue blood flows in neonatal animals. Increases in BW are not linear in early life and must be explicitly described when simulations are performed for more than a single age. Neonatal growth can be incorporated using linear interpolation to predict the BW between measured data points or by using explicit equations [62,99,163,183,192]. Tissue growth during early life depends on the tissue where patterns of growth and development differ substantially. For example, in

the neonatal rat, the fat increases from approximately 2.7% to 11% of the total BW between postnatal days 2 and 16, followed by a gradual decrease to the adult value of 4.61% [111,201]. To the extent that the individual tissues must be explicitly defined in the model, the corresponding model parameters must account for the changing tissue volumes.

Neonatal exposure: The dose to the suckling neonate depends on maternal kinetics (absorption, clearance, etc). Thus, maternal exposure, clearance, and tissue distribution affect the dose of the chemical transferred to the offspring. Furthermore, for long-lived chemicals, fetal exposures significantly affect chemical concentrations in the neonate. In these cases, the prenatal exposure may be accounted for by linking the neonatal model to a gestation model or by accounting for initial tissue concentrations of the chemicals in the state variables (mass balance equations for the tissues) of the neonatal model. Neonatal dose from suckling is a function of the milk chemical concentration and the amount of milk ingested by the neonate. The physicochemical properties of the parent chemical or metabolites determine the extent of uptake into the milk from maternal blood. Highly lipophilic compounds readily concentrate in milk and transfer with breast milk during lactation, providing a potentially important route of postnatal exposure. Modeling uptake of chemicals into the milk usually follows passive diffusion and concentration through blood/milk partition coefficients.

Milk production and secretion are highly dynamic. Temporal variations occur within a single day and across the period of lactation. Daily variation in milk ingestion is typically omitted from models to reduce model complexity. As such, the neonatal dose from suckling is presented as the daily average. The pattern of milk production over lactation follows an inverse U-shape, with an increase after gestation, followed by a decrease near the time of weaning. In the rat and human, data are available for milk production/neonate milk ingestion [202,203]. Milk production data for the lactating rat can be incorporated into a PBPK model using the following TABLE function in ACSL:

```
TABLE KtransC,1,8/24,216,384,456,504,552,
720,960,1.18e-02,1.14e-02,1.01e-02,6.40e-03,4.17e-
03,3.69e-03,0.0,0.0/.
```

The data in this statement are for production rate of milk (L/h) divided by the weight of the litter—BWL [202]. This rate of milk production would be multiplied by the BW of the litter (which will also be changing over the course of lactation) and used together with the milk chemical concentration to describe neonatal dose from suckling [99]. In this formula, KtransC is the rate of milk production/milk transfer scaled by BWL. The values 1 and 8 preceding the brackets indicate the size of the data matrix (1 × 8). The first eight values inside of the brackets denote the time postbirth in hours, and the final eight numbers denote the measured values for milk production adjusted by litter weight.

Maternal kinetic parameters during lactation: During lactation, the maternal system is returning to its prepregnancy state with regard to many of the kinetic parameters (e.g., GFR and serum-binding proteins). These parameters may be determined by fitting the model output to data collected in the tissues of lactating animals. This approach is feasible in laboratory animals, but not in the human. The parameters may also be set for the naive animal, based on kinetic data, and then altered using published data on protein activity, protein concentration, or glomerular filtration during lactation. This method has been used successfully in the rodent and human and is more useful for extrapolating to populations where tissue data are not available.

Kinetic parameters in the neonate: Important kinetic parameters that show highly dynamic behavior in the neonate include glomerular filtration and metabolic enzyme activity. In both the human and rodents, changing enzyme expression and activity lead to significant alterations in chemical kinetic profiles. Likewise, the increasing GFRs associated with maturation of the kidneys lead to increased clearance for chemicals eliminated in the urine [99,163,182,183]. The most comprehensive analysis of the effect of metabolism, glomerular filtration, and physiological changes after birth on chemical kinetics was for the human [183]. This study incorporated age- and gender-specific differences in physiological and biochemical processes into a predictive PBPK model spanning the time from birth to adulthood. The resulting life-stage model was then exercised for several environmental chemicals with a variety of physicochemical, biochemical, and mode-of-action properties. The most important age-dependent pharmacokinetic factor was determined to be the reduced activity of many metabolic enzyme systems in the infant.

Example PBPK Model of Lactation: Perchlorate

Perchlorate (ClO_4^-), the soluble anion of the solid rocket fuel ammonium perchlorate, is a thyroid iodide uptake inhibitor and drinking water contaminant. Since ClO_4^- has a similar size and shape to that of iodide (I^-), it binds to sodium–iodide symporter (NIS) at the membrane of the thyroid follicle and reduces the amount of iodide available for hormone synthesis. The presence of NIS in the mammary gland [204] also leads to inhibition of iodide uptake in milk together with accumulation and transfer of the ClO_4^- anion, into the milk. Because ClO_4^- mimics I^-, both anions were described using a similar model structure (Figure 6.17). A full description of the model and explanation of model elements are available elsewhere [99]. This example will focus on the description of transfer of the free anions, ClO_4^- and I^-, between the lactating and suckling rat.

Two anion symporters in the mammary gland move I^- (and ClO_4^-) into the mammary gland via an active uptake mechanism: NIS and a second Pendrin transporter [204–208]. These two transport processes provide active anion uptake (1) from the mammary blood to the mammary gland and (2) from the mammary gland to the milk. Active uptake equations used Michaelis–Menten kinetics. In this case, the mammary gland accounted for the transfer of the two anions and the inhibition of I^- in the milk since both transporters are possible sites of competition for the anions (Figure 6.18).

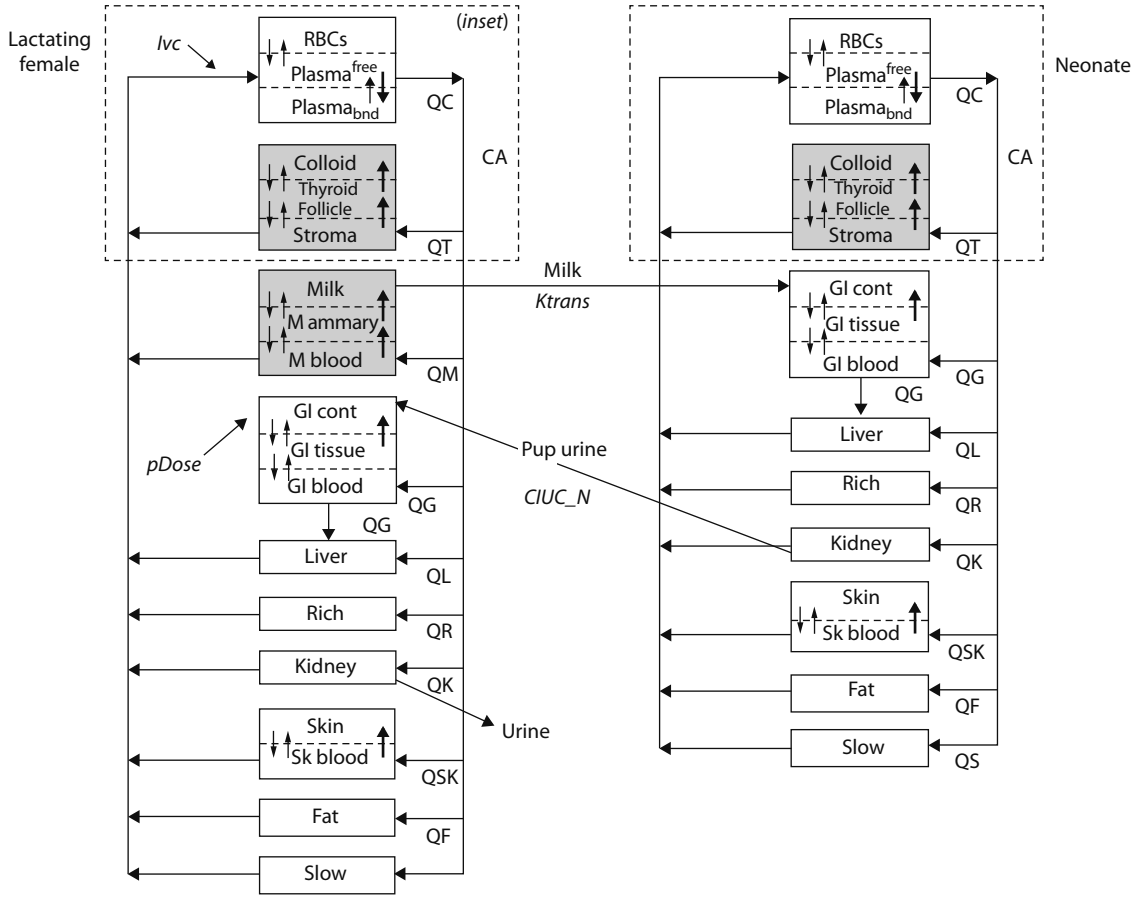

FIGURE 6.17 Schematic of perchlorate PBPK model for lactating dam (left) and neonate (right). Model structure for sister iodine model is identical with the exceptions of the inset area outlined with the dashed line. In the plasma and thyroid, some descriptions of iodine incorporation into hormones were included, which is described elsewhere. (From Clewell, R.A. et al., *Toxicol. Sci.*, 74, 416, 2003.)

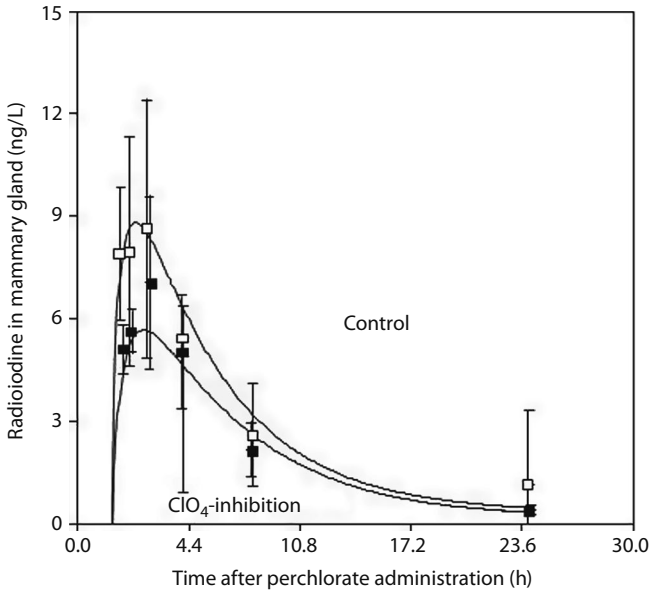

FIGURE 6.18 Radioiodide concentration in milk with and without ClO_4^- [162]. The top simulation and data indicate the control group. The lower simulation and data indicate the inhibition group. (Data from Potter, G.D. et al., *J. Biol. Chem.*, 234, 350, 1959.)

Clearly, it is not always necessary to include such detailed description of the mammary gland.

This model included transfer between pup urine and the maternal GI. This process reflects the ingestion of pup urine by the dam during grooming. In studies using radiolabeled iodine, as much as 60% of the dose administered to the neonate was transferred to the dam during grooming [209]. The importance of including these processes will vary depending on the relative amount of chemical eliminated via milk, which is determined by the pharmacokinetic properties of the compound [210]. For chemicals that are poorly transferred in the milk, the neonatal dose will present a negligible fraction of the dose, and ingestion of pup urine will not present a significant source of chemical to the dam. For chemicals that are efficiently transferred in milk, or where the chemical is administered to the neonate directly, this transfer from the pup to the dam may be important.

Comparing Susceptibility to Chemical Exposure across Life Stages

PBPK models for the developmental period can be used to determine which populations are likely to receive the greatest level of exposure to a particular chemical. The (ClO_4^- and I^-) models were developed for the naive adult, pregnant

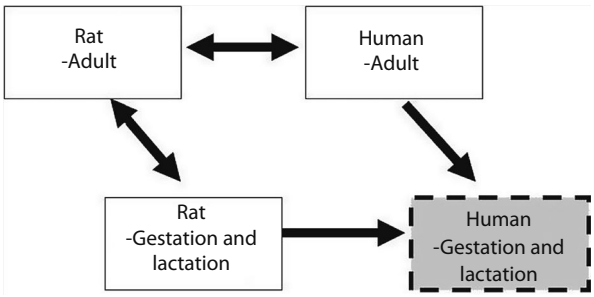

FIGURE 6.19 Parallelogram approach to estimating human developmental model parameters from rat perinatal models and rat and human adult models. Calculations are described in detail elsewhere. (From Clewell, R.A. et al., *J. Toxicol. Environ. Health A*, 70, 408, 2007.)

and fetal, and lactating and neonatal rat. These models were then used to extrapolate to human exposure using the *parallelogram approach* (Figure 6.19) [163]. Using the human models, together with descriptions of bottle-fed infants and extending the model from weaning to adulthood, it was possible to compare ClO_4^- exposure across all relevant life stages in the human (Figure 6.20). Using the published water ingestion rates for infants [211], a bottle-fed infant (1 month postpartum) would have the highest serum perchlorate levels, with an average serum AUC five times greater than that of a nonpregnant adult. The serum AUCs in fetus and breast-fed infant are approximately 3.5-fold higher than the adult. Thus, the fetus and the infant (bottle- and breast-fed) are the populations expected to have the greatest exposure to perchlorate (per kg BW). Relative exposure for several other chemicals across life stages has also been explored in the human [183,190]. The application of these life-stage PBPK models is an important tool in identifying susceptible populations for consideration in chemical risk assessments.

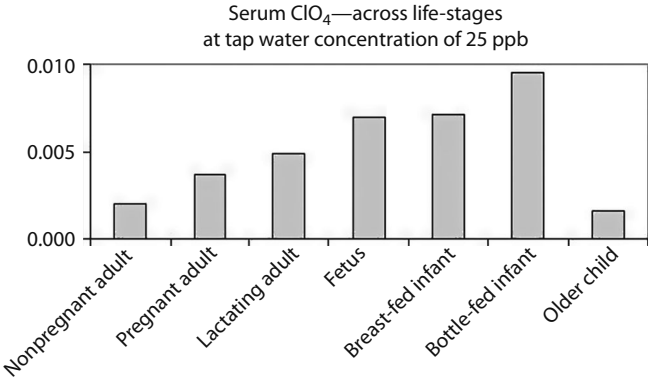

FIGURE 6.20 Predicted serum perchlorate area under the curve (AUC) in the adult, fetus, breast-fed infant, bottle-fed infant, and older child. Simulations in adults, fetus (gestation week 38), and breast-fed infant (postnatal month 1) were performed at daily maternal water intake of 0.029 L/kg-day (~2 L) and a drinking water perchlorate dose of 0.0007 mg/kg-day (25 ppb for ~70 kg adult). Simulations in the bottle-fed infant (postnatal month 1) and older child (7 years) assume daily water intake at 1 L/day at 25 ppb ClO_4^-.

CONCLUDING REMARKS

The desire to increase the biological basis of chemical risk assessments has driven the development of new methodologies such as PBPK modeling. The development and the application of PBPK models in turn demand well-formulated statements about the chemical mode of action. The requirement for an explicit mechanistic hypothesis gives PBPK models their power but at the same time serves as the greatest impediment to their acceptance by regulators. PBPK models also serve to make other uncertainties in the risk assessment more visible, such as cross-species and interindividual variation. In some cases, the increased visibility given to these uncertainties has led to improvements in the default risk assessment process. By replacing poorly characterized uncertainties (in the default approach) with definable model uncertainties, PBPK models have spurred the development and application of the sophisticated uncertainty analysis techniques, such as Monte Carlo analysis and hierarchical Bayesian analysis, that are now used to provide a better understanding of the range of risk estimates across a population consistent with the information available on a given chemical. It is crucial that this parallel development of biologically motivated descriptions of dosimetry and tissue response and methods for their quantitative evaluation continues as the emphasis inexorably shifts from modeling of pharmacokinetics to modeling of pharmacodynamics.

The growing popularity of the PBPK modeling approach represents a movement from simpler kinetic models toward more biologically realistic descriptions of the determinants that regulate disposition of chemicals in the body. To a large extent, the application of these PBPK models to study the time courses of compounds in the body is simply an integrated systems approach to understanding the biological processes that regulate the delivery of chemicals to target sites. Many PBPK models integrate information across multiple levels of organization, especially when describing interactions of compounds with molecular targets, such as reversible binding of ligands to specific receptors, as in the case of methotrexate binding to dihydrofolate reductase [50,212]. In such cases, the PBPK models integrate molecular-, cellular-, organ-, and organism-level processes to account for the time courses of compounds, metabolites, and bound complexes within organs and tissues in the body. The system under scrutiny in PBPK models is more the integrated physiological system, appropriate enough for a discipline defined as physiologically based modeling.

The main goal of PBPK models is quite simple—to predict the target tissue dose of compounds and their metabolites at target tissues and, in some cases, to describe interactions in target tissues. PBPK models once developed are extensible. They can be used to extrapolate to various other conditions because of their biological fidelity. While the goal in applying these models is to predict dosimetry, it is important to remember that the overall goal of using PBPK modeling in risk assessment is broader than simply estimating tissue

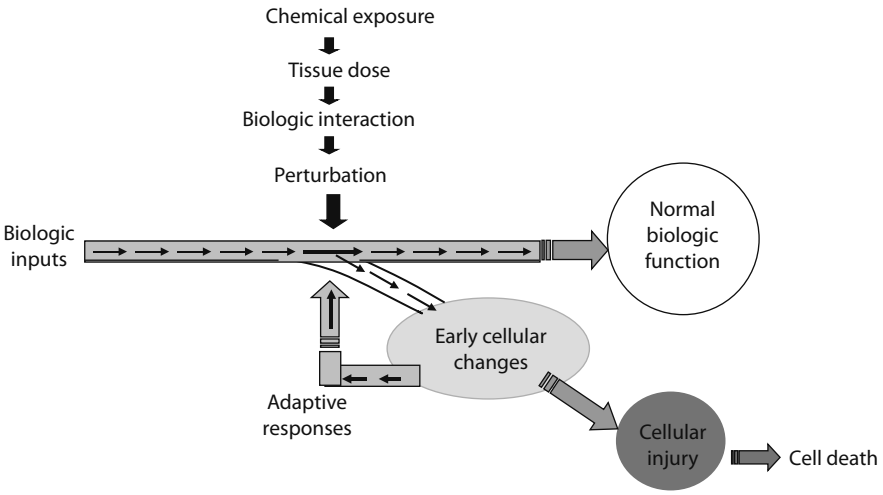

FIGURE 6.21 Diagram of the approach for understanding the pharmacological and toxicological effects of compounds in terms of their interaction with the biological system. The horizontal axis represents the biological component of the interaction, and the vertical axis represents the chemical component. Drugs can both restore altered biological function (efficacy) and produce altered function (toxicity).

dose, regardless of the level of detail provided in the interactions of compounds with tissue constituents. The goal in the larger context is to understand the relationship between dose delivered to target tissues and the biological sequelae of the exposure of target tissues to compounds. The specific steps that lead from these dose metrics to tissue-, organ-, and organism-level responses have usually been considered part of the pharmacodynamic process. Another inexorable development will be the expansion of these quantitative modeling approaches into the pharmacodynamic arena [5]. This latter area will represent a systems biology approach for describing perturbations of biological systems by compounds and the exposure/dose conditions under which these perturbations become sufficiently large to pose significant health risks.

The systems biology approach (Figure 6.21) focuses on normal biological function and the perturbations associated with exposure to compounds. Perturbations of biological processes by compounds lead to either adverse responses (chemical toxicity) or restoration of normal function to a compromised tissue (drug efficacy). The effects of compounds, whether for good or ill, can best be described by PBPK approaches linked through models of responses of cellular signaling networks. Toxicity and efficacy are then defined by an intersection of compound action with the biological system [213]. Toxicology and pharmacology are disciplines at the interface of chemistry/pharmacokinetics (primarily embedded in the vertical component) and biology/pharmacodynamics (primarily captured by the horizontal chain). Clearly, the main differences in the next generation of systems approaches in pharmacokinetic and pharmacodynamic modeling will be the increasingly detailed descriptions of biology afforded by new technologies and the expansion of modeling tools available for describing the effects of compounds on biological signaling processes.

QUESTIONS

6.1 What are the major criteria for deciding which tissues/organs to include in a PBPK model for a chemical?

6.2 Draw a box and arrow representation of a PBPK model to account for subcutaneous dosing of a volatile compound that is metabolized to a nephrotoxic metabolite in the kidney.

6.3 Write the mass balance equations for the compartments in the model from question 6.2.

6.4 Drug–drug interactions can alter the persistence and responses to individual drugs. Write equations for two different compounds metabolized by a common enzyme in liver. How would these equations change if the compounds shared a common enzyme for phase I metabolism and clearance?

6.5 Describe four different situations where it would be necessary to include changes in BW and volumes of specific tissues/organs over time.

6.6 Use the model code in the coding example to calculate the ventilatory air flow, tissue blood flows, and tissue volumes for a 500 g rat. Repeat for a 25 g mouse.

TOXICITY TESTING IN THE TWENTY-FIRST-CENTURY PARADIGM SHIFT

Toxicity testing is at a turning point now that long-range strategic planning is in progress to update and improve testing procedures for potential stressors. The report by the U.S. National Research Council (NRC)[1] envisions a shift away from traditional toxicity testing and toward a focused effort to explore and understand the signaling pathways perturbed by biologically active substances or their metabolites that have the potential to cause adverse health effects in humans. The identification of these *toxicity pathways* is imperative in order to understand the mode of action (MOA) of a given stimulus and for grouping together different stimuli based on the toxicity pathways they perturb. The first component of the vision focuses on pathway identification, which is preferably derived from studies performed in human cells or cell lines using omics assays. The second component of the vision involves *targeted testing* of the identified pathways in whole animals and clinical samples to further explain toxicity pathway data. This two-component toxicity-testing paradigm, combined with chemical characterization and dose–response extrapolation, delivers a much broader understanding of the potential toxicity associated with a biologically active substance.[2–5]

Systems biology plays an important role in this paradigm, consolidating large amounts of information that can be probed to reveal key cellular pathways perturbed by various stimuli. Programs such as Next Generation (NexGen) Risk Assessment from the Environmental Protection Agency (EPA)[6] encourage the community to incorporate systems biology data into toxicity testing as articulated in a statement of goals for the near future, created at the Prototypes Workshop held in 2011.[7] Current systems biology methodology should be reviewed and further developed using an iterative approach. Stimulus-specific signature pathways need to be developed by the careful clarification of already identified key pathways. Systems data may also provide a means to better correlate in vitro and in vivo findings. However, the consistency of data obtained from in vitro and in vivo methodology across species needs to be assessed, and appropriate scaling methods should be developed for in vitro to in vivo correlation.

The U.S. EPA commissioned the NRC to develop a vision for toxicity testing in the twenty-first century (Tox-21c).[1,8] The fundamental idea underpinning this request is to base the new toxicology primarily on pathways of toxicity (PoT).[9] The committee suggests that there is a finite number of distinct pathways resulting in toxicity, and if these can be successfully identified and mapped, then new assay test batteries can be developed. Tox-21c has identified the promise of new technologies and the need for large-scale efforts.

There are several research initiatives that revolve around the 3Rs (replacement, refinement, and reduction) principle aiming to establish research solutions, which will reduce and eventually replace animal testing in product safety assessment. For instance, the six research projects within the SEURAT-1 Initiative (safety evaluation ultimately replacing animal testing)[10] represent collaborations between over 70 European universities, public research institutes, and companies. The collaboration focuses on the development of the technology building blocks that will replace current repeated-dose systemic toxicity testing in animals. Work on nonstandard methods is also ongoing under the auspice of the Organisation for Economic Co-operation and Development (OECD). The quantitative structure–activity relationship (QSAR) toolbox aims to categorize chemicals based on their intrinsic properties, thus enabling robust hazard testing for an entire category of chemicals with supposedly similar structure–activity relationship by extrapolation of testing results from only some members in a particular category.[11–13] AXLR8 is a central European Commission-funded body mediating information exchange between the leading European and global research teams that work on improving the capacity and speed of safety testing. The essential goals also include the identification of more human-relevant testing methods as well as an effort to drive the shift toward a toxicity pathway-based standard.[14] Furthermore, the European Partnership for Alternative Approaches to Animal Testing (EPAA) aims to influence European regulatory testing and decision-making so the 3Rs can be efficiently applied to reduce redundant and unnecessary animal testing.[15]

NETWORK-BASED APPROACH TO QUANTIFY THE IMPACT OF BIOLOGICALLY ACTIVE SUBSTANCES

Systems biology approaches yield large molecular datasets organized into meaningful biological networks that can lead to mechanistic insights and understanding of potential toxic effects. We have developed a five-step approach to assess the biological impact of a stimulus, which combines systems-wide experimental data with a computational process. The intensity of the biological impact of a stimulus is expressed by a quantitative biological impact factor (BIF). The main goal of our five-step approach is to adopt a toxicological MOA framework to describe how any substance may adversely affect human health and to use this knowledge to develop complementary theoretical, computational, and experimental (in vitro) models that can be used for safety assessment.[16]

To produce systems-wide data, several well-chosen experimental systems are exposed to stimuli in a time- and dose-dependent manner. Instead of merely extracting differentially expressed gene or protein lists, the data are analyzed in the context of biological network models. Because the network models used for this approach are built with cause-and-effect

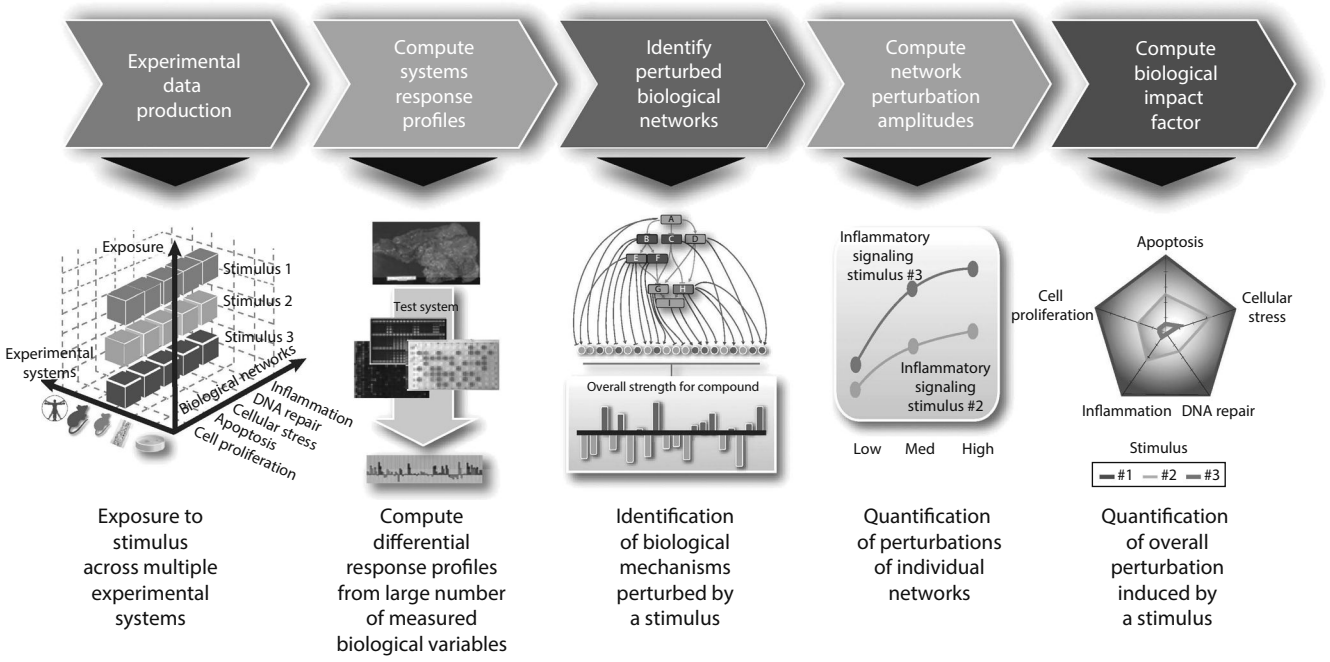

FIGURE 7.1 A network-based approach to quantifying the impact of biologically active substances. The five arrows illustrate the following steps: (1) design and conduct of a systems biology experiment, (2) calculation of systems response profiles, (3) building and identification of the relevant biological networks, (4) computing the NPA, and (5) computing the BIF.

relationships to describe biological processes, analyses of these networks can provide a more detailed molecular understanding of the observed biological perturbations. The approach thus provides the means for a mechanism-based quantitative comparison of the biological impact of a stimulus between individuals and species and can potentially exhibit predictive power through deterministic scoring algorithms. The five steps of our strategy are described in the following and comprise (Figure 7.1) (1) the design and execution of systems biology experiments, (2) the extraction of systems response profiles from the data generated in step 1, (3) the identification and building of relevant biological network models, (4) the computation of network perturbation amplitudes (NPA) scores, and finally (5) the aggregation of the NPA scores into a BIF.

DESIGN OF A SYSTEMS BIOLOGY EXPERIMENT

The success of the five-step strategy greatly depends on the quality of the design of the experiments to produce the systems biology data. To maximize this quality, a number of factors need to be taken into consideration. First, a clear scientific question has to be formulated, and the key assumptions that are made should be enunciated. These should drive the selection of the most adequate exposure modalities and biological test systems to address the scientific question. Second, it is crucial to select the most adequate measurement methods and ensure an optimal combination of dose- and time-dependent sampling schedules. Finally, a well-planned experiment is also statistically powered to enable proper interpretations of the results.

Ideally, the results from a well-designed experiment should do at least one of the following: (1) determine the reactivity (molecular bioactivity) profile of stimuli in order to associate them with likely molecular targets in a cell- and tissue-specific context; these profiles can in turn be linked to possible MOA, (2) capture specific MOA in order to discriminate stimuli that are likely or unlikely to induce toxicity in humans, (3) identify stimuli that are associated with a specific MOA and rank them with respect to their toxicokinetic potency, and (4) identify stimuli associated with a specific MOA and estimate threshold values for lethality that can be used to derive an in vivo effect level, as a function of dose dynamics.[10]

A thorough experimental design phase also enables the computational biologist to assess the experimental feasibility in concert with the experimental scientists who provide input on the kind of experimental information that is essential to a quantitative analysis.[17] Our strategy relies on three equally important dimensions in the experimental design space: (1) the experimental system, (2) the exposure regimen, and (3) the relevant biological networks, which will be measured and related to particular biological endpoints relevant to an adverse/toxic effect.

The experimental system is subjected to a standardized time- and dose-dependent exposure regimen (Figure 7.2a). A zero dose is used to represent control conditions. The treatment design consists of multiple biological replicas to ensure statistical power during the analysis. Additionally, the statistical design associated with the execution of the experiment is a crucial component to assess the experimental error by handling variation, eliminate any systematic bias, and account for

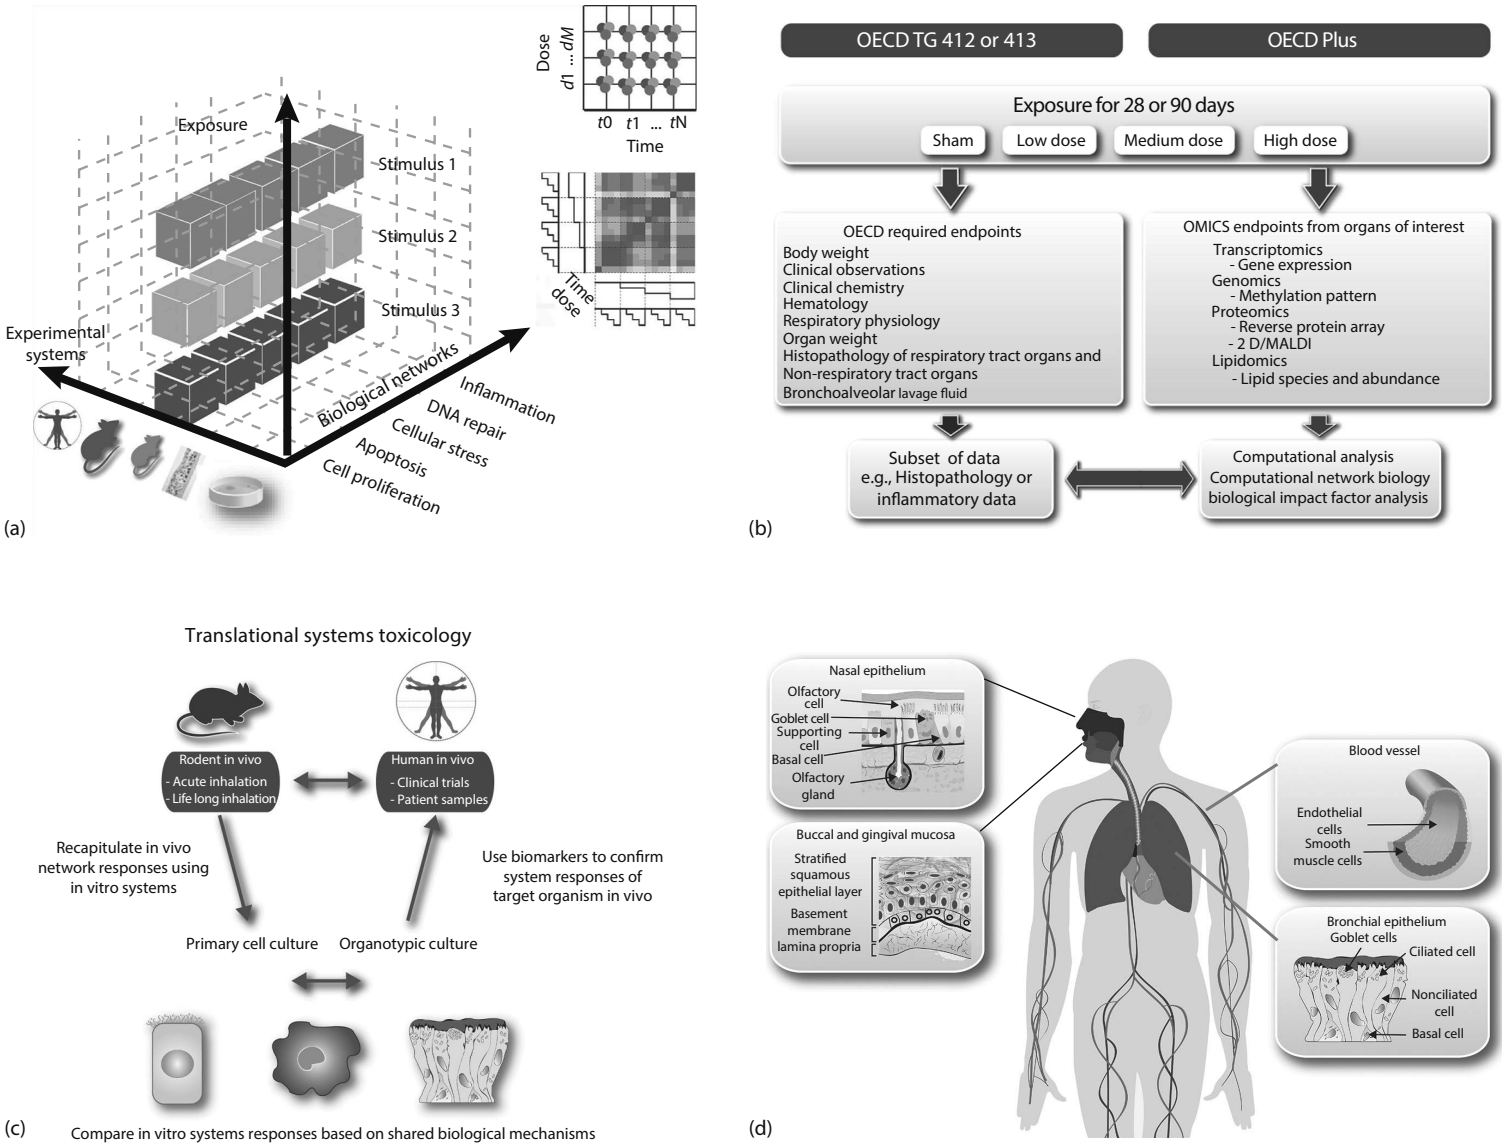

FIGURE 7.2 The experimental systems. (a) The cubic experimental design space with its three equally important components: (1) the experimental system, (2) the exposure regimen, and (3) the biological networks accompanied by the standardized time- and dose-dependent exposure regimen and a comparability heat map between two stimuli. (b) Comparison of the endpoints in the classical and OECD Plus concept. (c) Principle of translational systems toxicology from experimental animal models and in vitro models to human context. (d) Example of human tissues recapitulated through organotypic in vitro experimental models.

extraneous confounding variables including those linked to the used technology and the extraction/isolation steps. This means also that a sufficient number of biological replicas need to be included and processed individually throughout the entire workflow.

Experimental Systems

The data collected from longitudinal clinical studies are clearly the most relevant when assessing the potential human health risks associated with exposure to active substances. However, the adverse effects and disease(s) related to a stimulus usually take decades to manifest, and it is often difficult or even impossible to obtain datasets from such longitudinal human studies. Toxicity testing thus relies largely on animal models, as well as models based on cellular and organotypical (3D) in vitro cultures. While in vitro and in vivo models are known to have many shortcomings, however when appropriately used, they can provide mechanistic insights into the biological perturbations caused by a stimulus. By taking a systematic approach, we believe that the gaps between in vivo/in vitro systems and in vivo human biology can be reduced, potentially resulting in the identification of specific biomarkers for use in human studies. Eventually, these mechanisms provide the link from the initial exposure to a stimulus and the downstream onset of disease.

In Vivo Systems

Description of the 28-Day or 90-Day OECD Plus Concept

Traditional toxicological assessment approaches for experimental inhalation toxicology follow *OECD Guidelines for the Testing of Chemicals*. This is a collection of about 100 of the most relevant internationally agreed-upon testing methods for assessing, identifying, and characterizing potential hazards of new and existing chemical substances, chemical preparations, and chemical mixtures used by government, industry, and independent laboratories.[18] In particular, test guidelines (TG) 412 and 413 have been designed to fully characterize test article toxicity by the inhalation route for a limited duration (i.e., 28 or 90 days, respectively) and to provide robust data for inhalation risk assessments.[19,20]

The OECD TG 412 and 413 describe the methods to assess the inhalation toxicity of an inhalable material such as a gas, dust, mist, vapor, volatile substance, aerosol, or particulate suspension, using repeated exposures for a 28-day or 90-day inhalation period. Studies conducted in accordance with OECD guidelines have shown the assays to be suitable for the testing of cigarette prototypes and ingredients.[21–26] The study designs include the assessment of comparator products and a sham-exposed control group and/or vehicle controls as needed at three or more concentration levels. Exposure assessment, in-life observations (e.g., body weight, feed consumption, ophthalmoscopy), clinical pathology (blood and urine), gross pathology, and organ weights, as well as histopathology with particular attention to the respiratory tract, other relevant target organs, and gross lesions, are evaluated. The guidelines allow for the inclusion of satellite (reversibility) groups, bronchoalveolar lavage (BAL), neurologic tests, and additional clinical pathology and histopathological evaluations in order to better characterize the toxicity of a test article.

However, experience demonstrates that toxicological markers are only detectable after substantial damage has already occurred and therefore are considered to lack sensitivity.[27] Recently, the combined approach of omics and conventional toxicology has been shown to be a useful tool for mechanistic investigation and for the identification of putative biomarkers.[27,28]

In relation to chemical hazard/risk assessment, omics technology provides tools for improving the understanding of mechanisms of toxicity, reducing uncertainty in grouping of chemicals, and providing alternative methods for screening chemicals. OECD assists internationally collaborative efforts on molecular screening and toxicogenomics with the aim of defining needs and possibilities for their application in a regulatory context. Yet, their concepts have not been systematically applied across in vivo studies.[29]

In Figure 7.2b, a concept of combining the conventional toxicological assessment approach suggested in the OECD with additional molecular biological endpoints is presented. In brief, in a toxicity study employing additional animals for the purpose of obtaining *omics*, endpoints are employed. These animals undergo the same exposure conditions at the same time as the animals in the OECD study. Organs (e.g., lung, liver) and body fluids (e.g., blood, urine) of interest are collected from the exposed animals. Omics data (e.g., transcriptomics or proteomics) are generated, computationally analyzed and subsequently correlated with the endpoints described by the OECD guidelines. The omics data are obtained from the exact same tissue sites where a phenotypic change is expected to occur based on the corresponding classical endpoints as suggested by the OECD guidelines. In some cases, it is instructive to perform laser capture microdissection to excise and analyze a specific cell type of interest (i.e., lung parenchyma) prior to ribonucleic acid (RNA) or protein extraction: this facilitates the identification of the toxicity mechanisms at cell, tissue, and organ level.

These standardized toxicology testing guidelines do however not involve animal models designed to reproduce key features of the human diseases known to result from chronic exposure to stimuli such as environmental toxicants or cigarette smoke (CS). To test products in the context of such diseases, one would therefore need to leverage existing, or develop new, animal models, which reproduce at least some key features of the human diseases as a consequence of exposure to the toxicant(s). For instance, CS causes well-documented changes in lipid metabolism, and the resultant proatherogenic lipid profile is thought to be responsible for

the accelerated growth rate of atherosclerotic plaques and the increased incidence of cardiovascular disease in smokers.[30] Plaque development, a key feature of human cardiovascular disease, can be tested in the apolipoprotein E-deficient knockout mouse ($ApoE^{-/-}$),[31] which is a well-established model of human atherosclerosis.[32] The systemic proinflammatory status of $ApoE^{-/-}$ mice makes this strain a strong candidate model to extend the scope of smoking-related disease end points. For example, ApoE-deficient mouse is a suitable model to detect smoke-related COPD paramenters such as emphysema. COPD is defined as a progressive, irreversible airflow limitation caused by the combined effects of emphysema, chronic bronchitis, and narrowing of the small airways.[34] In the Western world, CS is the main etiological factor in the pathogenesis of this disease.[35] Published literature describes several rodent models mimicking at least one feature of COPD.[36–39] Different strains of mice have been reported to show different susceptibilities for the development of smoking-induced COPD.[40–42] The C57BL/6 mouse strain (the genetic background of the ApoE-deficient mice) and the A/J mouse strain are widely used as rodent models of CS-induced COPD.[43–47] Both mice strains develop smoke-induced emphysema that can be observed by parameters such as lung function as well as histopathology and gene expression of the lung and airway tissue.

In Vitro Systems

Animal models are usually used to assess the toxicological impact of certain stimuli on living beings. They provide a comprehensive view of how a substance interacts with a whole organism. Nevertheless, toxicity testing on animals presents considerable challenges. It is very expensive, time-consuming, and ethically controversial. More importantly, there are significant concerns regarding the poor predictability of animal studies for human outcomes. The actual effort to *replace, reduce, and refine* animal experiments (as stated by [48]) is based on the use of more appropriate cell-based assays that could provide more relevant data on the effects of short- and long-term exposure to toxicants. Figure 7.2c represents the different experimental systems and how they are connected following the principle of translational systems toxicology.[49] One example of in vitro, and in vivo, as well as interspecies, extrapolation has been illustrated by Kienhuis et al.,[50] where the assessment of acetaminophen-induced hepatotoxicity was conducted in the rat and in human in vitro cellular systems and additionally, between rat in vitro and in vivo systems at the level of gene expression.

To increase the relevance of in vitro assays and to further mimic physiologically relevant cellular functions, primary culture of target organ-specific cells obtained from human donor has been further investigated as a potential surrogate. Primary cells show more preserved cell-type-specific functions than immortalized cell lines.[51–53] In addition, the use of human primary cells also offers the advantage of testing the response to an exposure on cells from different donors allowing an evaluation of the importance of human genetic variability. To reproduce the tissue-specific architecture, the biochemical and mechanical cues, and the cell–cell interactions of the microenvironment in tissues, a number of in vitro models have been further developed as 3D tissue reconstruction models. The first consideration in assessing toxicity is to investigate the possible routes of exposure and therefore the target organs that, under normal circumstances, protect the body from environmental stressors. In the list of 3D models already developed (Table 7.1), the skin[54] and the respiratory tract[55] are already covered and used to assess how stimuli penetrate these tissues to impact the human organism.

When normal human bronchial epithelial (NHBE) cells are cultured at the air–liquid interface, they can differentiate into an organotypic pseudostratified bronchial epithelium-like tissue with all the morphological properties that define the bronchial epithelium in vivo.[56] Cells are polarized, develop tight junctions, and show typical aspects of ciliated and nonciliated cells, goblet cells, and basal cells as seen in vivo. In addition, cells forming the 3D airway cellular model express a comparable gene expression profile to tracheal and bronchial epithelial cells that have been collected in vivo by brushing human airways.[57] Furthermore, the gene expression profiles of a human 3D airway model (obtained from MatTek™) exposed to whole CS or air have been compared via computational methods to the in vivo smoking gene signature of bronchial epithelial cells obtained from a large group of smokers and nonsmokers.[58] The results of this study show that the human organotypic bronchial epithelium-like tissue culture exposed to whole CS at the air–liquid interface presents similar biological perturbations as the ones observed in smokers' airway epithelium. Similarly, a recent study on drug efficacy has shown that 3D cultures of endometrial cancer cells were better reflecting the effect of some drugs tested in patients than when cultured in two dimensions.[59] Experimental evidence demonstrating the relevance of 3D human organotypic cultures is accumulating, and more work will be required to further validate the use of such experimental models for toxicological assessment. Figure 7.2d illustrates the organotypic culture systems that are included in our strategy in testing tobacco products.

The establishment of co-culture systems in both two and three dimensions is also underway and promises to more closely recapitulate key biological functions. The presence of different cell types in the same in vitro model provides an important additional step to re-create essential physiological steps, which involve more than just one cellular player (such as the release of growth factors, modifications of extracellular matrix (ECM), cell–cell interactions). Finally, the design of complex flow or perfused systems has been reported in both large-scale bioreactors as well as smaller-scale metabolism toxicity models. One example recently published is the impressive reconstitution of organ-level lung functions on a chip.[60] The authors developed a mechanically active microdevice that reconstitutes the alveolar–capillary interface of the human lung and mimics the cyclic mechanical strain of breathing. The model also includes the presence of a microvascular channel.

TABLE 7.1
Example of Human In Vitro 3D Experimental Models Available Commercially or Already Developed and Described in the Literature

3D Human Reconstructed Models or Tissue Explants	References	Potential Applications
Skin epidermis	[10,215–217]	In product development, toxicological assessment, safety assessment, and drug discovery/development in cosmetics, personal care, household products, chemicals, pharmaceutical and biotech testing
Respiratory tract Tracheal/ bronchial epithelia	[10,15,216]	In product development, toxicological assessment, safety assessment, and drug discovery/development (e.g., intrabronchial drug delivery assessment) in personal care, household products, chemicals, pharmaceutical and biotech testing
Keratinocyte eye cornea	[10,216]	In toxicological assessment and safety assessment and drug discovery/development in the pharmaceutical industry (e.g., ocular irritation assay and corneal permeability, metabolism, and differential display)
Vaginal cervical mucosa	[10,216]	In toxicological assessment and safety assessment and drug/product discovery/development in pharmaceutical industry (e.g., vaginal irritation assay, bacterial or viral adhesion screening for antibiotics or products, in vitro candidosis research, vaginal permeability and metabolism)
Buccal and gingival mucosa	[10,216]	In toxicological assessment and safety assessment and drug/product discovery/development in pharmaceutical, personal care industry (e.g., oral irritation assay, oral anti-inflammatory assay, in vitro candidosis research, oral permeability and metabolism)
Nasal epithelia	[15]	In product development, toxicological assessment, safety assessment, and drug discovery/development (e.g., intranasal drug delivery assessment) in personal care, household products, chemicals, pharmaceutical and biotech testing
Blood–brain barrier	[218]	Assessment of drug transport and metabolism across the human blood–brain barrier to detect potential neurotoxicity effects
Placental barrier	[219]	Assessment of drug transport and metabolism across the human placental barrier to detect potential fetotoxicity effects
Lymph node	[220]	In drug discovery/development, organ research, and tissue regeneration
Liver	[124,221]	In product development, toxicological assessment, safety assessment, and drug discovery/development in household products, chemicals, pharmaceutical and biotech testing, as well as in organ research and tissue regeneration

Note: All of these models are using primary normal human cells.

Responding to the need for more reliable human in vitro models of in vivo responses, the National Institutes of Health (NIH), the U.S. Food and Drug Administration (FDA), the Defense Advanced Research Projects Agency (DARPA), and the Defense Threat Reduction Agency (DTRA) are sponsoring a variety of projects focused on developing 3D organotypic organ models as well as miniaturized human multi-micro-organ bioreactor systems.[61] Researchers in Germany are also developing a *human on a chip*, consisting of functional human organ units—human *microorganoids*—with feed supplies and waste reservoirs. These miniaturized dynamic 3D multitissue cultures are envisaged to be used for repeated-dose toxicity testing in lieu of 28-day or 90-day OECD rat studies.[62]

Exposures

Ideally, the exposure matrix will have been well characterized chemically, even in the case of a complex mixture. The goal is to re-create an exposure regimen, that is, the dose, frequency and timing, and overall duration of exposure that most realistically mimics the human situation while being technically feasible. It is therefore imperative to define a set of standard exposure regimens to be applied systematically to the selected experimental systems. Such exposure regimens should be validated and verified, at least in part, during the experiment to ensure that the expected exposure is actually taking place and the stimuli are indeed delivered to the target site. Furthermore, appropriate biological assays and measurements should be used to obtain time- and dose-dependent data in order to capture both early and late events and ensure that a representative dose range is covered.

If exposure information is available or can be estimated for the substance to be tested, then it should be considered in the study design. This step will minimize the chance of unrealistically high doses being used that could overwhelm the homeostatic mechanism of the experimental system, and thus fail to reflect the pathways that might be functional at more realistic doses.[63]

Exposure of In Vivo Systems

Methodologies to assess toxicity due to exposure to gases, aerosols, or combinations thereof require the generation of atmospheres that laboratory animals (mainly rodents) can be exposed to. The compositions of the atmospheres depend on the objective of the particular study but must be conducted under well-controlled conditions. Inhalation experiments use

TABLE 7.2
Summary of Different Exposure Modes in Experimental Models

Experimental Systems	Mode of Exposure	Stimuli
2D submersed Monolayer cell Co-culture of monolayer and suspension cells Permeable filter support[125]	Homogenous/heterogenous (apical vs. basal exposure)	Any soluble stimuli added to the medium
3D air–liquid interface[222]	Apical side exposure, at the air interface, or basal side exposure, at the liquid interface	Inhaled compounds (solids, liquids, gases, nanomaterials), whole CS
3D submersed multicellular spheroids (single or co-culture) Spontaneous cell aggregates[222] Liquid overlay[223] 3D hanging drop[224] 3D spinner flask/rotating wall vessels[225,226]	For cell aggregates, gradient of diffusion of gas/soluble nutrients/chemical agents	Any soluble stimuli added to the medium
3D co-culture on a scaffold[227,228]	For various cell types, exposed to the soluble nutrients/chemical agents	Any soluble stimuli added to the medium
Bioreactors[229]	For various cell types, perfusion of the cells, medium flow, gradient of diffusion of gas/exposed to the soluble nutrients/chemical agents. Heterogenous	Any soluble stimuli added to the medium
Laboratory animals	Parenteral (subcutaneous, intraperitoneal, intravascular, intradermal, intralesional, ocular, intranasal, intratracheal, intracranial, intrathoracic, intracardiac injections, osmotic pumps, and slow-release subcutaneous implants) Inhalation (nose-only, whole-body) Topical (skin, mucous membrane), irradiation Enteral (additives to the drinking water or food, intragastric via gavage)	

either whole-body exposure or nose-only exposure chambers.[64–66] Whenever possible, nose-only rather than whole-body modes of exposure should be used in inhalation studies that are designed to reduce exposure through nonrespiratory routes. The exception is for large animal numbers, chronic inhalation studies, or study types that require virtual continuous exposure.[65] Other routes of administration to expose laboratory animals are given in Table 7.2.

Exposure of In Vitro Systems

As mentioned in the previous paragraph, in vitro experimental systems are either made of cells in submersed cultures or cultures with an air–liquid interface. Thus, the exposure mode will be chosen depending on the selected in vitro systems and the type of stimulus to test (Table 7.2).

Regardless of the methods used, the toxicological principles underlying dose selection, frequency and timing of exposures, and duration of study need to be fully considered in the experimental design.

TECHNOLOGY PLATFORMS TO MEASURE MOLECULAR CHANGES

Genomics and Transcriptomics

Genomics is the field of research that focuses on the genome, that is, the mapping of the entire DNA sequence in a given organism and tracks any alterations associated with disease or resulting from exposure to harmful substances. The term *mutagenicity* refers to the induction of transmissible changes in the amount or structure of the genetic material of cells or organism. Such changes are permanent and will be inherited to the daughter cell upon division. Genomic changes include point mutations, copy number changes, as well as large-scale changes that affect the chromosomal structure. Deletions and duplications in a chromosome, referred to as copy number variations (CNVs), are a significant determinant of individual differences as well as contributors to many diseases. Recurrent CNVs are the result of homologous recombination between repeated sequences, and nonrecurrent CNVs can occur anywhere in the genome through nonhomologous recombination events.[67] Genetic changes may also lead to survival and growth advantages of the cell carrying them, frequently observed during malignant transformations. Even though evaluation of DNA damage is often included in the toxicity assessment, it is also important to further identify the affected genes when DNA damage leads to genomic changes.

Epigenomics: Reversible gene expression changes that are transmissible both mitotically and meiotically, but do not involve DNA sequence modifications are referred to as epigenetics. According to a long-standing model, hypermethylation of CG islands in the promoter regions of target genes inhibits the initiation of transcription, presumably by blocking the transcriptional regulator binding sites.[68]

Eukaryotic cell DNA is wrapped around eight histone proteins forming the nucleosome, the basic unit of chromatin. The chromatin structure is highly dynamic and undergoes covalent modifications that contribute to inactive heterochromatin or active euchromatin regulating the gene expression.[69]

While epigenetics serves an important purpose for various cellular functions during development, aberrations in methylation patterns or the histone code on individual genes as well as globally can signal system perturbation caused by a stimulus. It is clear that exposure to exogenous stimuli causes dose-dependent epigenetic changes and that certain malignancies resulting from chemical compounds stem from changes in the epigenetic landscape.[70–72]

Transcriptomics or gene expression profiling is used to study changes in gene expression taking into account the entire transcriptome, that is, all mRNAs in a cell population. Currently, transcriptomic analysis is probably the most well-established approach for identifying perturbed pathways and gaining mechanistic insight on the response to a stimulus. Transcriptomic research uses omics techniques, such as microarray and RNA sequencing.

Microarray technology is based on the inherent property of a DNA molecule to form a stable duplex (hybridization) from two complementary strands. One of the first applications of using short-labeled DNA probes to specifically bind other DNA molecules (derived from biological samples via hybridization) was described by Southern about 40 years ago.[73] An adaptation of this technique that used binding of labeled DNA probes to RNA molecules in order to detect RNA transcripts was correspondingly called northern blotting. It was the first molecular biology technique used to study gene expression and was essential for the development of microarrays. In northern blotting, the RNA isolated from biological samples is subjected to a size fractionation by electrophoresis and is then placed (blotted) on a membrane. DNA probes carrying the radioactive or chemiluminescent labels corresponding to the genes of interest are then applied. The concentration of the expressed RNA transcript is quantified by either radioactivity or chemiluminescence measurements of the bound labeled DNA probes.

cDNA microarrays: Although many journals still consider Northern blotting to be the *gold standard* for gene expression measurements, it suffers from drawbacks such as the low throughput (number of samples), low sensitivity, and limited number of genes that can be interrogated simultaneously. These limitations have been overcome by the introduction of cDNA microarrays, where individual fragmented, or full, cDNA clone sequences are printed on glass slides. In this approach, contrary to northern blotting, it is now the RNA transcripts that are isolated from biological material, labeled, and hybridized on a glass slide containing the cDNA probes (called a dual-channel array). In a typical experiment, the RNA is isolated from two samples, labeled with different fluorescent dyes (Cy3 and Cy5) and hybridized on the same array. Comparative image analysis of the two fluorescent colors from the same array allows for a medium throughput and for sensitive measurements of differential gene expression between the two samples.[74]

Oligonucleotide microarrays: The next major technological advance arrived with the invention of high-density array printing by Affymetrix. It is now possible to design an array of 25 oligomer probes that covers the whole collection of RNA transcripts (transcriptome) of a single organism. More than one million probes can be placed on the array in a particular order including mismatch and other quality control (QC) probes. In a typical experiment, each RNA sample is individually hybridized to a microarray, and comparisons are made between the samples at the data analysis stage. Up to 48 microarrays per run can be processed on an array scanner resulting in a high throughput. Initially, the microarrays were designed from the available 3′-expressed sequence tag (ESTs), thus covering mostly the 3′-end of expressed genes. With the progress in full cDNA sequencing and RNA sequencing by Next Generation Technologies, current microarrays can evenly cover each gene or each exon of the gene (so-called exon array). The exon arrays are now available for human, mouse, and rat.[75] The use of exon arrays has improved the analysis of alternatively spliced RNA transcripts as well as the accuracy of the overall gene expression measurements. Similar arrays have been developed by Roche NimbleGen and Illumina Inc.

Affymetrix GeneTitan: The idea of combining three major components—a hybridization oven, a fluidics station, and a scanner—into a single system has been realized by Affymetrix in the GeneTitan.[76] It supports gene expression studies in 16-, 24-, and 96-format of the lower-cost GeneChip® Array Plates and is able to process two plates per day and up to 750 samples per week. The gene expression profiling GeneChip® high-throughput (HT) perfect match (PM) array plates for human, mouse, and rat are listed among the available products of the new platform. However, as the processing of the array plates is completely different from that of the cartridge arrays, the results are not guaranteed to be similar especially for the expression measurements of low-expressed genes.[77]

Trends in gene expression: Next generation sequencing (NGS) technologies are emerging as the tools that will likely supersede microarray technologies in the near future because of their advantages in accuracy, throughput, and flexibility of gene expression measurements. For instance, gene expression studies can be made with organisms for which gene chip technology is not available such as model systems for environmental toxicology. The NGS protocols are designed to provide exact transcript counts and results that closely approach those of quantitative polymerase chain reaction (PCR). Increasing output and the number of multiplexing primers would allow for the processing of thousands of transcriptome samples in a single run. NGS methods require no prior knowledge of the probes and are directly applicable as soon as an RNA sample is available, although knowledge of the genome reduces the errors in annotation of expressed genes.

In the last decade, several parallel sequencing techniques have emerged based on a number of technologies, such as pyrosequencing, fluorescence-based sequencing by synthesis and sequencing by ligation, ion semiconductor, or single molecule real-time sequencing. The sequencers using these technologies offer read lengths and throughputs ranging from about 150,000 single-end long reads (~8 kb) to 6 billion 2 × 100 bp paired-end reads.[78] Although these technologies are continuously improving, with typical reads becoming longer and with higher accuracy, the characteristics of the offers from the leading sequencer providers vary as is summarized in Table 7.3.

Independent of the chosen technology, HT sequencing has applications in genomics, transcriptomics, and epigenomics. In a systems biology approach, the interpretation of the obtained results should be carried out in conjunction with the results of other analysis methods.

Deep sequencing of a genome (DNA-seq) is mainly used for de novo and resequencing assembly of whole genomes. However, it also enables a wide range of analyses that are gaining popularity as a result of the increased number of available annotated reference genomes. For example, by comparing an appropriate resequenced genome assembly to a reference genome, structural variations, CNVs, single-nucleotide polymorphisms (SNPs), or small insertions or deletions can be identified. If genomic regions of interest are known, targeted resequencing can be used to reduce cost, complexity, and time.

Gene expression profiling is also possible with deep sequencing of a transcriptome (RNA-seq). Unlike array-based methods, an advantage of RNA-seq is that it does not require prior gene identification or annotation. RNA-seq can therefore also be used for the discovery of novel transcripts and gene fusions.[79,80] In addition, array-based methods, which use target-specific probes, require the use of different arrays to study different biological aspects of a sample, such as gene expression, transcript expression, transcription start site utilization, or alternative splicing. On the contrary, depending on the methods used the same RNA-seq data can provide qualitative and quantitative measurements at the gene, transcript, transcription start site, or alternative splicing levels.[81]

Whole-genome DNA methylation can be investigated either at a single nucleotide level using shotgun bisulfite sequencing (MethylC-seq) and reduced representation bisulfite sequencing (RRBS) or at the level of a few tens of nucleotides with methylated DNA immunoprecipitation (MeDIP-seq), methylated DNA capture by affinity purification (MethylCap-seq), methylated DNA binding domain sequencing (MBD-seq), or methylation-sensitive restriction enzyme sequencing (MRE-seq).[82,83] MethylC-seq and RRBS require the sequencing of both the untreated and the bisulfite-treated genomes in order to compare them and identify methylated cytosines. With MeDIP-seq, MethylCap-seq, and MBD-seq, methylated genomic DNA fragments are enriched before sequencing. On the contrary, MRE-seq enriches unmethylated genomic DNA fragments. These methods reduce the amount of necessary sequencing, but do not provide single nucleotide accuracy.

Histone modifications can be studied using chromatin immunoprecipitation (ChIP) with antibodies specific for a given histone modification. After precipitation, the DNA bound to the precipitated chromatin can be hybridized on a microarray chip (ChIP-chip) or sequenced (ChIP-seq) on an HT platform. ChIP-chip will require a large number of arrays to cover whole mammalian genomes, while ChIP-seq provides the whole-genome coverage even at a low sequencing depth.[84]

With the development of platforms based on HT sequencing, genomic, transcriptomic, and epigenomic analyses are freed from the requirement for prior knowledge inherent to array-based platforms. The platforms thus move us closer to measuring what is in the sample rather than what is on the chip. Furthermore, as HT sequencing directly measures the DNA present in a sample, it can capture several modifications and alterations simultaneously. The data generated by these platforms are therefore more flexible in the way they can be analyzed and as a result can provide a wider spectrum of genomic information. Computational resources and

TABLE 7.3
Comparison of the Leading Sequencing Technology Providers (as of End-2013)

Provider	Technology	Detection	Number of Reads	Read Length	Advantages	Disadvantages
Roche 454 GS FLX+	Pyrosequencing	Luciferase light emission	1 million	700–1000	Relatively long reads	Prone to errors with homopolymers
Applied Biosystems SOLiD 5500xl	Sequencing by ligation	Fluorescent labeling of 5′-dimers	2 billion	50–75	Very high accuracy	Short read length
Illumina HiSeq-2500	Sequencing by synthesis	Four different fluorescent dyes	Up to 6 billion	100–150	Highest throughput	Long running time
Ion Torrent Proton	Ion semiconductor	pH change	165 million	200	Short running time	Prone to errors with homopolymers
Pacific Biosciences pacBio RS II	Single molecule real-time fluorescence	Fluorescence	150,000	~8000	Longest reads	Low number of reads, high error rate

methodologies for the analysis of large-scale epigenomic datasets have been developed in recent years; however, as noted by Huss,[84] "custom tools are needed to optimally analyze ChIP-seq data on histone modification and BS-seq data on DNA methylation." Furthermore, reaching the full potential of whole-genome epigenomic studies is still hindered by the lack of guidelines and repositories for data submission. Such provisions would speed up research and allow for advanced applications.[86]

Proteomics

The proteome represents the full complement of the proteins produced by an organism,[87] and proteomics is a systematic approach to characterizing all proteins in a cell population. The data produced by the proteomic technologies hold significant potential for drug discovery, diagnostics, and molecular medicine by complementing the genome-centric view of biological networks with protein-specific data. Proteomic data can be equally valuable in toxicity testing since the proteome responds readily to various stimuli, including those that can lead to adverse health effects in humans. Toxicoproteomics sets out to develop tools that can identify potentially damaging changes in the proteome thereby further increasing the understanding of a stimulus on the mechanisms of toxicity. Proteomic technologies can be divided into those used for the discovery and identification of potential biomarkers and those used in targeted approaches for biomarkers quantitation and verification.

Biomarker Discovery and Identifications Approaches

Gel-Based Approaches

2D polyacrylamide gel electrophoresis (2DGE) can be used to assess perturbations on the proteome. This technique relies on the separation of proteins based on their pH (charge) as well as their size and has the capability to separate and visualize up to 2000 proteins in one run. The first dimension, which is known as isoelectric focusing (IEF), separates the proteins at the pH where they exhibit neutral charge (isoelectric point), and the second dimension further separates the proteins by their mass. State-of-the-art image acquisition and analysis software such as SamSpots from nonlinear dynamics allow simultaneous comparison of control and treated samples to identify the differentially regulated proteins by their relative intensity and volume in a label-free approach. The difference in gel electrophoresis (DIGE) is the labeling of proteins with fluorescent cyanine dyes (Cy2, Cy3, and Cy5) of different samples or treatments. The characteristics of these dyes allow the analysis of up to three pools of protein samples or conditions simultaneously on a single 2D gel to detect differential variances in proteins between samples.[88] The most challenging aspect has been in the development of algorithms that can deal with the warping phenomenon. Investigators now account for gel warping by running several gels per sample and analyzing gels by principal component analysis (PCA) to determine which should be excluded from further analysis.[88] Figure 7.3c describes the workflow for the 2DGE for biomarkers identifications.

Even though 2DGE is a powerful tool to identify many proteins when using well-established protocols, the approach has serious limitations. The major limitation is that not all proteins can be separated by IEF. Membrane, basic, small (<10 kDa), and large (>100 kDa) proteins cannot be separated on the IEF and hence, cannot be detected in the 2DGE and require a separate approach based on membrane purification and 1D gel electrophoresis (1DGE). The second limitation is that less abundant proteins are often masked by the abundant proteins in the mixture.[89,90]

Gel-Free Liquid Chromatography Mass Spectrometry Approaches

Protein fractionation is crucial for simplifying the mixture before analysis with mass spectrometry (MS). Liquid chromatography (LC) is the most commonly used method for protein fractionations. The LC approach takes advantage of the differences in the physiochemical properties of proteins and peptides, that is, size, charge, and hydrophobicity. The use of 2D-LC fractionates proteins on two columns with different physiochemical properties to achieve the maximum separation of proteins and peptides in the complex mixture.[91]

MS is widely considered to be the central technology platform for toxicoproteomics. MS has brought many advantages to the advancement of toxicoproteomics including unsurpassed sensitivity and improved speed and the ability to produce HT datasets. Due to the high accuracy of MS, peptides in the femtomolar to attomolar range can be detected in tissues and biological matrices with an accuracy level of less than 10 parts per million (ppm). This is greatly beneficial in comparative analysis where simultaneous comparisons between control and treated samples are key to increase our understanding of how stimuli affect the proteome and the subsequent identification of potential biomarkers.[91]

There are two approaches that are widely used for protein identification and differential protein quantification. The first approach is a label-free approach where the proteins or peptides of each sample are separated by LC and subsequently analyzed by MS. The main advantages of this approach are the following: (1) comparison of multiple samples is possible (no restriction in sample number), (2) it covers a broad dynamic range of concentrations, and (3) no further sample treatment is required. This approach is however error-prone and requires large computational power to perform the data analysis. The second approach is a label-based approach. One of the most common techniques is the use of isotope tags for relative quantification (iTRAQ). The main advantages of iTRAQ are the following: (1) simultaneous comparison of up to eight samples, (2) reduction of sample number as samples are pooled before MS analysis, and (3) low probability of introducing experimental errors due to pooling. The limitations of the technique are the limited dynamic range and the fact that the protein profiles have

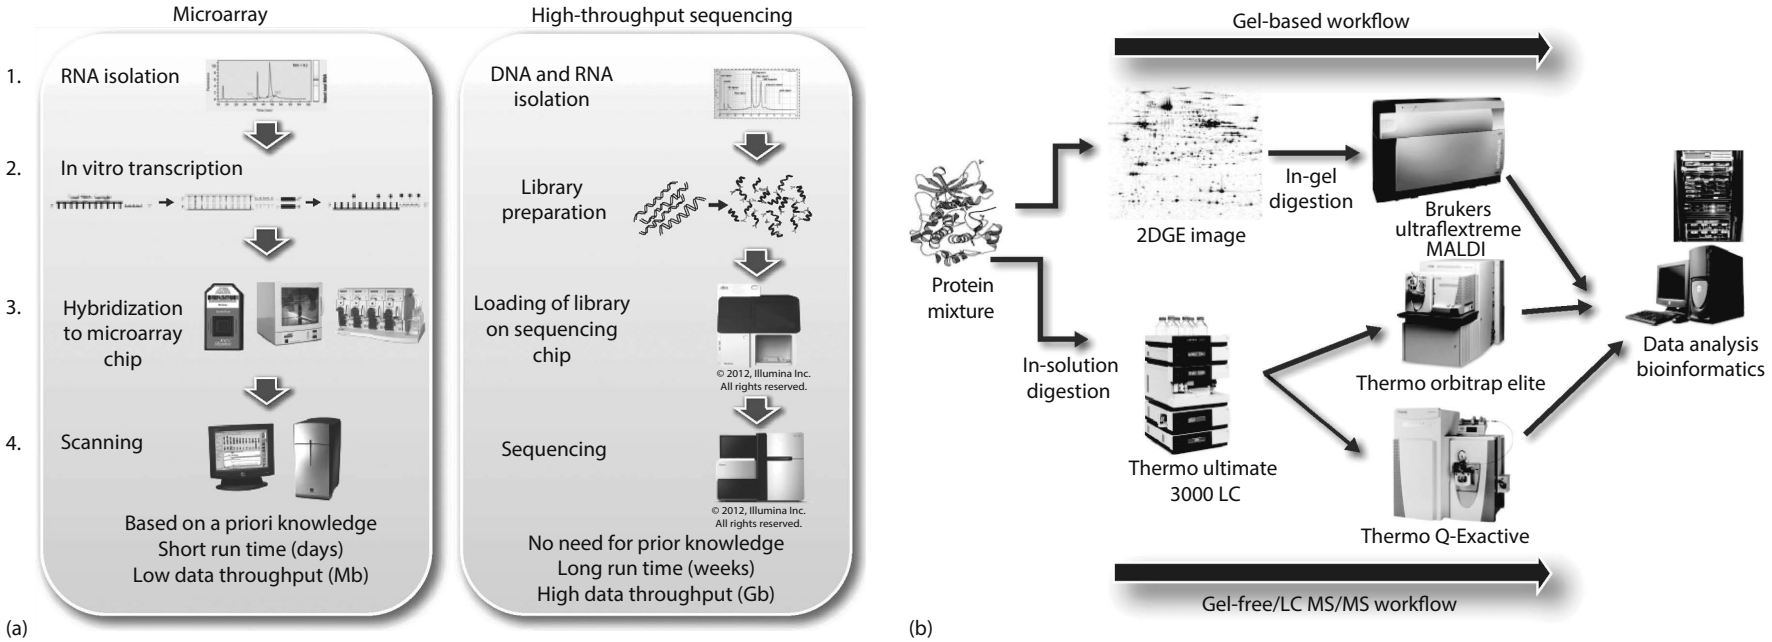

FIGURE 7.3 The technology platforms. (a) Microarray and HT sequencing data generation workflows for nucleic acids-based analysis. (b) Gel-based and gel-free proteomics workflows demonstrated for protein biomarkers identifications.

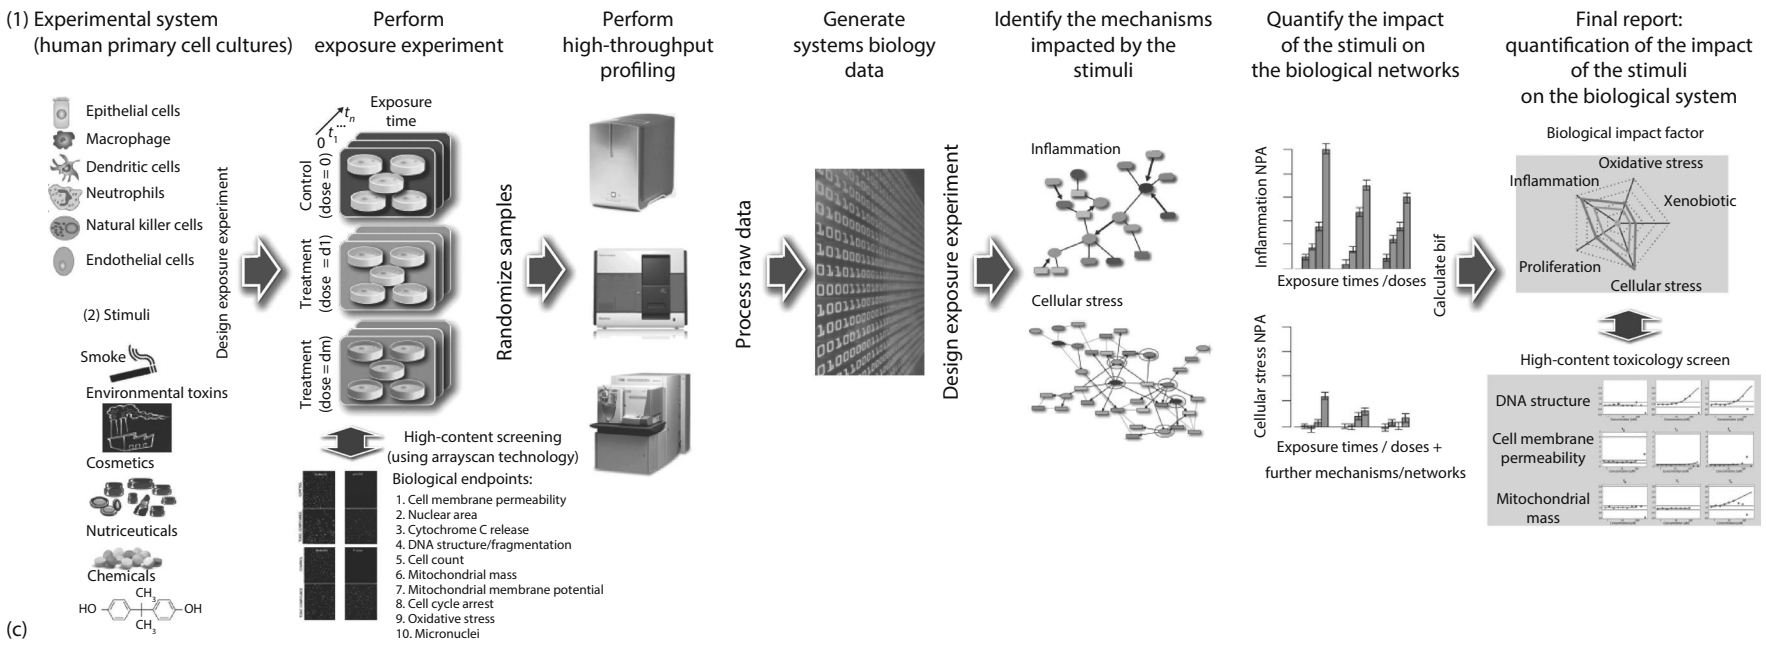

FIGURE 7.3 (continued) The technology platforms. (c) Schema representing the different steps of generating HT measurements in toxicological impact assessment. To test a specific stimulus, the chosen in vitro system is exposed following an experimental plan with defined dose ranges, exposure durations, and relevant time points to capture the different endpoints of interest. Obtained HT profiles are then analyzed to identify and quantify the time- and dose-dependent biological perturbations triggered by the exposure. These results can be further complemented with additional measurements (e.g., cell membrane permeability, cell count, cytochrome *c* release) using HCS technique.

to be similar.[92] Figure 7.3c illustrates the gel-free LC MS/MS workflow for biomarker discovery.

The major advantages of the gel-free approach are the following: (1) lower sample volumes can be analyzed, (2) less abundant proteins can be detected, (3) HT in sample analysis and data generations is possible, and (4) different classes of proteins can be analyzed. The major disadvantage is that posttranslational modifications (PTMs) of proteins and peptides cannot be detected or analyzed.[91]

Peptidomic Approaches

Peptides are generated by more than 400 proteases acting at different intracellular sites and, upon secretion, in the extracellular domain. Peptidomics complements proteomics in shedding light on the protein degradation processes, which are often part of disease mechanisms. The advantages of peptidomics are the following: (1) MS instrumentations offer good sensitivity to detect low amounts of peptides present in the samples, (2) peptide approaches can complement gel-based and gel-free approaches for protein biomarkers identifications, and (3) the biological function of individual peptides can be elucidated. The application of peptidomics is however limited by the number of peptides that can be captured, which can lead to an incomplete picture of the peptides involved in the studied biological networks.[93]

Biomarker Quantification Approaches

MS-Based Approaches

As systems biology requires accurate quantifications of a specified set of peptides/proteins across multiple samples, targeted approaches have been developed for biomarker quantification. Selected reaction monitoring (SRM) was developed to reliably deliver precise quantitative data for defined sets of proteins, across multiple samples using the unique properties of MS. SRM measures peptides produced by the enzymatic digestion of the proteome as surrogates to their corresponding proteins.

An SRM-based proteomic experiment starts with the selection of a target list of proteins, based on previous experiments, scientific literature, or prior knowledge. This step is followed by the following: (1) the selection of target peptides (at least 2) that optimally represent the protein, (2) the selection of a set of suitable SRM transitions for each target peptide, (3) the detection of the selected peptide in a sample, (4) the optimization of other SRM assay parameters if some of the peptides cannot be detected, and (5) the application of the assays to the detection and quantification of the proteins/peptides.

The major advantages of the SRM technique are the following: (1) multiplexed as 10s to 100s of protein can be monitored during the same run, (2) absolute and relative quantification is possible, (3) the method is highly reproducible, and (4) the method yields absolute molecular specificity. The limitations of the technique include the following: (1) only a limited number of measurable proteins can be included in the same run (the system is not able to monitor thousands of proteins per run or analysis), and (2) the sensitivity cannot reach the entire proteome space of all organisms (limit of detection is at the attomolar level).[94]

Antibody-Based Approaches

Enzyme-linked immunosorbent assay (ELISA) is one of the oldest antibody-based measurement platforms used to detect and quantify target proteins in a sample. Performing an ELISA involves at least one antibody with specificity for a particular antigen. The sample with an unknown amount of antigen is immobilized on a solid support either nonspecifically or specifically (via capture by another antibody specific to the same antigen, in a *sandwich* ELISA). After the antigen is immobilized, the detection antibody is added, forming a complex with the antigen. The detection antibody can be covalently linked to an enzyme or can itself be detected by a secondary antibody that is linked to an enzyme through bioconjugation. Between each step, the plate is typically washed with a mild detergent solution to remove any proteins or antibodies that are not specifically bound. After the final wash step, the plate is developed by adding an enzymatic substrate to produce a visible signal, which indicates the quantity of antigen in the sample.[94] While this is a very robust and well-established method, it does not allow for HT analysis and multiplexing. Two more recent approaches address these needs.

Reverse protein array (RPA) technology (for instance, proposed by Zeptosens) represents an example of a key measurement platform for systems biology-based risk assessment. RPA is an HT technology that allows the systematic analysis of up to 192 different lysates on a ZeptoCHIP, which currently can be probed with 200 antibodies validated by Zeptosens. The method has the sensitivity to detect posttranslational modifications such as phosphorylation. Using this technology, it has been shown, for example, that cancer progression is associated with increased phosphorylation of Akt, suppression of apoptosis pathways, and with decreased phosphorylation of extracellular-signal-regulated kinase (ERK).[96] The RPA data can lead to the expansion and refinement of previously identified disease networks. Phosphorylation changes outside of the networks implicated by systems response profiles (SRPs) from the gene expression data will lead to the expansion and rearrangement of network topologies, potentially elucidating novel biologic processes. Information pertaining to proteomic changes will also enable the dissection of a larger disease network by focusing attention on its modulated subnetworks. For example, while transcriptomic evidence may not clearly distinguish the effects of different epidermal growth factor (EGF)-family receptors, phosphoproteomic measurements of the receptors and their substrates can potentially identify specific control networks upstream of the observed gene expression changes. A major advantage of the technique is the ability to multiplex measurements and thereby facilitate the HT analysis of samples. A limitation of the technique is that each antibody must be thoroughly validated by western blot to make sure there is no cross-reactivity with other

proteins that may influence the measurement. Furthermore, lot-to-lot variations of the antibodies can also result in inaccurate measurements.[97]

Luminex is another antibody-based measurement platform, which allows multiplexing and exhibits high sensitivity and specificity. The principle behind this technology is the ability to measure multiple analytes simultaneously in a single-reaction well. With Luminex technology, molecular reactions take place on the surface of microsphere sets that have been color-coded using a blend of two dyes with different fluorescent intensities. The advanced optics captures the color signals, which are processed digitally in real time to quantify each reaction.[98]

Lipidomics

Defects in lipid homeostasis contribute to several pathophysiological conditions ranging from metabolic diseases to cancer. Lipids exert important functions as essential constituents of all cellular membranes, as bioactive compounds, and as energy stores. Current MS-based lipidomic techniques are capable of detecting and quantifying hundreds of molecular lipid species in various tissue and biofluid samples in an HT manner. Reproducible and precise results from large sample sets can be obtained by automated sample preparation and lipid extraction in a 96-well format.[99] The total lipid extracts can then be analyzed by multiple MS platforms, by either detecting the lipid extracts directly by shotgun lipidomics[100] or after LC-based separation[101] to detect low abundant lipid species. Optimally, using both approaches, hundreds of molecular lipids from several lipid classes of high and low abundance can be relatively quickly identified and accurately quantified from small sample volumes.

Profound changes in the cellular/tissue lipid composition occur in response to intracellular and environmental factors. Lipidomics is thus a powerful tool to monitor the overall status of cells and tissues and, due to its sensitivity, has great potential to identify and detect potential biomarkers indicating toxicity at an early stage. As an example, oxidized lipids, including eicosanoids, have been suggested to be major mediators of toxicity,[102] which can be readily measured in biofluids. Indeed, urinary leukotrienes have been associated with certain forms of cancer, including prostate and kidney cancer.[103,104] Lipids from necrotic tissues have also been demonstrated to be present in urine.[105] Moreover, urinary leukotriene T4 levels correlate with lung function in asthmatic patients.[106,107] It is highly likely that lipidomics will yield useful biomarkers indicating dysfunctionality or toxicity of other organs, such as the liver.

The utility of lipidomics as a tool to establish the MOA for active substances is highlighted in the case of Ximelagatran, an oral direct thrombin inhibitor, which was withdrawn from the market. The drug showed a potential risk of severe liver injury following its chronic use despite the fact that no signs of liver toxicity were observed in clinical trials. In a recent study, increased membrane fluidity induced by ximelagatran in hepatocytes was associated with a decreased phosphatidylcholine/phosphatidylethanolamine molar ratio after short exposure to the drug,[108] providing a potential explanation and measure for liver toxicity. It is important to note that these effects were observed after short exposure using low compound concentrations, underlining the sensitivity of the method. Moreover, the observed membrane fluidity effects were selective to primary human hepatocytes, with no similar effect seen in hepatocytes derived from rat. Since rat and human hepatocytes have strikingly different lipid contents, this may indicate that the response depends on the composition of the target membrane.

High-Content Screening

Molecular changes should be as often as possible correlated with cellular- or tissue-level changes. While histopathology is the main approach to gather such data, phenotypic assessment of cells in culture can be performed using high-content screening (HCS) methods.[109] This technique is based on the visual detection of a panel of functional biomarkers providing precise temporal, spatial, and contextual information that defines the biological status of the cells. The capture of the different biomarkers can be done either on fixed cells labeled with multiplexed, fluorescence-based reagents after stimulation/treatment or directly on living cells during the time of the exposure. The panel of parameters that could be simultaneously measured is broad and could reflect changes in the level of expression of cellular products (e.g., phosphorylated protein) and/or changes in the morphology (visual appearance) of the cell. Readouts can be adapted to the type of cells used in the assay and address key cellular mechanisms such as (1) apoptosis and autophagy, (2) cell proliferation, (3) cell viability, (4) DNA damage, (5) mitochondrial health, (6) mitotic index, (7) cytotoxicity and oxidative stress, (8) nascent protein synthesis, and (9) phospholipidosis and steatosis. Toxicity in cells exposed to stimuli is often the result of a combination of multiple mechanisms that are more likely to be captured with a panel of parameters easily and simultaneously obtained through an HCS approach. In addition, these mechanistic endpoints can be detected below the point of high cytotoxicity allowing the analysis of additional HT measurements such as transcriptomic or proteomic profiling (Figure 7.3c). HCS technology can be performed using automated digital microscopy (e.g., ArrayScan) or flow cytometry, both combined with computational systems required for data analysis and storage. There is a large choice of HCS instruments on the market, and all of them offer the ability to capture, store, and analyze images automatically. Some HCS instruments also integrate into large robotic cell/medium handling platforms that allow a rapid and unbiased assessment of a large number of experiments. This technology is thus largely used for explorative screening, in particular, in the systematic phenotypic assessment of in vitro models during or following exposure with different doses of stimuli. Figure 7.3c illustrates how HCS

can be combined with transcriptomic analysis and thereby not only enhance the identification of categories of stimuli with similar properties associated with a particular cellular event but also help to uncover toxicological mechanisms. Furthermore, the systems biology approach will establish the biological relevance of the pathways identified, and with the NPA scoring algorithm (discussed in the following), one will be able to determine their quantitative contribution to the phenotypic changes.[110]

Data and Information Management

Next-generation technologies for biological systems research challenge the researchers with unprecedented amounts of data. Consequently, the management and processing approaches of the accumulated data are continuously being developed. A plethora of open-source software solutions (e.g., caArray,[111] MARS,[112] BASE,[113] EMMA,[114] MIMAS,[115,116] TM[117]) are readily available for the storage and management of raw and preprocessed data, as well as experimental information. It is to be noted that an essential component of a systems biology data integration platform is the capability to capture detailed information describing the experiment, thus enabling reproducibility and proper analysis and interpretation. The Institute of Medicine (IOM) specified experimental transparency as one of the major requirements for the *Evolution of Translational Omics*.[118] A satisfactory solution has been provided for microarray data by the minimum information about microarray experiment (MIAME)-based[119] exchange format MAGE-TAB,[120] which has become the standard for datasets deposited in public microarray databases such as ArrayExpress[121] or Gene Expression Omnibus (GEO).[122] A similar standard exists for proteomics experiments, namely, the minimum information about a proteomics experiment (MIAPE).[123]

A large component of MAGE-TAB is, aside from the data model, the ability to control terminology by employing ontologies. An ontology is a formal representation of knowledge within a domain and typically consists of classes, the properties of those classes, and relationships between them. Due to their ability to account for semantic differences in terminologies, ontologies provide a common terminology over a domain that is necessary to enable interoperability and ensure formalization of the community view. The scientific community extensively uses ontologies including (1) the experimental factor ontology supporting research activities across the in silico, in vitro, and in vivo exposure domain,[124] (2) the National Cancer Institute (NCI) Thesaurus developed in collaboration with FDA where more than 10,000 FDA terms and codes were integrated,[125] and (3) the environmental exposure ontology that aims to link exposure science to diverse environmental health disciplines, including toxicology, epidemiology, disease surveillance, and epigenetics.[126]

An assessment of ontology development initiatives with a focus on their use in predictive toxicology has shown their suitability for the twenty-first-century mechanistic-based toxicology that supports the 3Rs principle.[127] CCNet's ToxWiz ontology[128] proves suitable for application to toxicology investigations. OpenTox[129] provides a semantic web framework that can be utilized to integrate various ontologies into software applications and linked resources. OpenTox supports the creation and curation of OpenToxipedia, a community-based predictive toxicology knowledge resource.[130]

Considering these primarily independent ontology development initiatives, there is a need for a broader international effort to coordinate activities and to ultimately provide the community with a globally accepted and useful open-source toxicology ontology, much like that demonstrated by the Gene Ontology.[131]

The advent of computational biology workflow management systems (e.g., Galaxy,[132–134] GenePattern,[135] and Taverna[136]) provides interoperative workflows, facilitates a reproducible data analysis process, and simplifies the exchange of methodologies. CaArray and caGrid[137] from the National Cancer Institute Biomedical Informatics Grid (NCI caBIG®) are prominent examples of a systems biology data integration environment that includes knowledge management and workflow systems. The infrastructure allows integration with commercial data analysis and biological pathway inferencing systems as well as advanced programming interface (API) that are highly flexible and allow efficient access. Data mining capabilities can be efficiently provided by BioMart,[138] an open-source biological query framework.

ArrayTrack,[139] an integrative solution for data management, analysis, and interpretation of pharmacogenomic and toxicogenomic studies is proposed by the FDA. ArrayTrack may also be used to facilitate FDA genomic data submissions.[140]

Improving the reproducibility of microarray experiments has been a focal point of the community for several years as illustrated by initiatives such as the Microarray Quality Control Phase I (MAQC-I) project.[141,142] Technological progress in the field of bioanalytics has also led to fairly robust protocols with experimental scientists having to ensure best laboratory practices at every step. Insufficient control over quality introduces variability in the data and is detrimental to the signal-to-noise ratio.

CALCULATE SYSTEMS RESPONSE PROFILES

Experimental Workflow

Figure 7.4 shows a typical workflow for a study to measure gene expression in an in vitro or in vivo experiment. The statistical design associated with the execution of the experiment is a crucial component to assess the experimental error by handling variation, eliminate any systematic bias, and account for extraneous confounding variables linked to the technology used, the extraction/isolation steps, and others.

It is particularly important to randomize the sample grouping during the intermediate steps of organ dissection

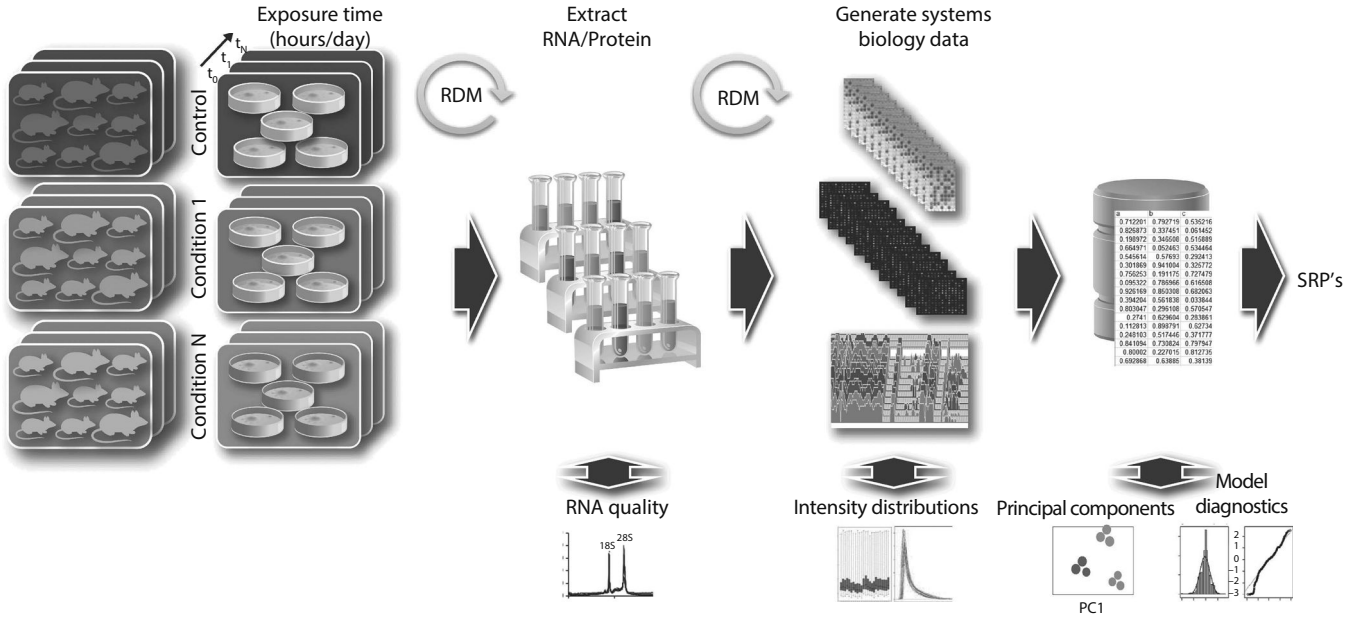

FIGURE 7.4 The workflow for computing SRPs for an experiment conducted in vitro or in vivo. The molecular species of interest are isolated from samples derived from an experiment conducted in vivo or in vitro with appropriate dose–time exposure regimen and several biological replicas. The systems biology data is generated and used for the calculation of the SRPs. Each step involves sample randomization (RDM) to avoid batch effects and QCs for each biological replicate.

and RNA extraction to avoid batch effects that can mask the actual treatment-induced signals.[143] When measuring gene expression with widespread DNA microarrays, single-channel technology (such as Affymetrix GeneChip®) circumvents the additional complications incurred by having to account for both channels when using dual-channel arrays. Finally, as indicated on the bottom of Figure 7.4, each biological sample must be controlled for quality. Once the experiment has been successfully completed, and all QCs deemed satisfactory, the generated data are ready for input into the next stage of the process where calculations of the SRPs are made.

From Experimental Data to Systems Response Profiles

The quality-controlled measurements generated by omics technologies constitute an SRP for each exposure in a given experimental system. The SRP expresses the degree to which each individual molecular entity is changed as a consequence of the exposure to the stimulus and is the result of rigorous QCs and statistical analysis as described earlier; the effects of interest are solely guided by the treatment design. In this way, different data types (transcriptomics for messenger RNAs and microRNAs, proteomics/phosphoproteomics, lipidomics, etc.) can be integrated and coanalyzed to provide the most accurate possible quantitative representation of the biology. Several processing steps are necessary in computational systems biology ranging from the raw data normalization, the design of the appropriate statistical models, to the acquisition of rich experimental meta-information in a standardized format. The following section discusses various aspects of the SRP computational workflow.

The experimental studies used to generate the data are assumed to be optimized for quality and relevance, with all measuring devices adjusted and validated according to manufacturers' instructions. The goal of the processing workflow is twofold. First, it transforms the input data (*raw data*) into the appropriate SRPs, accompanied by measures of their statistical significance. Second, it computes quality metrics at the various processing stages, in order to confirm the appropriateness of both data and applied transformation methods. Figure 7.4 gives a schematic view of the workflow. Its components are explained in the following paragraphs.

Raw data normalization: The input raw data contain intensity measurements performed directly on the images of the array (*probe level* for Affymetrix GeneChip®). As such, they do not yet provide the intensity values of actual genes (*probe set level* for Affymetrix GeneChip®). In addition, between-array comparisons might contain array-specific biases due to independent measurements of each array. The goal of raw data normalization is to generate mRNA-based intensities that can be compared across all arrays in the experiment. An efficient method to achieve this task is the robust multichip average (RMA) algorithm, based on the reasonable assumption that probe intensity distributions are identical across all arrays.[144] The first step consists of background subtraction where the effects of parasite hybridization on the microarray probes are reduced. An improvement of this step has led to the GeneChip® robust multichip average (GCRMA) algorithm, which explicitly takes into account the nucleotide content of the probes in the evaluation of the background contributions.[145] The next step is the actual normalization based on the quantile normalization algorithm that exploits

the earlier assumption of identical probe intensity distributions across all arrays. The last step is the summarization, which computes an estimate of the actual mRNA abundance based on the intensities of the multiple matching probes and uses the median polish algorithm.[146]

SRP calculation: Normalized data constitutes the input of the actual SRP calculation, together with the experimental design details that contain the relationships between all measured samples. For the sake of clarity, the simplest case of a pairwise comparison between one group of *treated* samples and one equally sized group of *control* samples is considered (see section *Design Experiment for Data Production*). More complex designs are common, and they can be handled in a similar manner to the pairwise comparison, as long as linear models are used appropriately in the calculation.[147] In a pairwise comparison context, the SRP measures the effect of the applied treatment at the gene level by comparing against a group of control samples that did not undergo the treatment. Specifically for a given gene, the response consists of the difference between mean log2 intensities of the group of treated samples and mean log2 intensities of the group of control samples. This quantity is usually referred to as differential gene expression. The associated statistical significance is provided by the *t*-statistic taking into account the expression variance within each group. In the case of microarray experiments, the number of samples is often small, so that variances are difficult to be estimated accurately. A solution to this problem is provided by the moderated *t*-statistic, which improves the specificity of the SRP statistical significance by using empirical Bayes methods[147] or the significance analysis of microarrays (SAM).[148] The SRP specificity is further increased by applying multiple testing corrections, for example, the Benjamini–Hochberg correction,[149] to account for the fact that thousands of genes are measured on the microarray. At the end of the process, the SRP is characterized by the differential expression values of all genes measured on the microarray, complemented by their statistical significance, usually in terms of *P*-values or false discovery rates (FDR).

QCs: The data quality is controlled at three different levels, and specific features are examined in each case. At the raw data level, several within-array metrics are computed that allow the detection of possible hybridization in homogeneities on the microarray as well as sensitivity issues in the intensity range.[150] Normalized data are used to perform between-array comparisons and thereby identify possible outliers. Multivariate approaches like PCA are used to verify the consistency of the data, typically by showing that in reduced-dimensional space, the samples belonging to the same treatment group are closer to one another than to samples from different treatment groups. Normalized data can also be corrected for possible (nonconfounding) experimental batch effects, if this information is available.[151] This operation reduces the fraction of data variance that is not due to the test treatment and therefore increases the statistical significance of the downstream-calculated SRPs. Several algorithms have been developed for performing this task such as the combat method that uses an empirical Bayes approach. At the SRP level, the assumptions underlying the statistical models used in calculations must be, at least partly, verified. This information is derived from the so-called diagnostics plots. For the *t*-test described earlier, MA-plots, volcano plots, QQ-plots, histograms of the residuals, and so on are used to visualize this information.

Several studies have shown that the reproducibility of published gene expression studies is not 100%.[152] In order to ensure optimal acceptance by both the scientific community and regulatory authorities, particular attention must be given to aspects of the process that can improve reproducibility. These are discussed in the following paragraphs.

Technical standardization: To facilitate a reimplementation of the processing pipeline, it is beneficial to use the free and open-source software, such as Bioconductor,[153] which has become a standard in computational biology. The algorithms described earlier are all available as Bioconductor R packages thereby enabling the full SRP pipeline to be run in the R environment. An additional capability of Bioconductor is its software versioning and archiving policy put in place in the repository,[90] which significantly contributes to the reproducibility of the processing pipeline.

BUILDING OF MOLECULAR NETWORKS AND QUANTIFYING THEIR ACTIVATION

Network Model Basics and Computational Aspects

While classical toxicogenomic studies use differentially regulated gene lists,[154] we are using network models to gain insight into the effects of a given stimulus. This approach provides a more detailed molecular understanding of biological network perturbations by extracting mechanistic information from HT datasets. The networks are built using biological expression language (BEL), a semantic programming language that allows for the representation of biological processes in a computable format.[22] BEL-encoded causal relationships describing the pathways of interest are extracted from the Selventa Knowledgebase,[155] a comprehensive repository containing over 1.5 million nodes (biological concepts and entities) and over 7.5 million edges (connections between nodes). The knowledge base is built by manually curating scientific literature and extracting causal molecular relationships from primary publications.

The nodes in the networks are biological entities—protein abundances, mRNA expressions, and protein activities (e.g., kinase or phosphatase activities, transcriptional complex activities)—or processes (e.g., apoptosis). For many nodes, there is also literature-derived and BEL-encoded knowledge about the ability of that node to regulate the expression of particular genes. For example, the cytokine tumor necrosis factor (TNF) may be represented in a network model as increasing the activity of its receptor, TNF-R1. In addition, there is inherent knowledge about the

genes that are regulated by TNF. This knowledge is collected from experiments where the genes whose expression levels change following exposure to TNF. The number of downstream genes can vary from few to several hundred depending on the node. These node–gene expression relationships are exploited by reverse causal reasoning (RCR), an algorithm that operates on molecular profiling data to infer the activity of an upstream node from differentially expressed genes.[155–158] RCR relies on the presence of nodes in the model that are computable for this particular algorithm, in this case, nodes where causal downstream knowledge about the ability of that node to influence the expression of a particular gene. Specifically, it relies on two metrics to compute potential upstream causal explanations for changes observed in the data: richness and concordance. Richness is calculated as a *P*-value based on a hypergeometric probability distribution and determines how significant the signal is (e.g., is there a predicted modulation in MAPK13 activity). Concordance is calculated as a *P*-value based on a binomial distribution and determines confidence in the directionality of the prediction (e.g., is the predicted activity of MAPK13 increased or decreased). Generally, predictions are only considered further if they meet criteria for both statistics and then are interrogated for biological plausibility given the context of the experiment under investigation. The BEL framework is an open-source technology for managing, publishing, and using structured life-science knowledge. It can be downloaded from the web (http://www.openbel.org/), along with a corpus of knowledge and tools that enable model investigation (KAM Navigator) or RCR on gene expression data (Whistle).

Model Building

Building network models is a multistep, iterative process shown in Figure 7.5a. The construction of network models starts with the careful selection of model boundaries, that is, the selection of appropriate tissue/cell context and biological processes to be included in the model. This is unlike other common approaches for building pathway or connectivity maps where connections are often represented out of tissue or disease context. Once the boundaries have been defined, the scientific literature is carefully reviewed to extract cause-and-effect relationships that comprise the literature model's nodes and edges (causal relationships between the nodes).[159]

Following the assembly of the literature-based network model scaffold, RCR on molecular profiling data is performed to ensure that the network accurately reflects the biological processes of interest. Multiple datasets are used to verify the network content, ideally from experiments where the experimental exposure perturbs the biological mechanisms captured by the network model under construction. RCR predictions are computed for all nodes with downstream genes in the Selventa Knowledgebase[155] from the differentially expressed genes in a dataset. Any predicted nodes that are not present in the literature model are investigated in detail by a scientist for relevance and mechanistic connection to the biological processes being modeled. Examples of this investigation process include the following interrogations: Determining whether an inferred change in the activity state of a biological mechanism or pathway is consistent with what would be expected in the context of the experiment under investigation and examining whether the inferred mechanism is known to be expressed in the tissue under study. This results in a more comprehensive, integrated model that includes nodes derived from existing literature as well as nodes derived from experimental datasets underscoring the value of combined use of molecular profiling data and prior biological knowledge of cause-and-effect relationships.

In the last steps of the model building, the integrated model is carefully reviewed by subject matter experts edge by edge and amended to include all relevant biology as well as exclude any inaccurate causal relationships and entities from the model. To verify that the model captures the desired biology, parts of the final model are validated with relevant datasets. The nodes that are predicted to change by RCR from the transcriptomic data are mapped to the model and evaluated against any phenotypic observations in the experiment. If the predicted nodes highlight relevant signaling pathways, the model is considered to capture the expected biology by linking the differential gene expression with observed phenotypes. Moreover, any new nodes that do not *fit* the current knowledge can be experimentally verified in the appropriate context to gain new biological insight.

Sometimes, public experimental data from an appropriate experiment are limited. In such cases, a focused experiment can be designed with relevant biological endpoints and systems biology data to validate parts of a network. To validate the cell proliferation network model, we used a well-controlled cell culture experiment where NHBE cells in culture were allowed to reenter the cell cycle after G1-arrest induced by exposure to a small molecule cyclin dependent kinase (CDK)4/6 inhibitor, PD-0332991. While this compound is highly specific for the cell cycle-dependent kinases CDK4 and CDK6, no activity has been found against a panel of 36 additional protein kinases.[159] PD-0332991-mediated inhibition of CDK4 and CDK6 has been shown to specifically reduce the phosphorylation of retinoblastoma (RB1) protein at Ser780/Ser795, thereby inducing an exclusive G1 arrest.[160] The cultures subsequently released from cell cycle arrest provide a systems biology dataset representing the reentry to cell cycle concomitant with a direct cell proliferation measurement in a human lung in vitro system and the means to experimentally validate the computational model. We chose the NHBE cells since they have been frequently used to assess lung epithelium responses, including cell cycle progression under various conditions,[161–164] and can be synchronized in vitro in G0/G1.[163] We confirmed the reentry to cell cycle by labeling of S-phase cells at 2, 4, 6, and 8 h after CDKI washout; an unperturbed proliferating control group receiving

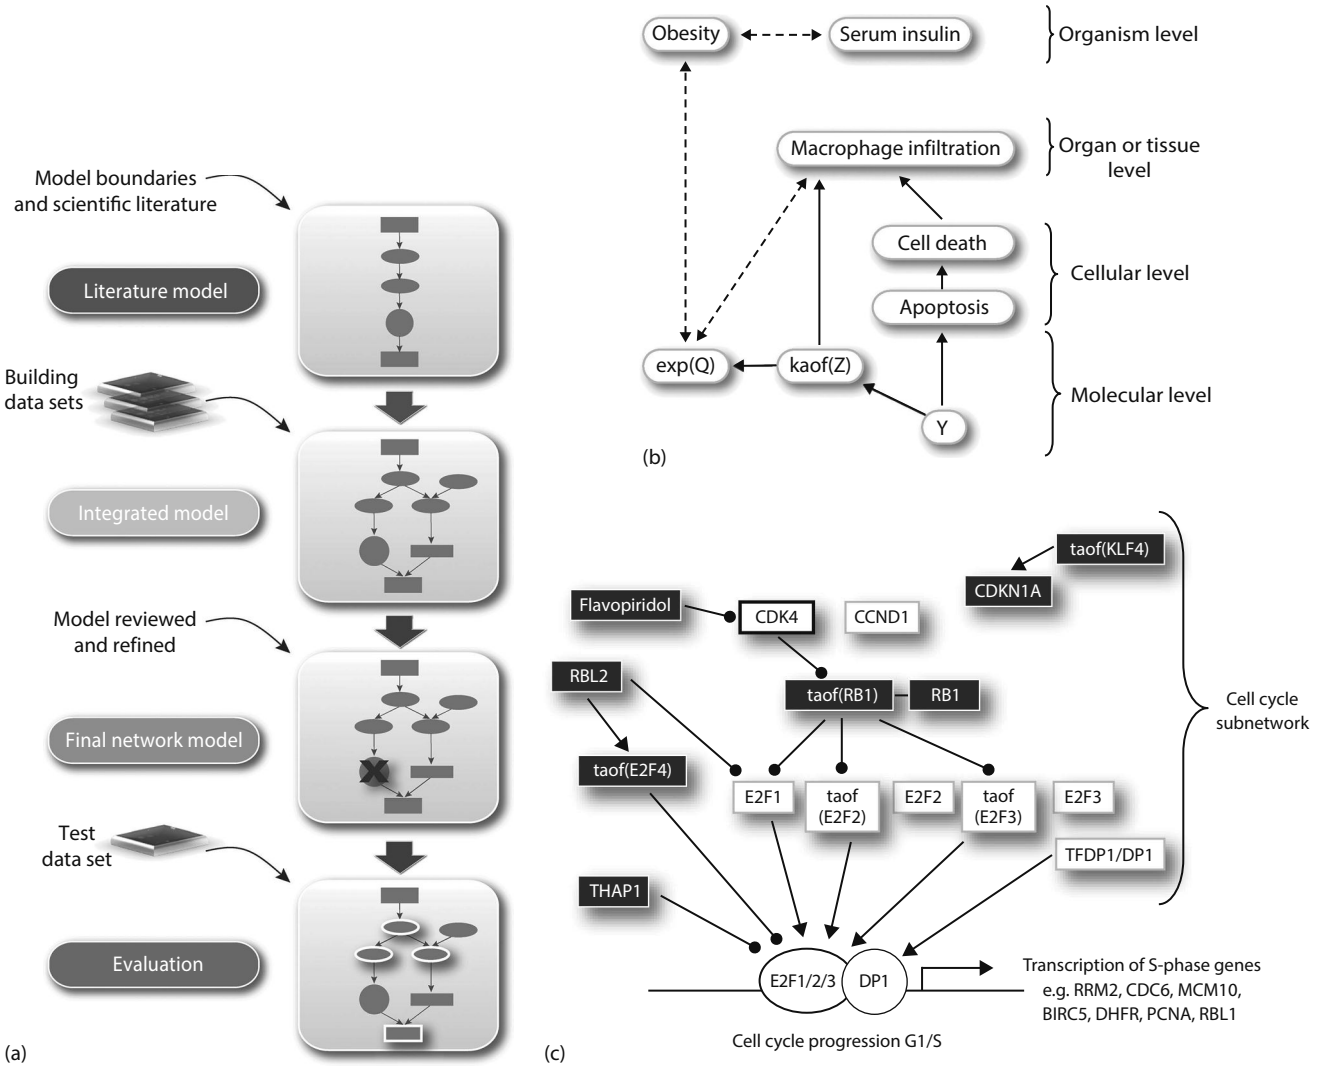

FIGURE 7.5 Model building using the BEL. (a) The network is built in steps starting with the literature analysis and extraction of causal life-science relationships. The integrated model is obtained by enhancing the literature model with molecular profiling data and RCR. The integrated model is carefully reviewed and finally validated with a relevant dataset. The *X* in the second last step indicates the decision to remove some nodes from the model as a result of model review. The highlighted nodes in the last step indicate the nodes that were specifically validated with relevant data. (b) The network model can represent knowledge from molecular, cellular, and organ level to an entire organism. (c) Transcriptomic data and RCR from a tailor-made validation experiment show the relevant pathways that are activated when cells reenter the cell cycle. The light boxes represent the nodes that are predicted increased, and the dark boxes represent the nodes that are downregulated upon removal of the CDK inhibitor.

only growth medium was also included. To validate the cell proliferation network, we applied RCR to the cell proliferation datasets described earlier (E-MTAB-1272). We used the differentially expressed gene list to compute RCR for more than two thousand biological entities, included in the Selventa Knowledgebase.

Within the cell cycle subnetwork, 26 nodes were predicted to be regulated. In agreement with the experimental setup, the node for CDK4 was predicted to be increased upon inhibitor washout. Several connections between the key players were identified as shown in Figure 7.5c. Remarkably, the node highlighting the activity of flavopiridol, a cyclin-dependent kinase inhibitor under clinical development, was also inhibited (Figure 7.5c). This underscores the utility of network models using relevant experimental data in verifying the MOA of active substances. A comprehensive validation of the cell proliferation network has been published along with valuable mechanistic information on proliferative processes in the context of the lung.[165]

Properties of Network Models

The causal network models resulting from the three-step building process described earlier provide many advantages over differentially expressed gene lists. The networks are highly dynamic, they can be modified to specific species and tissue contexts by the definition of appropriate boundaries, and they are easily updated as new knowledge

becomes available. They also capture a wide range of biology that exists in a system outside of mRNAs, including but not limited to genomics, transcriptomics, proteomics, phenotypic or clinical observations, chemicals, lipidomics, methylation states or other modifications (e.g., phosphorylation), and miRNAs. Owing to the preserved topology, the causal relationships within the network can be easily traced to a measurable entity thus providing a link between the upstream node and the SRPs. By mechanistically interpreting the SRPs, the networks provide the basis for the next two steps of the five-step strategy, the NPAs and BIF calculations. In addition to RCR, these are two more examples of analytics that rely on networks built on the computable BEL language.

The application of RCR on transcriptomic data in this way implies a critical divergence from more commonly known pathway techniques such as *Kyoto Encyclopedia of Genes and Genomes* (KEGG)[166] and ingenuity pathway analysis (IPA) for model building.[167] These methods identify differentially expressed genes whose protein product activities act in a pathway of interest, thereby relying on the *forward assumption*, where gene expression changes are only indicative of the abundance of the protein or the predicted activity of the encoded protein. The caveat remains that changes in gene expression do not always correlate with changes in protein activity. Furthermore, in these cases, it is not possible to make any inferences about genes whose biological function is entirely unknown. RCR does not rely on these assumptions and can take into account the multiple states of regulation that may exist for a protein before action due to the fact that BEL can capture the life cycle from mRNA to protein abundance to interactions with other proteins to various activity states.

Current Network Models

To date, we have built six complete biological network models that capture mechanistic detail of various biological processes. The proliferation network focuses on diverse biological areas that lead to the regulation of normal lung cell proliferation.[159] The cell stress network reflects the biology underlying the physiological cellular response to endogenous and exogenous stressors, including oxidative stress, hypoxia, shear stress, endoplasmic reticulum stress, and xenobiotic stress, elicited in response to common pulmonary and cardiovascular stressors.[168] We have also constructed network models that cover inflammatory processes in both pulmonary[169] and cardiovascular tissues as well as a network model for DNA damage response and the four main cellular fates induced by stress.[170] The final network model constructed describes angiogenesis and the processes involved in respiratory tissue remodeling and repair.[171] The main focus of these six networks is on the biological processes that can operate in nondiseased mammalian pulmonary and cardiovascular tissues. The detailed listing of the biological processes included in these six networks is described in Table 7.4. All network models are available for the scientific community through publications in peer-reviewed journals. The network models are provided in extensible graph markup and modeling language (XGMML) format so that they can be visualized and analyzed using freely available open-source network viewing software such as Cytoscape. Providing the network model in a format compatible with open-source access provides both a high degree of scientific transparency about the contents of the network models and provides the scientific research community with a unique set of network models to adapt for their own use.

The networks themselves are not static entities. Their content is based on prior knowledge, whether gained through literature curation or through integration with relevant predictions illuminated by RCR. However, it is necessary to update them as new knowledge becomes available. This relies on updates to the knowledgebase itself, and processes are being put in place to optimize sustainable knowledge augmentation solutions. Manual efforts are viable options, but can be time-consuming and expensive, and therefore assisting or replacing such a process with natural language processing (NLP) is under development. The NLP tools developed toward this end can also be made open source to benefit the BEL community at large.

The networks are also amenable to the investigation of interspecies translatability. Additional analytics have been developed that can interpret omics data based on a priori knowledge in order to facilitate comparison of specific biology across experimental conditions in different species. One of these conditions is the special case where data from an experiment performed in one species can be compared with data from another in order to determine areas of shared and unique biology. The Selventa Knowledgebase captures causal information about mouse, rat, and human relationships. If a causal relationship between two nodes has been captured for one species (e.g., A increases B), and homologs for A and B (e.g., A′ and B′) exist in a second species, then this same relationship is assumed to exist in the second species. In this way, networks that have been developed based largely on relationships describing human biology can be *homologized* in the Selventa platform to either mouse or rat. One main advantage of this property is that an area of biology that may be less comprehensively studied in humans, perhaps for technical or ethical reasons, can still be represented in the network.

We believe that our network approach is well positioned to meet twenty-first-century toxicity-testing needs. To progress, pathway definition, pathway annotation, and a central repository of the annotated pathways are needed. Moreover, new methods for pathway identification need to be established and evaluated. Finally, the pathways need to be continually refined as new knowledge emerges, and a peer-review process will be necessary to enable the scientific community to reliably develop new and updated versions of the pathway biology with emergent knowledge.

Our network building efforts are a good first step toward these goals. By organizing gene lists into a biologically meaningful context, it is more feasible to analyze omics data as well as identify potential toxicity pathways. These networks could provide a consistent way to group stimuli based on their MOA and could become the standard in toxicity testing.

Compute Network Perturbation Amplitudes

Any relevant dataset evaluated against our network models gives a qualitative overview on the biological pathways that are affected by a given stimuli. To enable a quantitative measure of the perturbation of biological networks, we have developed a computational approach that translates gene fold-changes into NPA scores. The NPA has two main components (Figure 7.6):

1. A biological network model describing a biological process or mechanism. As described earlier, the network models are a *cause-and-effect* mechanistic knowledge representation based on all relevant literature and published datasets.
2. An expression dataset resulting from an experiment, whose controlled perturbations are hypothesized to be involved in the biology related to the network.

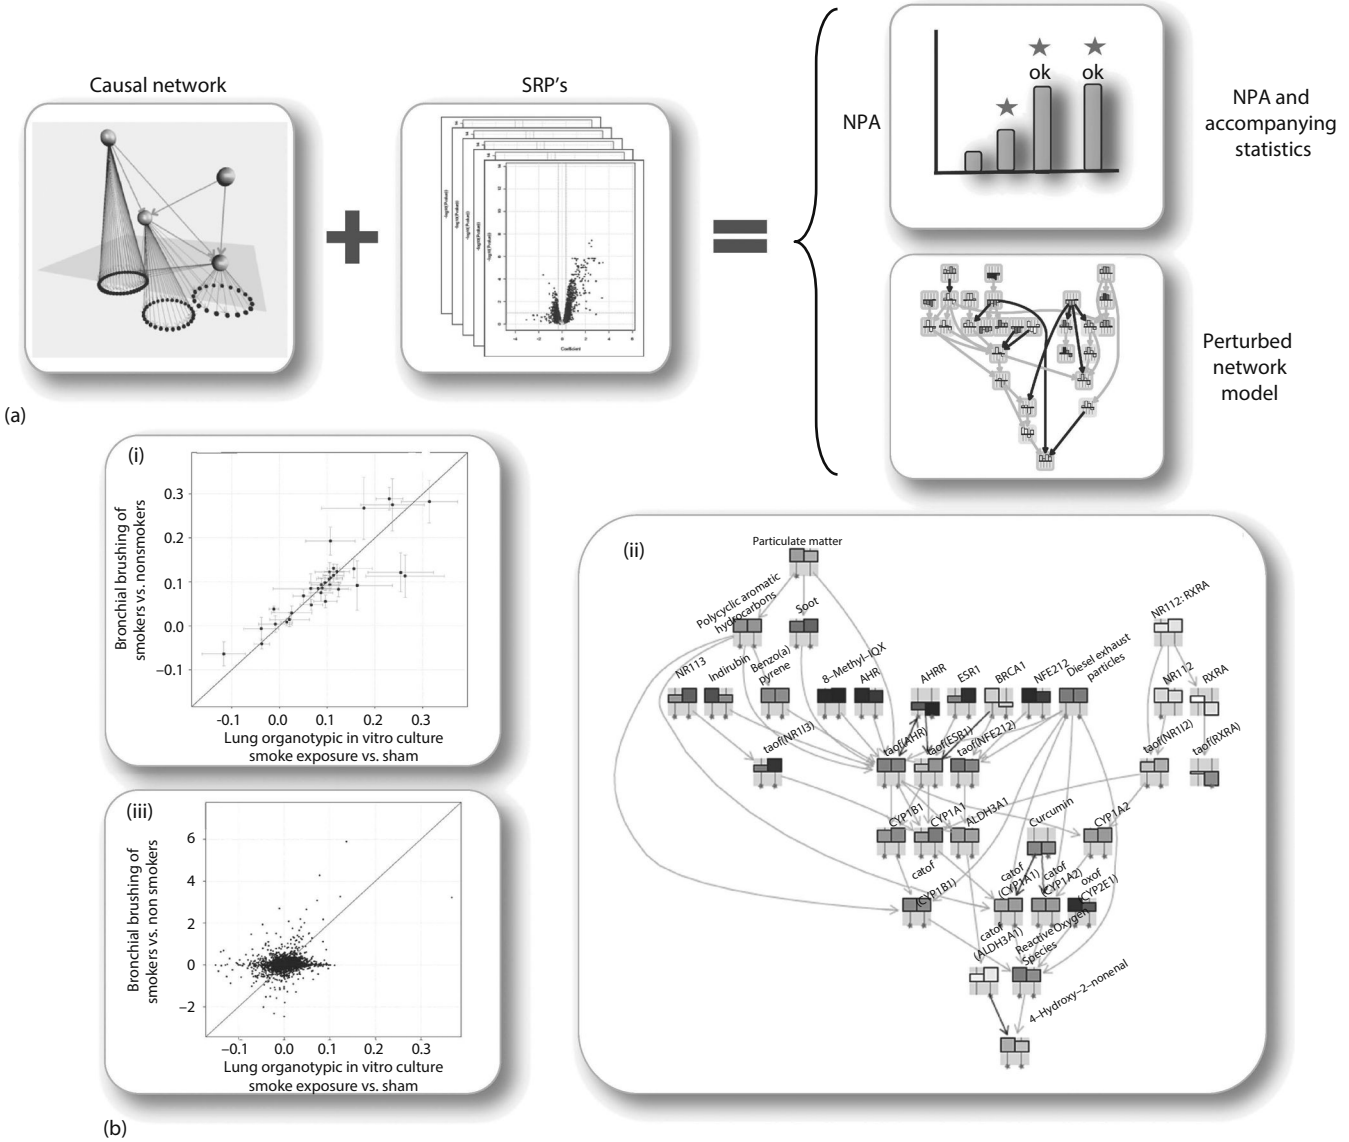

FIGURE 7.6 NPA. (a) The causal networks capture biology in the nodes (big balls) and causal relationships between the nodes. Differential expressions of genes (small black balls) are experimental evidences for the activation of an upstream node. With the use of a network model, the entire SRPs can be mathematically transformed into a small set of numbers, that is, the NPA scores. The NPAs are interpreted with their accompanying statistics. Besides the amplitude itself, backbone differential values will serve as the basis for the interpretation. The light and dark lines indicate positive or negative causal effects within the perturbed network backbone, respectively. (b) Comparison for the whole smoke-exposed and smoke-nonexposed groups in lung organotypic in vitro culture versus bronchial brushing data on the cell stress–xenobiotic response network: (i) NPA backbone differential values together with the 95% confidence intervals; (ii) the same data mapped onto the network backbone; for each node, the left-hand bar represents the perturbation amplitude for smokers as compared to healthy nonsmokers, and the right-hand bar represents the perturbation amplitude for smoke-exposed as compared to control lung organotypic in vitro culture. The intensity of the shading of each bar reflects the absolute value of the backbone differential values. (iii) The gene fold-changes underlying the cell stress–xenobiotic response network.

While RCR has been previously exclusively employed as an exploratory tool for identifying relevant perturbed biology by drawing qualitative mechanistic inferences based on statistical enrichments,[157,172,173] NPA derives a *response profile* at the network level, which then allows a coarse-grained view of the effects of the applied treatment encompassed by the SRPs. Similar to RCR, NPA takes advantage of the measured downstream effects to infer the activity of an upstream node, but also extends this by integrating the topology, the directionality, and the sign of the edges of the network in the computation. This, in turn, can be expressed as a linear combination of the measurable data. As a consequence, the NPA scores are expected to correspond to the resulting changes in the activity of the cellular processes described by the network model.

By this stage in our overall process, the SRPs have been obtained from an appropriately designed experiment, and the application of omics tools has been used to measure gene expression, protein abundance, posttranslational modifications, and lipids. The methodology described hereafter is built on our previously published algorithms.[174] Following the steps depicted in Figure 7.6a, NPA calculation first provides the assessment of the NPAs, and second, enables mechanistic interpretation of the data based on the biology contained in the network model.

Formally: Let $G = (V, E)$ be the complete signed directed graph underlying the biological network. The measurable evidences (the downstream genes) induced by the processes in the model (black nodes in Figure 7.6a) is denoted by V_0. Its complementary, $V \backslash V_0$, is called the backbone of the network model (grey nodes in Figure 7.6a).

The *backbone differential values* are the result of a fitting procedure between the network model and the input gene differential expressions. The more closely the gene differential expressions fit the cause and effects of the network model, the further from zero are the backbone differential values.

Formally: Let $\beta \in l^2(V_0)$ be an SRP for the downstream genes. Assuming that contrasts *propagate* through causal edges according to the signs and direction (linear approximations of the *real* transfer function), one wishes to compute the smoothest function $f \in l^2(V)$ with the boundary condition $f|_{V_0} = \beta$. It leads to the following optimization problem: $\arg\min_{f \in l^2(V)} \Sigma_{x \to y} (f(x) - sign(x \to y) f(y))^2 \cdot w(x \to y)$ such that $f|_{V_0} = \beta$, can be reformulated as

$$\arg\min_{f \in l^2(V)} f^T L f \quad \text{such that} \quad f|_{V_0} = \beta.$$

If $L = diag(d) - (A + A^T)$, where $A_{xy} = \begin{cases} sign(x \to y) \\ w(x, y) \end{cases}$ if $x \to y$, 0 else, if denotes the signed directed Laplacian of the graph and d the node degrees, denoting L_2 in the restriction of L to $l^2(V \backslash V_0) \to l^2(V_0)$ and L_3 to $l^2(V \backslash V_0) \to l^2(V \backslash V_0)$, and differentiating the earlier expression leads to the solution of (*): $f|_{V \backslash V_0} = -L_3^{-1} L_2^T f|_{V_0}$.

Now that values are inferred on the backbone, we define the perturbation amplitude to be the total backbone *energy*:

$$\mathrm{NPA}(G, \beta) \overset{\text{def}}{=} \frac{1}{|\{x \to y\} \quad \text{s.t.} \quad x, y \notin V_0|} \times \sum_{\substack{x \to y \\ \text{s.t.} \quad x, y \notin V_0}} (f(x) + sign(x \to y) f(y))^2.$$

Observe that the NPA score can be rewritten as a quadratic form: $\mathrm{NPA} = f|_{V \backslash V_0}{}^T \, Q f|_{V \backslash V_0}$, where

$$Q = \frac{1}{|\{x \to y\} \quad \text{s.t.} \quad x, y \notin V_0|} \times \left[\left(diag\left(\text{out}|_{l^2(V \backslash V_0)} \right) + diag\left(\text{in}|_{l^2(V \backslash V_0)} \right) - (-A - A^T) \right)|_{l^2(V \backslash V_0)} \right] \in l^2(V \backslash V_0)$$

Confidence intervals can be estimated for $f|_{V \backslash V_0}$ and for the NPA, calling for the central limit theorem, by using the following classical equalities $var(-L_3^{-1} L_2^T g) = (L_3^{-1} L_2^T) \Sigma (L_2 (L_3^{-1})^T)$ and $var(g^T Q g) = 2tr(Q \Sigma Q \Sigma) + 4 \mu^T Q \Sigma Q \mu$; where Σ is the variance covariance matrix of g.

In addition to the confidence intervals accounting for the experimental error (e.g., biological variation between samples in an experimental group), some companion statistics are derived to give a sense of the specificity of the NPA quantity with respect to the biology described in the network. Those additional statistics are vital for the interpretation of an NPA as it is by essence a backward *computation* whereby the experimental data are used to extract an amplitude.

To this end, two permutation tests are derived to assess whether the observed signal is a property inherent to the evidences (genes) or the structure given by the model. The first test is based on reshuffling the gene labels at the low model level (V_0) leading to a first NPA permutation *P*-value (denoted by *O in the figures when <0.05). The second test assesses whether the backbone structure ($V \backslash V_0$) is important for extracting the signal: the edges of the backbone model are randomly permuted, and a second NPA permutation *P*-value (denoted by K* in the figures when <0.05) is derived. The latter describes the importance of the *cause-and-effect* relationships encoded in the backbone of the network while the former is testing if the results are specific to the underlying evidences in the model. The network is considered to be specifically perturbed if both *P*-values are low (typically <0.05). The NPA results must always be interpreted in light of the three companion statistics: the two permutation *P*-values and the confidence interval.

NPA scoring is therefore an integrated approach that combines omics data with a knowledge-driven network model, to provide measurable quantities causally affected

by a targeted biological process. NPA quantifies the activity changes of the biological/toxicological process relative to a nonperturbed control state of the system. By providing a measure of biological network perturbation, together with its description, it allows correlation of molecular events with phenotypes that characterize the network at the cell, tissue, or organ level. While an NPA score, with its accompanying statistics, provides a quantifiable measure of the degree of perturbation of a biological network, the backbone differential values describe how a perturbation propagates through the network topology to further support biological interpretation. This approach differs from Gene Set enrichment analysis, which is based on the enrichment of sets of genes in experimental data and which enables qualitative investigation of experimental data in light of the statistical enrichment of mechanisms represented by each gene set.[175]

To summarize, NPA is a mechanistically driven quantitative measure of the amplitude of perturbation of a network that can enable a quantitative, system-wide understanding of the biological mechanisms leading to diseases or toxic endpoint. Besides being a comparative assessment tool, the NPA can serve to define biologically based dose–responses (toxicity thresholds).

Use case: In order to gain mechanistic insight into the biological effects of acute CS exposure on bronchial epithelial cells, we exposed the lung organotypic in vitro culture to mainstream CS for 7, 14, 21, or 28 min at the air–liquid interface and investigated various biological endpoints (e.g., gene expression and microRNA profiles, matrix metalloproteinase [MMP]-1 release) at multiple postexposure time points (0.5, 2, 4, 24, 48 h). The transcriptomic dataset has been made publically available (E-MTAB-874).

To show the validity of the NPA approach, we have used the aforementioned lung organotypic in vitro culture dataset (E-MTAB-874) and a public dataset of smoker bronchial brushings (GSE7895) to probe the translatability of the network perturbation using a well-defined network model. We and others have shown that the in vitro airway model closely resembles the human situation both morphologically as well as at a molecular level[56,57,176–180]. Coherence between smoking-induced responses, such as the antioxidant response, has been observed between human smoker bronchial epithelium samples and in vitro organotypic cultures. When scoring a network model that captures the signaling involved in *xenobiotic metabolism*, the perturbation amplitude is very similar for several nodes (Figure 7.6bi). The xenobiotic stress response recapitulated by the network is coherent in both systems (Figure 7.6bii), whereas the gene by gene comparison does not compare in an evident manner (Figure 7.6biii).

By extracting quantitative information from differentially expressed lists of genes using the networks, we have successfully reproduced the response of two systems to one stimulus.

Biological Impact Factor Calculations

The final step of the strategy is the computation of a BIF. As indicated by its name, the BIF aims to quantify the biological impact resulting from the exposure of a biological system to one or several stimuli; it represents a holistic score that describes the systems-wide effect of all the processes captured in the underlying network models and their associated NPA scores. The attributed BIF values for stimuli can then be quantitatively compared based on a high-level view of their biological effects. Since it aggregates NPA scores that have themselves already filtered a large fraction of the noise initially contained in the SRPs,[174] the BIF is expected to produce results with increased robustness against technical and biological sources of variability.

In Figure 7.7, the BIF is represented as a starplot in which the multiple axes contain the NPA scores computed for each of the considered biological network models. Computing the surface of the polygon formed by the NPA scores obtained for a given SRP constitutes an intuitive BIF algorithm. Similarly, the fundamental idea behind the BIF is to use the amplitudes of the perturbations induced by the exposure in an appropriate set of biological network models as the input of a simple scoring scheme, which provides a quantitative measure of their global effect. From this point of view, the BIF algorithm is first and foremost intended to detect and display trends in its input dataset. As a consequence, the a priori selection of networks to be included in the BIF calculation, while it must be biologically sound, does not constitute its most critical aspect, since only the significantly perturbed ones will contribute to the BIF results. Ideally, even if the chosen networks do not exhaustively cover the underlying biology, they will still capture a significant portion of the systems response due to the strategy put in place in Step 3.

Having computed the NPA scores for the selected biological network models (Step 4), the relative importance of each network model must be determined. While the BIF deduced from the radar chart in Figure 7.7 weights every axis equally, other choices are possible. Network preference based on a priori qualitative knowledge is not easily translatable into objective and reproducible weights. Data-driven weighting schemes, such as multivariate dimension reduction methods, may be more appropriate.[181] The final step of the BIF calculation consists of aggregating the weighted NPA scores. As illustrated by the surface-based BIF from the radar chart in Figure 7.7, a simple sum of the weighted NPA scores is not necessarily the most meaningful solution. Methods based on more advanced geometric considerations may be more appropriate and is the approach used for the use cases. The aggregation process is also expected to determine the contribution of nodes belonging simultaneously to several network models, such as the highly connected nuclear factor (NF)-κB transcription factor. Additional methods are being developed to avoid overweighting these contributions.

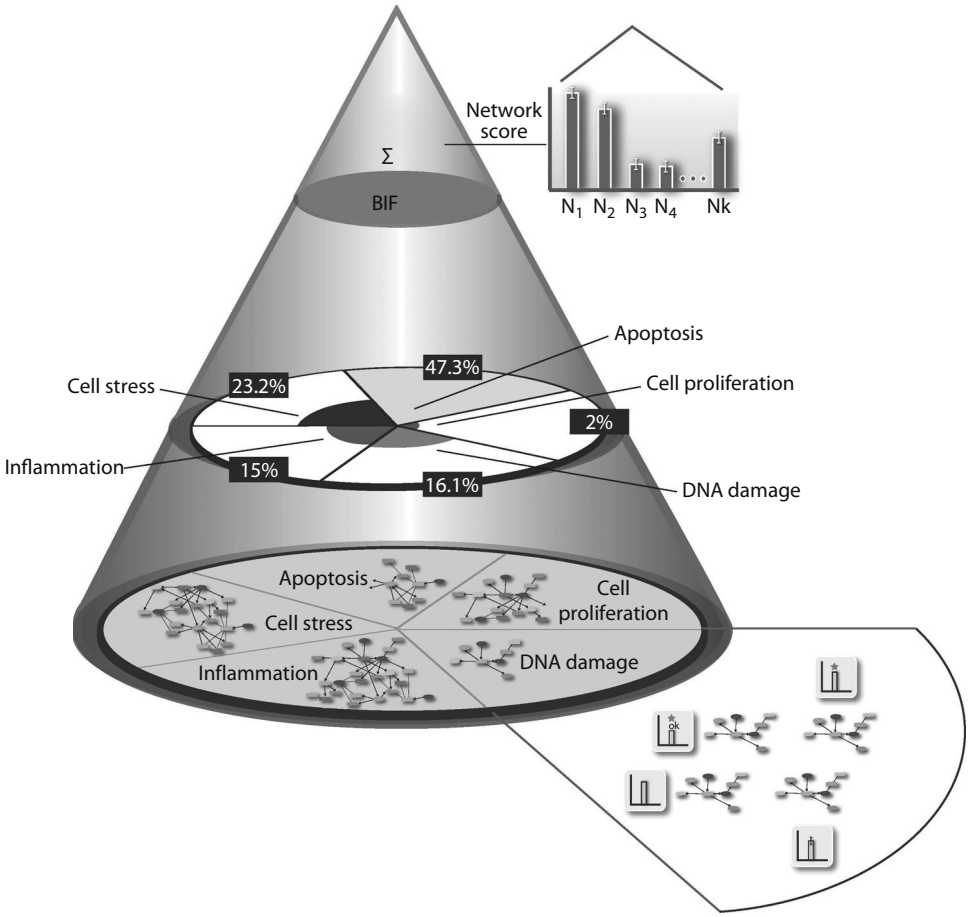

FIGURE 7.7 Calculation of the BIF. The bottom level of the BIF cone illustrates the networks and their individual perturbation amplitudes. The middle level contains a starplot showing the contribution of the mechanisms to the overall BIF (BIF at the top of the cone).

In summary, we have established a well-defined framework (Figure 7.7) that enables transparent information agglomeration such that entire SRPs can be mathematically transformed into a limited set of numbers (NPA scores and then a BIF value). If the validity requirements of the four steps are met, the BIF has the potential to provide a simple but scientifically sound measure of the biological impact of a stimulus on a system, thus serving as a biology-based dose–response model.

Although this aspect has not yet been extensively tested for the BIF, the MAQC-II study has clearly shown that results based on biomarkers involving multiple genes are much less sensitive to the variances inherent in the underlying technologies.[182]

USE CASES FOR A SYSTEMS TOXICOLOGY APPROACH

28-Day Rat OECD Plus Cigarette Smoke Inhalation

We have performed a 28-day rat inhalation study according to the OECD TG 412 by exposing rats for 28 days to filtered air (sham) or to a low, medium, or high concentration of mainstream CS from the reference cigarette 3R4F (n = 10 rats/group). Following CS inhalation, rats mainly develop irritative stress-related adaptive changes in the upper airways and signs of inflammation in the lung,[183] a common disease mechanism related to the pathogenesis of COPD and lung cancer. In order to investigate disease-relevant molecular perturbations at the sites of the histopathological changes, we added five more rats per exposure group.

We measured the free lung cells in bronchoalveolar lavage fluid (BALF) by flow cytometry and measured inflammatory mediators by multianalyte profiling (MAP). We sectioned the respiratory tract at defined sites for histopathology. We separated the respiratory epithelium of main bronchus and lung parenchyma from the left lung by laser capture microdissection. The RNA isolated from the main bronchus, lung parenchyma, and the respiratory nasal epithelium (RNE) was processed and analyzed for gene expression on whole genome Affymetrix microarrays (GeneChip® Rat Genome 230 2.0 Array).

Reflecting an inflammatory response, there was a strong increase in neutrophil and macrophage counts as well as an increased level of inflammatory mediators in BALF

(Figure 7.8a). Histopathological evaluation revealed the usual dose-dependent adaptive changes in the airways as well as inflammatory responses in lung. In Figure 7.8a, the scoring for alveolar macrophages in lung parenchyma and one representative image are presented. Based on gene expression data, the NPA and BIF calculation returned major perturbations of regulatory networks related to inflammation, cell stress, cell proliferation, and senescence (Figure 7.8b). Corresponding to the histological changes, the stress-related responses were more pronounced in the RNE and bronchi, while the inflammatory responses were more pronounced in the lung parenchyma.[183] These global BIF scores for the agglomerated network models can be broken down into NPA scores for the individual subnetworks. As an example, the NPA scores for three subnetworks of the *inflammatory network* (Figure 7.8c) are shown, which relate to the histopathological findings of increased numbers of alveolar macrophages and macrophage nests in the lung parenchyma, as well as to increased levels of inflammatory mediators in BALF (Figure 7.8a). NPA scores for *epithelial proinflammatory signaling*, *macrophage activation*, and *neutrophil response* networks were significantly increased for the lung parenchyma, while they were not activated in the bronchial epithelial tissue where it is known that this kind of inflammatory reaction does not usually occur as a response to CS inhalation (Figure 7.8c).

This example demonstrates that our modular network approach with the *inflammatory network* model can resolve cell-type-specific signaling contributions from transcriptomics data on the level of inflammatory subprocesses. The observed histopathological endpoints correlated with the degree of perturbation of their associated biological networks in vivo, thus providing support for the usefulness of this approach as a powerful tool to investigate disease mechanisms in vivo and to develop a systems biology-based risk assessment.

91-Day Rat Formaldehyde Inhalation

We have also applied our quantitative approach to a public dataset from an experiment exposing rats to several doses (ranging from 0.7 to 15 ppm) and durations of formaldehyde (FA) gas in vivo (GEO accession number GSE23179).[184] FA is a known carcinogen and irritant that causes dose-dependent tumor formation in rat nasal epithelium upon long-term exposure.[185] The transcriptomic data from the nasal epithelium after 5 days and 4 and 13 weeks following exposure was accompanied by multiple measured phenotypic endpoints, such as cell proliferation, necrosis, and inflammation, processes that are all well represented in our biological networks. Based on the list of differentially expressed genes, the original paper concluded that FA exposure of 6 ppm or greater induces changes in cell cycle, DNA repair, and apoptosis, as well as ErbB-, EGFR-, Wnt-, TGF-b-, hedgehog-, and notch-signaling-related pathways.[184]

Even though our networks represent biological processes in the lung context, it is reasonable to assume that the nasal epithelium behaves similarly as the pulmonary epithelium in response to stimuli.[186] This allowed us to assess the biological impact of FA exposure on rat nasal epithelium across multiple biological processes in both a dose- and time-dependent manner. To calculate the BIF for FA-induced perturbation, we used network models that best reflect the phenotypic observations in FA inhalation studies. These included the entire *cell stress*, *proliferation*, and *inflammatory* networks as well as the networks that reflect DNA damage and cellular fates after prolonged stress, that is, *necroptosis*, *autophagy*, *apoptosis*, and *senescence* (see Table 7.4). The overall BIF values for each treatment and time point are shown in Figure 7.9a. There is a monotonic trend with exposure concentration for all time points, and the highest perturbation is achieved in nasal epithelium from rats treated with 15 ppm FA for 5 days (1 week time point) compared with air-exposed rats. The decrease in BIF with increasing exposure duration obviously reflects an overall adaptation of the tissue responses to the repeated exposure. Remarkably, this overall BIF score can be correlated with future tumor incidence resulting from FA exposure. Figure 7.9b shows the tumorigenicity rate in the rate nasal tissue measured in a study conducted by Monticello et al.[187] The dosing procedure was identical to that in the dataset we have used for BIF calculations.[184] Similar to the threshold dose for tumorigenicity, 10 ppm FA has shown elevated BIF at all time points measured, linking the BIF scores for FA exposure to tumorigenesis rates in rat nasal epithelial tissue. Figure 7.9c starplots show the different network-level BIFs for the high-dose group. The most acute effects are on the inflammatory processes, which is a known consequence of necrotic cell death.[188] Necrosis is one of the measured biological endpoints in the nasal epithelium of the exposed animals[184] and a known effect of FA (157).[189] By 13 weeks, perturbation of *DNA damage* and *senescence* networks showed an increased contribution to the overall BIF as compared to the other networks studied. FA exposure is a known carcinogen and inducer of dose-dependent increases in DNA–protein cross-links, in both in vitro and in vivo contexts.[190,191] While there is only very limited information on FA effects on senescence in the relevant context, some evidence points to p53 activation by FA leading to apoptosis or senescence that may be dependent on the cell type.[192] Moreover, FA induces global hypomethylation in cultured lung cells,[193] a phenomenon that has been observed in cells undergoing premature, as well as replicative, senescence.[194] The perturbation of the *proliferation* network is also evident upon FA exposure throughout the time points, consistent with the increased proliferation observed in the nasal epithelium; its contribution to the overall BIF increases toward more chronic exposure.[184] We have further analyzed more specific biological processes within the selected networks. The NPAs for the individual processes analyzed are shown in Figure 7.9d. Several dose

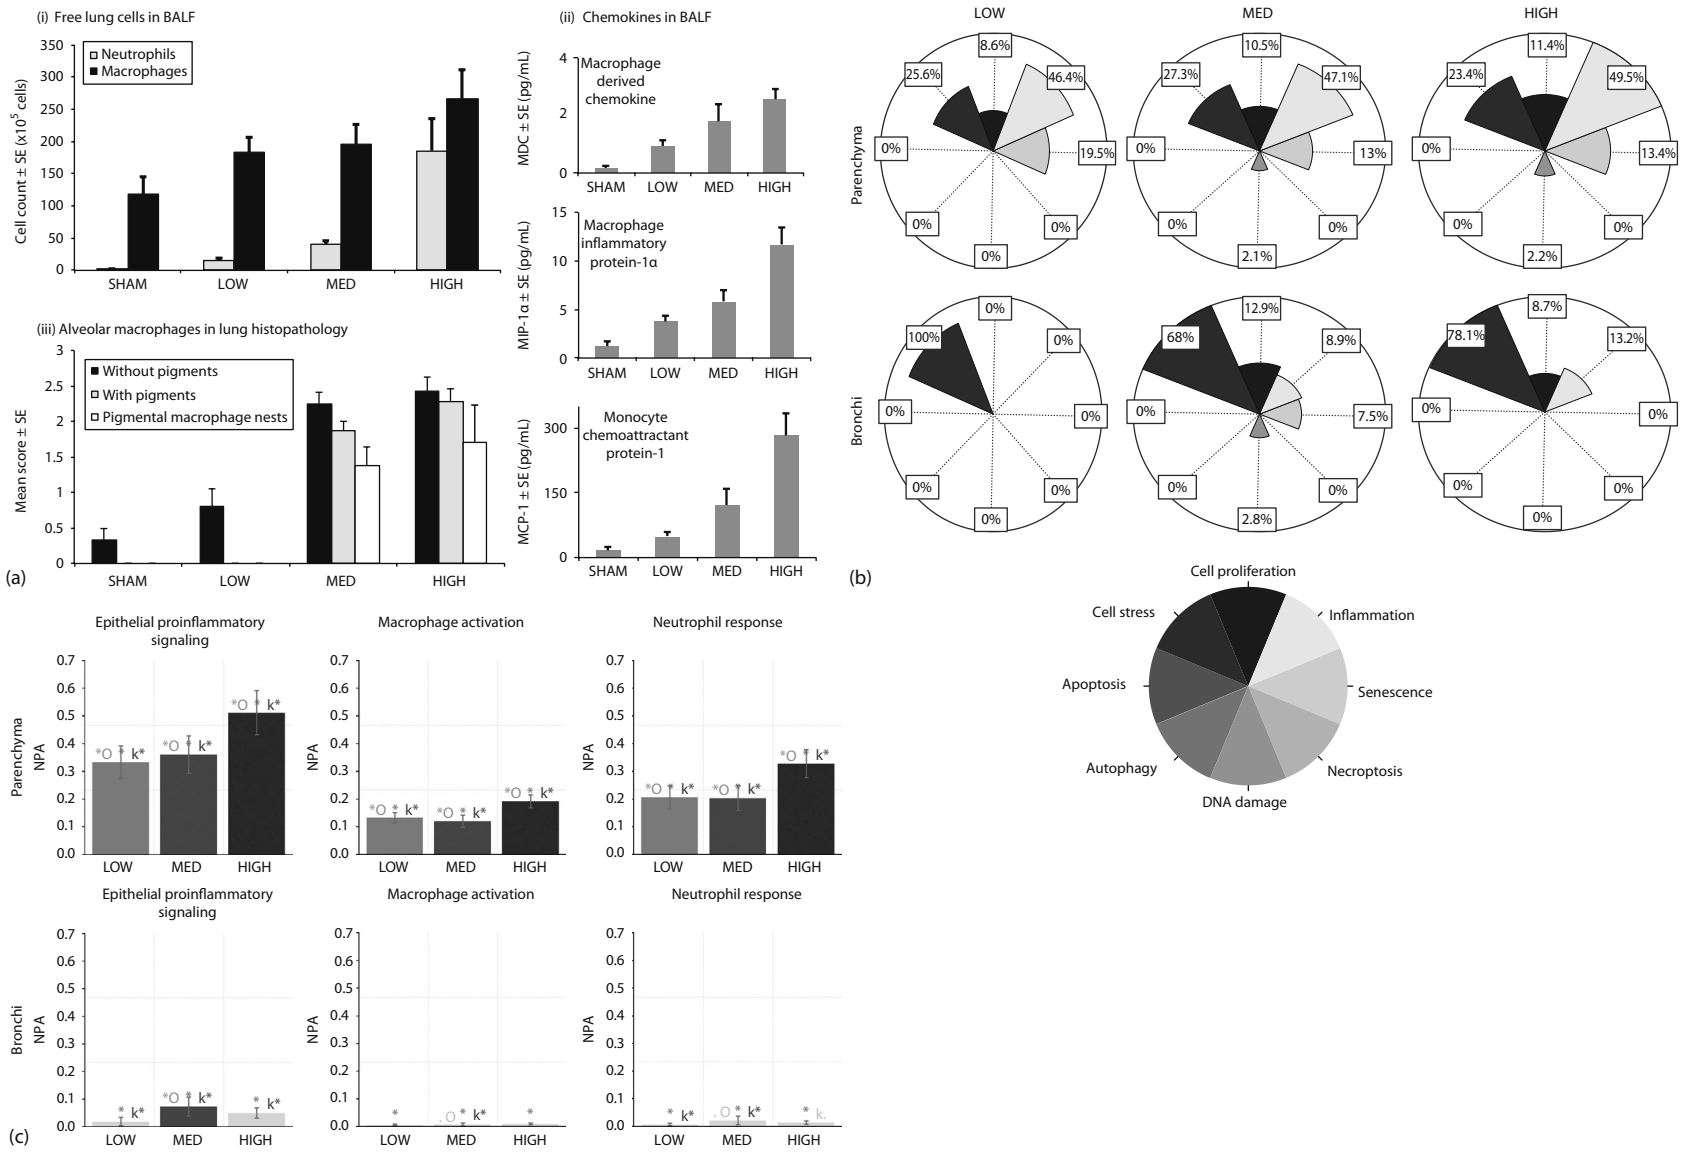

FIGURE 7.8 The 28-day rat CS inhalation study using an OECD Plus design. (a) Inflammatory measurements (i) differential cell count of free lung cells (neutrophils and macrophages) in BALF, (ii) measurement of BALF chemokines, (iii) histopathological findings in lung parenchyma given as mean score of macrophages. (b) Starplots for the smoke increasing dose (LOW, MED, HIGH) groups in parenchyma and bronchi, showing the different BIF at network level, weighted as a function of their contribution to the overall impact factor. The latter is shown in percentages. This shows that inflammation is the most important impacting process in parenchyma, whereas stress is clearly the dominant aspect for the impact of exposure to CS. (c) Quantification of the biological perturbations observed in the *inflammatory* network using NPA scoring method. Three subnetworks (*epithelial proinflammatory*, *macrophage activation* and *neutrophil response*) are shown from parenchyma and bronchi tissues.

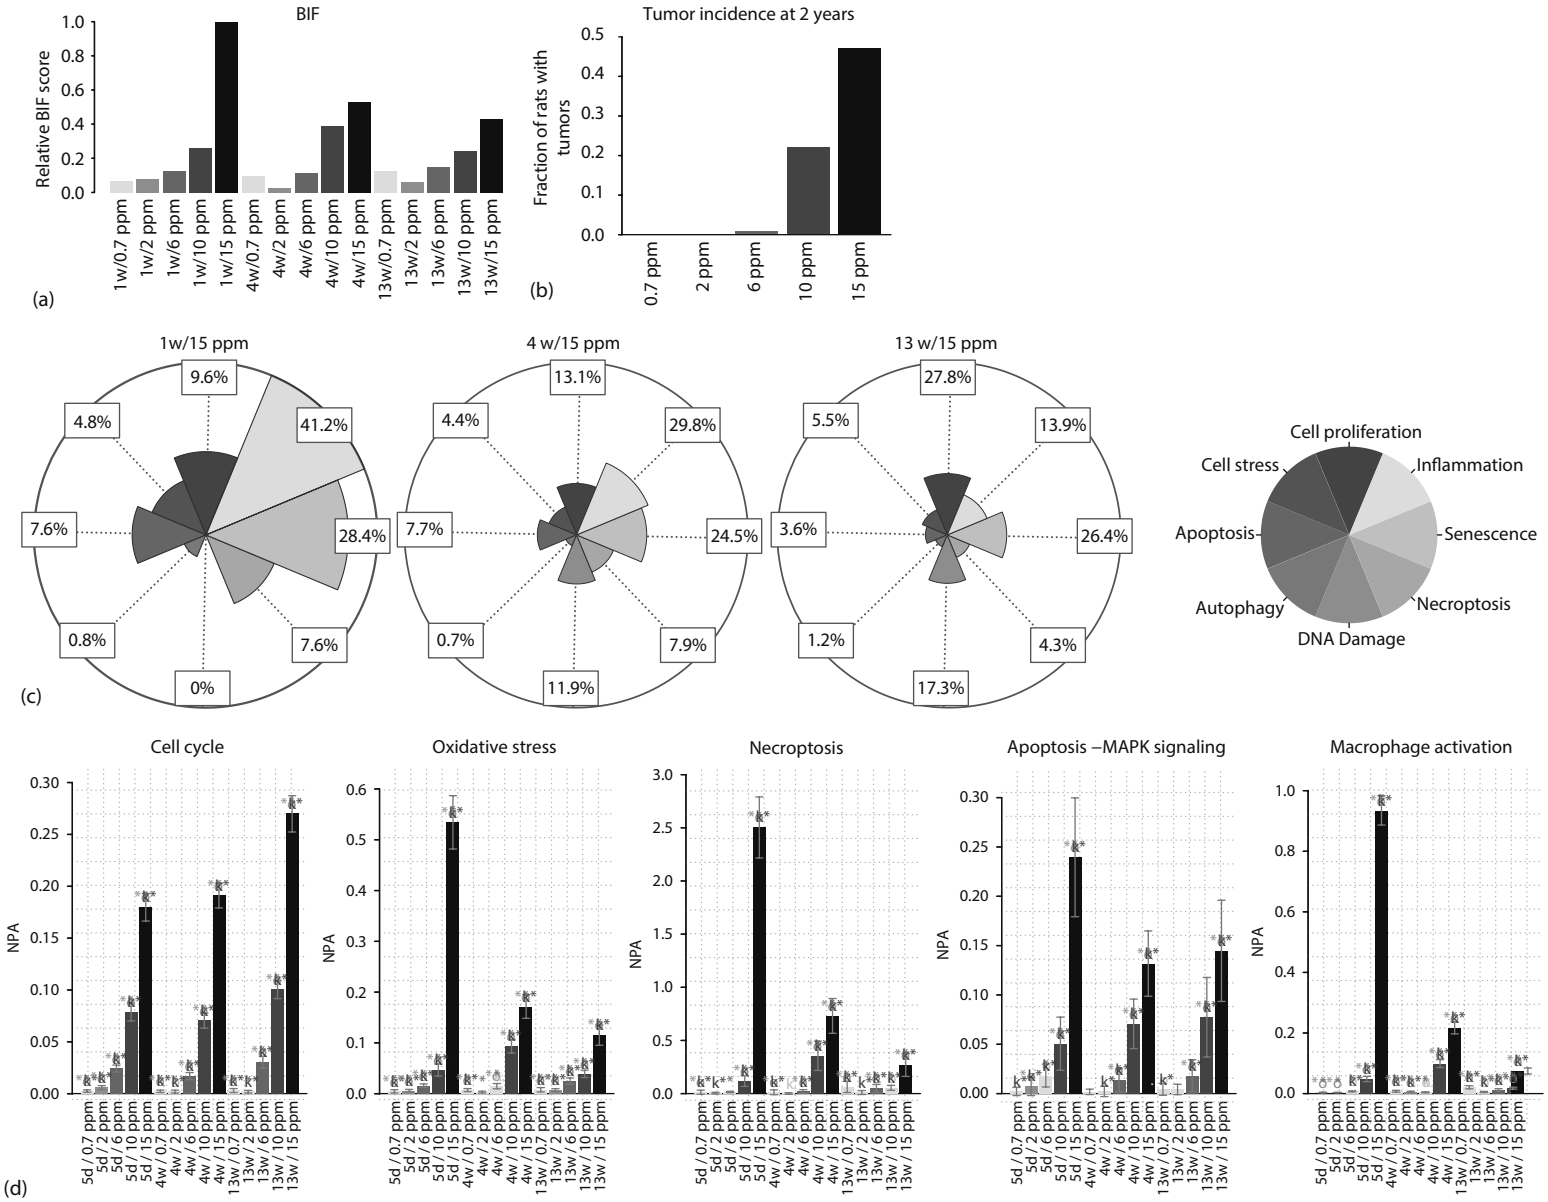

FIGURE 7.9 BIF for rat nasal epithelium exposed to FA. (a) Barplot showing the BIF values relative to the maximum response group (5 days/15 ppm). (b) The tumor incidence at 2 years is reported as the fraction of rats with squamous cell carcinoma in the nasal epithelium. These measurements were taken from a study with an identical dosing procedure as the one in A. (c) Starplots for the high-dose groups, showing the different network-level BIFs, weighted as a function of their contribution to the overall impact factor (shown in percentages). (d) Subnetwork NPA with companion statistics.

versus time response shapes are observed, for example, the perturbation amplitude on the *cell cycle* network is increased, whereas a decrease is seen on *oxidative stress* and *necroptosis* over time.

As shown by the earlier two use cases, our methodology not only identifies the biological processes that are perturbed following exposure to a stimulus, but it can also add a quantitative measure to these perturbations.

The most direct application of the BIF to toxicity testing is the explicit comparison between different stimuli. The BIF scores provide quantitative measures of the impact caused by each stimulus, and this allows the true ranking of the stimuli based on their capacity to perturb biological processes, that is, their toxicokinetic potency. This relative approach is also useful in situations where one of the stimuli is well characterized in terms of perturbed biological networks and long-term risk, while the others are less well studied. In this case, the BIF provides an explicit way to group the stimuli based on the pathways they perturb (and the magnitude of the perturbation) and consequently, to establish the MOA for the less well-characterized stimuli.

BIF can also be calibrated with a quantitative measure of health impact, when a disease-related phenotype is available alongside the measured SRPs as shown by the earlier rat FA exposure use case. If the calibration is done in a robust manner, it opens up broader perspectives in the context of personalized health and safety assessment. Even in the absence of an explicit disease phenotype, if the mechanistic characterization of early biological effect is strongly indicative of the long-term disease outcome, for example, increased cellular proliferation preceding the appearance of precancerous lesions, a BIF can be amenable to calibration and thus be used to encompass information relevant to disease risk. From this perspective, the perturbations of the biological networks are expected to collectively serve as prospective biomarkers for disease risk, similar to compound metabolites detected in body fluids.[195,196] In light of the recognized limited utility of epidemiologic studies to link short-term effects with long-term diseases, BIF can be used to calculate potential long-term risk by quantifying the short-term perturbation caused by stimuli, such as drugs, diets, or environmental conditions.

As emphasized throughout this chapter, since the BIF is supported by mechanistic information contained in all the underlying networks, it can be viewed as a *quantitative mechanistic metabiomarker* of the effects associated with exposure to test stimuli. The methodology enables the knowledge-driven paradigm for risk assessment—as set forward by the European Commission for toxicity testing.[2,4,197,198]

IMPROVER

With the unprecedented amounts of data accompanying various HT technologies, new computational approaches are being developed to facilitate robust analysis and interpretation of these large datasets. Questions arise as to how we can best manage the uncertainties inherent in the application of systems biology information to safety testing. Specifically, how can one ensure the validity of systems biology-based approaches and the resulting information?

With a goal to maintain scrutiny in data analysis and interpretation, we have recently proposed a systems biology verification process and a methodology for verifying the output of research processes in industry.[199,200] The industrial methodology for process verification in research (IMPROVER) decomposes a research workflow into building blocks that represent small pieces of a complex research program. The methodology further aims to identify the building blocks that are not accurate or robust (Figure 7.10). The core idea is that every building block can be verified by a challenge; some internally and some using the *wisdom of crowds*. An example of an internal challenge might be to ensure a sufficiently low noise level by comparing measurements with reference dataset of known quality or to verify that the datasets upon which the toxicity pathways are based on are carefully designed using appropriate dose/exposure levels and that comparisons within the experimental groups including controls are valid. In the external challenge, the question may be solved by external participants, who develop classification methods using public training data and then predict against an unpublished and hidden gold standard. The concurrent realization of the intellectual power that can be harnessed through community collaboration has led to the emergence of crowdsourcing models such as CASP,[201] BioCreative,[202,203] CAPRI,[204] and DREAM.[205–208] The approach has many obvious advantages over the self-assessment of methods. More importantly, it gathers and focuses the community around an important and relevant scientific problem and allows the comparison of the performance of different methods used to solve it. Additional value is added through the discovery of complementary methods to solve a problem, recognizing that the combination of solutions often outperforms the best performing single method.[209] At its best, crowdsourcing could allow the establishment of a state-of-the-art technology in the field and thus improve the quality of an industrial research program. The first IMPROVER challenge, the diagnostic signature challenge was launched and completed in 2012, and the challenge outcome has been shared at a dedicated conference as well as being published in proceedings.[210]

Similar challenges could be built around toxicity testing to find and verify stimulus-specific signatures and MOA for biologically active substances, which show a concordant temporal and dose–response relationship. Developing a community of researchers with similar interests in the twenty-first-century toxicology will foster faster advances to assess and verify the validity of the systems biology-based results (e.g., networks) than are possible with disjointed efforts. By using independent approaches and methods, it is possible to uncover the processes, where the output (biological

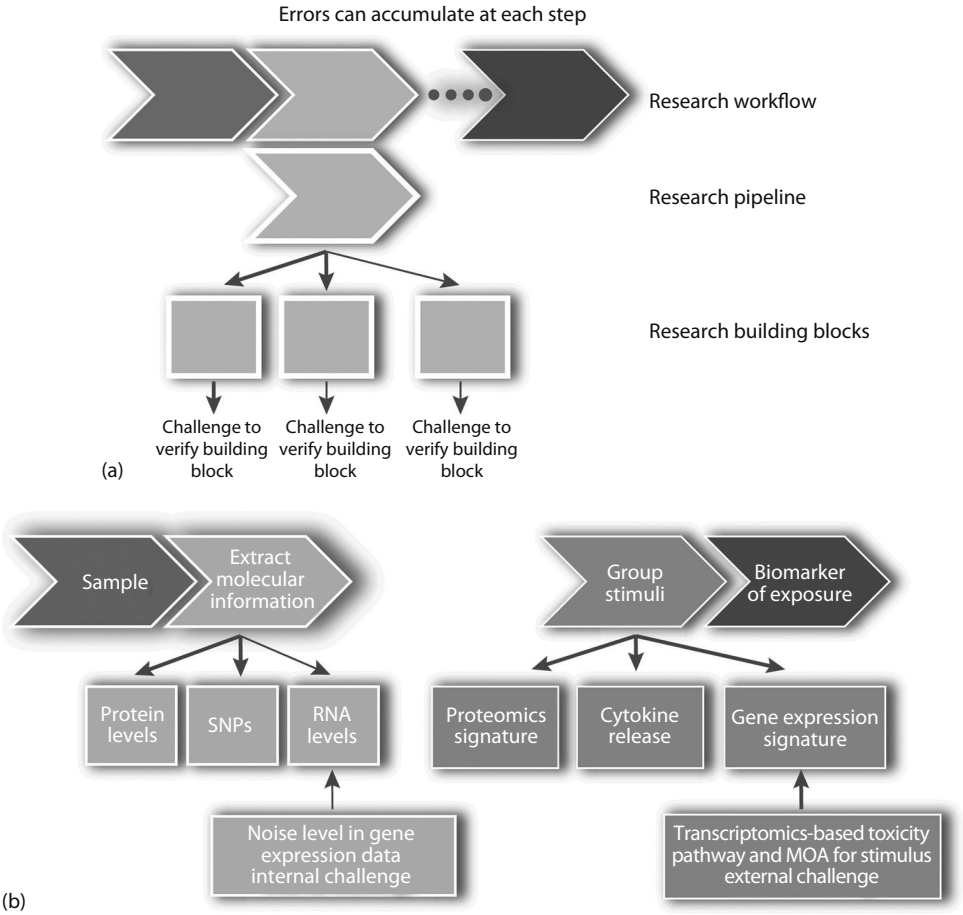

FIGURE 7.10 The basic principles of IMPROVER. (a) The methodology decomposes a research workflow into building blocks that can each be verified by a challenge. The challenge can be internal, within an organization, or external, where the larger scientific community is engaged to verify the robustness of a crucial step in a workflow. (b) A concrete example of the concept to verify the MOA and toxicity pathways for a given stimulus using transcriptomics data.

plausibility) points toward a coherent and complete set of relevant results. This set of results can be further used to assess the safety and biological impact of a substance or a treatment modality on a particular test system. Additionally, because the crowdsourcing approach directly addresses the issue of consistency of findings, which is important for the acceptance of omics approaches in toxicology, success stories will be an important measure of progress as well as critical to maintaining engagement and enthusiasm within the community.

CONCLUSION

Our five-step strategy described earlier tightly integrates experimental and computational approaches in a systems biology pipeline that allows the tandem analysis of biological network perturbations in the context of traditional toxicology data. Network- and mechanism-based impact assessment uses reverse-engineering principles to infer the activity states of signaling mechanisms from observed changes in gene expression. This allows for the determination of common mechanisms that are perturbed even if the underlying differentially regulated genes are not the same. This enables the causal analysis of the components and interactions that are important in a complex system, and thus increases our understanding of the essential features of a complex system. Moreover, the mechanism-based species translation aspects that the new approaches allow to be tackled are of immense potential value. Indeed, they have the potential to increase the predictive value of animal model systems and, more importantly, provide a solid foundation for the development of the 3Rs principle in toxicity assessment.[127]

Clearly, in addition to the biological network models and algorithms, an intelligent experimental design, state-of-the-art technology, and a well-defined workflow are necessary to accomplish the various aims of the five-step strategy. In combination, they build a robust methodology to identify toxicity pathways and MOA for stimuli that have the potential to induce adverse health effects in humans and provide a quantitative mechanistic framework for comparative product testing.

While the twenty-first-century toxicology paradigm shift is occurring, toxicologists and regulators need to closely follow the development of the approaches and the tools that will

be involved in the transformation toward the new era in safety assessment. However, care should be taken not only to evaluate the new methods against traditional toxicology; in addition the new methods should be used to assess how decisions may be supported by new versus traditional data. Evidence is steadily accumulating that the integration of systems biology data, along with conventional histopathology and clinical chemistry, can allow for better and more informed decision-making than traditional safety assessment alone. The focus should not be on measuring large numbers of endpoints, but rather on understanding these data. As such, systems biology could be positioned at the center of these efforts in the future.

To address these challenges, international participation and explicit quality assessments are important to establish common guidelines that can be enforced to reach the goals set by Tox-21c. It is our view that the robustness and reliability of new toxicity testing pipelines can be achieved with the help of systems biology verification methodologies, such as the IMPROVER.

The approaches and technologies outlined in this chapter may eventually also be applied in the field of ecotoxicology and ecological risk assessment where omics methodologies are starting to emerge to characterize molecular and cellular consequences of stressor exposure.[211,212]

Taking a *systems* approach to human biology that relies on mechanisms and pathways has inherent value, contributing both to improved toxicity testing and to the fundamental molecular elucidation of human disease. The *Holy Grail* of biologically based dose–response modeling has been sought for some time. It is believed that systems biology will underpin significant progress toward this lofty goal.

ATTRIBUTION STATEMENT

Selventa and Philip Morris International (PMI) authors performed the building of the six molecular networks together, and codeveloped the initial algorithm to develop the NPAs. The algorithm to score networks based on inferred values of backbone nodes computed using values of downstream gene expression data supported by O+K statistics was developed by Florian Martin (PMI).

PMI performed the 28-day OECD Plus cigarette smoke inhalation study[213] as well as the lung organotypic in vitro culture experiment (E-MTAB-1842 [ArrayExpress] and GSE50254 [GEO]).

ACKNOWLEDGMENTS

The authors would like to thank ZORA LIPIDOMICS for their insights in the utility of lipidomics in toxicity testing as well as Dr. Anthony Tricker for his review.

QUESTIONS

7.1 Which international initiatives work on validation of alternative methods to replace in vivo toxicology testing?
7.2 What are some of the questions that a well-designed exposure experiment is expected to answer?
7.3 What is the most important recent technological development for the genomics of common disease?
7.4 What is an ontology and what purpose does it serve?
7.5 What is a systems response profile?
7.6 How are NPAs computed?
7.7 How can the BIF be used to rank different stimuli?
7.8 How can crowdsourcing help to verify a research pipeline?

KEYWORDS

Systems toxicology, Biological impact assessment, OECD Plus studies, Toxicity pathways

8 Toxicologic Assessment of Pharmaceutical and Biotechnology Products

Michael A. Dorato, Carl L. McMillian, and Tracy M. Williams

CONTENTS

GENERAL OVERVIEW OF DRUG DEVELOPMENT

The World Health Organization (WHO) Scientific Group has defined a drug as "any substance or product that is used or intended to be used to modify or explore physiological systems or pathological states for the benefit of the recipient" [160]. The drug discovery/development process covers a wide range of therapeutic areas and treatment regimens and is a risky, multifaceted, expensive undertaking. The goal is to develop a new product with therapeutic benefits (efficacy) and few side effects (toxicity) [4]. The drug discovery/development process for a new chemical entity (NCE) starts at the chemist's computer with in silico generation and testing of theoretical molecules, followed by synthesis of molecules of interest, and then testing through various in vitro and in vivo pharmacology and toxicology models, including pharmacologic profiling (the determination of pharmacologic effects other than the desired therapeutic effect,

i.e., off-target-of-interest effects), based on the proposed clinical plan for the first human dose (FHD).

The principal aim of nonclinical safety testing is to understand the safety/efficacy of the drug candidate well enough to make a judgment that the risk/benefit profile is adequate to progress a potential drug candidate toward clinical trials [116]. Provided the efficacy pharmacology and initial toxicology profiles are acceptable, clinical safety, pharmacokinetic, and pharmacodynamic studies (phase I studies) are initiated. As the human clinical trials progress through phase II (proof of concept and safety studies) and phase III (pivotal registration studies), the drug candidate moves through nonclinical subchronic studies, chronic and developmental toxicology studies, and oncogenic evaluations. Zbinden [250] has provided a summary of the biological parameters that should be evaluated for new drug candidates (Table 8.1).

Accelerating the development of safe and effective drugs is not a new topic to the pharmaceutical industry [46]. The technical risks in new drug development programs are enormous. Drug development is complicated by the requirement to simultaneously address complex issues related to potency, selectivity, reversibility, solubility, duration, metabolic stability, permeability, toxicity, physical stability, patentability, and manufacturability for each drug candidate. The risk of failure related to one or more of these aspects has been reviewed by Chien [43], where it was reported that <0.02% of NCEs result in marketed drug products and even fewer (i.e., 0.002%) return a profit to support continued drug research (Figure 8.1). Very little of what enters the drug development pipeline ever enters the marketplace [74]. It has been estimated through many sources that the cost of developing an NCE could exceed $2–$3 billion [73–75,176].

By its nature, a drug must modify a biological process (i.e., alter or adjust a physiologic system in some way) [52]. Toxicology is a critical part of drug discovery/development, early- and late-phase drug development, and the role of toxicology in those processes has been extensively reviewed [72,77,97,106,156]. The purpose of toxicology testing

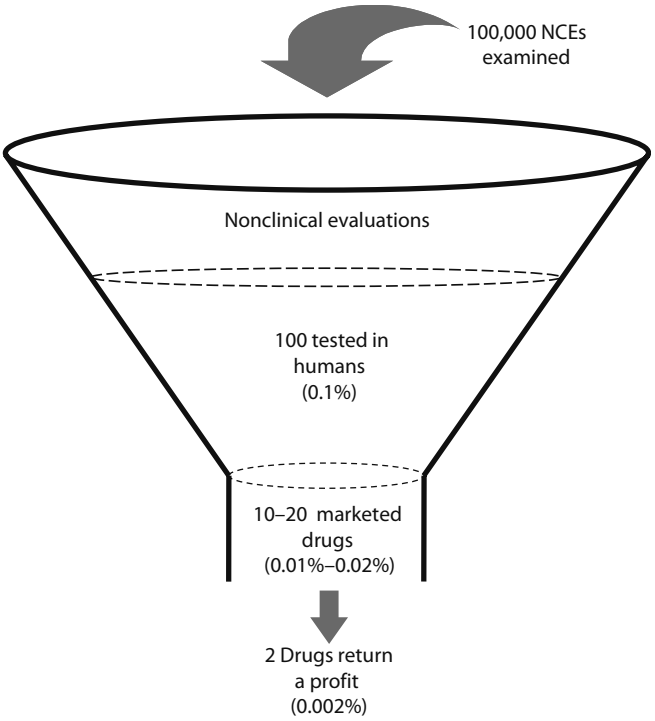

FIGURE 8.1 Attrition rate of new drug candidates. (Data from Chien, R.E., ed., *Issues in Pharmaceutical Economics, Lexington Books*, Lanham, MD, 1979; DiMasi, J.A. et al., *J. Health Econ*., 10, 107, 1991; DiMasi, J.A. et al., *J. Health Econ*., 22, 151, 2003.)

programs is to characterize the toxicity of the drug candidate under various testing conditions (e.g., dose, treatment duration, route) in order to understand potentially harmful effects [53]. A general approach to developing a toxicity profile for a pharmaceutical agent is given in Figure 8.2 and will be discussed more extensively in the following.

During early drug discovery, the input of the toxicologist is often solicited in order to understand the inherent risk associated with a particular pharmacologic target. Understanding the likely on-target (associated with the intended pharmacology) risks through literature reviews, target distribution, and manipulation evaluation (e.g., knockout mouse models) enables a tailored safety assessment early in the process to define an appropriate margin of safety (MOS), which is typically viewed as the ratio of the highest dose associated with no toxicity or manageable toxicity to the efficacious dose in the appropriate test system. In this construct, the highest dose associated with no toxicity is the no-observed-effect level (NOEL); the highest dose associated with manageable toxicity is the no-observed-adverse-effect level (NOAEL). Off-target toxicity, which is associated with responses other than the intended pharmacologic target and inherently driven by the chemical structures being evaluated, is often the focus of applied predictive toxicology tools early in order to influence the selection of a chemical series, with understood or manageable risk, to move into lead optimization.

During the early discovery process of identification of a lead chemical series, toxicologists employ rapid, quantitative in silico and in vitro screening methods, to help identify,

TABLE 8.1
Biological Properties Considered in the Development of Drug Candidates

Acute toxicity
Cumulative toxicity
Absorption from various routes
Elimination $t1/2$ and accumulation in deep compartments
Penetration of barriers
Milk excretion
Teratogenicity
Mutagenicity
Carcinogenicity
Sensitization
Local irritation
Reversibility
Abuse liability

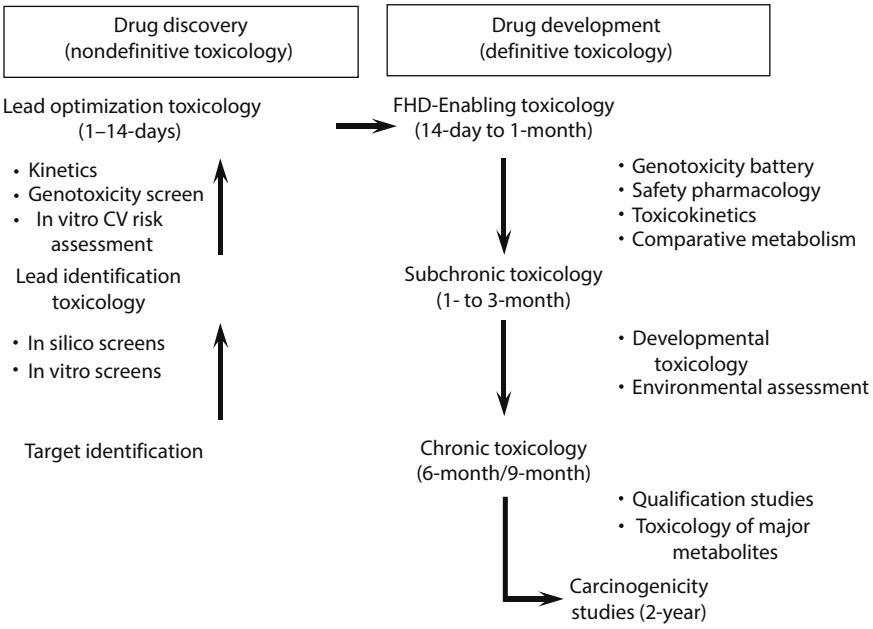

FIGURE 8.2 General approach to developing a toxicity profile for pharmaceutical agents.

out of a myriad of molecules, potential chemical scaffolds worthy of exploring in the hopes of selecting a drug candidate with the best safety profile (Figure 8.3). Computational toxicology tools, even though they have limitations, are advantageous in that quantitative structure–activity relationships can be assessed without the investment of chemical synthesis. Many of these tools are currently commercially available to predict toxicologic responses (e.g., cytotoxicity, cardiovascular, and genotoxicity risk), and this continues to be an area of rapid growth [151,226]. In vitro screening methods, often using high-throughput, medium-throughput, or high-content approaches, allow a great number of compounds to be evaluated, with minimal amounts of compound, in order to rank order compounds for further efficacy and safety investigation [213]. Numerous cell-based models are used to evaluate common toxicities encountered in vivo (e.g., cytotoxicity, phospholipidosis, cardiovascular risk via hERG blockade, and mutagenicity). Predictive toxicology tools continue to be investigated in an attempt to maximize success in lead optimization. The primary goals in the lead optimization toxicology phase of drug discovery/development are to perform in vivo studies to assess target organs, determine the dose-limiting toxicity, compare the adverse events with those measures of efficacy seen in the early pharmacology evaluations (i.e., in vivo pharmacology), and generate a drug candidate with an appropriate MOS for the intended therapeutic indication in humans. The strategies employed across the pharmaceutical industry in maximizing lead optimization [17] and early-stage development [18] have been extensively reviewed. The studies are often

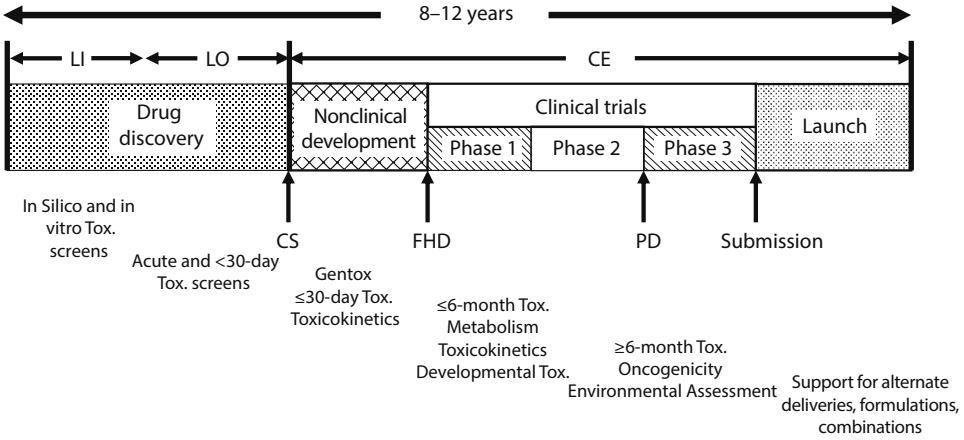

FIGURE 8.3 Duration of toxicology involvement in drug discovery and development showing the major milestones and study types by phase. The goal is to reduce development time while maintaining a focus on nonclinical and clinical safety assessment. CE, Candidate evaluation; CS, Candidate selection; FHD, First human dose; LI, Lead identification; LO, Lead optimization; PD, Product decision.

single- or repeated-dose studies, which are short in duration (<2 weeks), use minimal number of animals, and have abbreviated pathology and toxicokinetic end points. The integration of pharmacology end points improves the evaluation in the lead optimization phase. The lead optimization phase is iterative in that multiple compounds are evaluated in both toxicology and pharmacology studies for safety, efficacy, and pharmacokinetics, in order to declare a drug candidate worthy of advancement to definitive toxicology studies (i.e., those toxicology studies occurring after candidate selection, in the regulatory phases, and used to support first human dosing; nondefinitive toxicology is a general term used to describe those investigative studies conducted prior to the regulatory phase). Sasseville et al. wrote an excellent review on the application of predictive tools and testing paradigms for drug discovery [197].

These early screening procedures used in discovery toxicology, however, are only a prelude to the required comprehensive safety assessments expected from the toxicologist. Regulatory requirements, including guidance documents and good laboratory practices (GLPs), dictate many aspects of the toxicology study protocol and must be followed closely for all definitive (those that support human studies) toxicology studies [84]. The early toxicology studies, conducted in the discovery phase, do not require GLP compliance; however, a process of good research practices (GRPs), ensuring quality, validation, documentation, reproducibility, etc., should be applied.

Prior to initiating clinical trials, physicians need to understand the toxicologic profile produced by the drug candidate in relevant animal models. Prior to the FHD, determination of the relevance of animal models (e.g., metabolism relative to humans) is limited to in vitro evaluations using human and animal tissue preparations. On the basis of the clinicians' needs, the toxicology profile of an NCE is characterized by a number of questions [161]:

- What dose/exposure produces toxic effects in animals?
- What dose/exposure does not produce toxic effects in animals?
- Were the animals relevant models for predicting human toxicity?
- What were the signs and duration of toxic responses?
- Did effects differ following single or multiple dosing?
- Were the toxic responses reversible?
- What were the target organs or systems?
- Was the toxicity expected for this chemical class?
- Are toxic metabolites or reactive intermediates produced?
- Was accommodation to the toxic effects observed?

The answers to these questions form the basis of the toxicology profile supporting initial and continued clinical trials.

The major objectives of toxicologic evaluation change according to the stages of the discovery/development process [220]. The relationships of the studies used to develop a toxicology profile (Figure 8.2) to clinical trial phases are shown in Figure 8.3. The early stages of discovery focus on toxicologic screening (Table 8.2). A sample flow scheme through the early discovery toxicology phase (Figure 8.4) shows the stages of investigation and the integration of in vitro, ex vivo, and in vivo *safety* and efficacy procedures. Definitive toxicology studies are very time consuming and costly; thus, relatively inexpensive, short-term screening procedures are used to eliminate the most toxic compounds [249].

TABLE 8.2
Purpose of Toxicology Evaluations of New Drugs

Phase	Principal Activity	Purpose
Early discovery	Toxicologic screening	Guide chemistry
Lead optimization	Identification of principal target organs	Identification of drug candidates
Before FHD	Characterize safety profile	Regulatory prerequisites for human administration and establish safe clinical starting dose
During clinical trial	Assess toxicologic profile with longer administration	Cumulative effects and mechanisms
Premarketing	Complete routine test program	Regulatory requirements
Postmarketing	Identify special risks due to population or use circumstances	Improve utility and safety

Inherent to these initial approaches to evaluate potential drug toxicities are a number of imperfections: the target systems may not be routinely evaluated; the assay procedures may be inadequate or improperly timed relative to the onset of the response of interest; target-organ exposure may not be evaluated; identification and quantification of adverse events may be inadequate; translation of effects between species may be inadequate; and the test model may not be an appropriate surrogate for human response [253].

There is no simple answer to the often-asked question: "What toxicity profile would cause a company to stop development of a new drug candidate?" [130]. However, the demonstrated toxicity of other compounds in the class, if available, and the gravity of the disease state under study often provide guidance as to what might be an acceptable safety profile for an NCE. An overview of the international pharmaceutical industry's nonclinical testing strategies, in relation to clinical trial phase, is provided in the *Pharmaceutical R&D Compendium* [99].

In addition to the drug substance, the delivery system may also require nonclinical evaluation because it may alter pharmacodynamic (action of the drug on the body) and pharmacokinetic (action of the body on the drug) relationships. The regulatory requirements for the safety assessment of known and novel drug delivery systems have been reviewed by Weissinger [232,233].

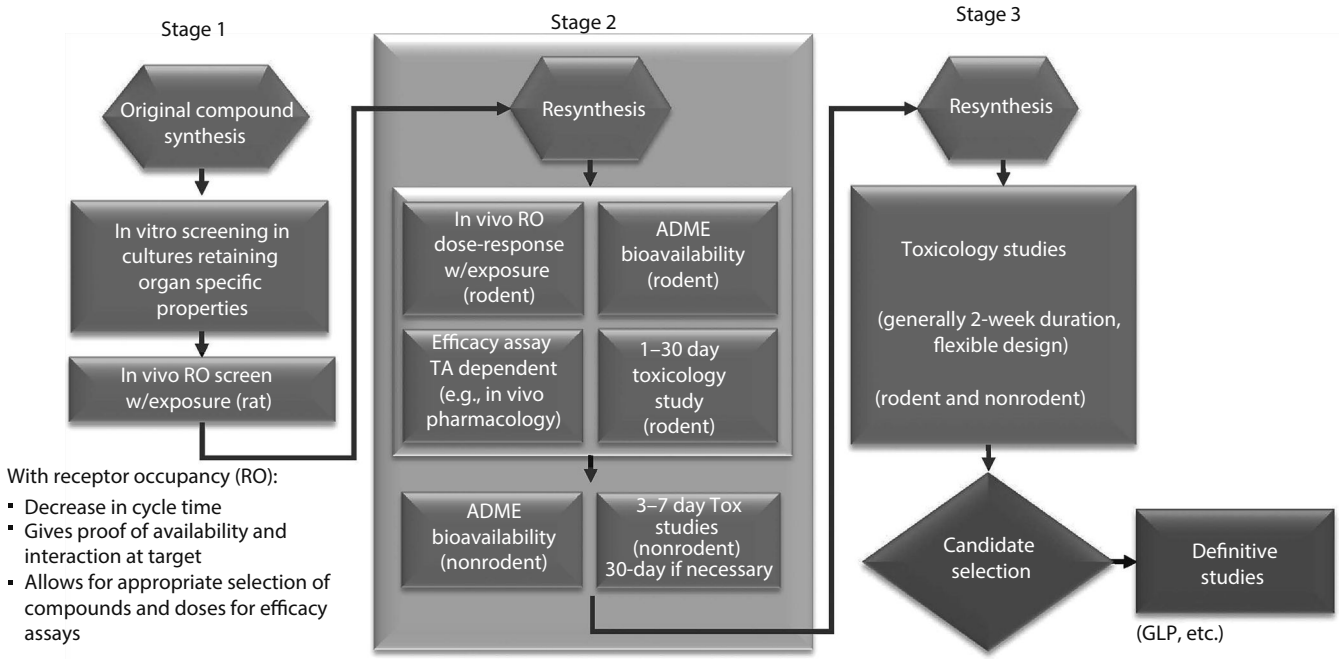

FIGURE 8.4 Drug discovery safety/efficacy flow scheme. ADME is absorption, distribution, metabolism and excretion.

Commercially advantageous forms of genetic manipulation date back to antiquity (e.g., inbreeding, cross-fertilization). The introduction of modern recombinant DNA (rDNA) technology has had a major impact on life science research and has allowed for the large-scale production of protein pharmacologic agents that would have been very difficult to produce by normal chemical synthetic means.

A new biological entity (NBE) is defined as a complex, high molecular weight material that cannot be fully characterized by standard chemical analysis and which may require immunologic, biochemical, or bioassay techniques to measure the quantity present and to assess activity [54]. The development, utility, and relative safety of human insulin [110], human growth hormone [172], and interferon (IFN) [178] have fueled the current interest in the production of biologically active peptides. As the interests of pharmacologists in biotechnology research expand, the difficulties of producing a comprehensive set of safety guidelines increase. Legal definitions of biotechnology products and regulatory guidance for nonclinical assessments have been reviewed by Tsang and Beers [217].

When NBEs were introduced, beginning with insulin, regulatory concepts were not in place to address the problems forthcoming from this new technology [40,114]. The regulatory issues relating to recombinant products are formidable, and the possibility that each biotechnology product might require customized safety testing has been given serious consideration [59,205,214]. Clearly, the immunologic response to foreign proteins may compromise the utility of using traditional animal models in the safety assessment of these agents. Other major regulatory issues include the assurance that recombinant production methods do not result in addition of contaminants and the demonstration to regulators that biosynthetic products are identical to natural substances [108]. In the biosynthetic human insulin (BHI) approval process, meetings between regulatory agency and industry scientists to review the manufacturing process, molecular biology, and purification of the hormone, as well as clinical trial programs, were critical in facilitating eventual approvals. Industry and regulatory agency representatives agreed that the chemistry of an NBE should prove its identity [52]. The identity and purity of rDNA insulin, therefore, received much attention [40]. Anticipation of problems and the communication of concerns were key to the rapid New Drug Application (NDA) approval for BHI (5.5 months). The U.S. Food and Drug Administration (FDA) has strongly recommended that it be involved early in the nonclinical and clinical development plan to facilitate the approval process for both NCEs and NBEs [114].

The U.S. biotechnology policy stated that "the same physical and biological laws govern the response of organisms modified by modern molecular and cellular methods and those produced by classical methods … no conceptual distinction exists between genetic modification of plants and microorganisms by classical methods or by molecular techniques that modify DNA and transfer genes" [6]. Thus, it would not be expected that NBEs per se pose an unusual risk to human health and the environment [6]. The toxicologist should be aware, however, that compounds made via rDNA techniques are not necessarily identical to the natural material, as might be assumed [239]. Dayan [63] suggested that the toxicology profile for an NBE should be defined in terms of chemical identity of the material, extent of prior knowledge, and intended use. The Pharmaceutical Research and

Manufacturers Association (PhRMA) has recommended that nonclinical toxicologic evaluations of NBEs should be decided on a case-by-case basis [215], and regulatory and industry representatives attending the first International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) have also supported this position [147]. The established toxicology information will guide the clinical trial and address possible hazards in the workplace, where humans are exposed to the compound and its precursors and contaminants that are also contained in the bulk material to be tested during the chemical or biological synthetic process.

The role of the toxicologist is usually less routine and requires more innovation in study design when dealing with NBEs than when dealing with NCEs [64]. As is the case with NCEs, however, the principal goals of the toxicologic evaluation of recombinant products are to detect major toxicity, to identify lesser toxicity, to determine the dose relationship of toxic effects and their duration to guide the clinical dose schedule, and to investigate the mechanisms of action related to the toxic response. Cavagnaro [37] has provided a comprehensive overview of the challenges and approaches to nonclinical safety evaluations of NBEs.

The three main areas of concern relative to the toxicity of NBEs are toxicity per se, exaggerated pharmacodynamic effects (anticipated toxicity based on the pharmacologic mechanism of action), and allergic reactions (Figure 8.5) [250,251]. *Intrinsic toxicity* has been defined as undesirable effects having no obvious relationship to the molecule's pharmacodynamic properties. Pharmacodynamic toxicity is defined as an exaggerated pharmacologic response (i.e., hypoglycemic shock from insulin). Immunotoxicity has been related to hypersensitivity, cell transformation, and the production of neutralizing antibodies. The loss of the biological activity of a recombinant therapeutic agent through production of neutralizing antibodies and the development of immune-complex disease in experimental animals are factors that must be given individual attention [215]. It has been suggested that animal models of immunotoxicity are

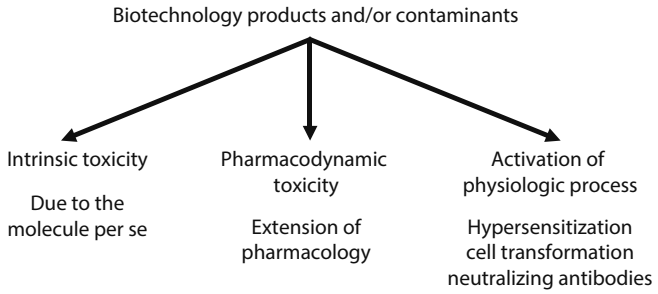

FIGURE 8.5 Main areas of concern with response to biotechnology products. (From Zbinden, G., Biotechnology products intended for human use, toxicological targets and research strategies, in Graham, C.E. and Liss, A.R., eds., *Preclinical Safety of Biotechnology Products Intended for Human Use*, Alan R. Liss, New York, pp. 143–159, 1987; Zbinden, G., *J. Toxicol. Sci*., 14(Suppl. 3), 3, 1989.)

of limited usefulness in that no animal model may be fully suitable for predicting the toxicity of highly species-specific proteins. Friedmann [104] has indicated, however, that the lack of hypersensitivity reactions in response to small peptides in animal experiments may be viewed as an indication of their acceptability in humans. Graham [115] emphasized the use of a case-by-case approach to toxicologic evaluations of NBEs based on their similarity to natural human proteins, immune response in animal models, and production of neutralizing antibodies in nonclinical and clinical studies.

The unique regulatory approval of recombinant insulin most likely resulted in unrealistic expectations in the biotechnology industry regarding the rapidity of review of NBE applications [159]. Two factors will facilitate the regulatory approval of NBEs. As is true in the development requirements for all NCEs, the first factor is therapeutic importance, and the FDA has established a *fast-track* rapid-approval procedure for NBEs that target unsatisfied indications. The second factor is the relationship of the NBE to an established drug. It appears likely that new therapeutic agents derived from biotechnology will have to satisfy all the traditional demands of regulatory agencies [159]. The possibility that subtle changes in chemical structure may exist and may thus influence pharmacokinetics, pharmacodynamics, or immunogenicity is used to support this regulatory position [107].

Questions of safety are not only properly asked about the NBE per se but also about contaminants or residues resulting from the manufacturing or purification processes, antigenic variation, or reversion to the wild type of a living organism [54]. Worker exposure in the production process may be of concern due to relatively high-level, long-term exposure to various end products of the biotechnology process (i.e., live and dead microorganisms and mammalian cells and their derivatives) [240]. This leads to the area where traditional scientific approaches and techniques do not provide a satisfactory toxicologic profile (e.g., transfer of an immortalization factor from a mammalian cell, allergic reactions) [103].

As we have learned with new technologies, every new technology seems *better* the less we know about it. As we develop an understanding of the true potential contributions of new technology over the long term, we realize that the promises of generating meaningful data in the short term were generally overstated. The prime example of this is the expectation that the Ames in vitro genotoxicity assay would replace the 2-year carcinogenicity assays. New focus also takes us in interesting directions; for example, the use of biomarkers (essentially a measured observation or outcome of any biological evaluation) is an old concept that is receiving renewed interest. The development of new procedures to track changes, longitudinally, is of increasing importance in drug discovery/development. If we think broadly enough, the common quote, "The dose alone makes a thing *not* a poison" [218], would have no meaning if Paracelsus (1493–1541) were not thinking about biomarkers. Toxicology studies have always depended on the evaluation of biomarkers, which have traditionally been used in toxicology studies to confirm exposure, to monitor susceptibility to a toxic agent, and to

assess adverse effects [3]. New biomarkers continue to be evaluated and validated for their use in both drug discovery and development as premonitory tools of toxicity as well as for possible translation to clinical trials [213,226,236].

RELEVANCE OF ANIMAL MODELS IN TOXICOLOGIC ASSESSMENT

The suitability of experimental animal data for assessing risk to humans as well as animal welfare concerns [192] are important contemporary issues in toxicology. Animals and humans have much in common anatomically, physiologically, and biochemically [244]. The two main guiding principles of experimental toxicology are that effects produced in animals, when properly qualified, are applicable to humans and that exposure of experimental animals to high doses of a test compound is necessary and valid in determining human risk [153]. Although it is generally agreed that animal assays are not 100% predictive of human effects, they are more predictive than generally thought [120,199]. It has been reported that animal assays are predictive of human toxicity in all but 10% of comparisons [167]. It must be recognized, however, that major differences in response to chemical agents can exist both within and between species [133]. The most serious differences between laboratory animal studies and human clinical trials are related to biochemical and physiological species differences, such as metabolism and genetics (hypersensitivity responses), as well as differences in experimental design, including quantity, route, and duration of drug administration [160]. Humans can be as much as 50 times more sensitive on a milligram-per-kilogram basis than experimental animals [160].

Regulatory agencies and research-based pharmaceutical companies consider laboratory animal toxicology studies as a critical part of the assessment of new drug candidates [102,165]. Confidence in the validity of experimental toxicology is based on the large inventory of chemically induced lesions that occur both in animals and humans. It may be incorrect to assume that what is demonstrated in animal toxicology studies will occur in human clinical trials, but until it is shown that the toxicity expressed is not relevant to humans, that assumption must be made [14]. Also, until our knowledge base expands, animal data must be extrapolated to the human situation using a conservative approach (e.g., use of relatively high doses, assuming that humans are more sensitive than the most sensitive species) [22].

The ultimate goals of the toxicology assessments are to characterize toxicity in animal models to identify potential problems in short- and long-term clinical studies, identify the circumstances under which toxicity occurs, evaluate the extent to which the data warrant extrapolation to humans, recommend safe levels of exposure, and contribute to the decision to test the new drug candidate in humans [12,62,166,185,193,222]. It has been recognized that qualitative extrapolation of drug toxicity from animals to humans is more reliable than estimation of the magnitude of dose producing a similar effect in animals and humans; that is, the pharmacodynamics of an agent are more predictable than its pharmacokinetics [186]. Complicating the ability to extrapolate data from animals to humans are the excessive doses sometimes used, and often required, in animal studies. As a result, adverse effects are described that may be the result of frank intoxication of the animal and are irrelevant in humans. Zbinden [245] has proposed that the ability of animal toxicity studies to predict potential human toxicity is related to the mechanism of drug action. Within limitations, animals and humans respond in ways similar enough, from a pharmacodynamic perspective, for animal toxicity evaluations to serve as useful predictors of human toxicity [60,124,163,166,180]. However, toxicologic evaluations in animals can predict toxic responses in humans only if the response is not unique to humans [102]. Those compounds that are toxic to humans but *relatively* nontoxic to animals (i.e., thalidomide) are of greatest concern. The extrapolation of animal data to humans is likely to become even more complicated as molecular biology techniques continue to allow the more sophisticated characterization of specific human therapeutic targets (human enzymes, receptors) and the ultimate development of drugs specific for these targets.

Table 8.3 lists common undesirable drug effects seen in human studies; 76% of the findings are predictable from animal studies. Predictability is enhanced for those adverse effects that can be directly related to the pharmacologic mechanism of action of the compound. Adverse responses commonly referred to as dose and time related are relatively well predicted from animal studies. It is more difficult to extrapolate effects that are not dose or time related [248].

There is a small element of toxicity that cannot be predicted until large-scale clinical studies are conducted [124]. This may be the result of a very low incidence of occurrence or idiosyncratic responses in a small subset of the patient population; however, considering the increased use of pharmaceutical agents and the relative infrequency of major incidence of human toxicity, the initial laboratory studies are clearly serving a valuable function [12]. A large majority of human drug exposures are relatively free of toxicity and in good accordance with the results of animal toxicity studies [249]. The use of adequate test systems is critical to the predictive (translational) ability of animal toxicity evaluations. Cahn [27] reported that the cardiac effects of calcium antagonists (i.e., ectopic beats, ventricular tachycardia, and ventricular fibrillation) were seen in humans but were not described in long-term animal studies. These effects, however, were demonstrable in animals using appropriate functional evaluations not always included in routine toxicologic testing, and it is these kinds of clinical findings that contribute to the evolution of the science of regulatory toxicology. Oftentimes, toxicologically important end points, such as cardiac, pulmonary, or renal function, are not taken into consideration in the design of *routine* toxicology studies, which are frequently focused on changes in clinical signs and pathology. The toxicologist is challenged to consider potential adverse effects related to the pharmacodynamics of the test compound in the design of appropriate safety studies [180]. Furthermore,

TABLE 8.3
Common Untoward Reactions to Drugs

Clinical Side Effect	Predictable from Animal Studies? (Y/N)	Clinical Side Effect	Predictable from Animal Studies? (Y/N)	Clinical Side Effect	Predictable from Animal Studies? (Y/N)

many new drug candidates are being targeted toward the aging population, where compromised hepatic or renal function may significantly modify the pharmacokinetics and thus toxicity of the compound. These examples emphasize the importance of using an adequate and appropriate test system to evaluate the toxicity of new drug candidates.

As with standard pharmaceuticals, no animal model is fully appropriate to evaluate the toxicity of highly specific human proteins [115]. Animal testing for biotechnology products is limited to the species showing the same pharmacologic response as humans, without showing signs of immunity [50,107]. This is only feasible when proteins are highly conserved across species. The production of neutralizing antibodies will limit the study duration and thus support for clinical trials. Administration of a highly specific human protein to laboratory animals for a sufficient duration to produce immune-complex disease will do nothing to reveal effects anticipated in clinical trials. Antigenicity of the test material can be a major complicating factor, in that the potential allergic etiology of all lesions developing in animals treated with human proteins must be considered [254]. Alternatively, nonclinical toxicology studies of biotechnology products may be less predictive of allergic responses that may occur in humans following chronic therapy [240]. The appropriate laboratory species for biotechnology product testing should demonstrate similar pharmacodynamics and adverse responses relative to humans. If an animal model demonstrating similar pharmacologic response to humans cannot be selected, species selection based on toxicity likely to be representative of that expected in humans may be acceptable [233]. The FDA does not currently require the study of recombinant proteins exclusively in primate models, but a study in a relevant species is expected. Nonhuman primate models demonstrate many similarities to humans at the molecular level and often turn out to be the most appropriate species for toxicity testing of NBEs [115].

The predictability of animal models debate affects decisions on moving potential drug candidates through the clinical trial phases. Animal models provide predictability, but that statement has many caveats. To keep the matter in perspective, while animal models are not a perfect predictor of either efficacy or safety in the clinical trial phase, the clinical trial phase is not a perfect predictor of efficacy or safety in the marketing phase. A clinical trial study of tens of thousands of patients may not be sufficiently large to show a subtle effect in the marketing of an approved medicine to a population of tens of millions. The increased application of genomics may pave the way for an improved safety risk–benefit assessment, that is, the right drug to the right patient.

An extensive review of in silico, in vitro, and in vivo models used to accelerate drug discovery and development has been published by Atkinson [10].

TOXICOKINETICS

Toxicokinetic analysis has become a standard component of the design and a valuable tool in the interpretation of the nonclinical safety profile of NCEs [61,76]. Various guidances that have been issued in recent years describe objectives and specific recommendations for toxicokinetic evaluation [134,135]. Well-designed toxicokinetic studies provide insight on exposure (typically expressed as drug concentration per unit time or area under the plasma concentration/time curve [AUC]) as well as other pharmacokinetic parameters such as clearance (Cl_T), volume of distribution (Vd), and half-life ($T_{1/2}$). These pharmacokinetic parameters are often further refined in specific studies to assess absorption, distribution, metabolism, and elimination (ADME).

Toxicokinetic parameters guide the assessment of dose proportionality, accumulation potential upon multiple doses, sex differences, and species differences. Figure 8.6 illustrates the relationship of dose vs. exposure after single and multiple doses.

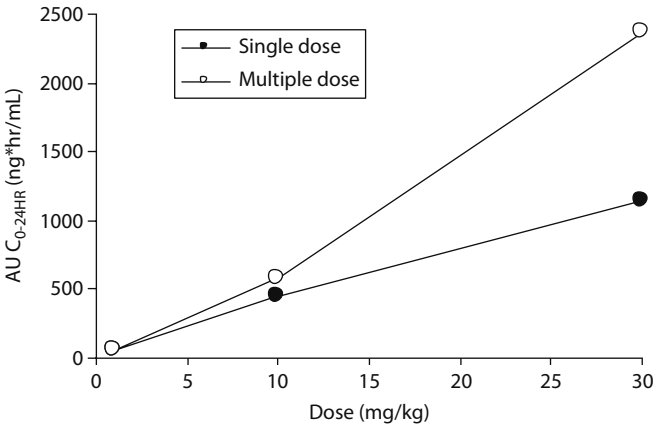

FIGURE 8.6 Relationship of dose vs. exposure after single and multiple doses.

This example shows a linear, predictable increase in exposure across the range of doses examined. It is also noteworthy to point out that the saturation of systemic exposure may occur after oral dosing as a result of absorption-related processes. When saturation is reached, increasing the dose does not result in increases of exposure. Toxicokinetic analysis is useful in determining the dose at which saturation occurs. This may then be used to justify selection of a high dose in a toxicology study.

The majority of toxicokinetic assessments are designed to evaluate parent drug or metabolite concentrations in plasma [16]. These studies are usually an integrated part of the design of various toxicology studies, including acute, subchronic, chronic, reproductive/developmental, and carcinogenicity studies, regardless of route of administration or test species. An understanding of the internal exposure associated with dose-limiting toxicities or premonitory signs and symptoms that precede dose-limiting toxicities or adverse events is fundamental to any toxicokinetic assessment. Such assessments provide the foundation for the establishment of a toxicokinetic/toxicodynamic (TK/TD) relationship of dose, exposure, and adverse events [181,255]. The role of clearance, absorption, or distribution in any observed changes in the relationship aids in the prediction of accumulation, saturation, or decreases in exposure observed after multiple doses.

Similarities in the qualitative profiles of metabolism of xenobiotics across rat, mouse, dog, and nonhuman primates have been reported for decades [34,35]. Quantitative profiles, however, are often quite dissimilar and have been studied extensively; consequently, recent guidance [16,206] has been published to offer additional insight into the appropriate instances in which to quantify metabolites. In addition to the guidance offered, multiple reports have been published, reviewed, and/or debated [109,241]. These offer greater insight into various approaches to investigate and analyze the absolute and relative exposure(s) of metabolites to parent or total drug–related material. Combined, these qualitative and quantitative assessments of an NCE early in the development cycle greatly aid in the selection of the appropriate preclinical species for safety assessment. This early assessment is often coupled with the previously mentioned ADME studies. Increasingly, various in vitro test systems are utilized for the initial assessment of some ADME properties. Specifically, the utilization of cellular and subcellular fractions and tissue slices or segments to assess absorption and metabolism is the most widely employed test system. For example, permeability across Caco-2 cell monolayers has been well established as a model for gut absorption [7].

Human and animal liver samples are utilized to create various in vitro test systems for metabolism. These systems offer the capability to study the rate, extent, and profile of metabolism in a comparative fashion across multiple species in a relatively short time frame. Subcellular fractions of hepatocytes are most commonly used and offer the advantages of speed, robustness, and capacity. In addition to containing the major drug-metabolizing enzymes (CYP450s and flavin-containing monooxygenases) and phase I (oxidative) capability present in subcellular fractions, liver slices and hepatocytes also possess greater capability to complete phase II (conjugative) metabolic transformations [212,214]. The intact cells are also thought to more closely mimic the intact functioning organ.

Both the activities and the abundance of individual isoforms of cytochrome P450s (CYP450s, the primary drug-metabolizing enzymes) have been extensively characterized in experimental animal species and humans. This level of characterization enables these systems to offer the potential for improvement of the selection of preclinical test species as well as decreased utilization of in vivo experiments. Predictions can also be made regarding the correlation of in vitro and in vivo estimates and the likelihood of clinical drug–drug interactions [33,148,171,180,190].

Advances in technology, most notably liquid chromatography–tandem mass spectrometry (LC–MS/MS), have greatly enhanced the ability to quantify both parent drug and metabolite concentrations routinely in the submicrogram-per-milliliter range [1]. This advance is often challenged by the trend to develop NCEs with increasingly higher potencies. The intended goal of toxicology studies is to dose animals in a fashion to obtain higher exposures than those predicted or observed in humans. Plasma concentration exposure assessments are now more widely used and accepted as a better estimate of safety multiples than comparisons of administered dose (e.g., mg/kg or mg/m^2). The assessment of systemic exposure in toxicity studies has been addressed by the ICH, and the objectives of toxicokinetic evaluation and specific recommendations are contained in ICH Topic S3A [134]. ICH M3 offers additional guidance on the assessment of metabolites as an integral part of the overall toxicokinetic assessment of NCEs [145].

TOXICOLOGY GUIDELINES

Drug Development Timelines

Development time (e.g., cycle time) has become an important focus for the pharmaceutical industry. The available data indicate a fourfold increase in drug development time between

the 1960s and the 1980s. From the early 1980s to 1996, however, mean drug development times have been relatively constant at about 10–12 years, with very wide variability [221]. Cycle time, in general, has not changed significantly from 1996 to 2012. The pharmaceutical industry has committed to increasing drug discovery/development efficiency, leading to a decrease in the mean drug development time to deliver innovative pharmaceuticals to patients more quickly and realize increased profitability to maintain aggressive research and development efforts. The FDA has also committed to increasing the development speed of safe and effective drugs through a program called the Critical Path Initiative, described in *Innovation or Stagnation: Challenge and Opportunity on the Critical Path to New Medical Products* [92]. The broad impact of these efforts has yet to be evaluated.

NBEs generally have had a shorter development time (approximately 6–9 years) than NCEs. The NBEs registered to date have generally been well-characterized natural molecules, and the shorter development time is probably related to a better understanding of their actions in humans. The introduction of analogs of natural proteins, some designed to be used at supraphysiologic levels, has led to an increase in development time for NBEs. From 1985 to 2004, the development times for NCEs have reportedly decreased approximately 22%, while the development time for NBEs has reportedly increased approximately 50% [183]. Information on pharmaceutical development cycle time and productivity is continuously evaluated by the Tufts Center for the Study of Drug Development, Tufts University (http://csdd.tufts.edu/).

Regulatory Guidelines for Toxicity Testing

In this section, the toxicology support packages for the registration of NCEs and NBEs are reviewed from slightly different perspectives. More detailed information on the specific studies conducted, their results, and their interpretation are included for the classical agents (omeprazole and zidovudine), because the majority of compounds currently in development would fall into this category and thus require similar testing strategies. Omeprazole was selected for discussion because it had a comprehensive toxicology package at the time of regulatory submission and represents an example of where additional mechanistic studies were critical in the approval process. Zidovudine (AZT) is discussed due to its proposed use in life-threatening disease where no adequate therapy was available. The rapid approval of the drug, in spite of significant toxicology findings and an abbreviated toxicology support package, demonstrates the inherent flexibility in the approval system even with regard to NCEs.

The discussion of specific human NBEs (gonadotropin-releasing hormone [GnRH] analogs, IFN, human insulin) is presented from a more philosophical perspective. Because these agents are naturally occurring and because the major limiting toxicity in animal studies (immunogenicity) is not applicable to clinical trials, the design of the toxicology package posed special issues that were considered on a case-by-case basis. Furthermore, the toxicologic profile was anticipated based on extensive clinical experience with less specific agents (animal-derived insulins) or a broad understanding of the physiological functions of the hormones. The following discussion of the NBEs poses questions, concerns, and general guidelines to be considered in the development of these agents.

Acute, Subchronic, and Chronic Testing

Toxicity testing to support drug development is composed of several major types [53]. Acute (single dose), subchronic (multiple dose; less than 6 months' duration), and chronic (multiple dose; greater than or equal to 6 months' duration) studies are intended to elucidate the target organs for toxicity, demonstrate dose–response relationships, and often are useful in determining potential mechanisms of toxic action. The single- and repeated-dose toxicology studies completed in lead optimization are often leveraged to design, both dose justification and study end points, the definitive toxicology studies described here. For dose selection, consideration of the maximum tolerated dose (MTD), the maximum feasible dose and limit dose based on regulatory guidance, is necessary to ensure the doses maximize the possibility of defining the toxicologic response [24].

A variety of end points are routinely evaluated in subchronic and chronic studies, including body weight, food consumption, hematology, clinical chemistry, urinalysis, and gross and histologic pathology of numerous tissues. A list of common parameters assessed in subchronic and chronic studies is presented in Table 8.4; however, the toxicologist is continually challenged to modify study design to address the anticipated actions of the compound under investigation. This may result in the addition of certain parameters or tissues to be evaluated or a more comprehensive analysis of tissues (i.e., electron microscopic evaluation, immunohistochemistry). Furthermore, previous studies, or knowledge of the toxicity of other agents in the therapeutic class or those that have a similar structure, may suggest alternative assessments, such as the determination of the propensity of the agent to induce hepatic microsomal enzymes, cause phospholipid accumulation, or result in peroxisome proliferation.

An assessment of bioavailability and pharmacokinetics is often an important end point of subchronic and chronic studies. As discussed previously, these data are critical to extrapolate toxicity findings to humans. Often, the toxicokinetic profile of the compound is determined early and late in the study so the potential for drug accumulation can be revealed. Alternatively, drug levels may be lower toward study termination or the metabolite profile may differ due to the induction of drug-metabolizing enzymes. Tissues may also be collected for drug analysis, so levels in affected tissues can be related to the extent of the histopathologic findings. Finally, important dose–response relationships can be established, relative to both parent compound and metabolites, that may be critical in the interpretation of toxicity data.

Subchronic (usually 2-week or 1-month studies) testing is required prior to the FHD. One-month studies in one rodent species (usually rat or mouse) and one nonrodent species (usually dog or primate) generally will support up to 1 month of

TABLE 8.4
Parameters That Might Typically Be Assessed in a Subchronic/Chronic Toxicology Study

Live Phase		
Body weight	Clinical observations	Electrocardiogram (large animal)
Food consumption	Ophthalmology	Physical examination
Efficiency of food utilization (g body weight gained per 100 g feed consumed)		
Hematology		
Erythrocyte count	Mean corpuscular hemoglobin	Thrombocyte count
Hemoglobin	Mean corpuscular hemoglobin concentration	Activated partial thromboplastin time
Packed cell volume	Total leukocyte count	Prothrombin time
Mean corpuscular volume	Leukocyte differential	M/E ratio (bone marrow smears)
Clinical Chemistry		
Glucose nitrogen	Gamma-glutamyltransferase	Cholesterol
Blood urea	Creatinine phosphokinase	Triglycerides
Creatinine	Calcium	Total protein
Total bilirubin	Inorganic phosphorus	Albumin
Alkaline phosphatase	Sodium	Globulin
Aspartate transaminase	Potassium	Albumin/globulin ratio
Alanine transaminase	Chloride	
Urinalysis		
Color	Protein	Ketones
Clarity	Glucose	Bilirubin
Specific gravity	Occult blood	Urobilinogen
pH		
Organ Weights		
Kidneys	Ovaries	Adrenals
Liver	Testes	Thyroids (with parathyroids)
Heart	Prostate	Brain
Histopathology		
Kidney	Stomach	Skin muscle
Urinary bladder	Duodenum	Skeletal
Liver	Jejunum	Bone
Gallbladder	Ileum	Bone marrow
Heart	Cecum	Adrenal
Aorta	Colon	Thyroid
Trachea	Rectum	Parathyroid
Lung	Ovary	Pituitary
Spleen	Uterus	Cerebrum
Lymph node	Cervix	Cerebellum
Thymus	Vagina	Brain stem
Salivary gland	Testis	Spinal cord
Pancreas	Epididymis	Sciatic nerve
Tongue	Prostate	Eye
Esophagus	Mammary gland	Harderian gland

Blood levels of parent compound/ metabolites	Hepatic microsomal enzyme activity/cytochrome P450 content	Peroxisome proliferation, tissue phospholipid phosphorus concentration

dosing in humans. Where possible, the animal studies should be carried out using the same route of administration anticipated for use in patients. As an aside, it should be acknowledged that clinical studies may initially be conducted by the intravenous route, regardless of the desired ultimate route of administration, particularly for those molecules that are anticipated to show efficacy rapidly, to demonstrate the proof of concept of a new pharmacologic mechanism. Drug developers might thus avoid the time and expense associated with formulation development and maximization of the desired properties of the chemical if it has been demonstrated that the molecule or mechanism is ineffective. These clinical trials require the support of intravenous toxicology assessments. In these circumstances, it is extremely important to evaluate the risk associated with the potential for demonstrating toxicity in the intravenous study that may be irrelevant to the ultimate route of administration.

Phase II and III efficacy testing in patients is supported by longer-term studies. Depending on the proposed duration of human exposure, toxicity studies to support phases II and III may be of 3-, 6-, or 9/12-month duration. Two or more subchronic or chronic studies may be conducted simultaneously (e.g., 3-month and 6-month studies may be initiated at the same time), so patients can be placed on the trial earlier (upon completion of the 3-month study) and maintained on the trial longer (supported by the 6-month study) if the human efficacy and safety data support continued therapy. A potential problem with this approach is that dose selection for the more extended study may be found to be inadequate (doses either too low or too high) based on the findings of the shorter test.

Much discussion has surrounded the utility of 1-year studies. The FDA had been a strong proponent of the 1-year study approach [51], but Japan and the European Union (EU) have suggested that 1-year studies reveal little new information beyond that gained from 6-month studies. These data have been reviewed by Lumley et al. [168], who suggested that for 154 compounds for which short-term (≤6 months) and long-term (>6 months) animal data are available, tests lasting longer than 6 months (excluding carcinogenicity studies) have not provided new substantive safety information. They also pointed out that, although new findings became evident after 6 months of treatment in 9 out of 75 cases, the data did not influence the decision of whether to continue the development of the compound. Parkinson et al. [184] have reported that long-term toxicity studies in dogs provide little new data when compared to 3-month dog studies in conjunction with short- and long-term rodent studies.

The ICH committees have resolved this difference of opinion [138]. We will review the ICH guidelines in the following, but the reader is encouraged to connect with the ICH website, http://ich.org, for an up-to-date review of the current guidelines.

Additional Toxicology Studies to Support Clinical Trials

Other tests conducted prior to initial clinical trials include mutagenicity studies and pharmacologic assessments (e.g., cardiovascular, central nervous system (CNS), and/or gastrointestinal function). A variety of mutagenicity studies are currently employed that assess various types of DNA damage in vitro and in vivo in an attempt to predict the oncogenic potential of the compound under investigation. In pharmacologic screening, the ability of the compound to produce toxicities or *side effects* based on its pharmacologic mechanism of action is assessed; for example, an agent that is shown to bind to β-receptors in vitro might be anticipated to influence cardiac function in subsequent toxicity and clinical testing. Mutagenicity and pharmacology safety studies are often employed as very early screens in the evaluation of potential drug candidates to select one of a group of structurally related compounds that would be least likely to result in carcinogenicity and most likely to demonstrate the specific desired pharmacologic activity. The types and utility of these studies are further described in the following. Finally, special studies might be conducted prior to initial clinical testing to address specific issues, such as irritation testing of an agent proposed for topical use in the patient population.

Reproductive and Developmental Toxicity Studies

The thalidomide incident raised a great deal of concern relative to predictive testing for developmental toxicity, as well as fertility effects in both males and females. Although regulations have differed substantially among countries, worldwide harmonized guidelines for reproductive toxicity testing have been established [140]. The ultimate goal of these studies is to assess reproductive risk to adults, as well as to the developing offspring, at all stages from conception to sexual maturity. Traditionally, animal studies have been conducted in three segments: in adults, treatment premating through mating in the male and premating through either implantation or lactation in the female (segment I); in pregnant animals, treatment during organogenesis (segment II or teratology studies); and in pregnant/lactating animals, treatment from the completion of organogenesis through lactation (segment III, peri- and postnatal study). The current ICH guidance addresses proposed study design approaches and offers that the most probable option for evaluation of reproductive effects includes a combination of three studies that address fertility and early embryonic development; peri- and postnatal development, including maternal function; and embryo fetal development [140].

The harmonized ICH guidelines [140] stress the need for flexibility in testing for reproductive and developmental toxicity and challenge the toxicologist to custom design a combination of studies that will reveal potential effects on all of the parameters considered in the classical segment I, II, and III studies. For treated adults, these include development and maturation of gametes, mating behavior, fertilization, implantation, parturition, and lactation. In the developing organism, where the maternal animal may be exposed to the drug candidate from prior to mating through lactation, assessments of early embryonic development, major organ formation, fetal development and growth, postnatal development and growth (including behavioral assessments), and attainment of full reproductive function are required. These evaluations might be carried out as one comprehensive study with interim assessments, or they might be segmented into several treatment components. Thus, the new guidelines

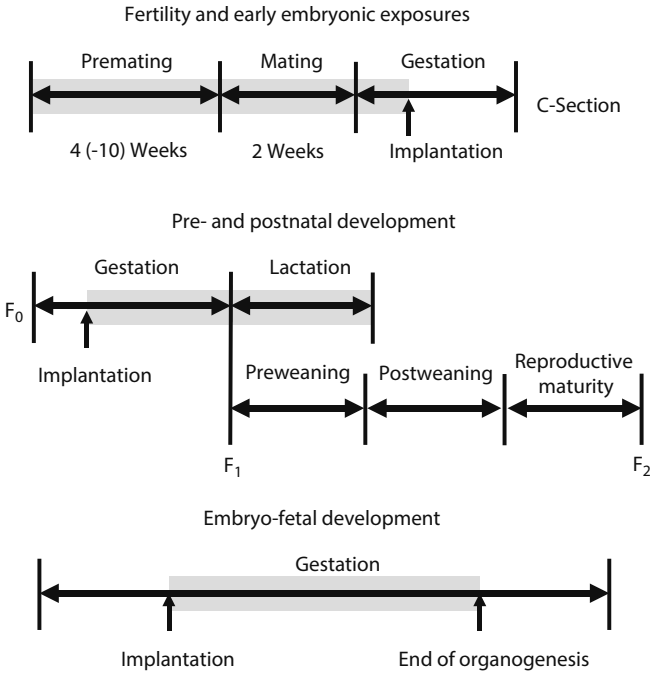

FIGURE 8.7 The three-study design proposed for the assessment of reproductive and developmental toxicity for a standard pharmaceutical. (From ICH, Detection of toxicity to reproduction from medicinal products and toxicity to male fertility, Topic S5(R2), Step 5, ICH Harmonized Tripartite Guideline, *International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use*, Geneva, Switzerland, 2005.)

have not diminished the extent of evaluation but allow flexibility in study design based on what is already known of the compound under investigation. The harmonized guideline suggests a three-study design that is likely to provide all of the developmental toxicity data necessary to support product registration, assuming no untoward toxicity. Our view of this approach is generally represented in Figure 8.7. Should toxicity be demonstrated, further mechanistic studies would be conducted to clarify effects and determine whether the responsible mechanisms would be applicable to humans. The results from previous subchronic and chronic studies (e.g., evidence suggesting an effect on spermatogenesis upon histopathologic examination of the testes) are critical in the design of an appropriate reproduction package.

Women of child-bearing potential are generally first recruited into phase II clinical trials, and several countries strongly suggest that efficacy be demonstrated in male patients prior to recruitment of women of child-bearing potential into trials, regardless of the outcomes of the nonclinical reproductive studies. However, it should be noted that the FDA has encouraged the inclusion of women of child-bearing potential in early clinical trials, especially in the case of drugs intended to treat life-threatening conditions or in the study of disease states that more commonly affect women. Typically, prior to the inclusion of women of child-bearing potential into clinical trials, studies are conducted to evaluate effects on organogenesis (segment II) in two species (usually the rabbit and the rodent species selected for the subchronic and chronic studies). Female fertility assessments are also usually undertaken prior to longer-term treatment or addition of significant numbers of patients. Despite the availability of these data, clinical protocols frequently require that women of child-bearing potential use reliable contraceptive intervention. Evaluation of toxicity to male fertility is now incorporated into the ICH guidance [140] and is supported by histological evaluation of the testes at the conclusion of the subchronic and chronic nonclinical studies, and specific animal studies to examine drug effects on male fertility are generally not conducted until phase III. Unless there are concerns regarding a specific chemical class or mechanism of action, the more sophisticated analyses of peri- and postnatal development and behavior (segment III studies) are often conducted in conjunction with the phase III clinical trials. Frequently, as is the case with other toxicity evaluations, special studies may be conducted to determine the mechanisms of observed reproductive effects in an effort to assess whether these findings are meaningful to humans and whether use of the compound should be restricted depending on the reproductive status of the patient (i.e., the drug should not be administered to pregnant women). Finally, the inclusion of female patients in clinical trials may be allowed following a more limited assessment of reproductive or developmental parameters if the compound under development is shown to be efficacious or is thought to provide distinct advantages over available therapies in the treatment of life-threatening disease. The ICH guidance refers to the availability of other test systems such as mammalian cell systems, tissues, organs, or organism cultures to help understand mechanism of effects [140]. As with all in vitro or ex vivo approaches, these studies provide useful information in a very specific and limited environment; they lack the complexity of the developmental process and the dynamic interaction between maternal and developing organism [140].

Carcinogenicity Studies

Among the final toxicity studies to be conducted to support the registration of chronic-use therapeutics are the carcinogenicity bioassays [136,137]. These lifetime (2-year) studies are usually conducted in two rodent species (normally, rat and mouse). Selection of the top dose for the carcinogenicity bioassays has been an intensely debated topic of discussion in the international harmonization process. The international consensus has based the selection of the top dose for carcinogenicity bioassays on any one of the following [143,234]:

- MTD
  - AUC rodent-to-human ratio of 25-fold, which applies when no genotoxicity is identified
- Saturation of absorption
- Dose-limiting pharmacodynamics (i.e., hypotension, hypoglycemia, decreased blood clotting time)
  - Use of a limit dose (1000 mg/kg), which applies when the maximum recommended human dose is ≤500 mg/day and the AUC (rodent–human) is ≥10

The middle and low doses should also be selected to provide additional information to use in the risk assessment. The consideration of dose linearity, saturation of metabolic pathways, MOS, pharmacodynamics, specific animal physiology, threshold effects, and progression of toxic effects should be included in the selection of the middle and low doses for carcinogenicity evaluations.

The use of an MTD as the top dose in a carcinogenicity study has been a subject of much discussion and debate, as has the choice of an appropriate high dose in any nonclinical toxicology study [24]. The current ICH guidance [143] provides some general guidelines for dose selection in rodent bioassay studies, adequate MOS over human exposure; produces no significant physiological dysfunction or effects on survival, guided by animal and human data; and permits data interpretation in the context of clinical use. The MTD has been classically defined as the dose that causes no more than a 10% decrease in body weight and does not produce mortality, clinical signs of toxicity, or pathologic lesions that would be predicted to shorten the natural life span of an experimental animal for any reason other than the induction of neoplasms [143,209]. Because the MTD is often based on a body weight effect, Hoffman et al. [132] have proposed an improved evaluation of growth data in rodent toxicology studies using a powerful statistical analysis method that reduces the number of false positives and provides a comprehensive summary of compound-related effects. The MTD is suggested to produce a level of toxicity indicative of sufficient chemical challenge to define chronic toxic manifestations [128]. Many regulatory bodies default to the use of the MTD as the maximum dose in the rodent bioassays. A major concern with the MTD approach is that metabolic saturation, as discussed previously, may occur at high doses, leading to abnormal metabolism [178] or, in the case of inhaled therapeutics, abnormal clearance [177]. Chemicals administered at the MTD in animal bioassays tend to induce mitogenesis as a result of cell death due to frank intoxication, with the target tissues differing among species and sexes [113]. This stimulation of cell proliferation, a natural recovery process in response to severe toxicologic insult that does not normally occur at reasonable multiples of human exposure levels, can account for the carcinogenic response of nongenotoxic compounds [49]. Thus, the fact that a chemical is a carcinogen at MTD levels in rodents may provide little meaningful information relative to low-dose risk assessment in humans [2]. MTDs for chronic toxicity studies are usually estimated based on the results of subchronic toxicity studies; however, because compound distribution and disposition may be affected by the dose or duration of treatment, this may be a very crude estimate [178,182].

The choice of an MTD is a critical aspect of chronic toxicity evaluations [216]. Cell proliferation indices in subchronic toxicology studies may provide a useful estimation of an appropriate MTD by determining the highest dose that does not result in the phenomenon [26]. The use of kinetic parameters (C_{max}, AUC related to dose) would better predict the dose at which saturation (nonlinearity) might occur and therefore provide a better estimate of the MTD in a particular species. Also, changes in the urinary metabolite profile, in relation to dose, may be a good way of indicating metabolic overload and could aid in more accurately selecting upper dose levels in toxicology studies [242]. A systemic exposure-based alternative to the MTD for carcinogenicity studies has been presented by Contrera et al. [52]. This alternative was discussed as being suitable for nongenotoxic compounds with low rodent toxicity and similar metabolism in rodents and humans. The relevance to human risk assessment of a carcinogenicity finding for nongenotoxic compounds was addressed by Silva Lima and van der Lann [205]. They discussed the main causes of carcinogenicity from nongenotoxic compounds: chronic cell injury, immunosuppression, increased secretion of trophic hormones, receptor activation, and other mechanisms such as CYP450 induction. An overall approach to addressing the human relevance of the mode of animal carcinogenicity (i.e., genotoxic or nongenotoxic) has been addressed by Cohen et al. [48].

The utility of using two rodent species has also been an active area for discussion. The ICH has indicated that the rat would be preferable to the mouse for conducting carcinogenicity studies [136]. The rat seems to have been given a preference because background mechanistic data are usually available for rats (not mice), studies of metabolic disposition are more often carried out in rats than in mice, and mouse carcinogenicity studies are dominated by liver tumors of questionable relevance to humans. A review of the European regulatory database has concluded that studies in the mouse add little to the ability to detect carcinogenic risk from pharmaceuticals [53,227,228]; however, the review found that carcinogenicity studies in two rodent species are necessary to identify trans-species tumorigens. NCEs active across species are considered to pose a relatively greater risk to humans than NCEs positive in only one specie. The conduct of a study using an alternative in vivo carcinogenicity model along with a standard bioassay in one species was considered to be an acceptable alternative for assessing carcinogenic potential [43].

The use of alternative models for carcinogenicity assessment meets the desire of the FDA to have an assessment in two species and offers the advantages of using fewer animals, being of shorter duration and being capable of enhancing the predictability of the rodent bioassay [50,137]. A number of transgenic animal models are currently being evaluated as alternatives to the 2-year bioassay [8,42,111]; however, it is early yet to evaluate the validity of alternative models of carcinogenic potential to the risk assessment process, and it would be advisable to discuss the selection of alternative models with the appropriate regulatory agency prior to study initiation, as the use of alternative models is not routinely accepted by the FDA.

Within the FDA, it is highly recommended that protocols, dose justification documents, and supporting data be submitted to the Carcinogenicity Assessment Committee (CAC) for evaluation prior to initiation of carcinogenicity studies. The CAC provides consultation on study designs, ensures

consistency and quality in the analysis and interpretation of animal carcinogenicity studies across industry and within the agency, and monitors scientific developments to ensure that scientific standards of design and interpretation are upheld.

Since 1982, the number of NBEs presented for registration has risen; even so, these NBEs represent a relatively small number of molecules. Due, in part, to this lack of practical experience, the safety programs for the NBEs have been designed on a case-by-case basis. The ICH has provided two guidelines that address carcinogenicity studies with products of biotechnology [136,147]. It is generally acknowledged that carcinogenicity studies are not appropriate for biotechnology products given essentially as replacement therapy at physiological levels, especially when clinical experience exists (e.g., insulins, calcitonin, and pituitary-derived growth hormone) [121,136,147]. Product-specific assessment of carcinogenic potential may be necessary depending on clinical dosing regimen, patient population, and biological activity of the product. For products that have the potential to induce cell proliferation (e.g., growth factors), an in vitro evaluation of receptor expression in cells relevant to the patient population may be conducted. If these data indicate a need for further evaluation of carcinogenic potential, 2-year studies in a single rodent species should be considered.

Long-term carcinogenicity evaluations with endogenous peptides and proteins or their analogs are generally indicated when [136]

- Significant differences in biological effects to the natural substances are found
- Modifications lead to significant changes in structure compared to the natural substance
- Therapeutic exposure levels exceed those that normally occur in the systemic circulation or in tissues

A specific example of studies recommended for the analog of a naturally occurring decapeptide, GnRH, is presented under Biological Entities [192].

Regulatory guidelines as to when and why carcinogenicity studies should be conducted with naturally occurring substances and their analogs exist, as do opinions from industry, academia, and regulatory agencies regarding the propriety of conducting these studies [121,147]. For each NBE under development, the existing opinions and guidance must be considered, a reasonable plan to establish safety must be developed, and a discussion with the appropriate regulatory agency should be held to test the plan. Safety evaluation of NBEs is still very much a case-by-case consideration. The pharmaceutical industry must be careful not to overinterpret the position that carcinogenicity studies are not usually appropriate for biotechnology products.

CHEMICAL ENTITIES

The extent and types of safety testing of synthetic organic pharmaceutical agents in animal models depend on a variety of factors, including the potential duration of treatment of patients (e.g., short term, antibiotics; chronic, antihypertensives), route of administration, pharmacologic mechanism of action, proposed patient population, and clinical experience with other agents in that therapeutic class. Furthermore, the design of animal toxicity studies that occur later in development must carefully consider the results of previous tests in animals and humans relative to bioavailability, unanticipated toxic responses, and relevance of species selected.

Generally, toxicity testing in animals can be considered in four phases: testing to support candidate selection, testing to support FHD (single- and multiple-dose; phase I), testing to support longer-term and broader clinical efficacy studies (weeks to months; phase II), and testing to support final registration and, if appropriate, chronic treatment (phase III) (Figure 8.8). Although the great majority of testing is performed prior to registration, special studies may be requested by regulatory agencies during the review and approval processes. Following widespread clinical use of a new agent, further testing may be appropriate to examine potential mechanisms of action for unanticipated side effects that become evident in the increasing patient population or subpopulations. These may occur due to genetic differences, environmental factors, age, patient history, existence of other diseases or pathologies, and drug interactions. Other tests may be considered if new formulations of the drug are developed, if the drug is suggested for new indications, or if it will be used in patient populations that were not anticipated during initial development (e.g., pediatrics).

The primary purpose of initial nonclinical testing to support FHD is to determine the toxicity and pharmacokinetics (and oral bioavailability, if appropriate) of the drug candidate in humans following single or multiple doses. Usually, the drug is administered to humans at doses below the anticipated efficacious dose, and doses are escalated until a satisfactory multiple over the anticipated efficacious dose is achieved or toxicity becomes evident. Unless the drug candidate has known serious toxicity, as is the case with many oncolytics, it is usually first tested in a limited male, nonpatient population that is under constant observation. As indicated earlier, the FDA supports the early inclusion of women in clinical trials for new therapies, especially those to be used in the treatment of life-threatening diseases [87,89]. Because of this interest, studies of developmental toxicity, which usually occur later in drug development, may be moved to a much earlier point in the drug development process [184].

When designing animal studies to support FHD, a major consideration in dose selection must be the anticipated MOS between animals and humans. Ideally, doses in animal studies should provide exposure to the compound well in excess of what is anticipated at the highest doses to be tested in humans. As discussed previously, a comparison of these doses on a milligram-per-kilogram basis is no longer considered to provide adequate information in this respect due to potential species differences in absorption and rates and routes of metabolism; thus, a good estimate of the pharmacokinetic behavior of the agent in animals is an important

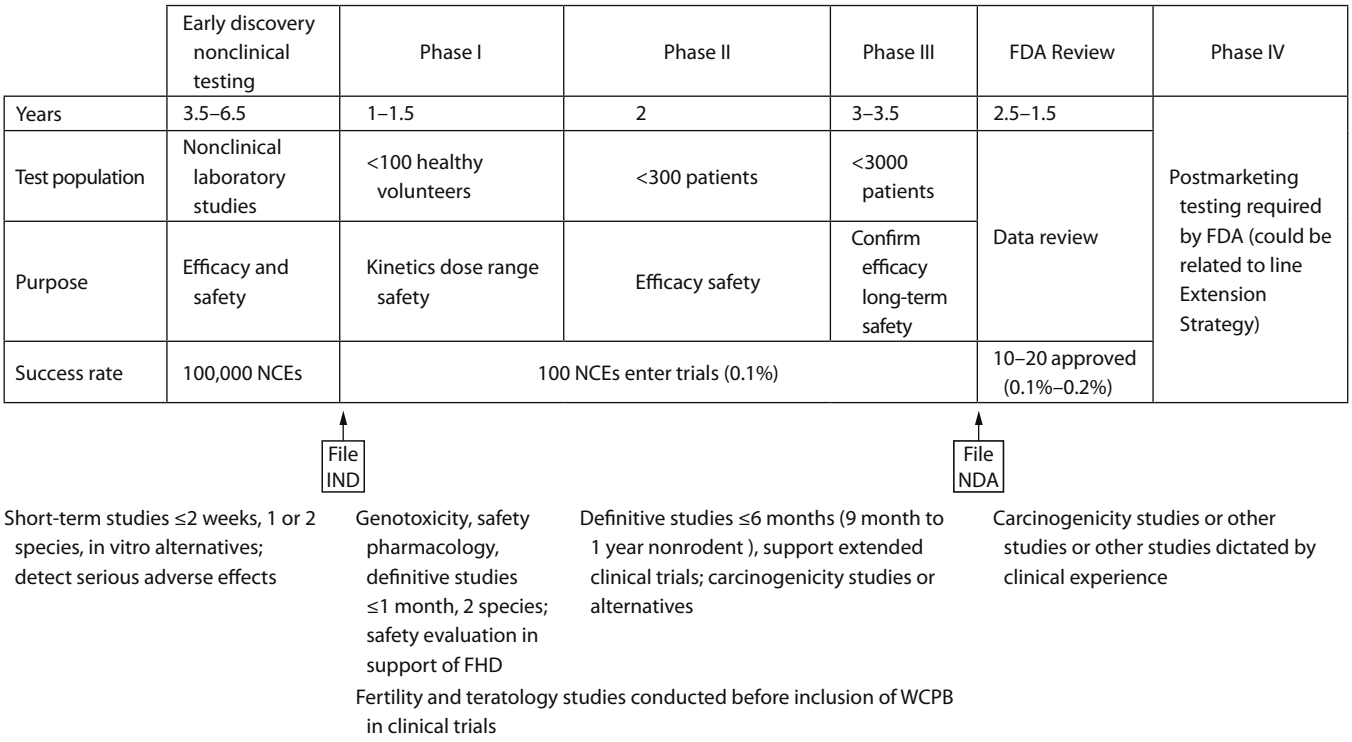

FIGURE 8.8 Schematic of the drug development and approval process in the United States. Similar processes are employed for worldwide pharmaceutical testing. (From Gordon, C.V. and Wierenga, D.E., *The Drug Development and Approval Process*, Pharmaceutical Manufacturers Association, Washington, DC, 1991.)

Source: Data from ICH, Guidance on non-clinical safety studies for the conduct of human clinical trials and marketing authorization for pharmaceuticals, ICH Topic M3(R2), Step 5, ICH Harmonized Tripartite Guideline, *International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use*, Geneva, Switzerland, 2009. See ICH website (http://www.ich.org) for further details and exceptions.

goal of nonclinical testing. No firm guideline exists regarding what should be considered an adequate MOS; however, a smaller margin between the potentially efficacious dose and a toxic dose is tolerated for those compounds under development for life-threatening diseases, particularly if they are expected to offer a distinct therapeutic advantage over other agents currently marketed in the class.

Based on the activities of the ICH, the designs and goals of clinical trials are similar throughout the world. Table 8.5 shows the recommendations for the duration of animal tests relative to proposed human exposure to NCEs. It is possible to discuss the nonclinical and clinical programs with regulatory bodies and, depending on the characteristics and proposed use of the chemical, modify these recommendations.

The duration of animal tests necessary to support a specific duration of clinical trials for NBEs is much more flexible than the comparable guidance for NCEs [147]. Short-term clinical trials for life-threatening conditions may be supported by

2-week nonclinical toxicology studies. Subchronic clinical trials can be supported with toxicology studies of 1–3-month duration. Clinical trials to support chronic therapy can be supported with 6-month toxicology studies.

Regulators throughout the world have recognized that resources could be used more efficiently and efficacious and safe drugs could be made available more rapidly, if guidelines for nonclinical testing and registration were comparable across countries. The ICH has developed a comprehensive set of safety guidelines to harmonize the regulatory requirements of the EU, United States, and Japan. The ICH Expert Working Groups (EWGs) have considered appropriate guidelines for all of the various types of toxicity tests, including acute and subchronic testing, chronic and carcinogenicity testing, reproduction and developmental toxicity studies, and mutagenicity testing. The required duration of animal studies to support human exposure has also been addressed. A good deal of collaboration has occurred between regulatory agencies and pharmaceutical companies in the development of the safety guidelines.

Dorato and Buckley [77] have provided a more complete discussion of toxicology testing and the role of the ICH process in drug development. Table 8.6 shows the ICH guidelines that address the various nonclinical studies required to support clinical trials and registrations in the three major regions (EU, United States, and Japan) and to qualify impurities. A proposal on nonclinical studies to support pharmaceutical excipient development has been made by Baldrick [15]. Selected Internet websites providing information on the design of toxicology studies to support clinical trials are shown in Table 8.7.

As mentioned previously, the speed with which safe and effective new drugs enter clinical trials and eventually the market is a focal topic for regulatory agencies and the pharmaceutical industry. In the past, the FDA [88] and the European Committee for Human Medicinal Products (CHMP) [44] have published guidelines that provide an exception to the minimum 2-week rodent and nonrodent study requirements of the ICH and allow for single-dose toxicity studies in support of targeted clinical trials. The FDA guidance [88] was intended to facilitate choosing compounds to enter phase I human studies. The CHMP [46] guidance was intended to facilitate early characterization of pharmacokinetic properties or receptor selectivity profiles using, for example, positron emission tomography (PET). The clinical trials could test several closely related pharmaceuticals with the intent of choosing the preferred candidate or formulation for further development. The CHMP guidance recommended a maximum dose of 100 μg. Following these attempts, the FDA, in keeping with their Critical Path Initiative [92], published a guidance on exploratory investigational new drug (eIND) studies [93]. The FDA guidance clarifies the nonclinical and clinical approaches to the conduct of exploratory studies that occur very early in phase I, involve very limited human exposure, and have no therapeutic intent (e.g., screening). The dosing duration in the clinical study is expected to be ≤7 days. The flexibility available for drug development and examples of the use of the eIND approach are presented. This is a proposal of an approach that could facilitate the development of safe and effective drugs.

Specific Agents

As mentioned previously, two NCEs (omeprazole and zidovudine) were selected for discussion due to their different target patient populations, which drove the design of customized toxicology testing strategies. While these still represent good examples of the drug development process from a toxicology perspective, updated regulatory guidances and recommendations govern current approaches. For example, the establishment of new limit doses (1000 mg/kg), use of transgenic mouse models in place of the traditional 2-year mouse carcinogenicity study, and the acceptability of a 9-month chronic nonrodent study are just a few that should be considered. As with any drug development program, strong partnership with the regulatory agencies is essential in providing the most appropriate safety package to support the registration of an NCE. The discussion that follows for omeprazole and zidovudine is limited primarily to the data that supported their initial approvals (and, in the case of zidovudine, include postapproval commitments) to demonstrate how disease state and early toxicology findings can influence subsequent development strategy.

Omeprazole (Prilosec®)

Omeprazole is a substituted benzimidazole that is a potent inhibitor of H^+/K^+ ATPase (proton pump) at the secretory surface of the gastric parietal cell, thereby inhibiting gastric acid secretion [20,158,196,231]. Omeprazole is indicated for the short-term (4–12-week) treatment of active duodenal and gastric ulcer, gastroesophageal reflux disease (GERD), severe erosive esophagitis, and maintenance of healing of erosive esophagitis, as well as the long-term treatment of pathological hypersecretory conditions such as the Zollinger–Ellison syndrome. It is also approved for use with clarithromycin and amoxicillin for the treatment of patients with *Helicobacter pylori* infection and duodenal ulcer disease. Omeprazole OTC, an over-the-counter product, is approved only for frequent heartburn occurring 2 or more days a week. The recommended dosage for short-term indications is 20–40 mg daily (approximately 0.4–0.8 mg/kg in a 50 kg individual). For long-term indications, the recommended initial dose is 60 mg daily; however, doses up to 120 mg three times daily have been administered [187,188]. Table 8.8 lists the toxicology studies that were submitted to the FDA [86] to support the U.S. registration of omeprazole. The content of the toxicology package suggests that the intravenous route may have also been a considered route for therapy.

The results of acute, subchronic, and chronic studies suggested that the toxicology profile of omeprazole was generally unremarkable [36,79,86,125]. The acute toxicity of the compound in rats and mice was low, as demonstrated by the oral LD_{50} values (the dose that kills 50% of the animals tested), generally in excess of 4 g/kg. Multiple-dose studies in rats

were conducted at doses up to 414 mg/kg/day for 3 months and up to 138 mg/kg/day for 6 months. No consistent effects on body weight or feed consumption were reported in those studies. Treatment-related findings that occurred at high doses in these studies included decreases in several erythrocytic parameters and decreases in plasma glucose and triiodothyronine. The latter finding was ascribed to a reduction in the peripheral conversion of thyroxine to triiodothyronine. Increased liver and kidney weights were observed in both studies, as well as in the 24-month rat oncogenicity study. Elevated kidney weights were correlated with an apparent exacerbation of the progress of chronic nephropathy that normally occurs in aging Sprague Dawley rats.

Dogs were treated with omeprazole for 3 months at doses up to 138 mg/kg/day or 12 months at doses up to 28 mg/kg/day. Clinical chemistry findings were generally

TABLE 8.8
Summary of Toxicology Studies Conducted to Support the Registration of Omeprazole in the United States

Acute Toxicology
- Oral study in mice
- Intravenous study in mice
- Oral study in rats
- Intravenous study in rats
- Oral study in dogs

Subchronic Toxicology
- 2-week intravenous study in rats
- 1-month intravenous study in rats
- 1-month intravenous study in dogs
- 3-month oral study in rats
- 3-month oral study in mice
- 3-month oral study in dogs
- 3-month oral study in dogs with 3-month recovery

Chronic Toxicology
- 6-month oral study in rats
- 3-month and 6-month oral studies in rats with 2-week to 6-month recovery
- 2-year study in female rats to examine gastrin-dependent variables
- 1-year oral study in dogs with 4-month recovery

unremarkable, although, as observed in the rat, some decreases in hematology parameters and plasma triiodothyronine were noted. The most significant nonclinical finding in both rats and dogs was a reversible gastric mucosal cell hyperplasia with increases in mucosal thickness and folding. In the 6-month study in rats, omeprazole induced a dose-related eosinophilia of the zymogen granules of the pepsinogen-secreting chief cells, with slight atrophy of these cells occurring at the high dose. Slight chief cell atrophy was also observed in dogs given the high dose of omeprazole for 3 or 12 months. To characterize these gastric changes more rigorously, a rather extensive reversibility study was conducted in rats in which animals were treated with either 0 or 138 mg/kg/day omeprazole for 14 days or 1, 3, or 6 months. Other groups of animals were treated with that dose of omeprazole for 3 or 6 months, followed by recovery periods of 14 days or 1, 3, or 6 months. This study demonstrated the time dependency and complete reversibility of the gastric lesions in rats. A 3-month recovery period following 3 months of treatment in dogs showed that the slight chief cell atrophy observed at 3 months was reversible. Also, a 4-month recovery period following 12 months of treatment in dogs demonstrated the reversibility of mucosal hyperplasia and chief cell atrophy, although increased mucosal folding was still evident.

No teratologic findings were observed in the rat at omeprazole doses up to 138 mg/kg/day administered on days 6–15 of pregnancy. The two highest doses tested in rabbits (approximately 70 and 140 mg/kg), administered during days 6–18 of pregnancy, resulted in maternal toxicity as evidenced by anorexia and reduced water intake. Signs were sufficiently severe that treatment of animals at the high dose was discontinued on day 14. Fetal mortality was increased in conjunction with maternal toxicity, but fetal development was unaffected by maternal omeprazole treatment. The major finding of the fertility and peri- and postnatal studies was a decrease in the weight gain of pups of maternal animals given the high dose of 138 mg/kg/day during late pregnancy and lactation. This correlated with a decrease in maternal body weight and feed consumption during late lactation. Whether the decrease in pup weight gain was the result of the decrease in maternal feed consumption or whether it may have been a direct effect on offspring via the breast milk transfer of the compound is not known.

In the mouse oncogenicity study, animals were treated with up to 138 mg/kg/day omeprazole for 18 months. A decrease in survival was noted at the high dose, but no neoplasia was observed in any organ. Different results, however, were obtained in the rat oncogenicity study, in which animals were treated with 13.8, 43, or 138 mg/kg/day omeprazole for 24 months. Enterochromaffin-like (ECL) cell hyperplasia, progressing to ECL cell carcinoids, occurred in dose-related fashion in these animals, with males being affected at doses of 43 and 138 mg/kg/day and females being affected at all

dose levels. These positive findings resulted in the temporary suspension of the clinical trial program. The carcinoids were characterized as *end-of-life* tumors, as the first was discovered at 82 weeks of treatment in an animal that had died prematurely. Carcinoid tumors were not identified as the cause of death in any animals, and no metastases were found. A 2-year study was repeated in females in an attempt to define a dose at which ECL cell carcinoids did not occur; however, carcinoid formation again occurred in a dose-related fashion, including at the lowest dose tested (1.7 mg/kg/day).

A major question that must be addressed following positive results in a carcinogenicity bioassay is whether tumorigenesis was the direct result of chemical insult or could be related to the pharmacologic mechanism of action of the compound. Furthermore, whether the model is appropriate for extrapolation of these findings to humans requires evaluation. For example, at this late stage in the development of a compound, sufficient pharmacokinetic data should be available in both the animal species tested and humans to determine whether a finding might be restricted to a species that metabolizes the compound quite differently from humans. If this is the case, further mechanistic studies can be designed to support or refute the applicability of the findings.

A number of in vivo and in vitro mutagenicity studies were conducted with omeprazole (Table 8.8). An initial mouse micronucleus test with omeprazole administered to animals at a high dose of 5000 mg/kg produced equivocal results, with slight increases in the mean numbers of micronucleated cells compared to controls (approximately twofold, compared to 30-fold following a 0.4 mg/kg dose of the positive control, mitomycin C). It was noted that the dose of 5000 mg/kg was not well tolerated. A second mouse micronucleus test conducted with a maximum dose of approximately 800 mg/kg did not show evidence of mutagenic potential. All other mutagenicity tests conducted produced negative results, suggesting that the tumorigenesis observed in the 2-year rat studies was not the result of a genotoxic action of omeprazole or its metabolites.

Mechanistic studies in dogs and rats, combined with correlative data from clinical trials, ultimately provided the information to support the safe use and registration of omeprazole. At the doses selected for the toxicity studies, the sustained decrease in luminal pH of the stomach resulting from the inhibition of gastric acid secretion by omeprazole caused a substantial increase in the release of gastrin into the blood. In fed rats, gastrin levels in plasma normally range from 150 to 200 pg/mL. Omeprazole administered at doses of 13.8–138 mg/kg/day increased plasma gastrin concentrations to 1000–3000 pg/mL. Gastrin has a trophic effect on the gastric mucosa and results in the hyperplasia of several cell types, including ECL cells, and consequent mucosal thickening. These data suggest that omeprazole does not inherently cause ECL cell hyperplasia and resulting carcinoid formation. Indeed, in antrectomized dogs (the major source of gastrin is surgically removed), high doses of omeprazole for 1 year resulted in neither hypergastrinemia nor mucosal hyperplasia [79]. Similarly, antrectomy in rats prevents the hypergastrinemia and ECL cell hyperplasia associated with omeprazole treatment [158].

The course of development of omeprazole demonstrates the importance of conducting mechanistic studies to elucidate the significance of findings in animal safety studies and whether the effects can meaningfully be extrapolated to humans. Clearly, a close collaboration between the toxicologist and clinician during advancing human trials is critical to resolve questions related to human safety. The extensive clinical experience with omeprazole has confirmed its safe and effective use for treatment of the described indications [20,188]. In a group of patients who required continuous treatment with 40 mg of omeprazole for up to 4 years, no evidence was found for dysplastic or neoplastic changes [58]. Over 12,000 endoscopic biopsies further supported the clinical safety of omeprazole relative to its potential for causing hyperplastic changes.

It should be noted that development of omeprazole probably took years longer than anticipated due to the need to conduct the supplementary mechanistic and carcinogenicity nonclinical studies, as well as additional clinical investigations. Clearly, in these situations, the sponsor needs to evaluate whether the additional time and expense required for approval are supported by the market need. In this case, in 2001, 12 years after approval and prior to being approved for over-the-counter distribution, Prilosec was the world's second biggest selling drug.

Zidovudine (Retrovir®/AZT)

Zidovudine (azidothymidine [AZT]) inhibits viral RNA-dependent DNA polymerase (reverse transcriptase) and, thus, viral replication. Furthermore, as a thymidine analog, zidovudine becomes incorporated into growing strands of DNA by viral reverse transcriptase and inhibits the further addition of nucleotides. It is intended for use in the management of adult patients with human immunodeficiency virus (HIV) infection when antiretroviral therapy is warranted [189]. It is also indicated for the prevention of maternal–fetal HIV transmission during gestation and labor and in the neonate after birth. The recommended dose for adults is 600 mg/day in divided doses in combination with other antiretroviral agents. Zidovudine is also available for intravenous infusion in patients with advanced disease and for use in women during labor and delivery. In spite of the intended long-term use of the compound, it was approved with a minimal toxicology package due to the serious nature of the disease and lack of alternative efficacious therapies.

The studies listed in the upper portion of Table 8.9 were either submitted as part of the original NDA in December of 1986 or as amendments to the application shortly thereafter [85]. At the time of the initial pharmacology/toxicology review, a variety of chronic toxicity studies were still underway or planned. The FDA commentary indicated that "Nonclinical toxicity data submitted in support of the application include results of studies in rats, dogs, and cynomolgus monkeys. FDA guidelines would have prescribed more extensive non-clinical testing than that reported thus far; however, the urgency for developing an anti-AIDS drug has been so great that clinical testing has preceded the usual/customary nonclinical testing. For example, while data from a 6-month *clinical* study are available, results for the

TABLE 8.9
Summary of Toxicology Studies Submitted for Initial FDA Review to Support the Registration of Zidovudine in the United States

Acute Toxicology
- Intravenous study in mice
- Intravenous study in rats

Subchronic Toxicology
- 2-week intravenous study in dogs with 2-week recovery
- 2-week oral study in rats
- 2-week oral study in dogs
- 2-week oral study in monkeys
- 1-month intravenous study in rats with 2-week recovery
- 3-month oral study in rats with 2-week recovery
- 3-month oral study in monkeys with 6-week recovery
- 6-month oral study in rats with 2-month recovery

Reproductive and Developmental Toxicology
- Segment II oral teratology in rats
- Segment II oral teratology in rabbits

Genetic Toxicology

- Ames *Salmonella* test with/without metabolic activation
- Cell transformation assay
- In vivo cytogenetic study in rats
- In vitro cytogenetic study in human lymphocytes

Summary of Toxicology Studies Planned or in Progress at the Time of Initial FDA Review of Zidovudine
- 6-month oral study in monkeys
- Segment I oral reproduction/fertility study in rats
- Segment III oral peri- and postnatal study in rats
- Segment II oral teratology study in rabbits
- 1-year oral study in rats
- 1-year oral study in monkeys
- Oral carcinogenicity study in rats
- Oral carcinogenicity study in mice

supporting 6-month *nonclinical* toxicity studies have not yet been submitted" [emphasis added]. An approvable letter issued by the FDA in March of 1987, less than 4 months following submission of the NDA, stipulated the timing for the conduct of these outstanding studies. Comprehensive reviews of the acute, subchronic, chronic, genetic, carcinogenic, reproductive, and developmental toxicity studies have been published [12,13,118].

Zidovudine demonstrated relatively low acute toxicity with intravenous median lethal doses (MLDs) of greater than 750 mg/kg in rats and mice. The most consistent findings in the subchronic and chronic studies with rats, dogs, and monkeys were effects on hematologic parameters. In rats given two divided doses of zidovudine at approximately 50, 150, or 500 mg/kg/day orally for 3 or 6 months, reversible decreases were observed in red blood cell counts and hemoglobin concentration, primarily in the mid- and high-dose groups. The severity of these effects appeared to progress slightly between 3 and 6 months of treatment. No remarkable histopathology was noted in these studies. A subsequent 1-year study, submitted well following the initial approval of zidovudine, revealed a toxicity profile similar to that observed in the 3- and 6-month studies. The severity of anemia did not progress between 6 and 12 months of exposure, and effects were again reversible following discontinuation of treatment.

Dogs were more sensitive to zidovudine treatment. In a 2-week study in which animals were administered 125–500 mg/kg/day orally in divided doses, leukopenia, thrombocytopenia, and decreases in erythroid values were observed at all dose levels. Cytostatic effects were observed in the small intestine at the high dose and were also evidenced by slight-to-moderate non-dose-related lymphoid depletion and mild-to-marked dose-related bone marrow hypocellularity at all dose levels. No cytostatic effects were observed at similar or higher doses in either rats or monkeys. Studies revealed that zidovudine was metabolized almost identically in monkeys and humans, and as a result, the continued nonclinical development of the drug was conducted in the monkey rather than the dog. The species differences in metabolism were not of sufficient magnitude, however, to account for the much greater sensitivity of the dog to zidovudine, and the design of subsequent nonclinical and clinical studies continued to respect the significant findings in this species.

Monkeys responded to a 2-week treatment at divided doses of 125–500 mg/kg/day with a slight reduction in hemoglobin concentrations in one animal at the low dose and in both monkeys given the high dose. In a 3-month monkey study, at divided doses of 35–300 mg/kg/day, dose-related decreases in erythron parameters were noted as early as day 15 of treatment and progressed to live-phase termination. Platelet counts were also increased. Values returned to normal during the 6-week recovery phase of the study. Subsequent (postapproval) 6- and 12-month studies were conducted in the monkey. In addition to the findings in the 3-month study, bone marrow cytology revealed changes consistent with the hematology findings, and marginal decreases in white blood cell counts were observed at the 300 mg/kg/day dose. All findings were reversible.

Teratology studies were also carried out in rats and rabbits prior to approval of zidovudine. Divided doses up to 500 mg/kg/day resulted in no evidence for teratogenicity in either species, but non-treatment-related low fertility rates and mortalities in the rabbit study prompted the FDA to request that a second study be initiated prior to drug approval. Effects were limited to an increase in fetal resorptions and an associated decrease in fetal body weights at the maternally toxic high dose. The potential use of zidovudine in pregnant women to inhibit transplacental HIV transmission prompted additional in vitro and in vivo reproductive and developmental toxicity studies following the initial approval of the compound. These subsequent studies demonstrated that zidovudine is embryotoxic in rats at doses that are not overtly maternally toxic. The postnatal survival, growth, and development of offspring from zidovudine-treated rats were unaffected following several treatment regimens. In general, exposure levels

associated with the effects observed in the reproductive and developmental toxicity studies were significantly higher than those observed clinically.

No evidence for mutagenicity by zidovudine was observed in the Ames *Salmonella* study either with or without mammalian metabolic activation. The compound was weakly mutagenic in the mouse lymphoma assay without metabolic transformation at concentrations of 4000 and 5000 μg/mL; it was also weakly mutagenic with metabolic activation at concentrations greater than or equal to 1000 μg/mL. A positive response was obtained in the mammalian cell transformation assay at concentrations of 0.5 μg/mL or greater. In an in vitro cytogenetic assay in human lymphocytes, zidovudine caused structural chromosomal abnormalities at concentrations equal to or greater than 3 μg/mL; however, in an in vivo rat assay, no chromosomal abnormalities were noted following the intravenous administration of doses up to 300 mg/kg (plasma levels over 400 μg/mL). Subsequent in vivo micronucleus studies in mice and rats revealed dose-related increases in micronucleated erythrocytes, reflecting chromosome breakage or mitotic spindle damage.

Carcinogenicity studies in mice were initiated using single-daily doses of 30, 60, or 120 mg/kg. These doses were reduced to 20, 30, or 40 mg/kg at 3 months of treatment due to treatment-related anemia. Rats were dosed with 80, 220, or 600 mg/kg/day, with the high dose being reduced to 450 then 300 mg/kg. As expected, hematologic changes were observed, but no deaths or morbidities occurred that were considered treatment related in either study. In the mouse study, one benign vaginal neoplasm occurred at 30 mg/kg, and five malignant and two benign neoplasms occurred at 40 mg/kg. Two vaginal neoplasms occurred at the high dose of the rat study. In both cases, the tumors were late occurring and nonmetastasizing. An eloquent argument was put forth suggesting that these vaginal tumors resulted from high local exposure to zidovudine due to the retrograde flow of urine containing high levels of the excreted compound into the vagina. An additional lifetime mouse study to support this hypothesis was conducted in which animals were administered zidovudine intravaginally. Thirteen vaginal squamous cell carcinomas occurred in animals receiving the highest concentration in that study, supporting the contention that systemic exposure to the drug was unlikely to be responsible for the neoplasia observed in the oral studies.

A variety of adverse reactions have been documented in patients receiving zidovudine. Due to the wide range of symptoms associated with the opportunistic infections seen in patients with autoimmune deficiency syndrome (AIDS), it is difficult to assess which adverse reactions are clearly the result of zidovudine therapy. The animal safety studies, however, were highly predictive of the major hematologic toxicities of zidovudine described in humans: granulocytopenia and severe anemia. Similar to the earlier discussion regarding the development of omeprazole, additional mechanistic studies were conducted with zidovudine to explain toxicity findings, even though the drug was intended for the treatment of a potentially fatal disease.

Although the toxicology support package for zidovudine ultimately responded to existing guidelines for registration of a chronic-use pharmaceutical in the United States, its development history demonstrates that the approval system allows considerable flexibility in cases where the market for a life-threatening disease is clearly not satisfied (i.e., antivirals, antifungals, oncolytics). This type of development strategy can only occur with close collaboration between the submitter and regulatory agency and after careful consideration of the risk/benefit assessments.

BIOLOGICAL ENTITIES

Specific Agents

The development of highly purified species-specific protein pharmaceutical agents, made possible through advances in rDNA technology, presents a significant challenge to toxicologists. The major question raised is "What nonclinical toxicology evaluations should be conducted to ensure safety in human clinical trials?" The major issue is the testing of these specific proteins in nonhomologous animal species, where the possibility of immunogenicity, not applicable to the clinical trial, exists [219]. Decisions on appropriate nonclinical study designs for NBEs are generally made on a case-by-case basis. The general consensus that nonclinical toxicity evaluations with species-specific proteins reveal little more than enhanced pharmacodynamic activity rather than predicting the potential for adverse effects needs constant reevaluation. Furthermore, the toxicity observed in animal studies may be the result of an immunologic response to the foreign protein. Toxicology studies with NBEs should demonstrate that the product has no adverse effects other than those specifically related to pharmacodynamics and that safety for the expected clinical dose range, rather than exaggerated toxicity (MTD), should be demonstrated [19,186,219]. The approach to nonclinical safety evaluation of biopharmaceuticals has been extensively reviewed [38].

Regulatory agencies have placed great emphasis on chemical characterization of the NBE as a means of establishing that it is identical with the naturally occurring protein (manufacturing contaminant issues aside). Establishing this identity has allowed for appropriate modification of toxicology requirements and abbreviation of the toxicology support package; however, NBEs are being developed that contain amino acid sequences that have been purposefully manipulated to differ from the naturally occurring protein to result, for example, in a prolonged duration of action over the naturally occurring agent. These molecules may require a more comprehensive toxicology package, such as those established for NCEs (see preceding text).

Safety testing of NBEs can be presented in three categories (Table 8.10). The reasonably clear-cut time sequence of nonclinical and clinical studies established with NCEs is not often feasible with NBEs. The interactions between toxicologists and clinicians are important in addressing suspected adverse reactions in the clinical trials [19]. Nonclinical

TABLE 8.10
Safety Testing of Biotechnology Products

Category	Requirements
1	Identity, purity, pharmacology, safety pharmacology
2	Category 1, plus detailed pharmacologic activity (human, animal), relationship of plasma concentration and antibody titer (human, animal, in vitro), tolerance, and selected toxicologic testing
3	Categories 1 and 2, plus studies guided by indication and studies guided by duration of treatment

Source: Bass, R. and Scheibner, E., *Arch. Toxicol*., 11(Suppl.), 182, 1987.

toxicology evaluations of NBEs should be designed according to the risks anticipated from the type of product, the contaminant profile, and the intended clinical use [19]. Major questions and differences of opinion will continue to exist relative to the evolution of nonclinical toxicology testing strategies of NBEs. The major questions will arise concerning appropriate species [74,219], the need to conduct genetic toxicology studies [14,209], the conduct of reproductive toxicology assessments [219], and the need for classical carcinogenicity studies. As examples of NBEs, we have chosen to discuss toxicology support for the registration of the GnRH analogs, IFN, and human insulin. The development of IFN has provided a great deal of guidance for nonclinical toxicity testing of NBEs. The pharmacologic effects of insulin are well known from extensive clinical experience. This experience has aided the relatively rapid approval of rDNA insulin products and has allowed the chemical characterization of test material to play a major role in supporting a more limited toxicology profile. Human insulin, therefore, provides an example of an NBE that was approved rapidly, in approximately 5 months [158] (insulin was approved through FDA CDER division, not CBER).

The ICH S6 guidance [147] addresses the international consensus on safety testing for biotechnology-derived pharmaceuticals. It is expected that the product used in the outlined pharmacology and toxicology evaluations is comparable to the product proposed for the initial clinical studies. The evaluations are also expected to be conducted in relevant animal models, for example, models in which the test material is pharmacologically active. The options around relevant test species [41] and the use of either one or two species are discussed in the published guidance [147]. The guidance confirms the generally held opinion that conventional toxicology approaches are generally not appropriate for biopharmaceuticals; options and alternatives around carcinogenicity, mutagenicity, reproductive toxicity, safety pharmacology, etc., are discussed in the guidance [147]. In developing plans for evaluation of biopharmaceuticals, it must be remembered that not all studies used to define safety will be able to comply with GLP guidance. The application of GRPs, in those cases, with attention to documentation and reproducibility/reconstruction of a study is necessary.

The use of homologous proteins is a potential option when no relevant species is identified. This approach has the ability to identify hazards but is not generally useful for quantitative risk assessment and is generally of little value in assessing the potential for carcinogenicity, should that be part of the development plan [147].

Gonadotropin-Releasing Hormone Analogs

GnRH analogs are either agonists or antagonists of the receptor for the naturally occurring hypothalamic decapeptide. The chemical modifications either increase the biological activity and duration of action or affect the solubility, potency, and kinetics of the molecule. GnRH analogs were first introduced for the treatment of cancer (e.g., prostatic carcinoma), and their toxicologic assessment was less complete than usually recommended for new drugs. Since their introduction, the use of GnRH analogs has expanded into treatment of non-life-threatening conditions, and they now are expected to have to undergo the same rigorous toxicology evaluation as other new drugs [192]. In the case of GnRH analogs, the FDA has allowed the multiple-dose toxicity studies to be conducted at a multiple of human exposure (30- to 50-fold) rather than at doses that define the toxic limits of the compound. Due to the chronic nature of therapy and the chemical dissimilarity with native GnRH, the FDA has recommended that both rat and mouse carcinogenicity studies be conducted. As is the case with multiple-dose toxicity studies, the FDA has allowed that the MTD need not be used but some multiple of the human clinical exposure must be used to set the top dose in the carcinogenicity studies (e.g., 15- to 50-fold). The full toxicity profile recommended for GnRH analogs includes single-dose acute toxicity (rodent and nonrodent), repeated-dose toxicity studies through 6 months in rodents and 9 months in nonrodents, genetic toxicology, developmental toxicology, and carcinogenicity [192].

Interferon

IFNs are classified as IFN-α (leukocyte), IFN-β (fibroblast), or IFN-γ (immune). IFN-α consists of a family of at least 14 highly homologous species. The amino acid sequence homology of the IFN-α subtypes has been reported to be 52%–75% [210,211,224]. The biologic activities of IFNs include antiviral, anticellular, and immunomodulatory activities [224]. The properties of IFNs and their potential uses have been reviewed by Bocci and Trotta [21,223].

The adverse clinical experiences reported with the use of IFNs include fever, chill/rigor, headache, tremor, nausea, vomiting, myalgia, anxiety, fatigue, malaise, anorexia, confusion, local inflammation, cardiovascular toxicity, hepatotoxicity, and abnormal electroencephalograms (EEGs) [96,202,203,210,230]. The most commonly reported adverse effects are fever, fatigue, and leukopenia [210]. The effects that cause the most distress in clinical subjects are those related to CNS depression [230]. The toxicity seen with very pure and single-clone IFN preparations is almost identical to that reported for the less pure, more heterogeneous preparations of IFNs. The responses reported, particularly the influenza-like

syndrome, therefore, are likely intrinsically related to IFNs and not to a contaminant or impurity [210,230].

The species specificity of highly purified human IFNs implies that classical animal (nonhomologous) efficacy and toxicity models are not applicable in evaluation of these materials. Nonclinical safety testing of IFNs has not identified an appropriate animal model [100,127,193,199,210,253], supporting the recommendation that the routine safety tests applied to NCEs should not be applied haphazardly [205] to NBEs. Yet, given the traditional significance and predictive nature of nonclinical toxicology evaluations and acknowledging the lack of generally accepted and validated nonclinical animal models for the testing of these entities, drug regulatory agencies have published safety testing guidelines that place NBEs on a level with conventional drugs relative to the comprehensive requirements for animal safety studies [103,150]. A representative example of these guidelines and requirements is given in Table 8.11.

IFN-α2a (Roferon®-A) is a commercially available NBE identical to 1 of the 15 subtypes of human leukocyte IFN [224,225]. At the time that clinical trials were initiated with this drug, considerable clinical data were available from studies with other leukocyte IFNs to indicate the types of adverse reactions, described earlier, that might be expected [210,229]. The species specificity of recombinant IFN-α2a has led to production of neutralizing antibodies in rodent and nonrodent species [224]. This has impaired the ability of toxicology studies to detect the expected adverse clinical signs in common toxicology species.

Acute, single-dose toxicology studies (Table 8.12) were conducted in a variety of species in an attempt to disclose any unexpected acute toxicity related to the clinical dosage form (excipients, active ingredients). No mortalities were noted in the species tested. The LD_{50} of IFN-α2a was determined to be >22.8 × 106 units/kg i.v. These studies were conducted at multiples of a single clinical dose (3×10^6 units/kg), ranging from 10- to 167-fold. Multiple-dose toxicology studies were conducted over a range of 5–26 weeks at 3- to 78-fold the weekly clinical dose (9×10^6 units/kg) (Table 8.13). A low frequency of treatment-related adverse findings was reported: slight weight loss in rats; a slight, reversible increase in platelets and total leukocytes in mice; a slight decrease in hemoglobin and hematocrit in squirrel monkeys; dose-dependent anorexia and weight loss in *Macaca mulatta*; and transient anorexia in *Macaca fascicularis*. In studies longer than 2 weeks, neutralizing antibodies developed in rabbits, guinea pigs, and *M. fascicularis* [216]. These results were expected and may have affected the signs of toxicity. Reproductive studies carried out in *M. mulatta* indicated that a dose-dependent increase in abortion was related to the administration of IFN-α2a.

TABLE 8.11
Recommendations for Interferon Testing by the French Ministry of Social Affairs

Toxicologic Test	Recommendation
Acute	Two species, both sexes in one species; two routes; 2-week observation
Subchronic	Two species, rodent and primate; 3 months of daily injections
Reproduction	Segments I, II, and III
Mutagenicity	In vivo and in vitro clastogeneses
Carcinogenicity	Not required
Pyrogenicity	Rabbit
Safety pharmacology	In vivo cardiopulmonary, isolated organs; neurobehavioral studies
Cell culture	Cytostatic and cytotoxic effects

Insulin

The nonclinical toxicity of BHI was evaluated in an unconventional way. The use of graded increments of dose representing multiples of the projected clinical exposure was not feasible due to the pharmacologic effect of hypoglycemia caused by the insulin molecule. Because the pharmacologic effects of insulin were well known, a primary goal of the

toxicology evaluations was to determine whether BHI contained potentially toxic contaminants or impurities (e.g., *Escherichia coli* proteins, endotoxins) that are introduced as a result of the synthetic process. Toxicology studies on BHI were conducted simultaneously with purified porcine pancreatic insulin (PPI) as a positive control, at doses previously established to produce hypoglycemia but not mortality. The doses selected for toxicology studies were varied according to species sensitivity, route of administration, and duration of treatment. In acute, single-dose toxicity studies (Table 8.14), the minimal lethal dose of BHI to rats and mice was >10 units/kg s.c. Dogs given single doses of 2 units/kg BHI s.c. showed the expected hypoglycemia, but no toxicity. No toxic effects were seen in either rats or dogs given BHI s.c. or i.v. for 1 month (Table 8.15). Chronic toxicity, reproductive toxicity, and carcinogenicity studies were not conducted due to the extensive clinical experience with animal-derived insulin and the extensive chemical analysis of the NBE, establishing its identical nature with natural human insulin. BHI was negative in a genetic toxicology screen composed of bacterial mutation, DNA repair, and sister chromatid exchange evaluations. BHI was also not pyrogenic. Overall, BHI did not induce any effects different from those induced by PPI, and all effects seen were extensions of known insulin pharmacology. Investigations demonstrating the virtual absence of endogenous *E. coli* proteins and the absence of antigenic response in rats and guinea pigs sensitized with *E. coli* polypeptides further addressed the safety of the rDNA-derived human insulin product.

TABLE 8.15
Multiple-Dose Toxicology Studies Conducted with Biosynthetic Human Insulin

Species	Route[a]	Duration (Weeks)	Dose (Units/kg)	Clinical Multiple[b]
Rat	s.c.	4	2.4	10×
Dog	s.c.	4	2.0	8×
Dog	i.v.	4	0.1	—

[b] Anticipated clinical dose = 0.24 units/kg/day, s.c.

SPECIAL ISSUES

No-Observed-Adverse-Effect Level

The NOAEL is an important concept in the evaluation of potentially toxic agents [30,162]. The use of the NOAEL in the development of pharmaceuticals has been reviewed by Dorato and Engelhardt [78]. The NOAEL for pharmaceuticals may be defined as the "highest dose/exposure that does not cause important increases in the frequency or severity of adverse effects between exposed and control groups based on careful biological and statistical analysis. While minimum toxic effects or pharmacodynamic responses may be observed at this dose, they are not considered to be adverse to human health or as precursors to serious adverse events with continued duration of exposure" [78]. This approach fits very well with the ICH position that the effect to be determined is the toxicologically relevant effect; that is, the effect that may endanger human health [131].

In addition to the more traditional approach to NOAEL determination, alternatives have been discussed. The benchmark dose approach claims to be a more powerful statistical tool than traditional NOAEL approaches [98]. The term *hormesis* may be considered to describe a response that is stimulatory at low doses and inhibitory at high doses; however, no universally accepted definition of hormesis relative to its use in safety assessment exists. Hormesis theory has been proposed as a method to improve toxicology risk assessment [28,29,31,32]. As a perspective, Axelrod et al. [11] have presented an argument that the existing toxicology data do not support a universal extension of the hormesis concept to regulatory policy. The last 40 years of drug safety evaluations support the more traditional NOAEL methodology as an appropriate approach to risk/benefit for pharmaceuticals. Toxicologists should be open, however, to alternative approaches and challenges to established practices.

Immunotoxicology

Immunotoxicology can be defined as the discipline concerned with the study of adverse effects on the immune system as a result of exposure to xenobiotics [68]. The development of immunotoxicology, since the 1970s, has been reviewed by Koller [155]. It is not the purpose of this section to review in detail the specific evaluations conducted to define immunotoxicity [67,68,221,242] but to discuss the use of these evaluations in a hazard assessment tier approach. Adverse responses of the immune system are known to occur secondary to malnutrition, radiation exposure, neonatal thymectomy, and exposure to certain drugs and chemicals [71,228]. Historically, few chemicals have been shown to be immunosuppressive in toxicology evaluations, probably because the lymphoid organs and the immune system, in general, have been poorly examined. It would be desirable, therefore, to establish an effective tier approach to detect immunotoxicity in standard toxicology studies and also to evaluate the functional nature of the changes observed as a result of drug exposure. It is presumed that a functional change detected in the immune system is predictive of adverse health effects [242]. It must be remembered that a critical function

must be depressed beyond a defined, minimal point (reserve capacity) to indicate a health risk [169]. The tier approach is encouraged because it more carefully directs the use of resources, and a single immune function assay may not comprehensively characterize the myriad of potential toxic effects on the immune system [68]. Specific immune function tests for increasing the capability of toxicology studies to reveal effects on lymphoid tissue and to evaluate more fully the risk of chemical exposure by determining the functional significance of the responses observed have been reviewed [67]. It is known that acute and chronic effects of drug exposure on the immune system can result in three principal undesirable effects: immunosuppression or enhancement, autoimmunity, and allergic reactions [169]. Standard toxicology studies can be used to detect potential immunosuppression through the evaluation of hematologic changes, immune system organ weights and histology, changes in serum globulins, increased incidence of infections, and increased occurrence of tumors in the absence of other explanations [141]. This fits with the outcome of an early consensus meeting held by the National Institute of Environmental Health Sciences (1979) that resulted in the development of a list of relevant immunologic parameters for evaluating chemically induced immunotoxicity. This immunology screening panel has been reviewed [67] and includes pathotoxicology, hematology, host resistance, radiometric delayed hypersensitivity, lymphoproliferation, humoral immunity, and evaluation of bone marrow progenitor cells.

One of the first guidelines for immunotoxicology testing was that developed by the EU in the late 1970s. The focus of these guidelines was to evaluate the potential risk of chemical exposure by evaluating the functional significance of any histopathologic or hematologic effects seen on lymphoid organs in routine toxicity studies [182]. The intention was to pursue the significance of these effects with specific function tests as necessary. It is known that immunotoxicity following drug exposure may take the form of changes in lymphoid tissue organ weights or histology or changes in bone marrow or peripheral leukocytes [68]. Norbury [182], however, pointed out that the evaluation of drug effects on the immune system is related to immune responsiveness and is not simply a single-point examination of lymphoid tissue using histopathology and hematology. Histopathologic changes are generally not believed to be sensitive indicators of drug-induced immunotoxicity, are seen only at fairly high dose levels, and do not necessarily equate with functional immune alterations [68,182,242]. The route and time of exposure relative to the maturational development of the immune system are important considerations in designing an immunotoxicity protocol [39,69].

The application of nonspecific immunotherapy for bacterial and viral diseases has led to an increased level of importance in the determination of immunotoxic effects. The standard toxicology studies that form the basis of toxicologic evaluations should be complemented with specific evaluations useful in determining functional effects on the immune system, especially if the agent in question is a known immune modulator [141]. Immune system function results from a balance of the activities of various cellular components and their

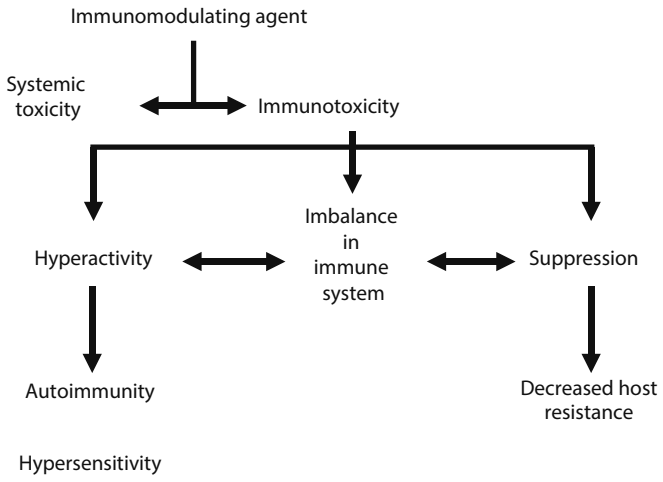

FIGURE 8.9 Potential toxic responses of immunomodulating agents. (Adapted from Falchetti, R. et al., in *Current Problems in Drug Toxicology*, Zbinden, G. et al., eds., John Libbey Euro-text, London, U.K., pp. 248–263, 1983.) Toxicity to the immune system encompasses a variety of adverse effects, including suppression or enhancement of immune response. (From ICH, Immunotoxicology studies for human pharmaceuticals, Topic S8, Step 5, ICH Harmonized Tripartite Guideline, *International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use*, Geneva, Switzerland, 2005.)

soluble factors [195], and an alteration in any factor could result in an imbalance of the entire system [82]. The effects of immunomodulating agents, therefore, could result in either enhancement (e.g., hypersensitivity, autoimmunity) or suppression (e.g., decreased host resistance) (Figure 8.9).

Several tier approaches to immunotoxicity testing have been proposed [66,169]; for example, the National Toxicology Program (NTP) has proposed an immunotoxicology testing strategy that includes a limited number of functional and host resistance assays [66]. The two-tier approach consists of a screen (tier 1), which represents a limited effort that includes the assessment of cell-mediated immunity, humoral immunity, and immunopathology. Tier 1 provides little information on the specificity of an observed immune defect or its relevance to the host; however, it can detect an immune alteration resulting from drug exposure (163). Tier 2 represents an in-depth evaluation, initiated only if functional changes are seen in tier 1 at otherwise nontoxic doses [169]. The in-depth immune function and host resistance evaluations provide information on the mechanisms of the immunotoxicity and aid risk assessment. Luster et al. [169] have reported that no compound evaluated to date has been found to produce an effect in tier 2 without demonstrating some effect in tier 1. The NTP procedure for detection of immune alterations following chemical or drug exposure in rodents is shown in Table 8.16. The concept of performing functional tests is critical to defining potential mechanisms of the toxic response and their applicability to humans. An international collaborative effort has focused on the evaluation of limited pathology or enhanced pathology evaluations to better understand potential immunotoxicity [208,220]. The enhanced pathology

TABLE 8.16
NTP Immunotoxicology Procedure

Immunopathology	Hematology (complete and differential blood count)	Immunopathology	Quantitation of splenic B and T cells
	Organ weights (spleen, thymus, kidney, liver)	Humoral-mediated immunity	IgG response to sheep RBCs
	Body weight	Cell-mediated immunity	Delayed hypersensitivity
	Cellularity (spleen)	Nonspecific immunity	Macrophage function
	Histology (spleen, thymus, lymph node)	Host resistance	Syngenic tumor cells (tumor incidence)
Humoral-mediated immunity	Plaque-forming cells		*Listeria monocytogenes* (mortality)
Cell-mediated immunity	Lymphocyte response to mitogens		Influenza (mortality)
Nonspecific immunity	Natural killer cell activity		*Plasmodium yoelii* (parasitemia)

approach (e.g., weight determination, examination of additional lymphoid organs, grading of changes in the principal compartments of lymphoid tissue) was determined to provide an advantage in revealing effects on the immune system.

The direction for pharmaceutical development is to include tests of potential immune system involvement in the traditional toxicologic evaluations for subchronic and chronic toxicity. Due to the sensitivity of the immune system to toxicants that could adversely affect the critical balance of the various immune factors and the adverse health effects that could ensue, it is extremely important to define any potential interaction of a new drug and immune system function [242].

As can be anticipated from the previous discussion, immunogenicity is a major scientific issue relative to the development of biotechnology products. Concern has been raised over comparison of the recombinant protein and the naturally occurring protein, as animal models are thought to be inadequate to assess the chemically subtle, but potentially immunologically significant, differences in the human response to these molecules. It has been assumed that a recombinant protein, designed for human use, would produce a number of adverse effects (e.g., the production of neutralizing antibodies) in experimental animals. It has now become clear, through chronic exposures in nonclinical studies, that some low molecular weight human proteins are not immunogenic in animals or are only weakly so. They have also been observed not to produce neutralizing antibodies. In the case where antibodies to human proteins have been detected in nonclinical studies, they do not necessarily cause expected immunopathology or neutralization activity. The rhesus monkey has been shown to predict the relative immunogenicity of several recombinant proteins in humans [254] and may serve as a good model.

A further question is, "Should all rDNA products be routinely screened in animals prior to their introduction into humans?" The major reason for conducting immunotoxicity evaluations in experimental animals is to detect those compounds that could induce anaphylaxis or anaphylactoid reactions in humans (Wierda, D. (2006): Personal communication. Eli Lilly and Company, Greenfield, IN.). New molecules, previously minimally tested in animals, such as enkephalins, would have a greater potential risk than well-known molecules, such as insulin. An approach to testing recombinant proteins as well as NCEs for immunogenicity or antigenicity has been suggested based on the extent of the clinical database and the existing regulatory requirements (Figure 8.10). Although studies in animals seem

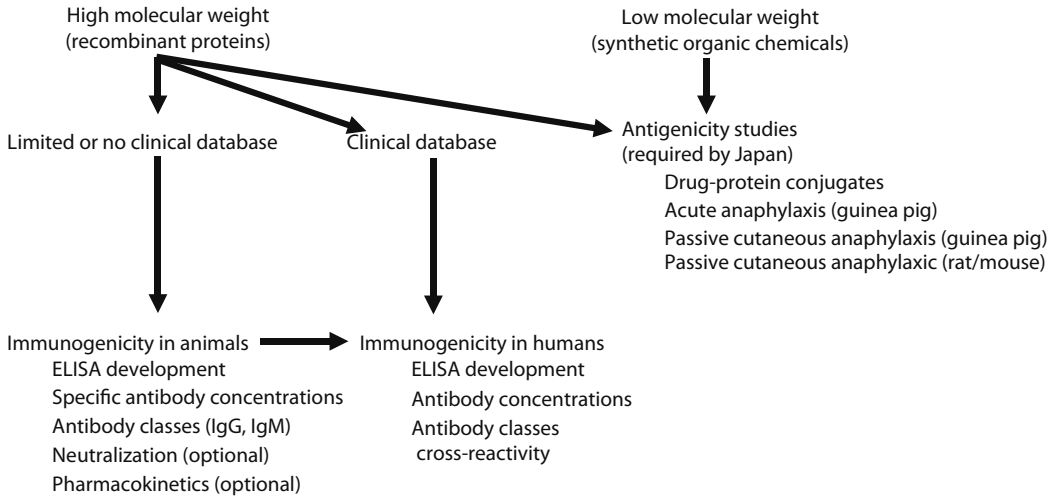

FIGURE 8.10 Proposed approach for addressing immunogenicity and antigenicity issues with established and novel biotechnology products and NCEs. (From Wierda, D., Personal communication, Eli Lilly and Company, Greenfield, IN, 1992.)

well justified for poorly characterized chemicals, it remains an open question whether or not regulatory agencies will accept an existing extensive clinical database as justification for not performing immunogenicity evaluations. Again, the chemical characterization of the recombinant product relative to the natural material will have some bearing on this debate.

The importance of defining the potential interaction between a new drug and the immune system is emphasized in the new regulatory approaches addressing immunotoxicology. The FDA has issued a guidance for industry [91] that identifies five major areas of immunotoxicology:

- Immunosuppression (decreased immune function)
- Immunogenicity (immune reaction to drugs)
- Hypersensitivity (immunological sensitization)
- Autoimmunity (immune reaction to self-antigens)
- Adverse immunostimulation (antigen-nonspecific uncontrolled activation of the immune system)

European Medicines Agency (EMA) has also published a position on immunotoxicology [81]. The major difference between the guidance documents is the mandatory requirement for functional testing in the EMA guidance [65]. The FDA guidance [91] supports a weight-of-evidence approach involving standard tests for each potential new drug [129]. Despite the new guideline approaches, histopathologic evaluation of lymphoid organs and tissues has been important in identifying potential immunotoxicology [157].

The ICH has agreed to harmonize the immunotoxicology guidance among the United States, EU, and Japan (Table 8.6). They have published a guidance on a weight-of-evidence decision-making approach to address nonclinical testing for immunosuppression induced by low molecular weight drugs; the guidance does not apply to biotechnology-derived pharmaceuticals [141]. For the purpose of the guideline, immunotoxicity is defined as unintended immunosuppression or enhancement. Although the guidance does not specify how each immunotoxicity study is performed, it does address the general approach to immunotoxicity testing for new and marketed drugs and provides a flow diagram for the application of recommended immunotoxicity evaluations. The guidance does make a strong connection with the use of the standard toxicity studies and to the use of in vivo pharmacology studies to provide information leading to a weight-of-evidence decision.

Genetic Toxicology

Genotoxicity has been defined as the ability of either a chemical or physical agent to damage DNA, resulting in a mutation [45]. An important element of toxicology is the early identification of potentially hazardous substances [200]. Because the actions of toxicants are ultimately exerted at the cellular level, isolated cell systems represent an important model for identifying toxic effects. In vitro assays allow a greater control over xenobiotic metabolism (e.g., addition of enzymes or inhibitors) and facilitate mechanistic studies that could not be performed in vivo [152]. In vitro tests generally provide a reasonable approximation of the potential for an agent to have an effect on genetic material; in vivo procedures provide a better test for the potential for genetic alterations to occur in the intact organism [154]. The short-term in vitro tests for genotoxicity, potentially predictive of in vivo carcinogenicity, are among the most important techniques available for the rapid determination of potential severe undesirable effects of compounds selected for development. They are also useful in the prioritization of compounds to be studied in the more extended and expensive in vivo toxicology studies. A number of assays are available to evaluate the potential for genotoxicity. The majority opinion is in favor of a battery approach to identify potential genotoxic activity because different assays assess different types of genetic damage and that no one assay is capable of detecting all genotoxic mechanisms relevant in tumorigenesis [152,201]. The ICH has published an updated guideline on how to conduct genotoxicity tests that includes the recommended standard genotoxicity testing battery for evaluations of pharmaceuticals [146]. The ICH test battery includes

- Gene mutation in bacteria to detect relevant genetic changes and the majority of genotoxic rodent carcinogens
- In vitro mammalian cell chromosomal aberration, the in vitro micronucleus assay, or in vitro mouse lymphoma thymidine kinase (TK) assay to detect chromosomal damage
- In vivo assessment of chromosomal effects that allows evaluation of additional relevant factors (e.g., absorption, distribution, metabolism, excretion), through the analysis of micronuclei in erythrocytes or chromosome aberrations in metaphase cells of the bone marrow

This battery may be expanded or modified when appropriate, such as when compounds with structural alerts are negative in the three standard tests or replacing an in vitro mammalian cell assay with the well conducted in vivo assays [146].

Excellent reviews of methods to study the genotoxic potential and issues concerning nongenotoxic but carcinogenic chemicals are available [23,25,149,235,237]. In vivo exposure assays have the advantage of an intact metabolic system to effectively assay those compounds that must be activated (metabolized to a reactive entity) to achieve an effect. The in vitro assays may be conducted with or without the addition of a postmitochondrial supernatant fraction from livers of rats treated with polychlorinated biphenyls to maximally induce drug-metabolizing enzyme activities and thus enhance the detection of indirect-acting agents.

In vitro genotoxicity assays are often used in the early drug discovery process aimed at selecting drug candidates for further development. Often when positive genotoxicity results

emerge, in silico and in vitro screens are commonly used much earlier in the discovery process to guide the chemistry to molecules with no genotoxic risk. The definitive in vitro genotoxicity evaluations of mutation and chromosomal damage are generally submitted prior to the FHD. The complete battery of recommended tests should be submitted prior to phase II clinical development.

Conducting genotoxicity screens on NBEs has been an area of much discussion. The ICH has recognized that the standard genotoxicity testing battery is not applicable to NBEs and generally should not be conducted [147].

Safety Pharmacology

Safety pharmacology involves establishing the pharmacologic profile of new drug candidates by evaluating the pharmacodynamics related to the therapeutic indication and by evaluating the pharmacodynamics on other organ systems not related to the therapeutic indication [56]. These studies are usually conducted at doses well below those used to establish the toxicology profile. It is not necessary or even desirable to produce frank toxicity to establish a valid pharmacologic profile. By definition [139], pharmacology studies are divided into three categories: primary pharmacodynamics, secondary pharmacodynamics, and safety. The traditional approach to safety pharmacology is focused on the third category. However, integration of these techniques with the basic pharmacologic assessment of the primary pharmacodynamics (i.e., cardiovascular pharmacology) is essential in making good decisions about drug development. The inclusion of safety pharmacology approaches in general toxicology studies should be considered whenever possible; the impact of potentially large doses must be considered in the ability to detect the desired responses. The dose–response design of toxicology studies should provide a dose where the evaluation of safety pharmacology parameters is appropriate.

Pharmacologic profiling was initially focused on guiding the synthetic chemist in the discovery of new pharmacologically active chemicals, rather than on the detection of adverse drug effects in humans [247]. Historically, in reviewing the common adverse drug findings in humans, Zbinden [247] pointed out that some responses are easily detected in both humans and experimental animals (e.g., sedation, anorexia, body weight changes, tremor, tachycardia), and some responses are only detectable in humans (e.g., tinnitus, vertigo, nausea, headache). In any event, when one considers the nature of the functional disturbances encountered in both nonclinical and clinical testing, it becomes evident that pharmacologic profiling is critical to the safety evaluation of potential therapeutic agents [238,239]. Every chemical that enters the body has the potential for creating effects that may or may not be related to its pharmacologic activity. Antihistamines, for example, produce sedation, which is related to their desired pharmacologic effects, and anticholinergic responses, which are not [238]. Pharmacologic profiling can help identify the potential incidence of effects unrelated to the known pharmacologic activity. Pharmacologic profiling also provides crucial information for the selection of NCEs during the early discovery process, for the design of toxicology studies, and for the approach to safety monitoring appropriate for clinical trials [167,191]. Traditionally, it is the objective of safety pharmacology to identify risks associated with the pharmacologic characteristics of a particular agent (some would call this toxicology), essential at therapeutically relevant doses and potentially over time, if indicated. There is an advantage in the active integration of basic pharmacology and safety pharmacology approaches; they need to be conducted independently, but with active communication around the outcomes. In the basic pharmacology assessments, imaging technologies are used to provide longitudinal assessments of compound effects in many therapeutic areas. In cardiovascular pharmacology, the use of echocardiography (ultrasound) provides assessment of drug-induced changes in cardiac function and is used in both safety and efficacy studies to great advantage [126].

Again, from an historical perspective, the Japanese Ministry of Health Labor and Welfare (MHLW) had published guidelines for general pharmacology studies (the original reference for safety pharmacology studies) [5]. These studies are designed to characterize effects and potency and to determine mechanism. The guidelines include studies to determine effects on general activity and behavior, the CNS, the autonomic nervous system and smooth muscle, the respiratory and cardiovascular systems, the gastrointestinal tract, and renal excretion.

The ICH guidelines now include select pharmacology guidance (Table 8.6). ICH Topic S7A [139] addresses the definition, objectives, and scope of safety pharmacology studies, as well as studies required prior to phase I clinical trials and prior to marketing approval. The safety pharmacology core battery has been built based on previously existing regional draft guidances [44] and now includes the following vital organ systems:

- CNS
- Cardiovascular system
- Respiratory system

Follow-up studies are recommended to provide a greater depth of understanding of the effects observed in the core battery or from clinical trials on pharmacovigilance: renal/urinary system, autonomic nervous system, gastrointestinal system, dependency potential, skeletal muscle, and immune and endocrine functions; in vitro and in vivo approaches can be used in concert [139,142].

The EU Committee for Proprietary Medicinal Products (CPMP) has published a *Points to Consider* document on QT interval prolongation [55]. The impact of QT prolongation and related occurrence of torsades de pointes with the use of quinolones has been reviewed by Frothingham [105]. The ICH Topic S7B [142] now provides recommendations for nonclinical studies to address the potential for QT interval prolongation. It also provides guidance on integrated risk assessments. The prolongation of the QT interval is one of

the few single physiological responses that could end the development of a potential new pharmaceutical [117].

Measure of Exposure

The relationship of administered dose to toxicologic response is not always a simple correlation. Traditionally, the administered dose (mg/kg) has been the most commonly used expression to compare toxicologic responses between species. The value of the administered dose term as the most appropriate comparator with toxicologic response, however, has been questioned in scientific and regulatory circles. It is becoming increasingly well recognized that both beneficial and toxic effects of therapeutic agents are dependent on the quantity of material reaching the target site [175,222,252]. This has led to in vivo exposure assessments, usually done by measurement of plasma or blood levels of the administered agent, being the most widely used and generally accepted approach to evaluate exposure. These measures also form the basis for any subsequent determinations of exposure multiples or safety margins.

Knowledge of the level of exposure is critical for understanding not only safety but also efficacy. Fully elucidating this knowledge base provides the most robust estimates of safety multiples. In its simplest representation, the safety multiple can be calculated by dividing the highest exposure observed without the presence of an adverse effect by the exposure needed to elicit efficacy. In practice, much more complexity is encountered in making this estimate. Variables such as exposure comparisons across species, the absence of exposure determinations at the target site of activity or toxicity, and nonlinearity of the dose/exposure–response complicate the assessment.

Measures of exposure are also useful in establishing nonlinearity in kinetics, which is important in explaining toxic responses seen in particular species [175]. It seems more rational to establish an upper dose in toxicology studies based on linearity of kinetics rather than at the MTD, as it is often the case that the MTD falls in the range of nonlinear kinetics, saturating normal metabolic processes. Thus, an animal treated at the MTD may be exposed to much higher levels of parent drug or toxic metabolites than would be observed at meaningful multiples of the clinical dose.

The exposure differences often observed across species can sometimes be explained by known differences in rates of absorption and/or metabolic clearance across species. Figure 8.11 illustrates the general relationship of clearance to body weight for dog, rat, and monkey. From this generic depiction, it is apparent how a lower administered dose on a milligram-per-kilogram basis produces a higher exposure in dog compared to rat. This relationship can be extrapolated further to humans, who, in general, would have even slower rates of clearance [179]. The relationship of administered dose to delivered dose remains a central issue in the interpretation of toxicology data. The measurement of plasma concentrations of parent compound and metabolites represents a partial resolution to this problem. There are limitations, however,

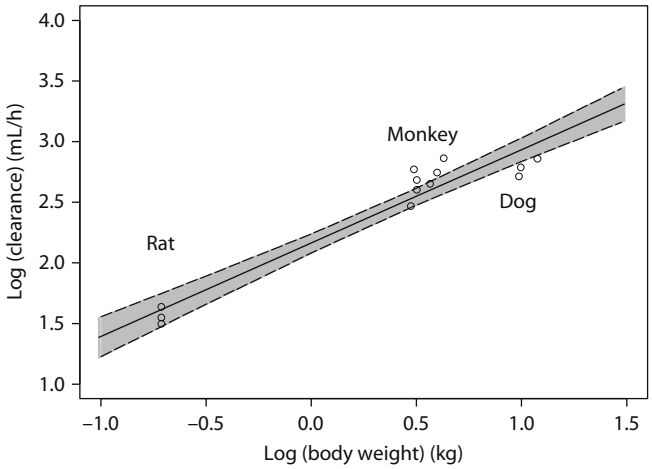

FIGURE 8.11 The general relationship of clearance to body weight for dog, rat, and monkey.

in using plasma concentration as a relevant measure of exposure for those compounds that are tissue sequestered [173]. It has been noted that, although many therapeutic agents achieve tissue levels proportional to plasma concentration, some continue to accumulate in tissue with continued dosing.

Levels of exposure of test compounds or their metabolites at sites of action can be assessed by measuring tissue kinetics. Lovastatin is an example of a compound that exerts its primary pharmacology and toxicity at the same site. In this case, the pharmacokinetics of both lovastatin and its active metabolite has been well characterized [123]. An increasingly more common method is the utilization of quantitative whole-body autoradiography. This technique uses radioactive drug (^{14}C or ^{3}H) to assess concentrations in tissues across the entire body (Figure 8.12). Concentration time profiles can be generated that subsequently can be used to derive various pharmacokinetic parameters. A shortcoming of this technique is its inability to distinguish parent compound from metabolite [42]. Perhaps the most critical aspect of the role of the toxicologist is to complete the multifaceted exposure comparisons, couple this knowledge with that of the observed effects of the test compound, and render an informed opinion of the overall safety profile of the test compound under study.

Clinical Trials in Pediatric Populations

The FDA has found that most products indicated for treatment of diseases that occur in both adults and children have little clinical trial support for pediatric use. As a result, a regulation requiring pediatric studies for certain NCEs and NBEs had been proposed and updated [90,95]. The CPMP had also concluded that specific age-dependent differences in pharmacokinetics, pharmacodynamics, growth process and development, and specific pathology require that therapeutic agents be tested in the target age group [54]. The European Medicines Agency (EMA) has published a guidance covering the conduct of juvenile animal studies in support of pediatric indications [80]. The ICH has recommended that pediatric

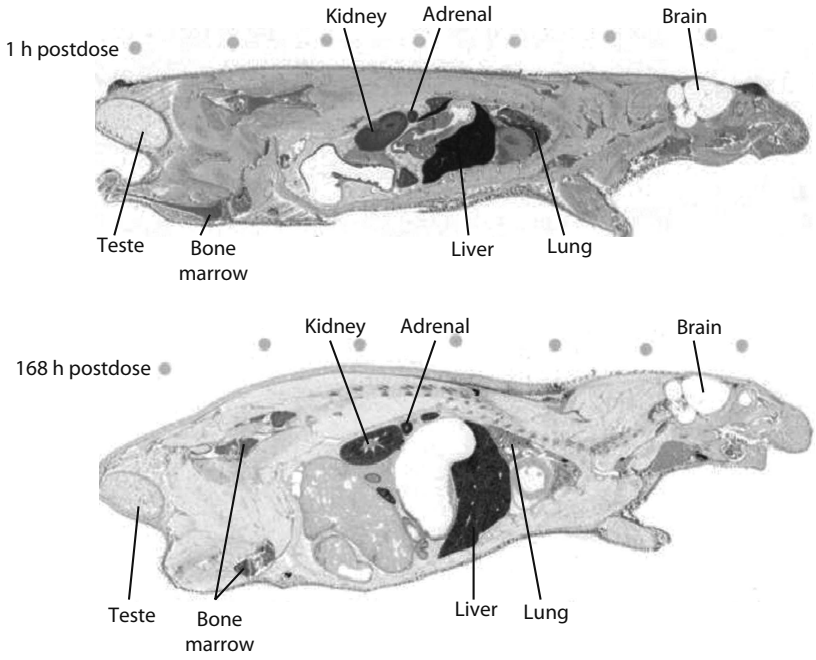

FIGURE 8.12 Phosphor images of whole-body sections from male Fischer 344 rats after receiving a single dose of [14C]-test compound.

clinical trials be supported by repeated-dose toxicity studies of an appropriate duration, all developmental toxicity studies, and the full battery of genotoxicity tests. These studies should be concluded before the pediatric clinical trials begin [145]. Due to the potentially long duration of treatment, carcinogenicity studies must be considered prior to the initiation of long-term pediatric clinical trials. The performance of nonclinical studies in juvenile animals may also be necessary if previous toxicology evaluations and human safety data are not sufficient or raise a cause for concern. In the relatively new guidance on nonclinical evaluation of anticancer drugs [144], it has been stated that the general approach to investigating anticancer drugs in pediatric patients is first to define a relatively safe dose in adult populations. This is the general approach that has existed for including pediatric populations for many years. For oncology indications specifically, juvenile animal toxicology studies are not usually conducted to support the inclusion of pediatric populations. Morford et al. [174] have reviewed the strategies, challenges, and current practice of providing nonclinical safety evaluations for inclusion of pediatric populations in the development of biopharmaceuticals. Pediatric safety assessments supported by nonclinical safety evaluations are now required for every NDA and Biologics License Application in the United States and for Marketing Authorization Applications in Europe [174].

Nonclinical Evaluation of Anticancer Drugs

As discussed earlier, the development of drugs for life-threatening diseases such as cancer and AIDS requires a modification of the approach established for the standard safety assessment of NCEs or NBEs. The treatment of cancer usually includes the use of potent agents designed to halt cell replication. The therapeutic index for these agents is often small. Due to the life-threatening nature of the disease, a greater tolerance of drug toxicity and a shorter nonclinical testing strategy are generally accepted for therapeutic agents in this class, as serious drug effects are often less threatening than the targeted disease; however, due to the greater intrinsic toxicity of the agents in this class, the early clinical trials are often conducted in patients rather than normal volunteers, as with other therapeutic agents.

The history of anticancer drug development has been extensively reviewed [70,119,198,222]. The basic approach for the development of anticancer drugs includes

- Establishment of a safe clinical trial entry dose
- Determination of potential dose-limiting target-organ toxicity
- Evaluation of reversibility of effects
- Determination of MTD in animals
- Determination of dose schedule toxicity

The use of nonclinical studies has been useful in accurately predicting MTDs in humans and safe starting doses for clinical trials [119]. The CPMP has provided a specific note for guidance on the nonclinical evaluation of anticancer agents [57]. Safety pharmacology is generally required prior to phase I studies, as are the determination of C_{max} (maximum plasma concentration of the drug) and AUC at the animal MTD. Other kinetic parameters are expected to be determined prior to phase II/III testing. Determination of the single-dose MTD in rodents and the approximate MTD in nonrodents, using a relevant route of exposure, is also expected prior to phase I. Repeated-dose toxicity studies in two rodent species

are expected prior to phase I clinical studies. Longer-term repeated-dose studies, in a rodent and nonrodent species, that are equal in duration to the clinical trial but less than 6 months are expected prior to phase II/III. Genotoxicity testing is not necessary prior to phase I/II, but the genotoxicity battery is expected to be conducted prior to phase II/III. Because cytotoxic anticancer agents are known to have an adverse effect on reproduction, developmental toxicity studies are not required but are encouraged. The development of anticancer drugs and other therapies for life-threatening diseases has unique characteristics based on the nature of the disease and the inherent toxicity of the therapeutic agents.

ICH guidance S9 [144] now addresses an international consensus on the nonclinical evaluation of pharmaceuticals for the treatment, but not for the prevention, of advanced cancer. The guidance [144] applies to both NCEs and NBEs. As stated earlier in the historical review, the development of therapy for advanced cancer requires a good deal of flexibility in the application of established nonclinical approaches. The nonclinical evaluation calls for the development of a nonclinical proof of principle as established by in vivo pharmacology studies of efficacy and in pharmacologic evaluations of effects on the heart, lungs, and CNSs. In the general toxicology approaches, the determination of the NOEL or NOAEL is not essential. The toxicology studies are designed to support the schedule of administration in the clinical trials and to help with an assessment of reversibility of (or recovery from) adverse events. Reproductive toxicology and genotoxicity evaluations are generally required for support of marketing. The study of carcinogenicity is not required. It is recommended that the reader review ICH S9 [144] for information on kinetics, combined therapies, pediatric populations, etc.

Alternative Methods for Carcinogenicity Determination

The testing for carcinogenic potential has relied primarily on the rodent bioassay [207]. Recently, through the ICH process, the rat has been identified as either the most acceptable or most relevant model for the 2-year bioassay. In addition to the rat bioassay, an alternative short-term method of carcinogenicity evaluation is recommended [144]. These approaches may include studies in transgenic mice (e.g., heterozygous $p53^{+/-}$ gene-deficient mouse or Tg.AC mouse) or the use of a neonatal rodent tumorigenicity model.

To evaluate and verify the available alternative models, the International Life Sciences Institute (ILSI) has initiated a collaborative effort among industry, academic, and government laboratories to study chosen chemicals in the alternative models and evaluate the results in light of the known bioassay data. Current information is insufficient to guide us in the choice of suitable alternative models for carcinogenicity evaluation. It is highly recommended that any deviation from the standard two species (mouse and rat) carcinogenicity bioassay be discussed with the FDA prior to implementation.

When fully validated, the proposed transgenic animal model may be used as follows [34]:

- To confirm results in equivocal 2-year rodent bioassays
- To set priorities for 2-year carcinogenicity bioassays
- As an alternative to the mouse 2-year bioassay, in conjunction with the rat 2-year bioassay
- To assess carcinogenic potential of new genotoxic contaminants or degradants in a drug product after 2-year bioassays are completed

In addition, the use of transgenic animals may support weight-of-evidence decisions; they are relatively short term and are generally less expensive than the 2-year rodent bioassay.

Several transgenic mouse models are available to complement the rat 2-year bioassay. The Tg.AC transgenic mouse, the heterozygous $p53^{+/-}$ gene-deficient mouse, and the $Tg/rasH_2$ mouse are discussed as examples. It must be remembered that these models are not fully validated.

The Tg.AC mouse model [210] examines chemically initiated skin as a target for tumorigenesis. The Tg.AC line may be able to differentiate carcinogens from noncarcinogens but may not be able to differentiate genotoxic carcinogens from those that cause only tumor promotion activity. This model may only be useful in combination with other transgenic animal models [202]. The heterozygous $p53^{+/-}$ gene-deficient mouse model is based on rendering mice heterozygous for the p53 tumor suppressor gene [111]. These animals are at elevated risk for tumor development. The model has been proposed to best approximate humans at risk for heritable forms of cancer. This model may be able to detect genotoxic carcinogens in a 6-month period. The $Tg/rasH_2$ transgenic mouse contains multiple copies of the human c-Ha-*ras* gene. It has been found to respond well to both genotoxic and nongenotoxic carcinogens [170].

The neonatal mouse assay has been available longer than the transgenic animal models. The detailed protocol for this 1-year study has been previously reviewed [101]. Neonates are treated with the test compound on days 8 and 15 of age and then observed to 1 year of age. At that time, the animals are evaluated for tumor production. This assay is sensitive to direct-acting carcinogens, primarily those that work through formation of covalently bound DNA adducts.

The assessment of carcinogenicity in the drug development process is at a crossroads. The rodent bioassay has been used for over 25 years and has provided useful data, although it is not a perfect system and has received much criticism. The investigation of alternatives to the standard bioassay in two rodent species has been encouraged by the ICH. Conducting a 2-year study in the rat and an alternative study in the mouse may provide an acceptable transition. The available alternative models generally accepted as useful in carcinogenicity testing include the $Tg/rasH_2$ transgenic mouse and the $p53^{+/-}$ knockout mouse. The $Tg/rasH_2$ model is preferred for testing nongenotoxic compounds, and the $p53^{+/-}$ knockout model is preferred for testing genotoxic compounds. The general

utility of available alternative models of carcinogenicity testing has been reviewed by MacDonald et al. [170]. Alternative assay results should not be considered on their own but should be included in a weight-of-evidence approach for risk assessment [170]. A historical perspective on the industry's experience with alternative carcinogenicity models has been provided by Ashton et al. [9]. Much work remains to be done before the alternative models are validated and fully useful as potential replacements in carcinogenicity risk assessments. The alternative assays are relative newcomers full of promise but short on experience. Undue enthusiasm about their ability to dramatically improve our carcinogenicity risk assessment process is not warranted. An alternative approach to carcinogenic risk evaluation, focusing on chemical exposure rather than the 2-year rodent bioassay, has been proposed by Cohen [47].

CONCLUSION

The future engagement of toxicologists in drug development decisions appears to be very promising. Physicians and patients continue to expect more efficacious and safer medications, more quickly and less expensively. Basic research efforts in biochemistry, physiology, and pharmacology have allowed the more precise characterization of receptors and the normal and perturbed sequelae of receptor binding, thus continuing to stimulate the development of more specific, potent modulators of cellular functions. The etiologies of human diseases are becoming better understood, thanks to the technologic ability to elucidate their characteristics at the molecular level. This has resulted in the potential to therapeutically modify the disease process at its origin: the human genome. These molecular approaches have already resulted in the development of agents that are highly species specific, and the use of these techniques to elucidate normal and pathological cellular function will only continue to escalate. The development of NBEs has already challenged the established norms of safety assessment. Consider the example of an agent that has shown selectivity for modifying the activity of a human-specific enzyme critical to a pathological process. Although traditional animal studies are likely to be predictive of toxicity that is unrelated to the pharmacology of the compound, they will not be useful for the prediction of adverse findings relative to the action of the drug at the enzyme, which will occur only in humans. Thus, not only may data generated from classical animal studies be inadequate to predict toxic responses in humans, but also the information may be irrelevant or misleading. A major concern is whether modification of this enzyme activity in the only responsive species (humans) might result in unanticipated, severe toxicity. How can this best be predicted prior to the initiation of clinical trials?

It is unlikely that the classical/traditional tools/approaches of toxicology will be sufficient to ensure the human safety of the new highly specific therapeutics forthcoming from sophisticated technologies. It would, however, be unwise to think that the strong foundation in classical toxicologic assessment and risk/benefit analysis has no place in the future of drug development; it is all about balance and the ability to apply new approaches based on a strong understanding of established procedures.

The future direction of discovery research suggests that industrial and regulatory toxicologists will need to collaborate more closely in the design of the toxicology studies to support registration, and ultimately these may have to be considered on a case-by-case basis. Indeed, the current guidelines resulting from global harmonization efforts repeatedly emphasize the need for defending the scientific rationale supporting the design of proposed toxicologic assessments. Although these guidelines are viewed as much more flexible than the country-specific regulations of the past, they also place a greater burden on toxicologists relative to defending the relevance of their studies. The era of *checking the "tox." box* has, thankfully, come to a close.

Another challenge on the horizon concerns the need to improve the efficiency of the drug development process without compromising its quality. Currently, the drug development and approval processes are taking longer and costing more than ever before. More stringent regulatory requirements have resulted in the conduct of more studies (in both animals and humans) that take more time and cost more money. These costs are passed on to the patient, who ultimately must also compensate for the resultant decreased market life, due to patent length restrictions, of the registered product. Furthermore, the use of large numbers of experimental animals remains a concern from both the ethical and financial points of view. One approach to solving these dilemmas is to ensure that the toxicology studies conducted meet the needs of the regulatory agency, the physician, and ultimately the patient. As suggested earlier, this can be most efficiently accomplished by early and routine interactions between the industry and these customers, especially in cases where the agent under development represents a unique therapeutic approach.

The application of omics technologies, such as genomics (toxico- or pharmaco-genomics), proteomics, and metabonomics, is expected to enhance the toxicology toolbox for evaluation of drug safety. Proteomics, the analysis of protein expression patterns, and metabonomics, the evaluation of metabolite profiles, are relative newcomers to drug safety evaluation. Toxicogenomics (or pharmacogenomics) has, perhaps, the greatest potential to affect nonclinical safety assessment [194]. Toxicogenomics focuses on the study of differential gene expression (DGE) as an adaptation to chemical or environmental stress. A basic assumption is that DGE underlies all drug-induced toxic events, with the possible exception of very rapid cell death [129,157]. A goal of toxicogenomics is to identify gene expression patterns that predict potential toxicity [83,195]. The identification of a causal relationship between DGE and delayed manifestations of frank toxicity can facilitate early drug development. It is anticipated that toxicogenomics will be increasingly integrated into all phases of drug development, particularly in mechanistic and predictive toxicology and biomarker identification [122].

The FDA has published a guidance document on submission of pharmacogenetic data [94]. Within the guidance, the FDA acknowledges that the toxicology database required to support clinical trials and marketing of drugs is well established. Any proposal for substitution of new animal genomics safety testing will involve the international scientific and drug development committees [94].

Finally, the major role of the toxicologist as a mechanistic scientist will continue to be enhanced. For the reasons discussed previously, the design of toxicology studies and the interpretation of toxicology data will become increasingly more sophisticated, requiring a *broad* knowledge base in a variety of other scientific disciplines and a strong foundation in classical toxicology approaches [204]. Elucidation of the mechanisms responsible for observed toxicities would improve the ability to achieve the traditional, ultimate purpose of the discipline of toxicology: appropriate extrapolation of these data to humans [243]. Achievement of this goal will surely become more challenging, but also more exciting, as the future approaches to drug development unfold.

QUESTIONS

8.1 What are the differences between NCEs and NBEs?
8.2 What are the safety testing suggestions for category 2 biotechnology products?
8.3 The U.S. FDA has issued guidance that identifies five major areas of immunotoxicology. Please name.
8.4 According to ICH S7A, the core battery of safety pharmacology includes what three vital organ systems?
8.5 What is the basic approach to the development of anticancer drugs?
8.6 Name one alternative method/test that has been proposed for carcinogenicity determination for a new drug.

ACKNOWLEDGMENT

The authors would like to thank the late Dr. John L. Emmerson, Distinguished Lilly Research Scholar, for initiating the inclusion of this chapter in the third edition, 1994.

9 Statistics and Experimental Design for Toxicologists

Shayne C. Gad

CONTENTS

INTRODUCTION

This chapter has been written (and updated six times) for both practicing and student toxicologists and pathologists as a practical guide to the common statistical problems encountered in toxicology and toxicological pathology and the methodologies that are available to solve them. The chapter has been enriched by the inclusion of discussions of why a particular procedure or interpretation is recommended, by the clear enumeration of the assumptions that are necessary for a procedure to be valid, and by the discussion of problems drawn from the actual practice of toxicology and toxicological pathology.

Since 1960, the field of toxicology has become increasingly complex and controversial in both its theory and practice. Much of this change is due to the evolution of the field and science and technology in general. As in all other sciences, toxicology started as a descriptive science. Living organisms, be they human or otherwise, were dosed with or exposed to chemicals or physical agents, and the adverse effects that followed were observed. But as a sufficient body of descriptive data was accumulated, it became possible to infer and study underlying mechanisms of action—to determine in a broader sense why adverse effects occurred. Toxicology has thus transitioned to the mechanistic stage, where active contributions to the field encompass both descriptive and mechanistic studies.

Studies continue to be designed and executed to generate increased amounts of data. Genomics and proteomics have even accentuated this process. The resulting problems of data analysis have then become more complex, and toxicology has drawn more deeply from the well of available statistical techniques. Statistics has also been very active and growing during the last 40 years, to some extent, at least, because of the parallel growth of toxicology. These simultaneous changes have led to an increasing complexity of data and, unfortunately, to the introduction of numerous confounding factors that severely limit the utility of the resulting data in all too many cases.

A major difficulty is the very real necessity to understand the biological realities and implications of a problem as well as to understand the peculiarities of toxicological data before procedures are selected and employed for analysis. These characteristics include the following:

1. It is necessary to work with a relatively small sample set of data collected from the members of a population (laboratory animals, cultured cells, and bacterial cultures) that is not actually our population of interest (i.e., humans or a target animal population).
2. Frequently, data obtained from a sample are censored on a basis other than by the investigator's design. By censoring, of course, we mean that not all data points were collected as might be desired. This censoring could be the result of either a biological factor (the test animal being dead or too debilitated to manipulate) or a logistic factor (equipment being inoperative or a tissue being missed in necropsy).
3. The conditions under which our experiments are conducted are extremely varied. In pharmacology (the closest cousin to at least classical toxicology), the possible conditions of interaction of a chemical or physical agent with a person are limited to a small range of doses via a single route over a short course of treatment to a defined patient population. In toxicology, however, all these variables (dose, route, time span, and subject population) are determined by the investigator.
4. The time frames available to solve our problems are limited by practical, regulatory, and economic factors, which conspire to compress time. This frequently means that there is not time to repeat a critical study if the first attempt fails, so a true iterative approach is not possible.

The training of most toxicologists in statistics remains limited to a single introductory course that concentrates on some theoretical basics. As a result, the armamentarium of statistical techniques of most toxicologists is limited, and the tools that are usually present (*t*-tests, chi-square, analysis of variance [ANOVA], and linear regression) are neither fully developed nor well understood. It is hoped that this chapter will help change this situation.

As a point of departure toward this objective, it is essential that any analysis of study results be interpreted by a professional who firmly understands three concepts: (1) the difference between biological significance and statistical significance, (2) the nature and value of different types of data, and (3) causality. For the first concept, we should consider the four possible combinations of these two different types of significance, for which we find the relationship shown as follows:

		Statistical Significance	
		No	**Yes**
Biological	No	Case I	Case II (false positive)
Significance	Yes	Case III (false negative)	Case IV

TABLE 9.1
Approximate Total Sample Sizes for Comparisons Using the *t*-Test and Equal Group Sizes

	β = 0.1		β = 0.2	
Δ/σ	α = 0.05	α = 0.10	α = 0.05	α = 0.10
0.25	672	548	502	396
0.50	168	138	126	98
0.75	75	62	56	44
1.00	42	34	32	24
1.25	28	22	20	16
1.50	18	16	14	12

Note: Δ is the difference in the treatment group means, and σ is the standard deviation.

Cases I and IV give us no problems, for the answers are the same statistically and biologically, but cases II and III present problems. In case II (the *false positive*), we have a circumstance where there is a statistical significance in the measured difference between treated and control groups, but there is no true biological significance to the finding. This is not an uncommon happening, for example, in the case of clinical chemistry parameters. This is called a *type I* error by statisticians, and the probability of this happening is called the α (alpha) level. In case III (the *false negative*), we have no statistical significance, but the differences between groups are biologically or toxicologically significant. This is called a *type II* error by statisticians, and the probability of such an error happening by random chance is called the β (beta) level. An example of this second situation is when we see a few of a very rare tumor type in treated animals. In both of these latter cases, numerical analysis, no matter how well done, is no substitute for professional judgment. Along with this, however, one must have a feeling for the different types of data and for the value or relative merit of each. Note that the two error types interact, and in determining sample size, we need to specify both α and β levels. Table 9.1 demonstrates this interaction in the case of the *t*-test.

The reasons why biological and statistical significance are not identical are multiple, but a central one is certainly causality. Through our consideration of statistics, we should keep in mind that just because a treatment and a change in an observed organism are seemingly or actually associated with each other, this does not *prove* that the former caused the latter. Although this fact is now widely appreciated for correlation (e.g., the fact that the number of storks' nests found each year in England is correlated with the number of human births that year does not mean that storks bring babies), it is just as true in the general case of significance. Timely establishment and proof that treatment causes an effect require an understanding of the underlying mechanism and proof of its validity. At the same time, it is important that we realize that not finding a good correlation or suitable significance associated with a treatment and an effect likewise does not prove that the two are not associated—that a treatment does not cause an effect. At best, it gives us a certain level of confidence that, under the conditions of the current test, these items are not associated.

These points will be discussed in greater detail in the "Assumptions and Formulations" sections for each method, along with other common pitfalls and shortcomings associated with the method. To help in better understanding the discussion to come, terms frequently used throughout this chapter should first be considered. These are presented in Table 9.2.

TABLE 9.2
Some Frequently Used Terms and Their General Meanings

Term	Meaning
95% Confidence interval	A range of values (above, below, or above and below) the sample (mean, median, mode, etc.) that has a 95% chance of containing the true value of the population (mean, median, mode); also called the fiducial limit equivalent to $p < 0.05$
Bias	Systemic error as opposed to a sampling error; for example, selection bias may occur when each member of the population does not have an equal chance of being selected for the sample
Degrees of freedom	The number of independent deviations; usually abbreviated df
Independent variables	Also known as predictors or explanatory variables
p-Value	Another name for significance level; usually 0.05
Power	The effect of the experimental conditions on the dependent variable relative to sampling fluctuation. When the effect is maximized, the experiment is more powerful. Power can also be defined as the probability that there will not be a type II error (1-beta); conventionally, power should be at least 0.07
Random	Each individual member of the population having the same chance of being selected for the sample
Robust	Having inferences or conclusions little affected by departure from assumptions
Sensitivity	The number of subjects experiencing each experimental condition divided by the variance of scores in the sample
Significance level	The probability that a difference has been erroneously declared to be significant, typically 0.05 and 0.01, corresponding to 5% and 1% chance of error
Type I error (false positives)	Concluding that there is an effect when there really is not an effect; its probability is the alpha level
Type II error (false negatives)	Concluding that there is no effect when there really is an effect; its probability is the beta level

Each measurement we make—each individual piece of experimental information we gather—is called a *datum*; however, we gather and analyze multiple pieces at one time, the resulting collection being called *data*. Data are collected on the basis of their association with a treatment (intended or otherwise) as an effect (a property) that is measured in the experimental subjects of a study, such as body weights. These identifiers (i.e., treatment and effect) are termed *variables*. Our treatment variables (those that the researcher or nature control and which can be directly controlled) are termed *independent*, and our effect variables (such as weight, life span, and number of neoplasms) are termed *dependent* variables; their outcome is believed to be dependent on the treatment being studied.

All the possible measures of a given set of variables in all the possible subjects that exist are termed the *population* for those variables. Such a population of variables cannot be truly measured; for example, one would have to obtain, treat, and measure the weights of all the Fischer-344 rats that were, are, or ever will be. Instead, we deal with a representative group: a *sample*. If our sample of data is appropriately collected and of sufficient size, it serves to provide good estimates of the characteristics of the parent population from which it was drawn.

Bias and Change

Any toxicological study aims to determine whether a treatment elicits a response. An observed difference in response between treated and control groups need not necessarily be a result of treatment. There are, in principle, two other possible explanations: *bias*, or systematic differences other than treatment between the groups, and *chance*, or random differences. A major objective of both experimental design and analysis is to try to avoid bias. Wherever possible, treated and control groups to be compared should be alike with respect to all other factors. Where differences remain, these should be corrected for in the statistical analysis. Chance cannot be wholly excluded, as identically treated animals will not respond identically. Although even the most extreme difference in theory might be due to chance, a proper statistical analysis will allow the experimenter to assess this possibility. The smaller the probability of a false positive, the more confident the experimenter can be that the effect is real. Good experimental design improves the chance of picking up a true effect with confidence by maximizing the ratio between *signal* and *noise*.

Hypothesis Testing and Probability (p) Values

A relationship of treatment to some toxicological endpoint is often stated to be *statistically significant* ($p < 0.05$). What does this really mean? A number of points have to be made. First, statistical significance need not necessarily imply biological importance, if the endpoint under study is not relevant to the animal's well-being. Second, the statement will usually be based only on the data from the study in question and will not take into account prior knowledge. In some situations, such as when one or two of a very rare tumor type are seen in treated animals, statistical significance may not be achieved, but the finding may be biologically extremely important, especially if a similar treatment was previously found to elicit a similar response. Third, the p value does not describe the probability that a true effect of treatment exists; rather, it describes the probability of the observed response, or one more extreme, occurring on the assumption that treatment actually had no effect whatsoever. A p value that is not significant is consistent with a treatment having a small effect not detected with sufficient certainty in this study. Fourth, there are two types of p values. A one-tailed (or one-sided) p value is the probability of getting by chance a treatment effect in a specified direction as great as or greater than that observed. A two-tailed p value is the probability of getting, by chance alone, a treatment difference in either direction that is as great as or greater than that observed. By convention, p values are assumed to be two-tailed unless the contrary is stated. Where one can rule out in advance the possibility of a treatment effect except in one direction (which is unusual), a one-tailed p value should be used. Often, however, two-tailed tests are to be preferred, and it is certainly not recommended to use one-tailed tests and *not* report large differences in the other direction. In any event, it is important to make it absolutely clear whether one- or two-tailed tests have been used.

It is a great mistake, when presenting results of statistical analyses, to mark, as do some laboratories, results simply as significant or not significant at one defined probability level (usually $p < 0.05$). This poor practice does not allow the reader any real chance to judge whether or not the effect is a true one. Some statisticians present the actual p value for every comparison made. Although this gives precise information, it can make it difficult to assimilate results from many variables. One practice we recommend is to mark p values routinely using plus signs to indicate positive differences (and minus signs to indicate negative differences) as follows: $+++p$, 0.001; $++0.001 \le p < 0.01$; $+0.01\ p < 0.05$ ($+0.05 \le p < 0.1$). This highlights significant results more clearly and also allows the reader to judge the whole range from *virtually certain treatment effect* to *some suspicion*. Note that, when using two-tailed tests, bracketed plus signs indicate findings that would be significant at the conventional $p < 0.05$ level using one-tailed tests but are not significant at this level using two-tailed tests. In interpreting p values, it is important to realize they are only an aid to judgment to be used in conjunction with other available information. One might validly consider a $p < 0.01$ increase as chance when it was unexpected, occurred only at a low dose level with no such effect seen at higher doses, and was evident in only one subset of the data. In contrast, a $p < 0.05$ increase might be convincing if it occurred in the top dose and was for an endpoint one might have expected to be increased from known properties of the chemical or closely related chemicals.

Multiple Comparisons

When a p value is stated to be <0.05, this implies that, for that particular test, the difference could have occurred by chance less than 1 time in 20. Toxicological studies frequently involve making treatment–control comparisons for large numbers of variables and, in some situations, also for various subsets of animals. Some statisticians worry that the larger the number of tests, the greater the chance of picking up statistically significant findings that do not represent true treatment effects. For this reason, an alternative *multiple comparisons* procedure has been proposed in which, if the treatment was totally without effect, then 19 times out of 20 *all* the tests should show nonsignificance when testing at the 95% confidence level. Automatic use of this approach cannot be recommended. Not only does it make it much more difficult to pick up any real effects, but also there is something inherently unsatisfactory about a situation where the relationship between a treatment and a particular response depends arbitrarily on which other responses happened to be investigated at the same time. It is accepted that in any study involving multiple endpoints will inevitably exist a gray area between those showing highly significant effects and those showing no significant effects, where there is a problem distinguishing chance and true effects. However, changing the methodology so the gray areas all come up as nonsignificant can hardly be the answer.

Estimating the Size of the Effect

It should be clearly understood that a p value does not give direct information about the size of any effect that has occurred. A compound may elicit an increase in response by a given amount, but whether a study finds this increase to be statistically significant will depend on the size of the study and the variability of the data. In a small study, a large and important effect may be missed, especially if the endpoint is imprecisely measured. In a large study, on the other hand, a small and unimportant effect may emerge as statistically significant.

Hypothesis testing tells us whether an observed increase can or cannot be reasonably attributed to chance but not how large it is. Although much statistical theory relates to hypothesis testing, current trends in medical statistics are toward confidence interval (CI) estimation, with differences between test and control groups expressed in the form of a best estimate, coupled with the 95% CI. Thus, if one states that treatment increases response by an estimated 10 units (95% CI, 3–17 units), this would imply a 95% chance that the indicated interval includes the true difference. If the lower 95% confidence limit exceeds zero, this implies that the increase is statistically significant at $p < 0.05$ using a two-tailed test. One can also calculate, for example, 99% or 99.9% confidence limits, corresponding to testing for significance at $p < 0.01$ or $p < 0.001$. In screening studies of standard design, the tendency has been to concentrate mainly on hypothesis testing; however, presentation of the results in the form of estimates with CIs can be a useful adjunct for some analyses and is very important in studies aimed specifically at quantifying the size of an effect.

Two terms refer to the quality and reproducibility of our measurements of variables. The first, *accuracy*, is an expression of the closeness of a measured or computed value to its actual or true value in nature. The second, *precision*, reflects the closeness or reproducibility of a series of repeated measurements of the same quantity. If we arrange all of our measurements of a particular variable in order as points on an axis marked as to the values of that variable and if our sample were large enough, the pattern of distribution of the data in the sample would begin to become apparent. This pattern is a representation of the frequency distribution of a given population of data—that is, of the incidence of different measurements, their central tendency, and dispersion.

The most common frequency distribution—and one we will talk about throughout this chapter—is the normal (or Gaussian) distribution. The normal distribution is such that two-thirds of all values are within one standard deviation (SD) of the mean (or average value for the entire population) and 95% are within 1.96 SDs of the mean. Symbols used are μ for the mean and σ for the SD.

In all areas of biological research, optimal design and appropriate interpretation of experiments require that the researcher understand both the biological and technological underpinnings of the system being studied and of the data being generated. From the point of view of the statistician, it is vitally important that the experimenter both know and be able to communicate the nature of the data and understand its limitations. One classification of data types is presented in Table 9.3.

The nature of the data collected is determined by three considerations: (1) the biological source of the data (the system being studied), (2) the instrumentation and techniques being used to make measurements, and (3) the design of the experiment. The researcher has some degree of control over each of these, least over the biological system (the researcher normally has a choice of only one of several models to study) and most over the design of the experiment or study. Such choices, in fact, dictate the type of data generated by a study.

TABLE 9.3
Types of Variables (Data) and Examples of Each Type

Classified by	Type	Example
Scale	Scalar	Body weight
Continuous	Ranked	Severity of a lesion
Discontinuous	Scalar	Weeks until the first observation of a tumor in a carcinogenicity study
	Ranked	Clinical observations in animals
	Attribute	Eye colors in fruit flies
	Quantal	Dead/alive or present/absent
Frequency distribution	Normal	Body weights
	Bimodal	Some clinical chemistry parameters
	Others	Measures of time to incapacitation

Statistical methods are based on specific assumptions. Parametric statistics (those that are most familiar to the majority of scientists) have more stringent underlying assumptions than do nonparametric statistics. Among the underlying assumptions for many parametric statistical methods (such as the ANOVA) is that the data are continuous. The nature of the data associated with a variable (as described earlier) imparts a value to that data, the value being the power of the statistical tests that can be employed.

Continuous variables are those that can at least theoretically assume any of an infinite number of values between any two fixed points (such as measurements of body weight between 2.0 and 3.0 kg). Discontinuous variables, meanwhile, are those that can have only certain fixed values, with no possible intermediate values (such as counts of five and six dead animals, respectively).

Limitations on our ability to measure constrain the extent to which the real-world situation approaches the theoretical, but many of the variables studied in toxicology are in fact continuous. Examples of these are lengths, weights, concentrations, temperatures, periods of time, and percentages. For these continuous variables, we may describe the character of a sample with measures of central tendency and dispersion that we are most familiar with: the mean, denoted by the symbol x and also called the arithmetic average, and the SD, which is denoted by the symbol σ and is calculated as being equal to

$$\sqrt{\frac{\sum x^2 - \left(\left(\sum x\right)^2 \Big/ N\right)}{N-1}}$$

where

x is the individual datum

N is the total number of data in the group

Contrasted with these continuous data, however, we have discontinuous (or discrete) data, which can assume only certain fixed numerical values. In these cases, our choice of statistical tools or tests is, as we will find later, more limited.

Probability

Probability is simply the frequency with which, in a sufficiently large sample, a particular event will occur or a particular value be found. Hypothesis testing, for example, is generally structured so the likelihood of a treatment group being the same as a control group (the so-called *null hypothesis*) can be assessed as being at less than a selected low level (very frequently 5%), which implies that we are $1.0 - \alpha$ (i.e., 1.0 – 0.05, or 95%) sure that the groups are *not* equivalent.

FUNCTIONS OF STATISTICS

Statistical methods may serve to perform any combination of three possible tasks. The one we are most familiar with is hypothesis testing—that is, determining if two (or more) groups of data differ from each other at a predetermined level of confidence. A second function is the construction and use of models that may be used to predict future outcomes of chemical–biological interactions. This is most commonly seen in linear regression or in the derivation of some form of correlation coefficient. Model fitting allows us to relate one variable (typically, a treatment or independent variable) to another. The third function, reduction of dimensionality, continues to be less commonly utilized than the first two. This final category includes methods for reducing the number of variables in a system while only minimally reducing the amount of information, thus making a problem easier to visualize and understand. Examples of such techniques are factor analysis and cluster analysis. A subset of this last function is the reduction of raw data to single expressions of central tendency and variability (such as the mean and SD). There is also a special subset of statistical techniques that is part of both the second and third functions of statistics. This is data transformation, which includes such things as the conversion of numbers to log or probit values.

Descriptive Statistics

Descriptive statistics are used to summarize the general nature of a dataset. As such, the parameters describing any single group of data have two components. One of these describes the location of the data, and the other gives a measure of the dispersion of the data in and about this location. Often overlooked is the fact that the choice of which parameters are used to give these pieces of information implies a particular type of distribution for the data.

Most commonly, location is described by giving the (arithmetic) mean and dispersion by giving the SD or the *standard error of the mean* (SEM). The calculation of the first two of these has already been described. If we again denote the total number of data in a group as N, then the SEM would be calculated as

$$\text{SEM} = \frac{\text{SD}}{\sqrt{N}}$$

The use of the mean with either the SD or SEM implies, however, that we have reason to believe that the sample of data being summarized is from a population that is at least approximately normally distributed. If this is not the case, then we should instead use a set of statistical descriptions that do not require a normal distribution. These are the *median* (for location) and the *semiquartile distance* (for a measure of dispersion). These somewhat less familiar parameters are characterized as follows.

When all the numbers in a group are arranged in a ranked order (i.e., from smallest to largest), the *median* is the middle value. If the group has an odd number of values, then the middle value is obvious; for example, in the case of 13 values, the seventh largest is the median. When the number of values in the sample is even, the median is calculated as the midpoint between the $(N/2)$th and the $([N/2] + 1)$th number;

for example, in the series of numbers 7, 12, 13, and 19, the median value would be the midpoint between 12 and 13, which is 12.5.

The SD and the SEM are related to each other but yet are quite different. The SEM is quite a bit smaller than the SD, making it very attractive to use in reporting data. This size difference is because the SEM actually is an estimate of the error (or variability) involved in measuring the means of samples and not an estimate of the error (or variability) involved in measuring the data from which means are calculated. This is implied by the *central limit theorem*, which tells us three major things:

- The distribution of sample means, which will be approximately normal regardless of the distribution of values in the original population from which the samples were drawn
- The mean value of the collection
- The SD of the collection of all possible means of samples of a given size, called the standard error of the mean, which depends on both the SD of the original population and the size of the sample

The SEM should be used only when the uncertainty of the estimate of the mean is of concern, which is almost never the case in toxicology; rather, we are concerned with an estimate of the variability of the population, for which the SD is appropriate.

When all the data in a group are ranked, a quartile of the data contains one ordered quarter of the values. Typically, we are most interested in the borders of the middle two quartiles, Q_1 and Q_3, which together represent the semiquartile distance and which contain the median as their center. Given that there are N values in an ordered group of data, the upper limit of the fourth quartile (Q) may be computed as being equal to the [($jN \div 1$)/fourth] value. Once we have used this formula to calculate the upper limits of Q_1 and Q_3, we can then compute the semiquartile distance (which is also called the *quartile deviation* and as such is abbreviated as QD) with the formula $QD = (Q_3 - Q_1)/2$. For example, for the 15-value dataset 1, 2, 3, 4, 4, 5, 5, 5, 6, 6, 6, 7, 7, 8, 9, we can calculate the upper limits of Q_1 and Q_3 as

$$Q_1 = \frac{1(15+1)}{4} = \frac{16}{4} = 4$$

$$Q_2 = \frac{3(15+1)}{4} = \frac{48}{4} = 12$$

The 4th and 12th values in this dataset are 4 and 7, respectively. The semiquartile distance can then be calculated as

$$QD = \frac{7-4}{2} = 1.5$$

There are times when it is desired to describe the relative variability of one or more sets of data. The most common way of doing this is to compute the *coefficient of variation* (CV), which is calculated simply as the ratio of the SD to the mean, or

$$CV = \frac{SD}{\bar{X}}$$

A CV of 0.2 or 20% thus means that the SD is 20% of the mean. In toxicology, the CV is frequently between 20% and 50% and may at times exceed 100%.

Sampling

Sampling—the selection of which individual data points will be collected, whether in the form of selecting which animals to collect blood from or to remove a portion of a diet mix from for analysis—is an essential step upon which all other efforts toward a good experiment or study are based. Three assumptions about sampling are common to most of the statistical analysis techniques that are used in toxicology: the sample is collected without bias, each member of a sample is collected independently of the others, and members of a sample are collected with replacements. Precluding bias, both intentional and unintentional, means that at the time of selection of a sample to measure, each portion of the population from which that selection is to be made has an equal chance of being selected. Independence means that the selection of any portion of the sample is not affected by and does not affect the selection or measurement of any other portion. Finally, sampling with replacement means that, in theory, after each portion is selected and measured, it is returned to the total sample pool and thus has the opportunity to be selected again. This is a corollary of the assumption of independence. Violation of this assumption (which is almost always the case in toxicology and all the life sciences) does not have serious consequences if the total pool from which samples are drawn is sufficiently large (say, 20 or greater) that the chance of reselecting that portion is small anyway.

The four major types of sampling methods are *random*, *stratified*, *systematic*, and *cluster*. Random is by far the most commonly employed method in toxicology. It stresses the fulfillment of the assumption of avoiding bias. When the entire pool of possibilities is mixed or randomized, then the members of the group are selected in the order in which they are drawn from the pool.

Stratified sampling is performed by first dividing the entire pool into subsets or strata, then doing randomized sampling from each strata. This method is employed when the total pool contains subsets that are distinctly different but in which each subset contains similar members. An example is a large batch of a powdered pesticide in which it is desired to determine the nature of the particle size distribution. Larger pieces or particles are on the top, progressively smaller particles have settled lower in the container, and at the very bottom, the material has been

packed and compressed into aggregates. To determine a timely representative answer, proportionally sized subsets from each layer or strata should be selected, mixed, and randomly sampled. This method is used more commonly in diet studies.

In systematic sampling, a sample is taken at set intervals (such as every fifth container of reagent or taking a sample of water from a fixed sample point in a flowing stream every hour). This is most commonly employed in quality assurance or (in the clinical chemistry lab) in quality control.

In cluster sampling, the pool is already divided into numerous separate groups (such as bottles of tablets), and we select small sets of groups (such as several bottles of tablets) then select a few members from each set. What one gets then is a cluster of measures. Again, this is a method most commonly used in quality control or in environmental studies when the effort and expense of physically collecting a small group of units is significant.

In classical toxicology studies, sampling arises in a practical sense in a limited number of situations. The most common of these are as follows:

- Selecting a subset of animals or test systems from a study to make some measurements (which either destroys or stresses the measured system, or is expensive) at an interval during a study; this may include such cases as doing interim necropsies in a chronic study or collecting and analyzing blood samples from some animals during a subchronic study.
- Analyzing inhalation chamber atmospheres to characterize aerosol distributions with a new generation system.
- Analyzing diet in which test material has been incorporated.
- Performing quality control on an analytical chemistry operation by having duplicate analyses performed on some materials.
- Selecting data to audit for quality assurance purposes.

We have now become accustomed to developing exhaustively detailed protocols for an experiment or study prior to its conduct. A priori selection of statistical methodology (as opposed to the post hoc approach) is as significant a portion of the process of protocol development and experimental design as any other and can measurably enhance the value of the experiment or study (see Table 9.4). Prior selection of statistical methodologies is essential for proper design of other portions of a protocol such as the number of animals per group or the sampling intervals for body weight. Implied in such a selection is the notion that the toxicologist has both an in-depth knowledge of the area of investigation and an understanding of the general principles of experimental design, for the analysis of any set of data is dictated to a large extent by the manner in which the data are obtained.

The four basic statistical principles of experimental design are *replication*, *randomization*, *concurrent* (*local*) *control*, and *balance*. In abbreviated form, these may be summarized as follows:

- *Replication*—Any treatment must be applied to more than one experimental unit (animal, plate of cells, litter of offspring, etc.). This provides more accuracy in the measurement of a response than can be obtained from a single observation, because underlying experimental errors tend to cancel each other out. It also supplies an estimate of the experimental error derived from the variability among each of the measurements taken (or replicates).

TABLE 9.4
Rules for Form Design and Preparation

1. Forms should be used when some form of repetitive data must be collected. They may be either paper or electronic.
2. If only a few (two or three) pieces of data are to be collected, they should be entered into a notebook and not onto a form. This assumes that the few pieces are not a daily event, with the aggregate total of weeks/months/years ending up as lots of data to be pooled for analysis.
3. Forms should be self-contained but should not try to repeat the content of the standard operating procedures or method descriptions.
4. Column headings on forms should always specify the units of measurement and other details of entries to be made. The form should be arranged so sequential entries proceed down a page, not across. Each column should be clearly labeled with a heading that identifies what is to be entered in the column. Any fixed part of entries (such as °C) should be in the column header.
5. Columns should be arranged from left to right so there is a logical sequential order to the contents of an entry as it is made. An example would be date/time/animal number/body weight/name of the recorder. The last item for each entry should be the name or unique initials of the individual who made the data entry.
6. Standard conditions that apply to all the data elements to be recorded on a form, or the columns of the form should be listed as footnotes at the bottom of the form.
7. Entries of data on the form should not use more digits than are appropriate for the precision of the data being recorded.
8. Each form should be clearly titled to indicate its purpose and use. If multiple types of forms are being used, each should have a unique title or number.
9. Before designing the form, carefully consider the purpose for which it is intended. What data will be collected, how often, with what instrument, and by whom? Each of these considerations should be reflected in some manner on the form.
10. Those things that are common or standard for all entries on the form should be stated as such once. These could include such things as instrument used, scale of measurement (°C, °F, or K), or the location where the recording is made.

In practice, this means that an experiment should have enough experimental units in each treatment group (i.e., a large enough *N*) so that reasonably sensitive statistical analysis of data can be performed. The estimation of sample size is addressed in detail later in this chapter.

- *Randomization*—This is practiced to ensure that every treatment has its fair share of extreme high and extreme low values. It also serves to allow the toxicologist to proceed as if the assumption of independence is valid; that is, there is no avoidable (known) systematic bias in how one obtains data.
- *Concurrent control*—Comparisons between treatments should be made to the maximum extent possible between experimental units from the same closely defined population; therefore, animals used as a control group should come from the same source, lot, age, etc., as test group animals. Except for the treatment being evaluated, test and control animals should be maintained and handled in exactly the same manner.
- *Balance*—If the effect of several different factors is being evaluated simultaneously, the experiment should be laid out in such a way that the contributions of the different factors can be separately distinguished and estimated. There are several ways of accomplishing this using one of several different forms of design, as will be discussed later.

The four basic experimental design types used in toxicology are the *randomized block*, *Latin square*, *factorial design*, and *nested design*. Other designs that are used are really combinations of these and are rarely employed in toxicology. Before examining these four basic types, however, we must first examine the basic concept of blocking.

Blocking is, simply put, the arrangement or sorting of the members of a population (such as all of an available group of test animals) into groups based on certain characteristics that may (but are not sure to) alter an experimental outcome. Such characteristics that may cause a treatment to give a differential effect include genetic background, age, sex, and overall activity levels, among others. The process of blocking then acts (or attempts to act) so each experimental group (or block) is assigned its fair share of the members of each of these subgroups.

We should now recall that randomization is aimed at spreading out the effect of undetectable or unsuspected characteristics in a population of animals or some portion of this population. The merging of the two concepts of randomization and blocking leads to the first basic experimental design, the randomized block. This type of design requires that each treatment group has at least one member of each recognized group (such as age), the exact members of each block being assigned in an unbiased (or random) fashion.

The second type of experimental design assumes that we can characterize treatments (whether intended or otherwise) as belonging clearly to separate sets. In the simplest case, these categories are arranged into two sets that may be thought of as rows (for, say, source litter of test animal, with the first litter as row 1, the next as row 2, etc.) and the secondary set of categories as columns (for, say, our ages of test animals, with 6–8 weeks as column 1, 8–10 weeks as column 2, and so on). Experimental units are then assigned so each major treatment (control, low dose, intermediate dose, etc.) appears once and only once in each row and each column. If we denote our test groups as A (control), B (low), C (intermediate), and D (high), such an assignment would appear as shown in Table 9.5.

TABLE 9.5
Sample Table

	Age (Weeks)			
Source Litter	**6–8**	**8–10**	**10–12**	**12–14**
1	A	B	C	D
2	B	C	D	A
3	C	D	A	B
4	D	A	B	C

The third type of experimental design is the factorial design, which has two or more clearly understood treatments, such as exposure level to test chemical, animal age, or temperature. The classical approach to this situation (and to that described under the Latin square) is to hold all but one of the treatments constant and at any one time to vary just that one factor. In the factorial design, however, all levels of a given factor are combined with all levels of every other factor in the experiment. When a change in one factor produces a different change in the response variable at one level of a factor than at other levels of this factor, there is an interaction between these two factors that can then be analyzed as an interaction effect.

The last of the major varieties of experimental design is the nested design, where the levels of one factor are nested within (or are subsamples of) another factor; that is, each subfactor is evaluated only within the limits of its single larger factor.

Another concept that is essential to the design of experiments in toxicology is *censoring*. Censoring is the exclusion of measurements from certain experimental units, or indeed of the experimental units themselves, from consideration in data analysis or inclusion in the experiment at all. Censoring may occur either prior to initiation of an experiment (where, in modern toxicology, this is almost always a planned procedure), during the course of an experiment (when they are almost universally unplanned, resulting from such as the death of animals on test), or after the conclusion of an experiment (when usually data are excluded because of being identified as some form of outlier).

In practice, a priori censoring in toxicology studies occurs in the assignment of experimental units (such as animals) to test groups. The most familiar example is in the common practice of assignment of test animals to acute, subacute, subchronic, and chronic studies, where the results of otherwise

random assignments are evaluated for body weights of the assigned members. If the mean weights are found not to be comparable by some preestablished criterion (such as a 90% probability of difference by ANOVA), then members are reassigned (censored) to achieve comparability in terms of starting body weights. Such a procedure of animal assignment to groups is known as *censored randomization*.

The first precise or calculable aspect of experimental design encountered is determining sufficient test and control group sizes to allow one to have an adequate level of confidence in the results of a study (i.e., in the ability of the study design with the statistical tests used to detect a true difference—or effect—when it is present). The statistical test contributes a level of power to such a detection. Remember that the power of a statistical test is the probability that a test results in rejection of a hypothesis (say, H_0) when some other hypothesis (say, H) is valid. This is considered the power of the test with respect to the (alternative) hypothesis H.

If there is a set of possible alternative hypotheses, the power, regarded as a function of H, is termed the *power function* of the test. When the alternatives are indexed by a single parameter θ, simple graphical presentation is possible. If the parameter is a vector θ, then one can visualize a *power surface*.

If the power function is denoted by β(θ) and H_0 specifies $\theta = \theta_0$, then the value of β(P)—the probability of rejecting H_0 when it is in fact valid—is the significance level. The power of a test is greatest when the probability of a type II error is the least. Specified powers can be calculated for tests in any specific or general situation.

Some general rules to keep in mind are as follows:

- The more stringent the significance level, the greater the necessary sample size. More subjects are needed for a 1%-level test than for a 5%-level test.
- Two-tailed tests require larger sample sizes than one-tailed tests. Assessing two directions at the same time requires a greater investment.
- The smaller the critical effect size, the larger the necessary sample size. Subtle effects require greater efforts.
- Any difference can be significant if the sample size is large enough.
- The larger the power required, the larger the necessary sample size. Greater protection from failure requires greater effort. The smaller the sample size, the smaller the power (i.e., the greater the chance of failure).
- The requirements and means of calculating the necessary sample size depend on the desired (or practical) comparative sizes of test and control groups.

This number (N) can be calculated, for example, for equal-sized test and control groups using the formula:

$$N = \frac{\left(t_1 + t_2\right)^2}{d^2} S$$

where

t_1 is the one-tailed t value with ($N - 1$) degrees of freedom corresponding to the desired level of confidence

t_2 is the one-tailed t value with ($N - 1$) degrees of freedom corresponding to the probability that the sample size will be adequate to achieve the desired precision

S is the sample SD, derived typically from historical data and calculated as

$$S = \sqrt{\frac{1}{N-1}\sum\left(V_1 - V_2\right)^2}$$

A number of aspects of experimental design are specific to the practice of toxicology. Before we look at a suggestion for step-by-step development of experimental designs, these aspects should first be considered as follows:

1. Frequently, the data gathered from specific measurements of animal characteristics are such that there is wide variability in the data. Often, such wide variability is not present in a control or low-dose group, but in an intermediate-dosage group, variance inflation may occur; that is, a large SD may be associated with the measurements from this intermediate group. In the face of such a set of data, the conclusion that there is no biological effect based on a finding of no statistically significant effect might well be erroneous.
2. In designing experiments, a toxicologist should keep in mind the potential effect of involuntary censoring on sample size. In other words, although a study might start with five dogs per group, this provides no margin should any die before the study is ended and blood samples are collected and analyzed. Just enough experimental units per group frequently leave too few at the end to allow meaningful statistical analysis, and allowances should be made accordingly in establishing group sizes.
3. It is certainly possible to pool the data from several identical toxicological studies. For example, if we performed an acute inhalation study where only three treatment group animals survived to the point at which a critical measure (such as analysis of blood samples) was performed, we would not have enough data to perform a meaningful statistical analysis. We could then repeat the protocol with new control and treatment group animals from the same source. At the end, after assuring ourselves that the two sets of data are comparable, we could combine (or pool) the data from survivors of the second study with those from the first. The costs of this approach, however, would then be both a greater degree of effort expended (than if we had performed a single study with larger groups) and increased variability in the pooled samples (decreasing the power of our statistical methods).

4. Another frequently overlooked design option in toxicology is the use of an unbalanced design—that is, of different group sizes for different levels of treatment. There is no requirement that each group in a study (control, low dose, intermediate dose, and high dose) has an equal number of experimental units assigned to it. Indeed, there are frequently good reasons to assign more experimental units to one group than to others, and all the major statistical methodologies have provisions to adjust for such inequalities, within certain limits. The two most common uses of the unbalanced design have larger groups assigned to either the highest dose, to compensate for losses due to possible deaths during the study, or the lowest dose, to give more sensitivity in detecting effects at levels close to an effect threshold or more confidence to the assertion that no effect exists.
5. We are frequently confronted with the situation where an undesired variable is influencing our experimental results in a nonrandom fashion. Such a variable is called a *confounding variable*; its presence makes the clear attribution and analysis of effects at best difficult and at worst impossible. Sometimes such confounding variables are the result of conscious design or management decisions, such as the use of different instruments, personnel, facilities, or procedures for different test groups within the same study. Occasionally, however, such confounding variables are the result of unintentional factors or actions, in which case the variable is referred to as a *lurking variable*. Examples of such variables are almost always the result of standard operating procedures being violated (e.g., water not being connected to a rack of animals over a weekend, a set of racks not being cleaned as frequently as others, or a contaminated batch of feed being used).
6. Finally, some thought must be given to the clear definition of what is meant by experimental unit and concurrent control. The experimental unit in toxicology encompasses a wide variety of possibilities. It may be cells, plates of microorganisms, individual animals, litters of animals, etc. The importance of clearly defining the experimental unit is that the number of such units per group is the *N* that is used in statistical calculations or analyses and critically affects such calculations. The experimental unit is the unit that receives treatments and yields a response that is measured and becomes a datum. What this means in practice is that, for example, in reproduction or teratology studies where we treat the parental generation females and then determine results by counting or evaluating offspring, the experimental unit is still the parent; therefore, the number of litters, not the number of offspring, is the *N* [8]. A true concurrent control is one that is identical in every manner with the treatment groups except for the treatment being evaluated. This means that all manipulations, including gavaging with equivalent volumes of vehicle or exposing to equivalent rates of air exchanges in an inhalation chamber, should be duplicated in control groups just as they occur in treatment groups.

The goal of the four principles of experimental design (*replication*, *randomization*, *concurrent control*, and *balance*) is statistical efficiency and the economizing of resources. The single most important initial step in achieving such an outcome is to clearly define the objective of the study and have a clear statement of what questions are being asked.

EXPERIMENTAL DESIGN

Toxicological experiments generally have a twofold purpose. The first question is whether or not an agent results in an effect on a biological system. The second question, never far behind, is how much of an effect is present. It has become increasingly desirable that the results and conclusions of studies aimed at assessing the effects of environmental agents be as clear and unequivocal as possible. It is essential that every experiment and study yield as much information as possible and that the results of each study have the greatest possible chance of answering the questions it was conducted to address. The statistical aspects of such efforts, so far as they are aimed at structuring experiments to maximize the possibilities of success, are called *experimental design*.

Ten facets of any study may affect its ability to detect an effect of a treatment. The first six concern minimizing the role of chance; the last four relate to avoidance of bias:

- *Choice of species and strain*—Ideally, the responses of interest should be rare in untreated control animals but should be reasonably readily evoked by appropriate treatments. Some species or specific strains, perhaps because of inappropriate diets [1], have high background tumor incidences that make increases both difficult to detect and difficult to interpret when detected.
- *Dose levels*—This is a very important and controversial area. In screening studies aimed at hazard identification, it is normal, to avoid requiring huge numbers of animals, to test at dose levels higher than those to which humans will be exposed but not so high that marked toxicity occurs. A range of doses is usually tested to guard against the possibility of misjudgment of an appropriate high dose and that the metabolic pathways at the high doses differ markedly from those at lower doses and, perhaps, to ensure that no large effects occur at dose levels in the range to be used by humans. In studies aimed more at risk estimation, more and lower doses may

be tested to obtain fuller information on the shape of the dose–response curve.

- *Number of animals*—This is obviously an important determinant of the precision of the findings. The calculation of the appropriate number depends on (1) the critical difference (i.e., the size of the effect it is desired to detect); (2) the false-positive rate (i.e., the probability of an effect being detected when none exists; equivalent to the α level or type I error); (3) the false-negative rate, (i.e., the probability of no effect being detected when one of exactly the critical size exists; equivalent to the β level or type II error); and (4) some measure of the variability in the material. Tables relating numbers of animals required to obtain values of critical size α and β are given in Lee [2], and software (e.g., nQUERY ADVISOR) is also available for this purpose. As a rule of thumb, to reduce the critical difference by a factor n for a given value of α and β, the number of animals required will have to be increased by a factor of n^2.
- *Duration of the experiment*—It is obviously important not to terminate the study too early for fatal conditions, which are normally strongly age related. Less obviously, going on for too long in a study can be a mistake, partly because the last few weeks or months may produce relatively few extra data at a disproportionate cost and partly because diseases of extreme old age may obscure the detection of tumors and other conditions of more interest. For nonfatal conditions, the ideal is to kill the animals when the average prevalence is around 50%.
- *Accuracy of determinations*—This is of obvious importance. Although good laboratory practices and advances in technology have improved the situation here, it is necessary for those taking part in the study to be diligent.
  - *Sampling*—Sampling is an essential step upon which any meaningful experimental result depends. Sampling may involve selection of the individual data points that will be collected, determining which animals tissue samples will be collected from or taking a sample of a diet mix for chemical analysis. Three assumptions about sampling are common to most of the statistical analysis techniques used in toxicology. The assumptions are that the sample is collected without bias, each member of a sample is collected independently of the others, and members of a sample are collected with replacements.
  - *Stratification*—To detect a treatment difference with accuracy, it is important that the groups being compared are as homogeneous as possible with respect to other known causes of the response. In particular, suppose that there is another known important cause of the response for which the animals vary, so the animals are a mixture of hyper- and hyporesponders from this cause. If the treated group has a higher proportion of hyperresponders, it will tend to have a higher response even if the treatment has no effect. Even if the proportion of hyperresponders is the same as in the controls, it will be more difficult to detect an effect of treatment because of the increased between-animal variability. Given that this other factor is known, it will be sensible to take it into account in both the design and the analysis of the study. In the design, it can be used as a blocking factor so animals at each level are allocated equally (or in the correct proportion) to control and treated groups. In the analysis, the factor should be treated as a stratifying variable, with separate treatment–control comparisons made at each level and the comparisons combined for an overall test of difference. This is discussed later, where we refer to the factorial design as one example of the more complex designs that can be used to investigate the separate effect of multiple treatments.
  - *Balance*—If the effect of several different factors is being evaluated simultaneously, then the experiment should be laid out in such a way that the contributions of the different factors can be separately distinguished and estimated. There are several ways to accomplish this using different forms of design, as will be discussed later. It is important to recognize that mathematical comparisons are best when group sizes are similar. It may be tempting to place more animals in the treated group to *see* the effect, but such an action weakens the statistical analysis of the experiment.
  - *Randomization*—Random allocation of animals to treatment groups is a prerequisite of good experimental design. If not carried out, one can never be sure whether treatment–control differences are due to treatment or due to confounding by other relevant factors. The ability to randomize easily is a major advantage animals experiments have other over methods such as epidemiology. Although randomization eliminates bias (as least in expectation), simple randomization of all animals may not be the optimal technique for producing a sensitive test. If there is another major source of variation (e.g., sex or batch of animals), it will be better to carry out stratified randomization (i.e., separate randomizations within each level of the stratifying variable). The need for randomization

applies not only to the allocation of animals to the treatment but also to anything that can materially affect the recorded response. The same random number that is used to apply animals to treatment groups can be used to determine cage position, order of weighting, order of bleeding for clinical chemistry, order of sacrifice at terminations, and so on.

- *Adequacy of control group*—Although, on occasion, historical control data can be useful, a properly designed study demands that a relevant concurrent control group be included with which results for the test group can be compared. The principle that like should be compared with like, apart from treatment, demands that control animals should be randomized from the same source as the treatment animals. Careful consideration should also be given to the appropriateness of the control group. Thus, in an experiment involving the treatment of a compound in a solvent, it would often be inappropriate to include only an untreated control group, as any differences observed could be attributed only to the treatment–solvent combination. To determine the specific effects of the compound, a comparison group given the solvent only, by the same route of administration, would be required. It is not always generally realized that the position of the animal in the room in which it is kept may affect the animal's response. An example is the strong relationship between the incidence of retinal atrophy in albino rats and closeness to the lighting source. Systematic differences in cage position should be avoided, preferably via randomization.

For the reader who would like to further explore experimental design, a number of more detailed texts are available that include more extensive treatments of the statistical aspects of experimental design [3–8].

GENERALIZED METHODOLOGY SELECTION

One approach for the selection of appropriate techniques to employ in a particular situation is to use a decision-tree method. Figure 9.1 is a decision tree that leads to the choice of one of three other trees to assist in technique selection, with each of the subsequent trees addressing one of the three functions of statistics that was defined earlier in this chapter. Figure 9.2 illustrates the selection of hypothesis-testing procedures, Figure 9.3 modeling procedures, and Figure 9.4 the reduction of dimensionality procedures. For the vast majority of situations, these trees will guide the user to the choice of the proper technique. The tests and terms used in these trees will be explained subsequently.

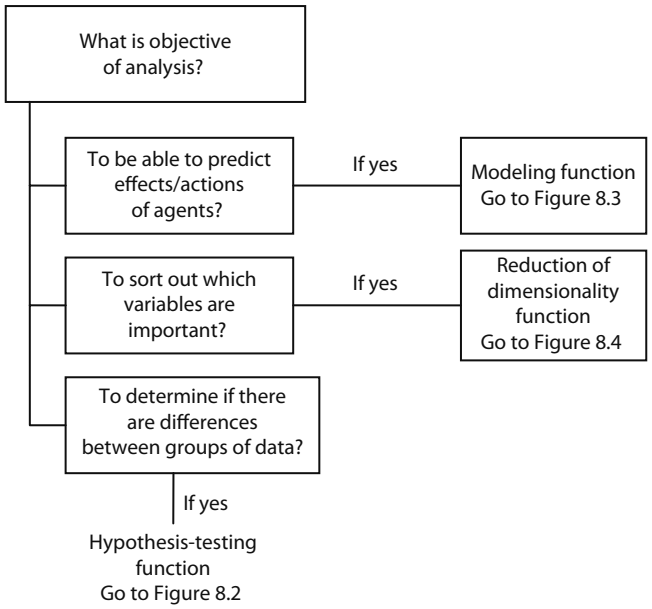

FIGURE 9.1 Overall decision tree for selecting statistical procedures.

GENERAL CONSIDERATIONS AND DATA CHARACTERIZATION FOR STATISTICAL ANALYSIS

Variables to Be Analyzed

Although some pathologists still regard their discipline as providing qualitative rather than quantitative data, it is abundantly clear that pathology, when applied to routine screening of animal toxicity and carcinogenicity studies, has to be quantitative to at least some degree so statistical statements can be made about possible treatment effects. Inevitably, there will be some descriptive text that will not be appropriate for statistical analysis. However, the main objective of the pathologist should be to provide information on the presence or absence (with severity grade or size where appropriate) of a list of conditions, consistently recorded from animal to animal by well-defined criteria, that can be validly used in a statistical assessment.

Given that statistical analysis is worth doing and data are available that would be analyzed, should one then analyze all the endpoints recorded? Some arguments have been put forward against analyzing all the endpoint studies, none of which really holds water. One argument is that some endpoints are not of interest. Perhaps the study is essentially a carcinogenicity study, so nonneoplastic endpoints are not considered to be background pathology and almost per se unrelated to treatment. In our view, this is illogical. If the pathologist has gone to the trouble of recording the data, then surely, in general, they ought to be analyzed; otherwise, why record them in the first place? After all, the costs of the statistical analyses are much less than those of doing the study and the pathology. While one might justify failure to analyze nonneoplastic data where tumor analysis

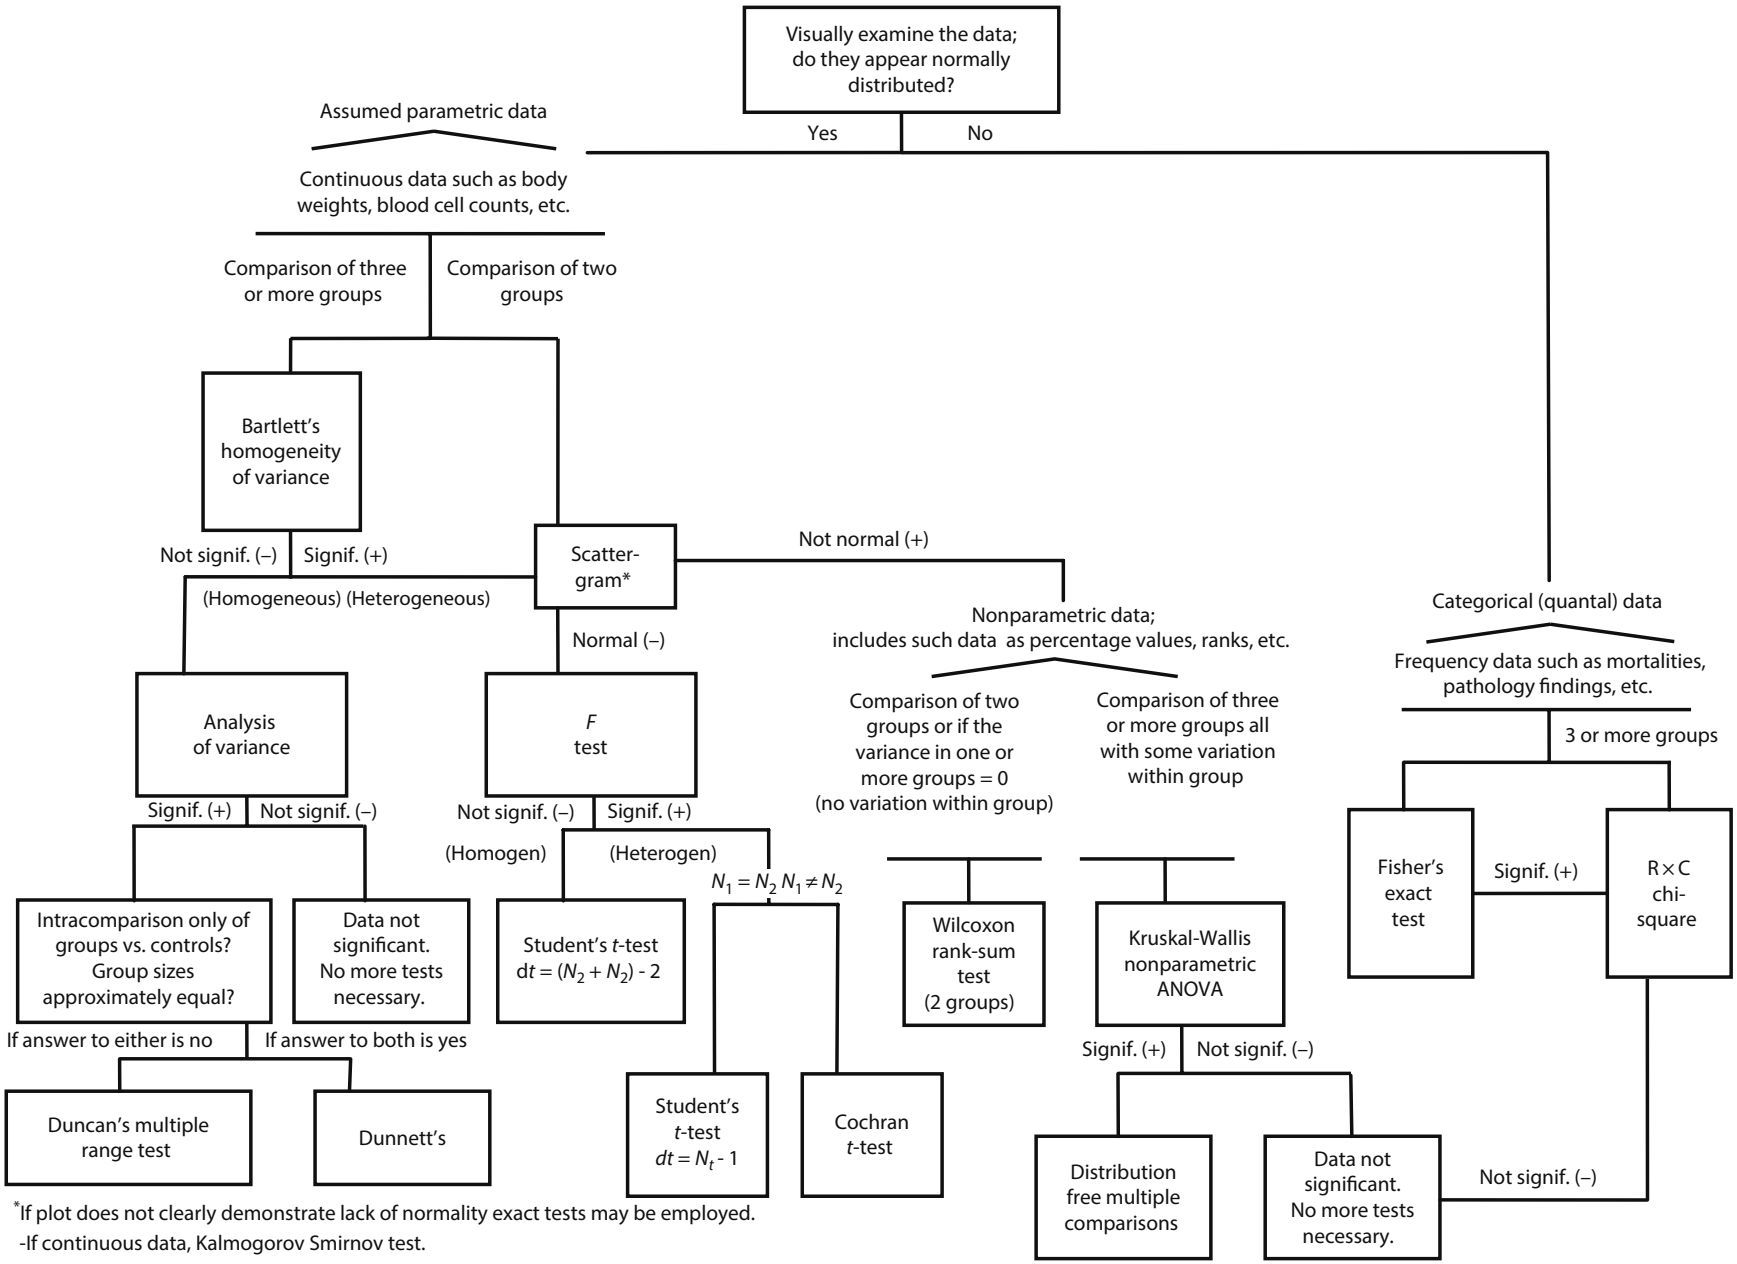

FIGURE 9.2 Decision tree for selecting hypothesis-testing procedures.

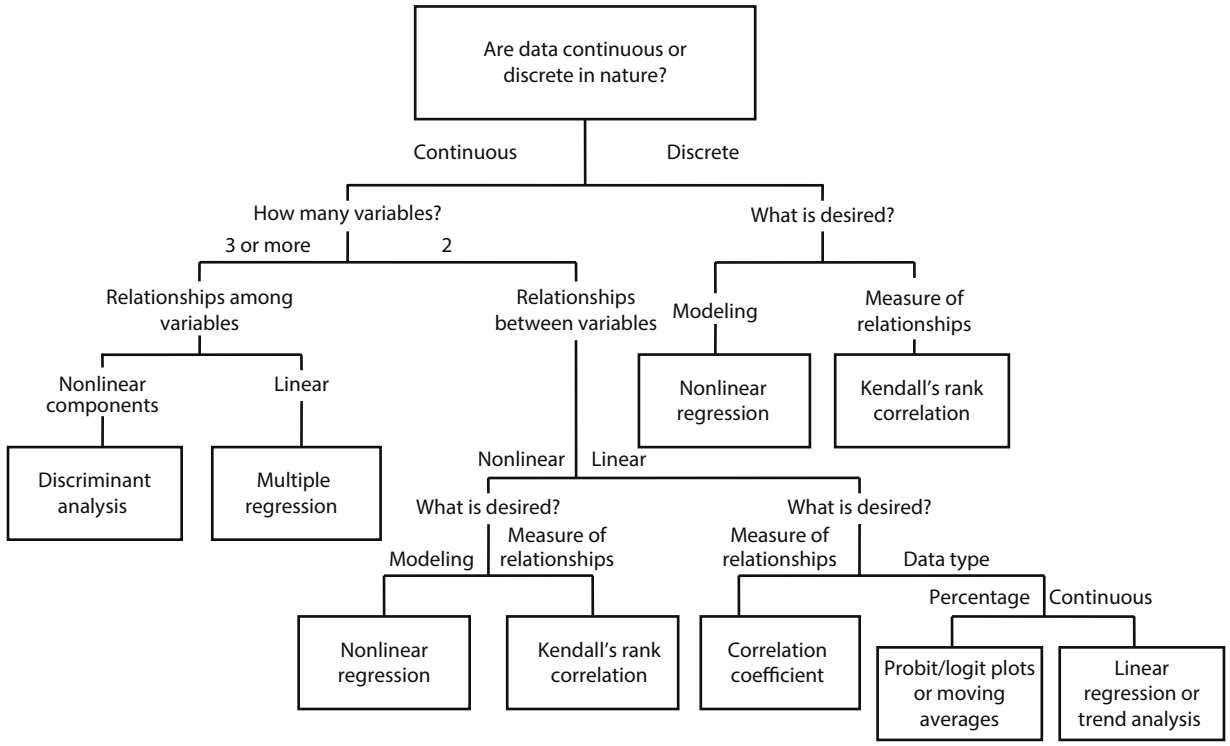

FIGURE 9.3 Decision tree for selecting modeling procedures.

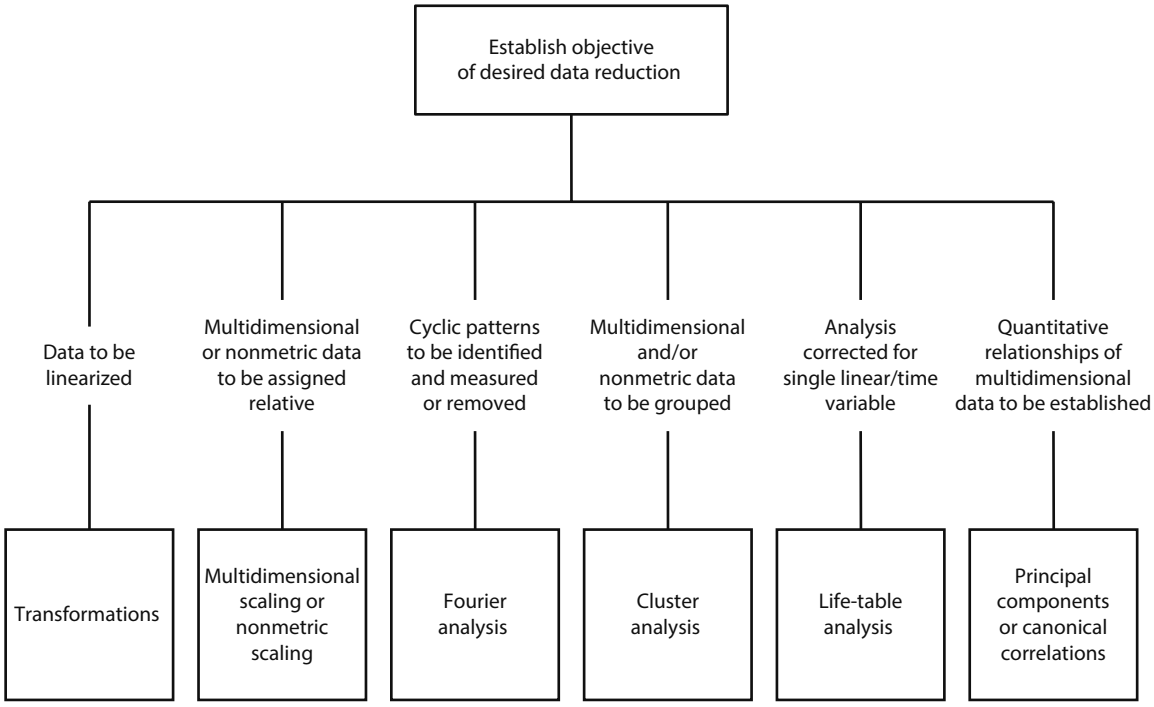

FIGURE 9.4 Decision tree for the selection of reduction of dimensionality procedures.

has already shown that the compound is clearly carcinogenic and no longer of market potential, the general rule ought to be to analyze everything that has been specifically investigated.

Another argument put forward against doing multiple analyses is that it may yield many chance significant p values that have to be explained away. This seems to us a poor reason for not exploring the data fully. A detailed look at the data can only aid interpretation, provided that one is not hide-bound by the false argument that statistical significance necessarily equates with biological importance and definitely indicates a true effect of treatment.

TABLE 9.6
Three Dimensions of Dose–Response

As Dose Increases
Incidence of responders in an exposed population increases.
Severity of response in affected individuals increases.
Time to occurrence of response or of progressive stage of response decreases.

Another reason not to analyze might be that visual inspection of summary tables reveals no suspicion of an effect for some endpoint. This seems to be, in this age of rapid and efficient computer programs, totally the wrong way to organize things. If the data are held on a computer, it is much better and quicker to do the actual analysis than to do the inevitably subjective, unreliable, and slow prescreening process. In any case, where substantial differences in survival between groups exist, it is very difficult to form a reliable view by inspection of non-age-adjusted frequencies on whether an effect might or might not have occurred.

A final, more valid, reason is that some endpoints occur only very rarely. One should, however, be clear what *very rarely* means. For a typical study with a control and three dose groups of equal size, one would get a significant trend statistics if all three cases occurred at the top dose level or in the control group (two-tailed $p \approx 0.03$), so a total of three cases will normally be enough for statistical analysis. Endpoints occurring once or twice only are not worth analyzing formally, although, if seen only in the top dose group, they may be worth noting in the report. This is especially true if they are lesions that are rarely reported (see Table 9.6).

Combination of Pathological Conditions

There are four main situations when one might consider combining pathological conditions in a statistical analysis. The first is when essentially the same pathological condition has been recorded under two or more different names or even under the same name in different places. Here, failure to combine these conditions in the analysis may severely limit the chances of detecting a true treatment effect. It should be noted, however, that grouping together conditions that are actually different may also result in the masking of a true treatment effect, particularly if the treatment has a very specific effect.

The second is when separately recorded pathological conditions form successive steps on the pathway of the same process. The most important example of this is the incidence of related types of malignant tumor, benign tumor, and focal hyperplasia. It will normally be appropriate to carry out analyses of (1) the incidence of malignant tumor, (2) the incidence of benign or malignant tumor, and, where appropriate, (3) the incidence of focal hyperplasia, benign tumor, or malignant tumor. It will not normally be appropriate to carry out analyses of benign tumor incidence only or of the incidence of hyperplasia only.

The third situation for combining is when the same pathological condition appears in different organs as a result of the same underlying process. Examples of this are the multicentric tumors (such as myeloid leukemia, reticulum cell sarcoma, and lymphosarcoma) or certain nonneoplastic conditions (such as arteritis/periarteritis and amyloid degeneration). Here, analysis will normally be carried out of only the incidence at any site, although in some situations, site-specific analyses might be worth carrying out.

The final situation where an analysis of combined pathological conditions is normal is for analyses of the overall incidence of malignant tumor at any site, of benign or malignant tumors at any site, or of multiple tumor incidence. Although analyses of tumor incidence at specific sites are normally more meaningful, because treatments often affect only a few specific sites, these additional analyses are usually required to guard against the possibility that treatment had some weak but general tumor-enhancing effect not otherwise evident.

In some situations, one might also envisage analyses of other combinations of specific tumors, such as tumors at related sites (e.g., endocrine organs if the compound had a hormonal effect) or of similar histological type.

Taking Severity into Account

The same line of argument that suggests that if the pathologist records data they should be analyzed also suggests that if the pathologist chooses to grade a condition for severity, then the grade should be taken into account in the analysis. There are two ways to carry out analysis when the grade has to be taken into account. In one, analyses are carried out not only of whether or not the animal has a condition but also of whether or not the condition is at least grade 2, at least grade 3, etc. In the other approach, nonparametric (rank) methods are used. The latter approach is more powerful, as it uses all the information in one analysis, although the output may not be so easily understood by those without some statistical training. Note that the analyses based on grade can be carried out only if grading has been consistently applied throughout. If a condition has been scored only as present/absent for some animals but has been graded for others, it is not possible to carry out graded analyses unless the pathologist is willing to go back and grade the specific animals showing the condition.

Using Simple Methods That Avoid Complex Assumptions

Different methods for statistical analysis can vary considerably in their complexity and in the number of assumptions they make. Although the use of statistical models has its place (more so for effect estimation than for hypothesis testing and more so in studies of complex design than in those of simple design), there are advantages in using, wherever possible, statistical methods that are simple, robust, and make

as few assumptions as possible. There are three reasons for this. First, such methods are more generally understandable to the toxicologist. Second, hardly ever enough data exist in practice to validate any given formal model fully. Third, even if a particular model is known to be appropriate, the loss of efficiency in using appropriate simpler methods is often only very small.

The methods we advocate for routine use for the analysis of tumor incidence tend, therefore, not to be based on the use of formal parametric statistical models. For example, when studying the relationship of treatment to incidence of a pathological condition and wishing to adjust for other factors (in particular, age at death) that might otherwise bias the comparison, methods involving stratification are recommended, rather than a multiple regression approach or time-to-tumor models. ANOVA methods can be useful in the case of continuously distributed data for estimating treatment effects; however, they involve underlying assumptions (normally distributed variables, variability equal in each group). If these assumptions are violated, nonparametric methods based on the rank of observations, rather than their actual value, may be preferable for hypothesis testing.

Using All of the Data

Often information is available about the relationship between treatment and a condition of interest for groups of animals differing systematically in respect to some other factor. Obvious examples are males and females, differing times of sacrifice and differing secondary treatments. Although it will be necessary, in general, to look at the relationship within levels of this other factor, it will also be advisable to try to come to some assessment of the relationship over all levels of the other factor and where a combined inference is not sensible, but in far more situations, this is not the case, and using all the data in one analysis allows a more powerful test of the relationship under study. Some scientists consider that conclusions for males and females should always be drawn separately, but there are strong statistical arguments for a joint analysis.

Combining, Pooling, and Stratification

Suppose, in a hypothetical study of a toxic agent that induces tumors that do not shorten the lives of tumor-bearing animals, the data regarding the number of animals with tumor out of the number examined are as shown in Table 9.7. It can be seen that if the time of death is ignored and the *pooled* data are studied, the incidence of tumors is the same in each group, resulting in the false conclusion that treatment had no effect. Looking within each time of death, however, an increased incidence in the exposed group can be seen. An appropriate statistical method would *combine* a measure of difference between the groups based on the early deaths and a measure of difference based on the late deaths and conclude correctly that incidence, after adjustment for time of death, is greater in the exposed groups.

TABLE 9.7
Dose–Response Effect on Time to Death

	Control	Exposed	Combined
Early deaths	1/20 (5%)	18/90 (20%)	19/110 (17%)
Late deaths	24/80 (30%)	7/10 (70%)	31/90 (34%)
Total	25/100 (25%)	25/100 (25%)	50/200 (25%)

In this example, time of death is the stratifying variable, with two strata—early deaths and late deaths. The essence of the methodology is to make comparisons only within strata (so one is always comparing like with like, except with respect to treatment) and then to combine the differences over strata. Stratification can be used to adjust for any variable or, indeed, combinations of variables.

Some studies are of factorial design, in which combinations of treatments are tested. The simplest such design is one in which four equal-sized groups of animals receive: (1) no treatment, (2) treatment A only, (3) treatment B only, and (4) treatments A and B. If one is prepared to assume that any effects of the two treatments are independent, one can use stratification to enable more powerful tests to be conducted of the possible individual treatment effects. Thus, to test for effects of treatment A, for example, one conducts comparisons in two strata, the first consisting of groups 1 and 2 not given treatment B and the second consisting of groups 3 and 4 given treatment B. Results combined from the two strata are based on twice as many animals and are therefore markedly more likely to detect possible effects of treatment A than is a simple comparison of groups 1 and 2. There is also the possibility of identifying interactions, such as synergism and antagonism, between the two treatments.

Multiple Control Groups

In some routine long-term screening studies, the study design involves 5 groups of (usually) 50 animals of each sex, 3 of which are treated with successive doses of a compound and 2 of which are untreated controls. Assuming that there is no systematic difference between the control groups (e.g., the second control group is in a different room or from a different batch of animals), it will be normal to carry out the main analyses with the control groups treated as a single group of 100 animals. It will usually be a sensible preliminary precaution to carry out additional analyses comparing incidences in the two control groups.

Trend Analysis, Low-Dose Extrapolation, and NOEL Estimation

Although comparisons of individual treated groups with the control group are important, a more powerful test of a possible effect of treatment will be to carry out a test for a dose-related trend. This is because most true effects of treatment tend to result in a response that increases (or decreases) with increasing dose and because trend tests take into account

all the data in a single analysis. In interpreting the results of trend tests, it should be noted that a significant trend does not necessarily imply an increased risk at lower doses, nor, conversely, does a lack of increase at lower doses necessarily indicate evidence of a threshold (i.e., a dose below which no increase occurs).

Note that the testing for trend is seen as a more sensitive way of picking up a possible treatment effect than simple pairwise comparisons of treated and control groups. Attempting to estimate the magnitude of effects at low doses, typically below the lowest positive dose tested in the study, is a much more complex procedure and is heavily dependent on the assumed functional form of the dose–response relationship.

Such low-dose extrapolation is typically conducted only for tumors believed to be caused by a genotoxic effect that some, but by no means all, scientists believe has no threshold. For other types of tumors and for many nonneoplastic endpoints, a threshold cannot be estimated directly from data at a limited number of dose levels and a no-observed-effect level can be estimated by finding the highest dose level at which there is no significant increase in effects.

Need for Age Adjustment

When marked differences in survival occur between treated groups, it is widely recognized that there is a need for an age adjustment (i.e., an adjustment for age at death or onset). This is illustrated in the earlier example, where, because of the greater number of deaths occurring early in the treated group, the true effect of treatment disappears if no adjustment is made. Thus, a major purpose of age adjustment is to avoid bias. It is not so generally recognized, however, that, even where there are no survival differences, age adjustment can increase the power to detect between-group differences. This is illustrated in Table 9.8. Here, treatment results in a somewhat earlier onset of a condition that occurs eventually in all animals. Failure to age-adjust will result in a comparison of 29/50 with 21/50, which is not statistically significant. Age adjustment will essentially ignore the early and late deaths, which contribute no comparative statistical information and will be based on the comparison of 9/10 with 1/10, which is statistically significant. Here, age adjustment sharpens the contrast, rather than avoiding bias, by avoiding the dilution of data capable of detecting treatment effects with data that are of little or no value for this purpose.

TABLE 9.8
Lethality Incidence

	Control	Exposed
Early deaths	0/20	0/20
Middle deaths	1/10	9/10
Late deaths	20/20	20/20
Total	21/50	29/50

Need to Take Context of Observation into Account

It is now widely recognized that age adjustment cannot properly be carried out unless the context of observation is taken into account. Three contexts are relevant, the first two relating to the situation where the condition is only observed at death (e.g., an internal tumor) and the third where it can be observed in life (e.g., a skin tumor). In the first context, the condition is assumed to have caused the death of the animal (i.e., to be *fatal*). In this case, the incidence rate for a time interval and a group is calculated by

$$\frac{\text{Number of animals dying in interval because of lesion}}{\text{Number of animals alive at start of interval}}$$

In the second context, the animal is assumed to have died of another cause (i.e., the condition is *incidental*). In this case, the rate is calculated by

$$\frac{\text{Number of animals dying in interval with lesion}}{\text{Total number of animals dying in interval}}$$

In the third context, where the condition is *visible*, the rate is calculated by

$$\frac{\text{Number of animals getting condition in interval}}{\text{Number of animals without condition at start of interval}}$$

A problem with the method of Peto et al. [9], which takes the context of observation into account, is that some pathologists are unwilling or feel unable to decide whether, in any given case, a condition is fatal or incidental. A number of points should be made here. First, where there are marked survival differences, it may not be possible to conclude reliably whether a treatment is beneficial or harmful unless such a decision is made. This is well illustrated by the example in Peto et al. [9], where assuming that all pituitary tumors were fatal resulted in the (false) conclusion that *N*-nitrosodimethylamine (NDMA) was carcinogenic and assuming that they were all incidental resulted in the (false) conclusion that NDMA was protective. Using, correctly, the pathologist's best opinion as to which were and which were not likely to be fatal resulted in an analysis that (correctly) concluded that NDMA had no effect. If the pathologist in this case had been unwilling to make a judgment as to fatality, believing it to be unreliable, no conclusion could have been reached. This state of affairs would, however, be a fact of life and *not* a position reached because an inappropriate statistical method was being used.

Although it will normally be a good routine for the pathologist to ascribe *factors contributory to death* for each animal that was not part of a scheduled sacrifice, it is in fact not strictly necessary to determine the context of observation for all conditions at the outset. An alternative strategy is to analyze under differing assumptions: (1) no cases fatal,

(2) all cases occurring in descendents fatal, and (3) all cases of same defined severity occurring in decedents fatal, with, under each assumption, other cases incidental.

If the conclusion turns out the same under each assumption or if the pathologist can say, on general grounds, that one assumption is likely to be a close approximation to the truth, it may not be necessary to know the context of observation for the condition in question for each individual animal. Using the alternative strategy might result in a saving of the pathologist's time by only having to make a judgment for a limited number of conditions where the conclusion seems to hang on the correct knowledge of the context of observation.

Finally, it should be noted that, although many nonneoplastic conditions observed at death are never causes of death, it is, in principle, as necessary to know the context of observation for nonneoplastic conditions as it is for tumors.

Experimental and Observational Units

In many situations, the animal is both the experimental unit and the observational unit, but this is not always so. To determine treatment effects by the methods of the next section, it is important that each experimental unit provides only one item of data for analysis, as the methods all assume that individual data items are statistically independent. In many feeding studies, where the cage is assigned to a treatment, it is the cage, rather than the animal, that is the experimental unit. In histopathology, observations for a tissue are often based on multiple sections per animal, so the section is the observational unit. Multiple observations per experimental unit should be combined in some suitable way into an overall average for that unit before analysis.

Missing Data

In many types of analysis, animals with missing data are simply removed from the analysis; however, in some situations, this can be an inappropriate thing to do. One situation is when carrying out an analysis of a condition that is assumed to have caused the death of the animal.

Although an animal dying at week 83 for which the section was unavailable for microscopic examination cannot contribute to the group comparison at week 83, one knows that it did not die because of any condition in previous weeks, so it should contribute to the denominator of the calculations in all previous weeks.

Another situation is when histopathological examination of a tissue is not carried out unless an abnormality is seen post mortem. In such an experiment, one might have the following data for that tissue:

- *Control group*—50 animals, 2 abnormal post mortem, 2 examined microscopically, 2 with tumor of specific type
- *Treated group*—50 animals, 15 abnormal post mortem, 15 examined microscopically, 14 with tumor of specific type

Ignoring animals with no microscopic sections, one would compare 2/2 = 100% with 14/15 = 93% and conclude that treatment nonsignificantly decreased incidence. This is likely to be a false conclusion, and it would be better here to compare the percentages of animals that had a post mortem abnormality that turned out to be a tumor—that is, 2/50 = 4% with 14/50 = 28%. Unless some aspects of treatment made tumors much easier to detect at post mortem, one could then conclude that treatment did have an effect on tumor incidence.

Particular care has to be taken in studies where the procedures for histopathological examination vary by group. In a number of studies conducted in recent years, the protocol has demanded full microscopic examination of a given tissue list in decedents in all groups and in terminally killed controls in high-dose animals. In other animals, terminally killed low- and mid-dose animals, microscopic examination of a tissue is conducted only if the tissue is found to be abnormal at post mortem. Such a protocol is designed to save money but leads to difficulty in comparing the treatment groups validly. Suppose, for example, that responses in terminally killed animals are 8/20 in the controls, 3/3 (with 17 unexamined) in the low-dose animals, and 5/6 (with 14 unexamined) in the mid-dose animals. Is one supposed to conclude that treatment at the low and mid doses increased response, based on a comparison of the proportions examined microscopically (40%, 100%, and 83%), or that it decreased response, based on the proportion of animals in the group (40%, 15%, and 25%)? It could well be that treatment had no effect but some small tumors were missed at post mortem. In this situation, a valid comparison can be achieved only by ignoring the low- and mid-dose groups when carrying out the comparison for the age stratum *terminal kill*. This, of course, seems wasteful of data, but these are data that cannot be usefully used due to the inappropriate protocol.

USE OF HISTORICAL CONTROL DATA

In some situations, particularly where incidences are low, the results from a single study may suggest an effect of treatment on tumor incidence but be unable to demonstrate it conclusively. The possibility of comparing results in the treated groups with those of control groups from other studies is then often raised; thus, a nonsignificant incidence of 2 cases out of 50 in a treated group may seem much more significant if no cases have been seen in, say, 1000 animals representing controls from 20 similar studies. Conversely, a significant incidence of 5 cases out of 50 in a treated group as compared with 0 out of 50 in the study controls may seem far less convincing if many other control groups had incidences around 5 out of 50. While not understating the importance of looking at historical control data, it must be emphasized that there are a number of reasons why variation between studies may be greater than variation within a study. Differences in diet, in duration of the study, in intercurrent mortality, and in who the study pathologist is may all contribute. Statistical techniques that ignore this and carry out simple statistical tests of

treatment incidence against a pooled control incidence may well give results that are seriously in error and are likely to overstate statistical significance considerably.

Methods for Data Examination and Preparation

The data from toxicology studies should always be examined before any formal analysis. Such examinations should be directed to determining if the data are suitable for analysis and, if so, what form the analysis should take (see Figure 9.2). If the data as collected are not suitable for analysis or if they are suitable only for low-powered analytical techniques, one may wish to use one of the many forms of data transformation to change the data characteristics so they are more amenable to analysis. For data examination, two major techniques are presented here: the *scattergram* and *Bartlett's test*. Likewise, for data preparation, two techniques are presented: *randomization* (including a test for randomness in a sample of data) and *transformation*. Exploratory data analysis (EDA) is presented and briefly reviewed later. This is a broad collection of techniques and approaches to probe data—that is, to both examine and perform some initial flexible analysis of the data.

Scattergram and Bartlett's Test

Two of the major points to be made throughout this chapter are (1) the use of the appropriate statistical tests and (2) the effects of small sample sizes (as is often the case in toxicology) on our selection of statistical techniques. Frequently, simple examination of the nature and distribution of data collected from a study can also suggest patterns and results that were unanticipated and for which the use of additional or alternative statistical methodology is warranted. It was these points that caused the author to consider a section on scattergrams and their use essential for toxicologists.

Bartlett's test may be used to determine if the values in groups of data are homogeneous. If they are, this (along with the knowledge that they are from a continuous distribution) demonstrates that parametric methods are applicable. But if the values in the (continuous data) groups fail Bartlett's test (i.e., are heterogeneous), we cannot be secure in our belief that parametric methods are appropriate until we gain some confidence that the values are normally distributed. With large groups of data, we can compute parameters of the population (kurtosis and skewness, in particular) and from these parameters determine if the population is normal (with a certain level of confidence). If our concern is especially marked, we can use a chi-square goodness-of-fit test for normality. But when each group of data consists of 25 or fewer values, these measures or tests (kurtosis, skewness, and chi-square goodness-of-fit) are not accurate indicators of normality. Instead, in these cases, we should prepare a scattergram of the data and then evaluate the scattergram to estimate if the data are normally distributed. This procedure consists of developing a histogram of the data and examining the histogram to gain a visual appreciation of the location and distribution of the data.

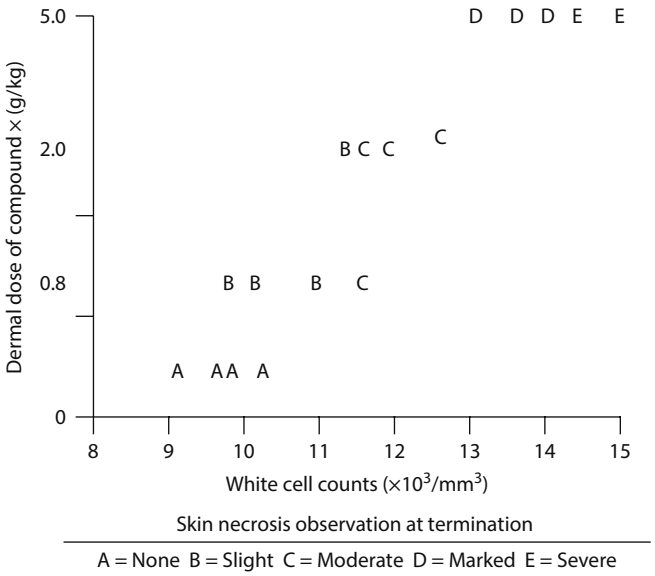

FIGURE 9.5 Exploratory data analysis.

The abscissa (or horizontal scale) should be in the same scale as the values and should be divided so the entire range of observed values is covered by the scale of the abscissa. Across such a scale, we then simply enter symbols for each of our values. Example 9.1 shows such a plot. Example 9.1 is a traditional and rather limited form of scatterplot, but such plots can reveal significant information about the amount and types of association between the two variables, the existence and nature of outliers, the clustering of data, and a number of other two-dimensional factors [10,11].

Current technology allows us to add significantly more graphical information to scatterplots by means of graphic symbols (letters, faces, or different shapes, such as squares and colors) for the plotted data points. One relatively simple example of this approach is shown in Figure 9.5, where the simple case of dose (in a dermal study), dermal irritation, and white blood cell (WBC) count is presented. This graph quite clearly suggests that as dose (variable x) is increased, dermal irritation (variable y) also increases; as irritation becomes more severe, WBC count (variable z), an indicator of immune system involvement suggesting infection or persistent inflammation, also increases. There is no direct association of variables x and z, however. Cleveland and McGill [12] presented an excellent, detailed overview of the expanded capabilities of the scatterplot, and the interested reader should refer to that article. Cleveland later expanded this to a book [13]. Tufte [14] has also expanded on this.

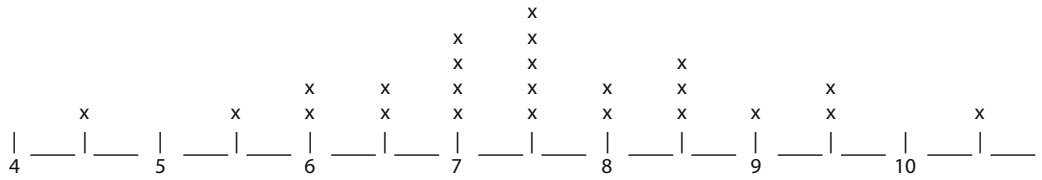
Suppose we have the following two datasets:

Group 1—4.5, 5.4, 5.9, 6.0, 6.4, 6.5, 6.9, 7.0, 7.1, 7.0, 7.4, 7.5, 7.5, 7.5, 7.6, 8.0, 8.1, 8.4, 8.5, 8.6, 9.0, 9.4, 9.5, and 10.4

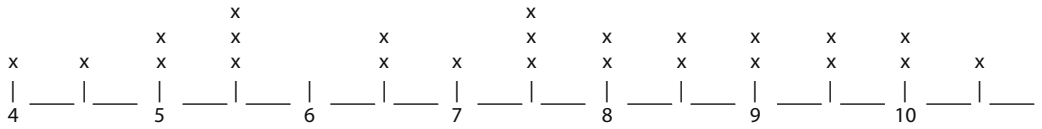
Group 2—4.0, 4.5, 5.0, 5.1, 5.4, 5.5, 5.6, 6.5, 6.5, 7.0, 7.4, 7.5, 7.5, 8.0, 8.1, 8.5, 8.5, 9.0, 9.1, 9.5, 9.5, 10.1, 10.0, and 10.4

Both of these groups contain 24 values and cover the same range. From them, we can prepare the following scattergrams:

Group 1



Group 2



Group 1 can be seen to approximate a normal distribution (bell-shaped curve); we can proceed to perform the appropriate parametric tests with such data. But group 2 clearly does not appear to be normally distributed; in this case, the appropriate nonparametric technique must be used.

Example 9.1

BARTLETT'S TEST FOR HOMOGENEITY OF VARIANCE

Bartlett's test [15] is used to compare the variances (values reflecting the degree of variability in datasets) among three or more groups of data, where the data in the groups are continuous sets (such as body weights, organ weights, red blood cell [RBC] counts, or diet consumption measurements). It is expected that such data will be suitable for parametric methods (normality of data is assumed), and Bartlett's test is frequently used as a test for the assumption of equivalent variances.

Bartlett's test is based on the calculation of the corrected χ^2 (chi-square) value by the formula:

$$\chi^2_{corr} = 2.3026 \frac{\sum \mathrm{df}\left(\log_{10}\left[\sum \mathrm{df}\left(S^2\right)/\sum \mathrm{df}\right]\right) - \sum\left[\mathrm{df}\left(\log_{10} S^2\right)\right]}{1+\frac{1}{3(K-1)}\left[\sum\frac{1}{\mathrm{df}} - \frac{1}{\sum \mathrm{df}}\right]}$$

where S^2 = variance, equal to

$$\frac{n\sum X^2 - \left(\sum X\right)^2}{(n/n-1)}$$

where

X is the individual datum within each group
n is the number of data within each group
df is the degrees of freedom for each group = (N – 1)
K is the number of groups being compared

The corrected χ^2 value yielded by the earlier calculations is compared to the values listed in the chi-square table according to the numbers of degrees of freedom [16]. If the calculated value is smaller than the table value at the selected p level (traditionally 0.05), the groups are accepted to be homogeneous, and the use of ANOVA is assumed proper. If the calculated χ^2 is greater than the table value, the groups are heterogeneous and other tests (as indicated by the decision tree in Figure 9.2) are necessary.

Assumptions and Limitations

- Bartlett's test does not test for normality but rather homogeneity of variance (also called equality of variances or homoscedasticity).
- Homoscedasticity is an important assumption for Student's *t*-test, ANOVA, and analysis of covariance (ANCOVA).
- The *F*-test is actually a test for the two-sample (i.e., control and one test group) case of homoscedasticity. Bartlett's test is designed for three or more samples.
- Bartlett's test is very sensitive to departures from normality. As a result, a finding of a significant chi-square value in Bartlett's test may indicate nonnormality rather than heteroscedasticity. Such a finding can be brought about by outliers, and the sensitivity to such erroneous findings is extreme with small sample sizes.

Statistical Goodness-of-Fit Tests

A goodness-of-fit test is a statistical procedure for comparing individual measurements to a specified type of statistical distribution; for example, a normal distribution is completely specified by its arithmetic mean and variance (the square of the SD). The null hypothesis that the data represent a sample from a single normal distribution can be tested by a statistical goodness-of-fit test. Various goodness-of-fit tests have been devised to determine if the data deviate significantly from a specified distribution. If a significant departure occurs, it

indicates that only the specified distribution can be rejected with some assurance. This does not necessarily mean that the true distribution contains two or more subpopulations. The true distribution may be a single distribution, based on a different mathematical relationship (e.g., lognormal). In the latter case, logarithms of the measurement would not be expected to exhibit by a goodness-of-fit test a statistically significant departure from a lognormal distribution.

Everitt and Hand [17] recommended the use of a sample of 200 or more to conduct a valid analysis of mixtures of populations. Even the maximum likelihood method, the best available method, should be used with extreme caution, or not at all, when separation between the means of the subpopulations is less than 3 SD and sample sizes are less than 300. None of the available methods conclusively establishes bimodality, which may, however, occur when separation between the two means (modes) exceeds 2 SD. Conversely, inflections in probits or separations in histograms less than 2 SD apart may arise from genetic differences in test subjects.

Mendell et al. [18] compared eight tests of normality to detect a mixture consisting of two normally distributed components with different means but equal variances. Fisher's skewness statistic was preferable when one component comprised less than 15% of the total distribution. When the two components comprised more nearly equal proportions (35%–65%) of the total distribution, the Engelman and Hartigan test [19] was preferable. For other mixing proportions, the maximum likelihood ratio test was best; thus, the maximum likelihood ratio test appears to perform very well, with only small loss from optimality, even when it is not the best procedure.

The method of *maximum likelihood* provides estimators that are usually quite satisfactory. They have the desirable properties of being consistent, asymptotically normal, and asymptotically efficient for large samples under quite general conditions. They are often biased, but the bias is frequently removable by a simple adjustment. Other methods of obtaining estimators are also available, but the maximum likelihood method is the most frequently used.

Maximum likelihood estimators also have another desirable property: *invariance*. Let us denote the maximum likelihood estimator of the parameter θ by $\hat{\sigma}$. Then, if $f(\theta)$ is a single-valued function of θ, the maximum likelihood estimator of $f(\theta)$ is $f(\hat{\sigma})$. Thus, for example,

$$\hat{\sigma} = \left(\hat{\sigma}^2\right)^{1/2}$$

The principle of maximum likelihood tells us that we should use that value as our estimate, which maximizes the likelihood of the observed event.

These maximum likelihood methods can be used to obtain *point estimates* of a parameter, but we must remember that a point estimator is a random variable distributed in some way around the true value of the parameter. The true parameter value may be higher or lower than our estimate. It is often useful therefore to obtain an interval within which we are reasonably confident the true value will lie, and the generally accepted method is to construct what are known as *confidence limits*.

The following procedure will yield upper and lower 95% confidence limits with the property that, when we say that these limits include the true value of the parameter, 95% of all such statements will be true and 5% will be incorrect:

1. Choose a (test) statistic involving the unknown parameter and no other unknown parameter.
2. Place the appropriate sample values in the statistic.
3. Obtain an equation for the unknown parameter by equating the test statistic to the upper 2.5% point of the relevant distribution.
4. The solution of the equation gives one limit.
5. Repeat the process with the lower 2.5% point to obtain the other limit.

One can also construct 95% CIs using unequal tails (e.g., using the upper 2% point and the lower 3% point). We usually want our CI to be as short as possible, however, and with a symmetric distribution such as the normal or *t*, this is achieved using equal tails. The same procedure very nearly minimizes the CI with other nonsymmetric distributions (e.g., chi-square) and has the advantage of avoiding rather tedious computation.

When the appropriate statistic involves the square of the unknown parameter, both limits are obtained by equating the statistic to the upper 5% point of the relevant distribution. The use of two tails in this situation would result in a pair of nonintersecting intervals. When two or more parameters are involved, it is possible to construct a region within which, we are reasonably confident, the true parameter values will lie. Such regions are referred to as *confidence regions*. The implied interval for p_1 does not form a 95% CI, however, nor is it true that an 85.7375% confidence region for p_1, p_2, and p_3 can be obtained by considering the intersection of the three separate 95% CIs, because the statistics used to obtain the individual CIs are not independent. This problem is obvious with a multiparameter distribution such as the multinomial, but it even occurs with the normal distribution because the statistic that we use to obtain a CI for the mean and the statistic that we use to obtain a CI for the variance are not independent. The problem is not likely to be of great concern unless a large number of parameters are involved.

Randomization

Randomization is the act of assigning a number of items (plates of bacteria or test animals, for example) to groups in such a manner that there is an equal chance for any one item to end up in any one group. This is a control against any possible bias in the assignment of subjects to test groups. A variation on this is censored randomization, which ensures that the groups are equivalent in some aspect after the assignment process is complete. The most common example of a

censored randomization is one in which it is ensured that the body weights of test animals in each group are not significantly different from those in the other groups. This is done by analyzing group weights both for homogeneity of variance and by ANOVA after animal assignment, then rerandomizing if there is a significant difference at some nominal level, such as $p \leq 0.10$. The process is repeated until there is no significant difference.

There are several methods for actually performing the randomization process. The three most commonly used are card assignment, use of a random number table, and use of a computerized algorithm. For the card-based method, individual identification numbers for items (plates or animals, for example) are placed on separate index cards. These cards are then shuffled and placed one at a time in succession into piles corresponding to the required test groups. The results are a random group assignment.

The random number table method requires only that one have unique numbers assigned to test subjects and access to a random number table. One simply sets up a table with a column for each group to which subjects are to be assigned. We start from the head of any one column of numbers in the random table (each time the table is used, a new starting point should be utilized). If our test subjects number less than 100, we utilize only the last 2 digits in each random number in the table. If they number more than 99 but less than 1000, we use only the last 3 digits. To generate group assignments, we read down a column, one number at a time. As we come across digits that correspond to a subject number, we assign that subject to a group (enter its identifying number in a column), proceeding to assign subjects to groups from left to right and filling one row at a time. After a number is assigned to an animal, any duplication of its unique number is ignored. We use as many successive columns of random numbers as we may need to complete the process.

The third (and now most common) method is to use a random number generator that is built into a calculator or computer program. Procedures for generating these are generally documented in user manuals.
